The earliest morphologically identifiable precursors of neutrophils in the bone marrow are myeloblasts, which are large cells constituting up to 3.5% of the nucleated cells in the marrow. The nucleus is large and contains 2–5 nucleoli. The cytoplasm is scanty and contains no granules. Promyelocytes are similar to myeloblasts but have some primary cytoplasmic granules, containing enzymes such as myeloperoxidase. Myelocytes are smaller cells without nucleoli but with more abundant cytoplasm and both primary and secondary granules. Indentation of the nucleus marks the change from myelocyte to metamyelocyte. The mature neutrophil is a smaller cell with a nucleus with 2–5 lobes, with predominantly secondary granules in the cytoplasm, which contain lysozyme, collagenase and lactoferrin.

Peripheral blood neutrophils are equally distributed into a circulating pool and a marginating pool lying along the endothelium of blood vessels. In contrast to the prolonged maturation time of about 10 days for neutrophils in the bone marrow, their half-life in the peripheral blood is extremely short, only 6–8 hours. In response to stimuli (e.g. infection, corticosteroid therapy), neutrophils are released into the circulating pool from both the marginating pool and the marrow. Immature white cells are released from the marrow when a rapid response (within hours) occurs in acute infection (described as a ‘shift to the left’ on a blood film).

Function

The prime function of neutrophils is to ingest and kill bacteria, fungi and damaged cells. Neutrophils are attracted to sites of infection or inflammation by chemotaxins. Recognition of foreign or dead material is aided by coating of particles with immunoglobulin and complement (opsonization) as neutrophils have Fc and C3b receptors (see p. 52). The material is ingested into vacuoles where it is subjected to enzymic destruction, which is either oxygen-dependent with the generation of hydrogen peroxide (myeloperoxidase) or oxygen-independent (lysosomal enzymes and lactoferrin). Leucocyte alkaline phosphatase (LAP) is an enzyme found in leucocytes. It is raised when there is a neutrophilia due to an acute illness. It is also raised in polycythaemia and myelofibrosis and reduced in CML.

Neutrophil leucocytosis

A rise in the number of circulating neutrophils to >10^5/L occurs in bacterial infections or as a result of tissue damage. This may also be seen in pregnancy, during exercise and after corticosteroid administration (Table 8.19). With any tissue necrosis there is a release of various soluble factors, causing a leucocytosis. Interleukin 1 is also released in tissue necrosis and causes a pyrexia. The pyrexia and leucocytosis accompanying a myocardial infarction are a good example of this and may be wrongly attributed to infection.

A leukaemoid reaction (an overproduction of white cells, with many immature cells) may occur in severe infections, tuberculosis, malignant infiltration of the bone marrow and occasionally after haemorrhage or haemolysis.

Neutropenia and agranulocytosis

Neutropenia is defined as a circulatory neutrophil count below 1.5×10^9/L. A virtual absence of neutrophils is called agranulocytosis. The causes are given in Table 8.20. It should be noted that black patients may have somewhat lower neutrophil counts. Neutropenia caused by viruses is probably the most common type. Chemotherapy and radiotherapy predictably produce neutropenia; many other drugs have been known to produce an idiosyncratic cytopenia and a drug cause should always be considered.

Clinical features

Infections may be frequent, often serious, and are more likely as the neutrophil count falls. An absolute neutrophil count of <0.5×10^9/L is regarded as ‘severe’ neutropenia and may be associated with life-threatening infections such as pneumonia and septicaemia. A characteristic glazed mucositis occurs in the mouth, and ulceration is common.

Investigations

The blood film shows marked neutropenia. The appearance of the bone marrow will indicate whether the neutropenia is due to depressed production or increased destruction of neutrophils. Neutrophil antibody studies are performed if an immune mechanism is suspected.
Treatment
Antibiotics should be given as necessary to patients with acute severe neutropenia (see p. 449).
If the neutropenia seems likely to have been caused by a drug, all current drug therapy should be stopped. Recovery of the neutrophil count usually occurs after about 10 days. G-CSF (see p. 373) is used to decrease the period of neutropenia after chemotherapy and haemopoietic transplantation. It is also used successfully in the treatment of chronic neutropenia.
Steroids and high-dose intravenous immunoglobulin are used to treat patients with severe autoimmune neutropenia and recurrent infections, and G-CSF has produced responses in some cases.

Eosinophils
Eosinophils are slightly larger than neutrophils and are characterized by a nucleus with usually two lobes and large cytoplasmic granules that stain deeply red. The eosinophil plays a part in allergic responses (see p. 52) and in the defence against infections with helminths and protozoa. Eosinophilia is >0.4×10^9/L eosinophils in the peripheral blood. The causes of eosinophilia are listed in Table 8.21.

Basophils
The nucleus of basophils is similar to that of neutrophils but the cytoplasm is filled with large black granules. The granules contain histamine, heparin and enzymes such as myeloperoxidase. The physiological role of the basophil is not known. Binding of IgE causes the cells to degranulate and release histamine and other contents involved in acute hypersensitivity reactions (see p. 68).
Basophils are usually few in number (<1×10^9/L) but are significantly increased in myeloproliferative disorders.

Monocytes
Monocytes are slightly larger than neutrophils. The nucleus has a variable shape and may be round, indented or lobulated. The cytoplasm contains fewer granules than neutrophils. Monocytes are precursors of tissue macrophages and dendritic cells and spend only a few hours in the blood but can continue to proliferate in the tissues for many years.
A monocyteosis (>0.8×10^9/L) may be seen in chronic bacterial infections such as tuberculosis or infective endocarditis, chronic neutropenia and patients with myelodysplasia, particularly chronic myelomonocytic leukaemia.

Lymphocytes
Lymphocytes form nearly half the circulating white cells. They descend from pluripotential stem cells (Fig. 8.1). Circulating lymphocytes are small cells, a little larger than red cells, with a dark-staining central nucleus. There are two main types: T and B lymphocytes (see p. 50).
Lymphocytosis (lymphocyte count >5×10^9/L) occurs in response to viral infections, particularly EBV, CMV and HIV, and chronic infections such as tuberculosis and toxoplasmosis. It also occurs in chronic lymphocytic leukaemia and in some lymphomas.

HAEMOSTASIS AND THROMBOSIS
The integrity of the circulation is maintained by blood flowing through intact vessels lined by endothelial cells. Haemostasis is the host defence mechanism that protects this integrity after injury to the vessel wall and tissue injury.

Haemostasis
Haemostasis is a complex process depending on interactions between the vessel wall, leucocytes, platelets, coagulation and fibrinolytic mechanisms. Haemostatic systems are normally quiescent but following tissue injury become rapidly activated. The formation of the haemostatic plug is shown in Figure 8.33.

Vessel wall
The vessel wall is lined by endothelium which, in normal conditions, prevents platelet adhesion and thrombus formation. This property is partly due to its negative charge but also to:
- Thrombomodulin and heparan sulphate expression
- Synthesis of prostacyclin (PGI2) and nitric oxide (NO), which cause vasodilatation and inhibit platelet aggregation
- Production of plasminogen activator.
Injury to vessels causes reflex vasoconstriction, while endothelial damage results in loss of antithrombotic properties, activation of platelets and coagulation and inhibition of fibrinolysis (Fig. 8.33).

Platelets
Platelet adhesion. When the vessel wall is damaged, the platelets escaping come into contact with and adhere to collagen and subendothelial bound von Willebrand factor. This adherence is mediated through glycoprotein Ib (GPIb). Glycoprotein Iib–Illa is then exposed, forming a second binding site for VWF. Within seconds of adhesion to the vessel wall platelets begin to undergo a shape change, from a disc to a sphere, spread along the subendothelium and release the contents of their cytoplasmic granules. These are the dense bodies (containing ADP and serotonin) and the
Platelet release. The release of ADP leads to a conformational change in the fibrinogen receptor, the glycoprotein IIb–IIIa complex (GPIIb–IIIa), on the surfaces of adherent platelets allowing it to bind to fibrinogen (see also Fig. 8.41).

Platelet aggregation (Fig. 8.33b). As fibrinogen is a dimer it can form a direct bridge between platelets and so binds platelets into activated aggregates (platelet aggregation) and further platelet release of ADP occurs. A self-perpetuating cycle of events is set up leading to formation of a platelet plug at the site of the injury.

Coagulation. After platelet aggregation and release of ADP, the exposed platelet membrane phospholipids are available for the assembly of coagulation factor enzyme complexes (tenase and prothrombinase; this platelet phospholipid activity has been called platelet factor 3 (PF-3). The presence of thrombin encourages fusion of platelets, and fibrin formation reinforces the stability of the platelet plug. Central to normal platelet function is platelet prostaglandin synthesis, which is induced by platelet activation and leads to the formation of TXA₂ in platelets (Fig. 8.34). Thromboxane (TXA₂) is a powerful vasoconstrictor and also lowers cyclic AMP levels and initiates the platelet release reaction. Prostacyclin (PGI₂) is synthesized in vascular endothelial cells and opposes the actions of TXA₂. It produces vasodilatation and increases the level of cyclic AMP, preventing platelet aggregation on the normal vessel wall as well as limiting the extent of the initial platelet plug after injury.

Coagulation and fibrinolysis
Coagulation involves a series of enzymatic reactions leading to the conversion of soluble plasma fibrinogen to fibrin-based clot (Fig. 8.35). Roman numerals are used for most of the

Figure 8.33 Formation of the haemostatic plug: sequential interactions between the vessel wall, platelets and coagulation factors. (a) Contact of platelets with collagen via the platelet receptor GP1b and factor VWF in plasma activates platelet prostaglandin synthesis which stimulates release of ADP from the dense bodies. Vasocostriction of the vessel occurs as a reflex and by release of serotonin and thromboxane A₂ (TXA₂) from platelets. (b) Release of ADP from platelets induces platelet aggregation and formation of the platelet plug. The coagulation pathway is stimulated leading to formation of fibrin. (c) Fibrin strands are cross-linked by factor XIII and stabilize the haemostatic plug by binding platelets and red cells.

Figure 8.34 Prostaglandin synthesis.

Figure 8.35 Coagulation mechanism. The in vivo pathway begins with tissue factor–factor VIIa complex activating factor X and also factor IX. Factor XI is activated by thrombin. TF, tissue factor; TFPI, tissue factor pathway inhibitor.
factors, but I and II are referred to as fibrinogen and prothrombin respectively; III, IV and VI are redundant. The active forms are denoted by ‘a’. The coagulation factors are primarily synthesized in the liver and are either serine protease enzyme precursors (factors XI, X, IX and thrombin) or cofactors (V and VIII), except for fibrinogen, which is polymerized to form fibrin.

**Coagulation pathway**

This enzymatic amplification system was traditionally divided into ‘extrinsic’ and ‘intrinsic’ pathways. This concept is useful for the interpretation of clinical laboratory tests such as the prothrombin time (PT) and activated partial thromboplastin time (APTT) (see p. 417) but unrepresentative and an oversimplification of in vivo coagulation. Coagulation is initiated by tissue damage (Fig. 8.35):

- Tissue damage exposes tissue factor (TF) which binds to factor VII.
- The TF–factor VII complex directly converts factor X to active factor Xa and some factor IX to factor IXa.
- In the presence of factor Xa, tissue factor pathway inhibitor (TFPI) inhibits further generation of factor Xa and factor IXa.
- Following inhibition by TFPI the amount of factor Xa produced is insufficient to maintain coagulation. Further factor Xa, to allow haemostasis to progress to completion, can only be generated by the alternative factor IX/factor VIII pathway. However, enough thrombin exists at this point to activate factor VIII, which dramatically increases the activity of factor IXa (generated by TF-factor VIIa) so further activation of factor X can proceed. Without the amplification and consolidating action of factor VIII/factor IX, bleeding will ensue as generation of factor Xa is insufficient to sustain haemostasis.
- Similarity thrombin activates factor V dramatically enhancing the conversion of prothrombin to thrombin by factor Xa.
- Thrombin hydrolyses the peptide bonds of fibrinogen, releasing fibrinopeptides A and B, and allowing polymerization between fibrinogen molecules to form fibrin. At the same time, thrombin, in the presence of calcium ions, activates factor XIII, which stabilizes the fibrin clot by cross-linking adjacent fibrin molecules.

**Factor VIII** consists of a molecule with coagulant activity (VIII: C) associated with von Willebrand factor. Factor VIII increases the activity of factor IXa by ~200 000 fold. WF functions to prevent premature factor VIII: C breakdown and locate it to areas of vascular injury. VIII: C has a molecular weight of about 350 000.

**Von Willebrand factor** (VWF) is a glycoprotein with a molecular weight of about 200 000 which readily forms multimers in the circulation with molecular weights of up to $20 \times 10^6$. It is synthesized by endothelial cells and megakaryocytes and stored in platelet granules as well as the endothelial cells. The high-molecular-weight multimeric forms of VWF are the most biologically active (see p. 422 and Fig. 8.39).

**Physiological limitation of coagulation**

Without a physiological system to limit blood coagulation dangerous thrombosis could ensue. The natural anticoagulant mechanism regulates and localizes thrombosis to the site of injury.

**Antithrombin.** Antithrombin (AT), a member of the serine protease inhibitor (serpin) superfamily, is a potent inhibitor of coagulation. It inactivates the serine proteases by forming stable complexes with them, and its action is greatly potentiated by heparin.

**Activated protein C.** This is generated from its vitamin K-dependent precursor, protein C, by thrombin; thrombin activation of protein C is greatly enhanced when thrombin is bound to thrombomodulin on endothelial cells (Fig. 8.36). Activated protein C inactivates factor V and factor VIII, reducing further thrombin generation.

**Protein S.** This is a cofactor for protein C, which acts by enhancing binding of activated protein C to the phospholipid surface. It circulates bound to C4b binding protein but some 30–40% remains unbound and active (free protein S).

**Other inhibitors.** Other natural inhibitors of coagulation include α2-macroglobulin, α1-antitrypsin and α2-antiplasmin.

**Fibrinolysis**

Fibrinolysis is a normal haemostatic response that helps to restore vessel patency after vascular damage. The principal component is the enzyme plasmin, which is generated from its inactive precursor plasminogen (Fig. 8.37). This is achieved principally via tissue plasminogen activator (t-PA) released from endothelial cells. Some plasminogen activation may also be promoted by urokinase, produced in the kidneys. Other plasminogen activators (factor XII and prekallikrein) are of minor physiological importance.

**Plasmin** is a serine protease, which breaks down fibrinogen and fibrin into fragments X, Y, D and E, collectively
known as fibrin (and fibrinogen) degradation products (FDPs). D-dimer is produced when cross-linked fibrin is degraded. Its presence in the plasma indicates that the coagulation mechanism has been activated.

The fibrinolytic system is activated by the presence of fibrin. Plasminogen is specifically adsorbed to fibrin and fibrinogen by lysine-binding sites. However, little plasminogen activation occurs in the absence of polymerized fibrin, as fibrin also has a specific binding site for plasminogen activators, whereas fibrinogen does not (Fig. 8.38).

*Fig. 8.38*  Fibrinolysis. (a) The conversion of plasminogen to plasmin by plasminogen activator (t-PA) occurs most efficiently on the surface of fibrin, which has binding sites for both plasminogen and t-PA. (b) Free plasmin in the blood is rapidly inactivated by $\alpha_2$-antiplasmin. Plasmin generated on the fibrin surface is partially protected from inactivation. The lysine-binding sites on plasminogen are necessary for the interaction between plasminogen and fibrin and between plasmin and $\alpha_2$-antiplasmin.

**Investigation of bleeding disorders**

Although the precise diagnosis of a bleeding disorder will depend on laboratory tests, much information is obtained from the history and physical examination:

- **Is there a generalized haemostatic defect?** Supportive evidence for this includes bleeding from multiple sites, spontaneous bleeding, and excessive bleeding after injury.

- **Is the defect inherited or acquired?** A family history of a bleeding disorder should be sought. Severe inherited defects usually become apparent in infancy, while mild inherited defects may only come to attention later in life, for example with excessive bleeding after surgery, childbirth, dental extractions or trauma. Some defects are revealed by routine coagulation screens which are performed before surgical procedures.

- **Is the bleeding suggestive of a vascular/platelet defect or a coagulation defect?**

**Vascular/platelet bleeding** is characterized by easy bruising and spontaneous bleeding from small vessels. There is often bleeding into the skin. Purpura includes both petechiae, which are small skin haemorrhages varying from pinpoint size to a few millimetres in diameter and which do not blanch on pressure, and ecchymoses, which are larger areas of bleeding into the skin. Bleeding also occurs from mucous membranes especially the nose and mouth.

**Coagulation disorders** are typically associated with bleeding after injury or surgery, and in more severe forms, haemarthroses and muscle haematomas. There is often a short delay between the precipitating event and overt haemorrhage or haematoma formation.

**Laboratory investigations**

- **Blood count and film** show the number and morphology of platelets and any blood disorder such as leukaemia or lymphoma. The normal range for the platelet count is 150–400 $\times 10^9/L$.

- **Coagulation tests** are performed using blood collected into citrate, which neutralizes calcium ions and prevents clotting.

  **The prothrombin time (PT)** (also see p. 428) is measured by adding tissue factor (thromboplastin) and calcium to the patient’s plasma. The normal PT is 12–16 s and when used to measure oral anticoagulants is expressed as the international normalized ratio, INR (see p. 369). The PT measures VII, X, V, prothrombin and fibrinogen (classic ‘extrinsic’ pathway) and is prolonged with abnormalities of these factors. It may also be abnormal in liver disease, or if the patient is on warfarin.

  **The activated partial thromboplastin time (APTT)** is also sometimes known as the PTT with kaolin (PTTK). It is performed by adding a surface activator (such as kaolin, microporized silica or ellagic acid), phospholipid (to mimic platelet membrane) and calcium to the patient’s plasma. The normal APTT is 26–37 s and depends on the exact methodology. The APTT measures XII, XI, IX, VIII, X, V, prothrombin and fibrinogen (classic ‘intrinsic’ pathway) and is prolonged with deficiencies of one or more of these factors. It is not dependent on factor VII.

  **The thrombin time (TT)** is performed by adding thrombin to the patient’s plasma. The normal TT is 12–14 s, and it is prolonged with fibrinogen deficiency, qualitative defects of fibrinogen (dysfibrinogenemia) or inhibitors such as heparin or FDPs.

**Correction tests** can be used to differentiate prolonged times in the PT, APTT and TT due to various coagulation factor deficiencies and inhibitors of coagulation. Prolonged PT, APTT or TT due to coagulation factor deficiencies can be corrected by addition of normal plasma to the patient’s plasma. Failure to correct after addition of normal plasma is suggestive of the presence of an inhibitor of coagulation.

**Factor assays** are used to confirm coagulation defects, especially where a single inherited disorder is suspected.

**Special tests of coagulation** will often be required to confirm the precise haemostatic defect. Such tests include estimation of fibrinogen and FDPs, platelet function tests such as platelet aggregation and platelet granule contents.

**Bleeding time** measures platelet plug formation in vivo. A sphygmanometer cuff is inflated to 40 mmHg and 1 mm deep. 1 cm long incisions in the forearm are made with a template. Wounds are blotted every 30 s and the time taken for bleeding to stop recorded (normally 3–10 min). Prolonged bleeding times are found in patients with platelet function defects, and there is a progressive prolongation with platelet counts less than 100 $\times 10^9/L$ – hence the bleeding time should
not be performed at low platelet counts. Nowadays it is rarely
done as it can scar and is painful.

Vascular disorders

The vascular disorders (Table 8.22) are characterized by easy
bruising and bleeding into the skin. Bleeding from mucous
membranes sometimes occurs but the bleeding is rarely
severe. Laboratory investigations including the bleeding time
are normal. The vascular disorders include the following.

**Hereditary haemorrhagic telangiectasia** is a rare disorder
with autosomal dominant inheritance. Mutations occur in
most cases in one of three genes, ENG, ALK1 or SMAD4,
that encode components of the TGF-β signalling pathway
that is involved in blood vessel development. Dilatation of
capillaries and small arterioles produces characteristic small
red spots that blanch on pressure in the skin and mucous
membranes, particularly the nose and gastrointestinal tract.
Recurrent epistaxis and chronic gastrointestinal bleeding are
the major problems which causes chronic iron deficiency
anaemia. Vascular malformations also occur in pulmonary,
hepatic cerebral and spinal vasculature.

**Easy bruising syndrome** is a common benign disorder
occurring in otherwise healthy women. It is characterized by
bruises on the arms, legs and trunk with minor trauma, possi-
bly because of skin vessel fragility. It may give rise to the
suspicion of a serious bleeding disorder.

**Senile purpura and purpura due to steroids** are both
due to atrophy of the vascular supporting tissue.

**Purpura due to infections** is mainly caused by damage
to the vascular endothelium. The rash of meningococcal sep-
ticaemia is particularly characteristic (see p. 127).

**Henoch–Schönlein purpura** (see p. 582) occurs mainly in
children. It is a type III hypersensitivity (immune complex)
reaction that is often preceded by an acute upper respiratory
tract infection. Purpura is mainly seen on the legs and but-
tocks. Abdominal pain, arthritis, haematuria and glomer-
ulonephritis also occur. Recovery is usually spontaneous, but
some patients develop renal failure.

**Episodes of inexplicable bleeding or bruising** may rep-
 resent abuse, either self-inflicted or caused by others. These

---

various forms of artificial or factitious purpura may be expres-
sions of emotional or psychiatric disturbances.

Platelet disorders

Bleeding due to thrombocytopenia or abnormal platelet func-
tion is characterized by purpura and bleeding from mucous
membranes. Bleeding is uncommon with platelet counts
above 50 x 10^9/L, and severe spontaneous bleeding is
unusual with platelet counts above 20 x 10^9/L (Table 8.23).

Thrombocytopenia

This is caused by reduced platelet production in the bone
marrow, excessive peripheral destruction of platelets or
sequestration in an enlarged spleen (Table 8.24). The under-
lying cause may be revealed by history and examination but
a bone marrow examination will show whether the numbers
of megakaryocytes are reduced, normal or increased, and will provide essential information on morphology. Specific laboratory tests may be useful to confirm the presence of such conditions as paroxysmal nocturnal haemoglobinuria (PNH) or systemic lupus erythematosus (SLE).

In patients with thrombocytopenia due to failure of production, no specific treatment may be necessary but the underlying condition should be treated if possible. Where the platelet count is very low or the risk of bleeding is very high, then platelet transfusion is indicated.

**Immune thrombocytopenic purpura (ITP)**

Thrombocytopenia is due to immune destruction of platelets. The antibody-coated platelets are removed following binding to Fc receptors on macrophages.

**ITP in children**

This occurs most commonly in age group 2–6 years. ITP has an acute onset with mucocutaneous bleeding and there may be a history of a recent viral infection, including varicella zoster or measles. Although bleeding may be severe, life-threatening hemorrhage is rare (~ 1%). Bone marrow examination is not usually performed unless treatment becomes necessary on clinical grounds.

**ITP in adults**

The presentation is usually less acute than in children. ITP is characteristically seen in women and may be associated with other autoimmune disorders such as SLE, thyroid disease and autoimmune haemolytic anaemia (Evans’ syndrome). It is also seen in patients with chronic lymphocytic leukaemia and solid tumours, and after infections with viruses such as HIV. Platelet autoantibodies are detected in about 60–70% of patients, and are presumed to be present, although not detectable, in the remaining patients; the antibodies often have specificity for platelet membrane glycoproteins IIb/IIIa and/or Ib.

**Clinical features**

Major haemorrhage is rare and is seen only in patients with severe thrombocytopenia. Easy bruising, purpura, epistaxis and menorrhagia are common. Physical examination is normal except for evidence of bleeding. Splenomegaly is rare.

**Investigation**

The only blood count abnormality is thrombocytopenia. Normal or increased numbers of megakaryocytes are found in the bone marrow (if examination is performed), which is otherwise normal. The detection of platelet autoantibodies is not essential for confirmation of the diagnosis, which often depends on exclusion of other causes of excessive destruction of platelets.

**Treatment**

**Children**

Children do not usually require treatment. Where this is necessary on clinical grounds, corticosteroids, intravenous immunoglobulin (i.v. IgG) and anti-D are effective; i.v. IgG is effective in >80% of children and raises the count more rapidly that steroids. Treatment should be reserved for very serious bleeding or urgent surgery. Chronic ITP is rare and requires specialist management.

**Adults**

Patients with platelet counts >30 x 10^9/L generally require no treatment unless they are about to undergo a surgical procedure. Patients with even lower platelet counts may not require treatment unless they have spontaneous bruising or bleeding.

**First-line therapy** consists of oral corticosteroids 1 mg/kg body weight. Approximately 66% will respond to prednisolone but relapse is common when the dose is reduced. Only 33% of patients can expect a long-term response and long-term remission is seen in only 10–20% of patients following stopping prednisolone. Patients who fail to respond to corticosteroids or require high doses to maintain a safe platelet count should be considered for splenectomy.

Intravenous immunoglobulin (i.v. IgG) is effective. It raises platelet count in 75% and in 50% the platelet count will normalize. Responses are only transient (3–4 weeks) with little evidence of any lasting effect. However, it is very useful where a rapid rise in platelet count is desired, especially before surgery. There are also advocates for high-dose corticosteroids for additional therapy.

**Second-line therapy** involves splenectomy, to which the majority of patients respond – two-thirds will achieve a normal platelet count. Patients who do not have a complete response can still expect some improvement.

**Third-line therapy.** For those that fail splenectomy, a wide range of other therapies are available. These include high-dose corticosteroids, intravenous immunoglobulin, Rh(D) immune globulin (anti-D), vinca alkaloids, danazol, immuno-suppressive agents such as azathioprine, ciclosporin and dapsone, combination chemotherapy, mycophenolate mofetil. Major difficulties with many third-line therapies are modest response rates and slow onset of action. Consequently there is also interest in the use of specific immunomodulatory monoclonal antibodies such as rituximab, which yields a 60% response rate. Due to a relative lack of thrombopoietin in ITP, clinical trials of recombinant thrombopoietin have been undertaken. However, these were stopped because of thrombocytopenia arising due to neutralization of endogenous thrombopoietin by cross-reacting antibodies. Alternative drug development is now based on thrombopoietin receptor agonists that do not have any homology with native thrombopoietin. Two such drugs, etrombopag and romiplostim, have been shown to significantly increase platelet count in ITP on a long-term basis and are approved drugs for refractory ITP. Platelet transfusions are reserved for intracranial or other extreme haemorrhage, where emergency splenectomy may be justified.

**Other immune thrombocytopenias**

Drugs cause immune thrombocytopenia by the same mechanisms as described for drug-induced immune haemolytic anaemia (see p. 400). The same drugs can be responsible for immune haemolytic anaemia, thrombocytopenia or neutropenia in different patients.

**Heparin-induced thrombocytopenia.** See page 427. **Neonatal alloimmune thrombocytopenia** is due to fetomaternal incompatibility for platelet-specific antigens, usually for HPA-1a (human platelet alloantigen), and is the platelet equivalent of haemolytic disease of the newborn (HDN). The mother is HPA-1a-negative and produces antibodies, which destroy the HPA-1a-positive fetal platelets. Thrombocytopenia is self-limiting after delivery, but platelet transfusions may be required initially to prevent or treat bleeding associated with severe thrombocytopenia; platelets are prepared from HPA-1a-negative volunteers or the mother herself. Severe bleeding such as intracranial haemorrhage may also occur in utero.
Antenatal treatment of the mother – usually with high-dose IgG and/or steroids – has been effective in preventing haemorrhage in severely affected cases.

Post-transfusion purpura (PTP) is rare, occurring 7–10 days after a transfusion of platelet-containing blood components, usually red cells. PTP is associated with a platelet-specific alloantibody, usually anti-HPA-1a in an HPA-1a-negative individual. PTP always occurs in patients previously immunized either by blood transfusion or by pregnancy – hence it is more common in women. The cause of the destruction of the patient’s own platelets is not well understood, but they may be destroyed as ‘bystanders’ during the acute immune response to HPA-1a. PTP is self-limiting, but intravenous IgG or plasma exchange may be required in severe bleeding.

Thrombotic thrombocytopenic purpura (TTP) (see p. 590)

TTP is a rare, but very serious condition, in which platelet consumption leads to profound thrombocytopenia. There is a characteristic symptom complex of florid purpura, fever, fluctuating cerebral dysfunction and microangiopathic haemolytic anaemia with red cell fragmentation, often accompanied by acute kidney injury. The coagulation screen is usually normal but lactic dehydrogenase (LDH) levels are markedly raised as a result of haemolysis. TTP arises due to endothelial damage and microvascular thrombosis. This occurs due to a reduction in ADAMTS-13 (A Disintegrin-like and Metalloproteinase domain with Thrombospondin-type motifs), a protease which is normally responsible for regulating the size of VWF. ADAMTS-13 is needed to break down large ultra von Willebrand factor multimers (UL VWFMs) into smaller haemostatically active fragments that interact with platelets. Reduction in ADAMTS-13 results in the adhesion and aggregation of platelets to UL VWFMs and multigran microthrombi. In most sporadic cases there is a true deficiency of the ADAMTS-13, associated with antibodies to ADAMTS-13. In some congenital cases the deficiency is due to mutations in the ADAMTS-13 gene. Secondary causes of acute TTP include pregnancy, oral contraceptives, SLE, infection and drug treatment, including the use of ticlopidine and clopidogrel. Such cases may have a variable ADAMTS-13 activity at presentation and may or may not have associated antibodies to ADAMTS-13.

**Treatment**

Treatment consists of plasma exchange as the mainstay of treatment. It provides a source of ADAMTS-13 and removes associated autoantibody in acute TTP. Cryoprecipitate and solvent-detergent FFP (fresh frozen plasma) both contain ADAMTS-13. Pulsed intravenous methylprednisolone is given acutely, as is increasingly rituximab as a primary treatment of choice. Disease activity is monitored by measuring the platelet count and serum LDH. Platelet concentrates are contraindicated. The untreated condition has a mortality of up to 90% but modern management has reduced this figure to about 10%. Recurrent and relapsing TTP occurs, often associated with a persistent lack of ADAMTS-13. In secondary TTP cases, identifiable precipitating drugs should be stopped.

**Platelet function disorders (Box 8.4)**

These are usually associated with excessive bruising and bleeding and, in some of the acquired forms, with thrombosis. The platelet count is normal or increased and the bleeding time is prolonged. The rare inherited defects of platelet function require more detailed investigations such as platelet aggregation studies and factor VIII: C and VWF assays, if von Willebrand’s disease is suspected.

If there is serious bleeding or if the patient is about to undergo surgery, drugs with antiplatelet activity should be withdrawn and any underlying condition should be corrected if possible.

Bleeding in renal disease is multifactorial, although platelet dysfunction is a major component. The degree of the defect of haemostasis is broadly proportional to the plasma urea concentration – platelet function is impaired by urea, guanidinosuccinic acid and other phenolic metabolites that accumulate in chronic kidney disease. Dialysis partially corrects platelet function. The haematocrit should be increased to >0.30 and the use of desmopressin may be helpful. Platelet transfusions may be required if these measures are unsuccessful or if the risk of bleeding is high.

**Thrombocytosis**

The platelet count may rise above $400 \times 10^9/L$ as a result of:

- Splenectomy
- Malignant disease
- Inflammatory disorders such as rheumatoid arthritis and inflammatory bowel disease
- Major surgery and post haemorrhage
- Myeloproliferative disorders
- Iron deficiency.

Thus, thrombocytosis is part of the acute-phase reaction, although following splenectomy platelet numbers are also elevated because of the loss of a major site of platelet destruction.

**Essential thrombocythaemia**, a myeloproliferative disorder which is described on page 404, and other myeloproliferative conditions such as polycythema vera (PV), myelofibrosis and chronic myeloid leukaemia (CML) may also be associated with a high platelet count.

A persistently elevated platelet count can lead to arterial or venous thrombosis. It is usual to treat the underlying cause of the thrombocytosis but a small dose of aspirin (75 mg) is also sometimes given. In myeloproliferative diseases the primary risk is thrombosis and specific action to reduce the platelet count, usually with hydroxycarbamide (hydroxyurea),
is often taken. Paradoxically there is also a risk of abnormal bleeding if the platelet count is very high.

Inherited coagulation disorders

Inherited coagulation disorders are uncommon and usually involve deficiency of one factor only. Acquired coagulation disorders occur more frequently and almost always involve several coagulation factors (see p. 423).

In inherited coagulation disorders, deficiencies of all factors have been described. Those leading to abnormal bleeding are rare, apart from haemophilia A (factor VIII deficiency), haemophilia B (factor IX deficiency) and von Willebrand’s disease.

Haemophilia A

This is due to a lack of factor VIII. VWF is normal in haemophilia (Fig. 8.39). The prevalence of haemophilia A is about 1 in 5000 of the male population. It is inherited as an X-linked disorder. If a female carrier has a son, he has a 50% chance of having haemophilia, and a daughter has a 50% chance of being a carrier. All daughters of men with haemophilia are carriers and the sons are normal.

Although a large number of different genetic defects have been found in the factor VIII gene, including deletions, duplications, frameshift mutations and insertions, in approximately 50% of families with severe disease, a common gene inversion in intron 22 is causative. There is a high mutation rate, with one-third of cases being apparently sporadic with no family history of haemophilia.

Clinical and laboratory features

The clinical features depend on the level of factor VIII. The normal level of factor VIII is 50–150 IU/dL.

- **Levels of less than 1 IU/dL (severe haemophilia)** are associated with frequent spontaneous bleeding from early life, typically into joints and muscles. Such recurrent bleeding into joints leads to joint deformity and crippling if adequate treatment is not given.
- **Levels of 1–5 IU/dL (moderate haemophilia)** are associated with severe bleeding following injury and occasional spontaneous bleeds.
- **Levels above 5 IU/dL (mild haemophilia)** are associated usually with bleeding only after injury or surgery. Diagnosis in this group is often delayed until quite late in life.

With treatment, the most common causes of death in people with haemophilia are cancer and heart disease, as for the general population, although cerebral haemorrhage is much more frequent than in the general population. In recent years, HIV infection and liver disease (due to hepatitis C) have become a more common cause of death. These infections were acquired from blood transfusion by many patients that were treated with factor concentrates prior to 1986. Since 1986 such plasma-derived products are all virally inactivated with heat or chemicals.

The main laboratory features of haemophilia A are shown in Table 8.25. The abnormal findings are a prolonged APTT and a reduced level of factor VIII. The PT, bleeding time and VWF level are normal.

**Treatment**

Bleeding is treated by administration of factor VIII concentrate by intravenous infusion to achieve normalization of levels. For surgery levels should be kept to normal levels until healing has occurred.

Factor VIII has a half-life of 12 h and therefore must be administered at least twice daily to maintain the required therapeutic level. Continuous infusion is sometimes used to
cover surgery. Factor VIII concentrate is freeze-dried and available as a small volume infusion so facilitating treatment at home and allowing it to be administered by the patient immediately after bleeding has started, reducing the likelihood of chronic damage to joints and the need for inpatient care.

*Factor VIII concentrate* is available as plasma-derived and recombinant products. Recombinant products are the treatment of choice for people with haemophilia, but economic constraints often limit availability, particularly in developing countries.

To prevent recurrent bleeding into joints and subsequent joint damage, patients with severe haemophilia are given factor VIII infusions regularly three times per week. Such ‘prophylaxis’ treatment is usually started in early childhood (around 2 years of age).

*Synthetic vasopressin* (desmopressin – an analogue of vasopressin) – intravenous, subcutaneous or intranasal – produces a 3–5-fold rise in factor VIII and is very useful in patients with a baseline level of factor VIII $>10$ IU/dL. It avoids the complications associated with blood products and is useful for treating bleeding episodes in mild haemophilia and as prophylaxis before minor surgery. It is ineffective in severe haemophilia.

People with haemophilia should be registered at comprehensive care centres (CCC), which take responsibility for their full medical care, including social and psychological support.

**Complications**

Up to 30% of people with severe haemophilia will, during their lifetime, develop antibodies to factor VIII that inhibit its action. Such inhibitors usually develop after the first few treatment doses of factor VIII. The prevalence of inhibitors is, however, only 5%–10% because inhibitory antibodies develop only rarely in moderate and mild haemophilia and often disappear spontaneously or with continued treatment.

Management of inhibitor patients is very difficult, as infused factor VIII is rapidly inactivated. Recombinant factor VIIIa at high ‘pharmacological’ levels can bypass factor IX/VIII activity and is an effective treatment in more than 80% of bleeding episodes in patients with high levels of inhibitor antibodies. Some prothrombin complex concentrates are also deliberately activated to produce factors, which also may ‘bypass’ the inhibitor and stop the bleeding.

The long-term aim of management is to eradicate the inhibitory antibody, particularly in those that have recently developed inhibitors. This is done using immune tolerance induction strategies, sometimes using additional immunosuppression and immunoadsorption.

Although a historical legacy of plasma-derived concentrates, the risk of viral transmission has been virtually eliminated (see p. 411)

Hepatitis A and B vaccination is offered routinely to all patients with haemophilia and von Willebrand’s disease. The clinical consequences of haemophilia patients infected with HIV are similar to other HIV-infected patients (see p. 175), except that Kaposis’s sarcoma does not occur. Similarly some hepatitis C infected patients progress to develop chronic liver disease and cirrhosis (see p. 323).

**Carrier detection and antenatal diagnosis**

Determination of carrier status in females begins with a family history and coagulation factor assays. Female carriers may have a low factor VIII level but the exact value is very variable, because of lyonization. Owing to this process early in embryonic life (that is, random inactivation of one chromosome; see p. 36), some carriers have very low levels of factor VIII while others will have normal levels. Carrier detection is carried out using molecular genetic testing/mutation analysis. Antenatal diagnosis may be carried out by molecular analysis of chorionic villus biopsy at $11–12$ weeks’ gestation if selective termination is being considered or by third trimester amniocentesis if not.

**Haemophilia B (Christmas disease)**

Haemophilia B is caused by a deficiency of factor IX. The inheritance and clinical features are identical to haemophilia A, but the incidence is only about 1 in 30,000 males. It has been identified as the type of haemophilia affecting the Russian Royal Family. The half-life of factor IX is longer at 18 hours. Haemophilia B is treated with factor IX concentrates, recombinant factor IX being generally available, and prophylactic doses are given twice a week. Desmopressin is ineffective. Gene therapy may be effective in managing seven haemophilia B.

**Von Willebrand’s disease (VWD)**

In VWD, there is defective platelet function as well as factor VIII deficiency, and both are due to a deficiency or abnormality of VWF (Fig. 8.39). VWF plays a role in platelet adhesion to damaged subendothelium as well as stabilizing factor VIII in plasma (see p. 414).

The VWF gene is located on chromosome 12 and numerous mutations of the gene have been identified. VWD has been classified into three types:

- **Type 1** partial quantitative deficiency of VWF and significant type 1 VWD is usually inherited as an autosomal dominant.
- **Type 2** is due to a qualitative abnormality of VWF, and it too is usually inherited as an autosomal dominant.
- **Type 3** is recessively inherited and patients have virtually complete deficiency of VWF. Their parents are often phenotypically normal.

Many subtypes of VWD are described, particularly type 2 variants, which reflect the specific qualitative changes in the VWF protein.

**Clinical features**

These are very variable. Type 1 and type 2 patients usually have relatively mild clinical features. Bleeding follows minor trauma or surgery, and epistaxis and menorrhagia often occur. Haemarthroses are rare. Type 3 patients have more severe bleeding but rarely experience the joint and muscle bleeds seen in haemophilia A.

Characteristic laboratory findings are shown in *Table 8.25*. These also include defective platelet aggregation with ristocetin.

**Treatment**

Treatment depends on the severity of the condition and may be similar to that of mild haemophilia, including the use of desmopressin where possible. Some plasma-derived factor VIII concentrates contain intact von Willebrand factor. These specific products are used to treat bleeding or to cover surgery in patients who require replacement therapy, such as those with type 3 (severe) VWD and those who do not respond adequately to desmopressin. Cryoprecipitate is used as a source of VWF, but should be avoided if possible since it is not virus inactivated.
Acquired coagulation disorders

**Vitamin K deficiency** (see also p. 207)

Vitamin K is necessary for the γ-carboxylation of glutamic acid residues on coagulation factors II, VII, IX and X and on proteins C and S. Without it, these factors cannot bind calcium.

Deficiency of vitamin K may be due to:

- **inadequate stores**, as in haemorrhagic disease of the newborn and severe malnutrition (especially when combined with antibiotic treatment) (see p. 208)
- **malabsorption of vitamin K**, a fat-soluble vitamin, which occurs in cholestatic jaundice owing to the lack of intraluminal bile salts
- **oral anticoagulant drugs**, which are vitamin K antagonists.

The PT and APTT are prolonged (Table 8.25) and there may be bruising, haematuria and gastrointestinal or cerebral bleeding. Minor bleeding is treated with phytomenadione (vitamin K1) 10 mg intravenously. Some correction of the PT is usual within 6 h but it may not return to normal for 2 days.

Newborn babies have low levels of vitamin K, and this may cause minor bleeding in the first week of life (classical haemorrhagic disease of the newborn). Vitamin K deficiency also causes late haemorrhagic disease of the newborn, which occurs 2–26 weeks after birth and results in severe bleeding such as intracranial haemorrhage. Most infants with these syndromes have been exclusively breast-fed, and both conditions are prevented by administering 1 mg i.m. vitamin K to all neonates (see p. 208). Concerns about the safety of this are unfounded.

**Liver disease**

Liver disease may result in a number of defects in haemostasis:

- **Vitamin K deficiency**. This occurs owing to intrahepatic or extrahepatic cholestasis.
- **Reduced synthesis**. Reduced synthesis of coagulation factors may be the result of severe hepatocellular damage. The use of vitamin K does not improve the results of abnormal coagulation tests, but it is generally given to ensure that a treatable cause of failure of haemostasis has not been missed.
- **Thrombocytopenia**. This results from hypersplenism due to splenomegaly associated with portal hypertension or from folate acid deficiency.
- **Functional abnormalities**. Functional abnormalities of platelets and fibrinogen are found in many patients with liver failure.
- **Disseminated intravascular coagulation**. DIC (see below) occurs in acute liver failure.

**Disseminated intravascular coagulation (DIC)**

Causes of DIC are listed in Box 8.5. There is widespread generation of fibrin within blood vessels, owing to activation of coagulation by release of procoagulant material, and by diffuse endothelial damage or generalized platelet aggregation. Activation of leucocytes, particularly monocytes causing expression of tissue factor and the release of cytokines, may play a role in the development of DIC. There is consumption of platelets and coagulation factors and secondary activation of fibrinolysis leading to production of fibrin degradation products (FDPs), which contributes to the coagulation defect by inhibiting fibrin polymerization (Fig. 8.40). The consequences of these changes are a mixture of initial thrombosis followed by a bleeding tendency due to consumption of coagulation factors and fibrinolytic activation.

**Clinical features**

The underlying disorder is usually obvious. The patient is often acutely ill and shocked. The clinical presentation of DIC varies from no bleeding at all to profound haemostatic failure with widespread haemorrhage. Bleeding may occur from the mouth, nose and venepuncture sites and there may be widespread ecchymoses.

Thrombotic events occur as a result of vessel occlusion by fibrin and platelets. Any organ may be involved, but the skin, brain and kidneys are most often affected.

**Investigations**

The diagnosis is often suggested by the underlying condition of the patient.

**Severe cases with haemorrhage**

- The PT, APTT and TT are usually very prolonged and the fibrinogen level markedly reduced.
- High levels of FDPs, including D-dimer, are found owing to the intense fibrinolytic activity stimulated by the presence of fibrin in the circulation.

**Box 8.5 Causes of DIC**

- Malignant disease
- Septicaemia (e.g. Gram-negative including meningococcal)
- Haemolytic transfusion reactions
- Obstetric causes (e.g. abruptio placentae, amniotic fluid embolism, pre-eclampsia)
- Trauma, burns, surgery
- Other infections (e.g. falciparum malaria)
- Liver disease
- Snake bite
Mild cases without bleeding

- Increased synthesis of coagulation factors and platelets
- Normal PT, APTT, TT and platelet counts
- FDPs are raised.

Treatment

The underlying condition is treated and this is often all that is necessary in patients who are not bleeding. Maintenance of blood volume and tissue perfusion is essential. Transfusions of platelet concentrates, FFP, cryoprecipitate and red cell concentrates is indicated in patients who are bleeding. Inhibitors of fibrinolysis such as tranexamic acid should not be used in DIC as dangerous fibrin deposition may result. Activated protein C concentrates have been used in selected cases. In those cases with a dominant thrombotic component the use of heparin seems logical but there is little evidence to suggest any benefit.

Excessive fibrinolysis

Excessive fibrinolysis occurs during surgery involving tumours of the prostate, breast, pancreas and uterus owing to release of tissue plasminogen activators.

Primary hyperfibrinolysis is very rare but activation of fibrinolysis occurs in DIC as a secondary event in response to intravascular deposition of fibrin.

The clinical picture is similar to DIC with widespread bleeding. Laboratory investigations are also similar with a prolonged PT, APTT and TT, a low fibrinogen level, and increased FDPs, although fragmented red cells and thrombocytopenia are not seen, since disseminated coagulation is not present.

If the diagnosis is certain, fibrinolytic inhibitors such as epsilon-aminocaproic acid (EACA) or tranexamic acid can be given but evidence for efficacy is lacking.

Massive transfusion

Few platelets and reduced levels of clotting factors are found in stored blood, although there are adequate amounts of the other coagulation factors. During massive transfusion (defined as transfusion of a volume of blood equal to the patient’s own blood volume within 24 hours, e.g. >10 units in an adult), the platelet count and PT and APTT should be checked at intervals.

Transfusion of platelet concentrates and FFP should be given if thrombocytopenia or defective coagulation are thought to be contributing to continued blood loss. Other problems of massive transfusion are described in Chapter 16.

Inhibitors of coagulation

Factor VIII autoantibodies arise occasionally in patients without haemophilia but with autoimmune disorders such as SLE; in elderly patients, with malignant disease and sometimes after childbirth. There can be severe bleeding. Immediate bleeding problems are managed as with bypassing factor concentrates (see p. 422). Longer-term therapy is to eliminate the autoantibody using immunosuppression, such as steroids, cyclophosphamide and, in severe cases, rituximab.

Lupus anticoagulant antibodies (see p. 538) are autoantibodies directed against phospholipids (antiphospholipid antibodies) and lead to prolongation of phospholipid dependent coagulation tests, particularly the APTT, but do not inhibit coagulation factor activity.

Thrombosis

A thrombus is defined as a solid mass formed in the circulation from the constituents of the blood during life. Fragments of thrombi (emboli) may break off and block vessels downstream. Thromboembolic disease is much more common than abnormal bleeding; nearly half of adult deaths in England and Wales are due to coronary artery thrombosis, cerebral artery thrombosis or pulmonary embolism.

A thrombus results from a complex series of events involving coagulation factors, platelets, red blood cells and the vessel wall.

Arterial thrombosis

This usually occurs in association with atheroma, which tends to form at areas of turbulent blood flow such as the bifurcation of arteries. Platelets adhere to the damaged vascular endothelium and aggregate in response to ADP and TxA2 to form a ‘white thrombus’. The growth of the platelet thrombus is limited at its margins by PGI2 and NO. Plaque rupture leads to the exposure of blood containing factor VIIa to tissue factor within the plaque, which may trigger blood coagulation and lead to thrombus formation. This results in complete occlusion of the vessel or embolization that produces distal obstruction. The risk factors for arterial thrombosis are related to the development of atherosclerosis (see p. 725).

Arterial thrombi may also form in the heart, as mural thrombi in the left ventricle after myocardial infarction, in the left atrium in mitral valve disease, or on the surfaces of prosthetic valves.

Venous thrombosis

Unlike arterial thrombosis, venous thrombosis often occurs in normal vessels. Major causes are stasis and hypercoagulability. The majority of venous thrombi occur in the deep veins of the leg, originating around the valves as ‘red thrombi’ consisting mainly of red cells and fibrin. The propagating thrombus is formed of fibrin and platelets and is particularly liable to embolize. Chronic venous obstruction following thrombosis in the deep veins of the leg frequently results in a permanently swollen limb and may lead to ulceration (post-phlebitic syndrome).

Risk factors for venous thrombosis are shown in Table 8.26. Venous thrombosis may occur with changes in blood cells such as polycythaemia and thrombocythaemia, and with coagulation abnormalities (thrombophilia; see below).

The clinical features and diagnosis of venous thrombosis are discussed on page 789.

Thrombophilia

Thrombophilia is a term describing inherited or acquired defects of haemostasis leading to a predisposition to venous or arterial thrombosis. It occurs in people with:

- Recurrent venous thrombosis
- Venous thrombosis for the first time under age 40 years
- An unusual venous thrombosis such as mesenteric or cerebral vein thrombosis
- Unexplained neonatal thrombosis
- Recurrent miscarriages
- Arterial thrombosis in the absence of arterial disease.
Antithrombin (AT) deficiency

This deficiency can be inherited as an autosomal dominant. Many variations have been described that lead to a conformational change in the protein. It can also be acquired following trauma, with major surgery and with the contraceptive pill. Low levels are also seen in severe proteinuria (e.g. the nephrotic syndrome). Recurrent thrombotic episodes occur starting at a young age in the inherited variety. Patients may be relatively resistant to heparin as antithrombin is required for its action. Antithrombin concentrates are available.

Protein C and S deficiency

These autosomal dominant conditions result in an increased risk of venous thrombosis, often before the age of 40 years. Homozygous protein C or S deficiency causes neonatal purpura fulminans, which is fatal without immediate replacement therapy. Protein C concentrate and a recombinant activated protein C are available.

Antiphospholipid antibody

See page 538.

Homocysteine

When elevated, this amino acid is associated with both arterial thrombosis and venous thromboembolism. The mechanism of vascular damage is unclear. Folate, B₁₂ and B₉ supplementation are often helpful in reducing levels.

 Investigations

Haemostatic screening test

- Full blood count including platelet count
- Coagulation screen including a fibrinogen level. These tests will detect erythrocytosis, thrombocytosis, and dysfibrinogenaemia and the possible presence of a lupus anticoagulant.

Testing for specific causes of thrombophilia

- Assays for naturally occurring anticoagulants such as AT, protein C and protein S
- Assay for activated protein C resistance and molecular testing for factor V Leiden and the prothrombin variant
- Screen for a coagulation factor inhibitor including a lupus anticoagulant (and antiphospholipid antibodies) (see p. 538).

Prevention and treatment of arterial thrombosis

Attempts to prevent or reduce arterial thrombosis are directed mainly at minimizing factors predisposing to atherosclerosis. Treatment of established arterial thrombosis includes the use of antiplatelet drugs and thrombolytic therapy.

Antiplatelet drugs

Platelet activation at the site of vascular damage is crucial to the development of arterial thrombosis, and this can be altered by the following drugs (Table 8.27):

- Aspirin irreversibly inhibits the enzyme cyclo-oxygenase (COX), resulting in reduced platelet production of TXA₂ (Fig. 8.34). At the low doses used in cardiovascular disease prevention or treatment, there is selective inhibition of the isoform COX-1 found within platelets. This inhibition cannot be repaired and is effective for the life of the circulating platelet, which is about 1 week. In recent years, it has been suggested there may be significant individual variability in the response to aspirin, although there is no clear reason for this. The term ‘aspirin resistance’ has been loosely applied when the clinical effects of aspirin are less than expected. No large body of clinical trial data is specifically available to correlate clinical events and laboratory findings with respect to aspirin response and so it is difficult to determine if the breakthrough events experienced by patients treated with aspirin represent aspirin resistance
Haematological disease

or are related to more mundane issues such as aspirin dose, drug interactions or drug non-compliance.

- **Dipyridamole** – which inhibits platelet phosphodiesterase, causing an increase in cyclic AMP with potentiation of the action of PGi2 – has been used widely as an antithrombotic agent, but there is little evidence that it is effective.

- **Clopidogrel** – irreversibly blockades the ADP (P2Y12) receptor on platelet cell membranes, so affecting the ADP-dependent activation of the glycoprotein IIb/IIIa complex. It is similar to ticlopidine but has fewer side-effects. Trials support its use in acute coronary syndromes (see p. 735).

- **Prasugrel**, a novel thienopyridine, is like clopidogrel and is licensed for use in acute coronary syndromes (see p. 735).

- **Glycoprotein IIb/IIIa receptor antagonists** block the receptor on the platelet for fibrinogen and von Willebrand factor (Fig. 8.41). Three classes have been described:

- murine–human chimeric antibodies (e.g. abciximab)
- synthetic peptides (e.g. epifibatide)
- synthetic non-peptides (e.g. tirofiban).

They have been used as an adjunct in invasive coronary artery intervention and as primary medical therapy in coronary heart disease. Excessive bleeding has been a problem.

- **Epoprostenol** is a prostacyclin, which is used to inhibit platelet aggregation during renal dialysis (with or without heparin) and is also used in primary pulmonary hypertension.

- **Terutoban** is a thromboxane prostaglandin receptor antagonist which is being trialled in secondary prevention of cerebrovascular and cardiovascular disease as an alternative to aspirin.

The indications for and results of antiplatelet therapy are discussed in the appropriate sections (p. 735).

### Thrombolytic therapy

**Streptokinase**

Streptokinase is a purified fraction of the filtrate obtained from cultures of haemolytic streptococci. It forms a complex with plasminogen, resulting in a conformational change, which activates other plasminogen molecules to form plasmin. Streptokinase is antigenic and the development of streptococcal antibodies precludes repeated use. Activation of plasminogen is indiscriminate so that both fibrin in clots and free fibrinogen are lysed, leading to low fibrinogen levels and the risk of haemorrhage.

**Plasminogen activators**

Tissue-type plasminogen activators (alteplase (t-PA), tenecteplase (TNK-tPA)) are produced by recombinant technology. Reteplase (r-PA) is also a recombinant plasminogen activator. They are not antigenic and do not give allergic reactions. They are relatively fibrin-specific, have relatively little systemic activity, and short half-lives (~5 min). The bleeding complications observed are similar in severity and frequency to those observed with streptokinase, suggesting that fibrin specificity does not confer protection against hemorrhage.

**Indications**

The use of thrombolytic therapy in myocardial infarction is discussed on page 739. The combination of aspirin with thrombolytic therapy produces better results than...
thrombolytic therapy alone. The extent of the benefit depends on how quickly treatment is given. They are also used in cerebral infarction (see p. 1102) and in massive pulmonary embolism where there is haemodynamic instability. The main risk of thrombolytic therapy is bleeding. Treatment should not be given to patients who have had recent bleeding, uncontrolled hypertension or a haemorrhagic stroke, or surgery or other invasive procedures within the previous 10 days.

**Prevention and treatment of venous thromboembolism**

Venous thromboembolism is a common problem after surgery, particularly in high-risk patients such as the elderly, those with malignant disease and those with a history of previous thrombosis (Table 8.28). The incidence is also high in patients confined to bed following trauma, myocardial infarction or other illnesses. The prevention and treatment of venous thrombosis includes the use of anticoagulants.

**VTE risk factors**

- Active cancer or cancer treatment
- Age >60 years
- Critical care admission
- Dehydration
- Known thrombophilias
- Obesity (BMI >30 kg/m²)
- One or more significant medical co-morbidities (e.g. heart disease, metabolic endocrine or respiratory pathologies, acute infectious diseases, inflammatory conditions)
- Personal history or 1st-degree relative with a history of VTE
- Use or HRT
- Use of oestrogen-containing contraceptive therapy
- Varicose veins with phlebitis

**Patients who are at risk of bleeding**

All patients who have any of the following:
- Active bleeding
- Acquired bleeding disorders (such as acute liver failure)
- Concurrent use of anticoagulants known to increase the risk of bleeding (such as warfarin with INR >2)
- Lumbar puncture/epidural/spinal anaesthesia within the previous 4 h or expected within the next 12 h
- Acute stroke
- Thrombocytopenia (platelets <75 x 10⁹/L)
- Uncontrolled systolic hypertension (>130/120 mmHg)
- Untreated inherited bleeding disorders (such as haemophilia or von Willebrand’s disease)

Anticoagulants

**Heparin (standard or unfractionated)**

Heparin is not a single substance but a mixture of polysaccharides. Commercially available unfractionated heparin consists of components with molecular weights varying from 5000 to 35000, with an average of about 13000. It was initially extracted from liver (hence its name) but is now prepared from porcine gastric mucosa. Heparin acts immediately, binding to antithrombin. This induces a conformational change which increases the inhibitory activity of antithrombin (at least 5000-fold) towards activated serine protease coagulation factors (thrombin, Xıa, Xıa, Xa, IXa and Xııa).

**Low-molecular-weight heparins (LMW heparins)**

These are produced by enzymatic or chemical degradation of standard heparin, producing fractions with molecular weights in the range of 2000–8000. Potentiation of thrombin inhibition (anti-IIa activity) requires a minimum length of the heparin molecule with an approximate molecular weight of 5400, whereas the inhibition of factor Xa requires only a smaller heparin molecule with a molecular weight of about 1700. LMW heparins have the following properties:

- Bioavailability is better than that of unfractionated heparin.
- They have greater activity against factor Xa than against factor IIa, suggesting that they may produce an equivalent anticoagulant effect to standard heparin but have a lower risk of bleeding, although this has not generally been confirmed. In addition, LMW heparins cause less inhibition of platelet function.
- They have a longer half-life than standard heparin and so can be given as a once-daily subcutaneous injection instead of every 8–12 h.
- They produce little effect on tests of overall coagulation, such as the APTT at doses recommended for prophylaxis. They are not fully neutralized by protamine.

LMW heparins are excreted renally and therefore dose reductions are required in those with renal impairment.

LMW heparins are widely used for antithrombotic prophylaxis, e.g. high-risk surgical patients and for the treatment of established thrombosis (see p. 747).

The main complication of all heparin treatment is bleeding. This is managed by stopping heparin. Very occasionally it is necessary to neutralize unfractionated heparin with protamine. Other complications include osteoporosis with prolonged therapy and thrombocytopenia.

**Heparin-induced thrombocytopenia (HIT)**. HIT is an uncommon complication of heparin therapy and usually occurs 5–14 days after first heparin exposure. It is due to an immune response directed against heparin/platelet factor 4 complexes. All forms of heparin have been implicated but the problem occurs less often with LMW heparins.

HIT is paradoxically associated with severe thrombosis and when diagnosed all forms of heparin must be discontinued, including heparin flush. Unfortunately the diagnosis can be difficult to make because patients on heparin are often very sick and may be thrombocytopenic for many other reasons. Laboratory tests based on bioassay or immunossay are available but are neither sensitive nor specific and management decisions often have to be made before results are available.

It is necessary to continue some form of anticoagulation in patients with HIT and the choice lies between the
heparinoid danaparoid and the direct thrombin inhibitor hirudin. The introduction of warfarin should be covered by one of these agents, as warfarin alone may exacerbate thrombosis as protein C levels fall.

**Fondaparinux**
This is a synthetic pentasaccharide, which inhibits activated factor X, similar to the LMW heparins. It is used in acute coronary syndrome (see p. 736). A long-acting version, idraparinux, which only needs to be given weekly is also available. Neither bind to platelet factor 4 and so have no capacity to cause HIT.

**Direct thrombin inhibitors**
A recombinant form of hirudin, lepirudin, is available. Hirudins bind directly to thrombin and are effectively irreversible inhibitors. They can be monitored by the use of the APTT and are excreted by the kidney, so must be used with caution in chronic kidney disease. *Lepirudin* is used for anticoagulation in patients with HIT.

**Bivalirudin** is a 20 amino acid synthetic analogue of hirudin. Compared with hirudin, it appears to cause less bleeding, is a reversible thrombin inhibitor (as it is broken down by thrombin) and has a shorter half-life. It is used in percutaneous coronary interventions.

**Oral anticoagulants**
These act by interfering with vitamin K metabolism. There are two types of oral anticoagulants, the coumarins and indanediones. The coumarin warfarin is most commonly used because it has a low incidence of side-effects other than bleeding.

The dosage is controlled by prothrombin tests (PT). Thromboplastin reagents for PT testing are derived from a variety of sources and give different PT results for the same plasma.

It is standard practice to compare each thromboplastin with an international reference preparation so that it can be assigned an international sensitivity index (ISI). The international normalized ratio (INR) is the ratio of the patient’s PT to a normal control when using the international reference preparation. Therapeutic ranges using the INR for warfarin in various conditions are shown in Box 8.6.

Each laboratory can use a chart adapted to the ISI of their thromboplastin to convert the patient’s PT to the INR. Suitably selected control plasmas can also be used to achieve the same objective. The use of this system means that PT tests on a given plasma sample using different thromboplastins result in the same INR and that anticoagulant control is comparable in different hospitals across the world.

**Contraindications** to the use of oral anticoagulants are seldom absolute and include:
- Severe uncontrolled hypertension
- Non-thromboembolic strokes
- Peptic ulceration (unless cured by *Helicobacter pylori* eradication)
- Severe liver and renal disease
- Pre-existing haemostatic defects
- Non-compliance.

Warfarin should be avoided in pregnancy because they are teratogenic in the first trimester and may be associated with fetal haemorrhage later in pregnancy. When anticoagulation is considered essential in pregnancy, self-administered subcutaneous heparin should be used as an alternative, although this may not be as effective for women with prosthetic cardiac valves. Specialist advice should be sought.

Many drugs interact with warfarin (see Ch. 17). More frequent PT testing should accompany changes in medication, which should occur with the full knowledge of the anticoagulant clinician.

**An increased anticoagulant effect due to warfarin** is usually produced by one of the following mechanisms:
- Drugs causing a reduction in the metabolism of warfarin, including tricyclic antidepressants, cimetidine, sulphonamides, phenothiazines and amiodarone
- Drugs such as clofibrate and quinidine which increase the sensitivity of hepatic receptors to warfarin
- Drugs interfering with vitamin K absorption (such as broad-spectrum antibiotics and cholestyramine) which also potentiate the action of warfarin
- Displacement of warfarin from its binding site on serum albumin by drugs such as sulphonamides (this is not usually responsible for clinically relevant interactions)
- Drugs that inhibit platelet function (such as aspirin) which increase the risk of bleeding
- Alcohol excess, cardiac failure, liver or renal disease, hyperthyroidism and febrile illnesses which result in potentiation of the effect of warfarin

**A decreased anticoagulant effect due to warfarin** This is usually produced by drugs that increase the clearance of warfarin by induction of hepatic enzymes that metabolize warfarin, such as rifampicin and barbiturates.

**Anticoagulant related bleeding.** Bleeding is the most serious side-effect of warfarin. Bleeding occurs in up to 4% of patients on oral anticoagulants per year, requires hospital admission in 2% and has a 0.25% morbidity associated with it. The benefit of anticoagulants must therefore be notably more than the risk of bleeding. Management of warfarin related bleeding (Emergency Box 8.1) is given dependent upon the INR and the degree of bleeding. Minor bleeding may be treated with cessation of warfarin alone, while serious bleeding will require additional use of vitamin K and factor concentrates.

**New orally active anticoagulants**
A large number of orally active direct thrombin (e.g. dabigatran) and Xa inhibitor drugs (e.g. rivaroxaban, apixaban) have been introduced for the treatment and prevention of venous and arterial thrombosis. Such drugs have a much broader therapeutic window than warfarin and offer the prospect of...
Prophylaxis to prevent venous thromboembolism (VTE)

Risk factors for VTE are well defined. Most hospitalized patients have one or more of these risk factors and VTE is common in hospitalized patients. The risk of developing deep vein thrombosis (DVT) after hip replacement surgery has been estimated to be as high as 50% when thromboprophylaxis is not used. Approximately 10% of hospital deaths may be due to pulmonary embolism (PE) and more people die from hospital-acquired venous thrombosis than the combined deaths from road traffic accidents, AIDS and breast cancer. PE is the most common preventable cause of hospital death.

Appropriate thromboprophylaxis is highly effective and cost effective. Such prophylactic measures include early mobilization, elevation of the legs, compression stockings, intermittent compression devices and use of anticoagulant drugs, such as LMW heparins and thrombin inhibitors. All patients, medical and surgical, admitted to hospital should be risk assessed for thrombotic risk and given appropriate thromboprophylaxis. National guidelines are available to guide appropriate management (NICE CG92). (See Table 8.28.)

Low-risk patients (Table 8.28) require no specific measures other than early mobilization.

High-risk patients based on risk assessment are most effectively managed using graduated compression stockings and LMW heparin subcutaneously daily.

The antithrombin agents dabigatran and rivaroxaban are routinely used after lower limb joint replacement surgery. They are as effective as LMW heparins and, as they are given orally, can be used for extended periods out of hospital.

Treatment of established venous thromboembolism

- The aim of anticoagulant treatment is to prevent further thrombosis and pulmonary embolization while resolution of venous thrombi occurs by natural fibrinolytic activity. Anticoagulation is started with heparin as it produces an immediate anticoagulant effect. Heparin should be administered for approximately 5 days, the time taken for simultaneously administered warfarin to produce an anticoagulant effect (INR 2.5).

- LMW heparin (e.g. tinzaparin 175 U/kg daily, dalteparin 200 U/kg daily, enoxaparin 1.5 mg/kg daily) is equally effective and as safe as unfractionated heparin in the immediate treatment of deep vein thrombosis and pulmonary embolism. This creates the opportunity for treatment of venous thromboembolism without admission to hospital, in compliant patients without co-existing risk factors for haemorrhage.

- Length of anticoagulation. This is recommended for at least 6 weeks after precipitated isolated calf vein thrombosis and at least 3 months after precipitated proximal DVT or PE in patients who have temporary risk factors. For patients with idiopathic VTE or permanent risk factors at least 3 months’ anticoagulation is recommended and consideration should be given to indefinite anticoagulation.

- Use of longer-term anticoagulation in patients with previous thrombosis. It has been suggested that a lower INR might be safer and equally effective but the current view is that the target INR should be 2.0–3.0 where oral anticoagulation is used. Indefinite anticoagulation is considered appropriate for those with two or more episodes of VTE.

- Outpatient anticoagulation is best supervised in anticoagulant clinics. Patients are issued with national booklets for recording INR results and anticoagulant doses. Home monitoring is possible in well-motivated patients.

Inferior vena caval filters are an important tool to prevent PE in patients that have a contraindication to anticoagulation. Many are now retrievable allowing removal once a temporary contraindication to anticoagulation has passed. Long-term use of an IVC filter is associated with a risk of thrombosis at and below the site of the filter.

The role of thrombolytic therapy in the treatment of venous thrombosis is not established. It is used in patients with massive pulmonary embolism who are haemodynamically unstable and in patients with extensive deep venous thrombi.

Thrombolytic therapy should be followed by anticoagulation with heparin for a few days and then by oral anticoagulants to prevent rethrombosis.

The term ‘malignant disease’ encompasses a wide range of illnesses, including common ones such as lung, breast and colorectal cancer (Table 9.1) as well as rare ones, like the acute leukemias. Malignant disease is widely prevalent and, in the West, almost one-third of the population will develop cancer at some time during their life. It is second only to cardiovascular disease as the cause of death. Although the mortality of cancer is high, many advances have been made, both in terms of treatment and in understanding the biology of the disease at the molecular level.

**THE BIOLOGY OF CANCER**

Most human neoplasms are clonal in origin, i.e. they arise from a single population of precursor or cancer stem cells. This process is typically initiated by genetic aberrations within this precursor cell. Cancer is increasingly common the older we get and can be related to a time dependent accumulation of DNA damage that is not repaired by the normal mechanisms of genome maintenance, damage tolerance and checkpoint pathways. Malignant transformation may result from a gain in function as cellular proto-oncogenes become mutated (e.g. ras), amplified (e.g. HER2) or translocated (e.g. BCR-ABL). However, these mutations are insufficient to cause malignant transformation by themselves. Alternatively, there may be a loss of function of tumour suppressor genes such as P53 that normally suppress growth. Loss or gain of function may also involve alterations in the genes controlling the transcription of the oncogenes or tumour suppressor genes (p. 46). Over subsequent cell divisions, heterogeneity develops with the accumulation of further genetic abnormalities (Fig. 9.1).

The genes most commonly affected can be characterized as those controlling cell cycle checkpoints, DNA repair and DNA damage recognition, apoptosis, differentiation, growth factor receptors and signalling pathways and tumour suppressor genes (Table 9.2). Recognition of critical genetic alterations has enabled extensive development of new targeted drugs such as imatinib that inhibits the growth signals of the abnormal tyrosine kinase BCR/ABL. Proliferation may continue at the expense of differentiation which, together with the failure of apoptosis, leads to tumour formation with the accumulation of morphologically abnormal cells varying in size, shape and cytoplasmic or nuclear maturity.

The hallmarks in developing cancer are shown in Figure 9.2.

**Tumour immunology**

Tumour cells are usually not recognized and killed by the immune system. There are two main reasons. The first is failure to express molecules such as HLA and co-stimulatory B7 molecules that are required for activation of cytotoxic, or ‘killer’, T lymphocytes. Second, tumours may also actively secrete immunosuppressive cytokines and cause a generalized immunosuppression. Successful strategies for tumour vaccines that overcome these obstacles are developing in renal cancer and prostate cancer. The monoclonal antibody ipilimumab against the inhibitory cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) molecule that is expressed after T-cell activation, is used in melanoma (p. 479).

**Angiogenesis**

For many tumours, there is a progressive slowing of the rate of growth as the tumours become larger. This occurs for many reasons, but outgrowing the blood supply is paramount. New vessel formation (angiogenesis) is stimulated by a variety of peptides produced both by tumour cells and by host inflammatory cells, such as basic fibroblast growth factor (bFGF), angiopoietin 2 and vascular endothelial growth factors (VEGFs), which are stimulated by hypoxia. The
Malignant disease

The hallmarks of cancer: the next generation. Six biological capabilities acquired during the multistep development of human tumours have been identified as shown in figure. Two others have been identified, viz reprogramming of energy metabolism and evading immune destruction. (From Hanagan D and Weinberg PA. The Hallmarks of cancer: the Next Generation. Cell 2011;144:646–474 with permission.)

### Invasion and metastasis

Solid cancers spread by both local invasion and by distant metastasis through the vessels of the blood and lymphatic systems. Infiltration into surrounding tissues is associated with loss of cell–cell cohesion, which is mediated by active homotypic cell adhesion molecules (CAMs). Epithelial cadherin (E-cadherin) is expressed by many carcinomas and mutated in some such as familial gastric carcinoma (see p. 252).

anti-VEGF-receptor monoclonal bevacizumab has had some success in colorectal and ovarian cancer.
Invasion is also determined by the balance of activators to inhibitors of proteolysis. The matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) are involved in tumour growth, invasion, metastasis and angiogenesis and are being targeted in new therapeutic drugs for cancer treatment.

Dissemination of tumour cells occurs through intravasation into the vascular and lymphatic vessels and dissemination to distant sites, partly by chance, but also because of specific interactions between receptors and cytokines found on stromal and tumour cells such as TNF, IL-6 and chemokines.

AETIOLOGY AND EPIDEMIOLOGY

For most patients, the cause of their cancer is unknown, probably representing a multifactorial interaction between individual genetic predispositions and environmental factors.

Genetic factors

Rather than occurring by somatic mutation in response to mutagens, germline mutations in the genes that predispose to the development of cancer may be inherited and therefore present in all tissues. Examples of such cancer syndromes are given in Table 9.3. Expression of the mutation and hence carcinogenesis, will depend upon the penetrance (due to the level of expression and the presence of other genetic events) of the gene and whether the mutated allele has a dominant or recessive effect. There is a small group of autosomal dominant inherited mutations such as RB (in retinoblastoma), and a small group of recessive mutations (Table 9.3). Carriers of the recessive mutations are at risk of developing cancer if the second allele becomes mutated, leading to ‘loss of heterozygosity’ within the tumour, although this is seldom sufficient as carcinogenesis is a multistep process.

Environmental factors

A wide range of environmental factors have been identified as being associated with the development of malignancy (Table 9.4) and may be amenable to preventative action such as smoking cessation, dietary modification and antiviral immunization (Box 9.1). Environmental factors interact with genetic predisposition. For example, subsequent generations of people moving from countries with a low incidence to those with a high incidence of breast or colon cancer acquire the cancer incidence of the country to which they have moved while northern European people exposed to strong UV radiation have the highest risk of developing melanoma.

Tobacco

The incidence of lung cancer in both men and women increased dramatically in the last 25 years worldwide, but is now falling in many developed countries. The association of smoking with lung cancer is indisputable and causative mechanisms have been identified: cigarette tobacco is responsible for one-third of all deaths from cancer in the UK. Smoking not only causes lung cancer, it is also associated with cancer of the mouth, larynx, oesophagus and bladder. Smoking is discussed on page 806.

Alcohol

Alcohol is associated with cancers of the upper respiratory and gastrointestinal tracts, and it also interacts with tobacco in the aetiology of these tumours. It may be associated with an increased risk of breast cancer.

Diet

Dietary factors have been attributed to account for one-third of cancer deaths, although it is often difficult to differentiate these from other epidemiological factors. For example, the incidence of stomach cancer is particularly high in the Far East, while breast and colon cancers are more common in

Box 9.1 Key messages for a healthy lifestyle for preventing cancer

- Stop smoking
- Moderate alcohol consumption
- Healthy weight
- Moderate exercise
- Healthy eating (fruit and vegetables, high fibre, low fat/sugar)
- Limited sun exposure
- Minimize occupational risk
- Minimize radiation exposure
- Vaccination against hepatitis B and HPV

Further Reading

Malignant disease

T-cell leukaemia, seen almost exclusively in residents of the southern island of Japan and in the West Indies, is caused by infection with the locally endemic retrovirus HTLV-1 (human T-cell leukaemia virus) and integration of the oncogene, \( \text{TAX} \), into the cellular genome.

Hepatocellular carcinoma occurs in patients with hepatitis B and C virus infections and Burkitt’s lymphoma and nasopharyngeal carcinoma are associated with the Epstein–Barr virus. EBV is also linked with Hodgkin’s lymphoma (see p. 459).

Patients with HIV infection or immunosuppression from organ transplantation have an increased incidence of EBV-related lymphoma and herpesvirus-8-associated Kaposi’s sarcoma.

The incidence of cervical cancer had increased among younger women in association with sexually transmitted HPV (human papillomavirus) infection types 16 and 18, for which an effective vaccine is now available.

Bacterial infection with \( \text{Helicobacter pylori} \) predisposes to the development of gastric cancer and gastric lymphoma, while \( \text{Schistosoma japonicum} \) infection predisposes to the development of squamous cell carcinomas in the bladder.

**Environmental/occupational**

Ultraviolet light is known to increase the risk of skin cancer (basal cell, squamous cell and melanoma). The incidence of melanoma is therefore particularly high in the white Anglo-Celtic population of Australia, New Zealand and South Africa, where exposure to UV light is combined with a genetically predisposed population.

Arsenical contamination of water supplies has been linked to high incidence of lung and colon cancers in Southeast Asia particularly where bore holes are the main water source.

Occupational factors. In 1775, Percival Pott described the association between carcinogenic hydrocarbons in soot and the development of scrotal epitheliomas in chimney sweeps. The principal causes now are asbestos (lung and mesothelial cancer) and polycyclic hydrocarbons from fossil fuel combustion (skin, lung, bladder cancers). Organic chemicals, such as benzene, may cause the development of bone marrow conditions such as myelodysplastic syndrome or acute myeloid leukaemia.

**Infectious agents**

The geographical distribution of a rare malignancy suggests that it might be caused by, or associated with, an infective agent. Chronic persistent infection provides growth stimulation while many viruses contain transforming viral oncogenes.

UK background radiation is 2.6 mSv per year. 1 mSv carries a lifetime cancer risk of 1 in 17 500 and 5 mSv a risk of 1 in 3500.

Figure 9.4 Percentage of all deaths due to cancer in the different regions of the world. (From: http://info.cancerresearchuk.org/cancerstats/world/the-global-picture/)

Asymptomatic detection through screening

Most common cancers start as focal microscopic clones of transformed cells and diagnosis only becomes likely once sufficient tumour bulk has accumulated to cause symptoms or signs. In order to try to make an earlier diagnosis and increase the curative possibilities, an increasing number of screening programmes are being developed which target the asymptomatic or preinvasive stages of the cancer as in cervix, breast and colon or use serum tumour markers as in prostate and ovarian cancers. Genetic screening can be used to target screening to groups at most risk of developing cancer, e.g. BRCA1 positive and breast cancer (see Table 9.3). The aim of screening programmes is to improve individual and/or population survival by detecting cancer at its very early stages when the patient is asymptomatic. This strategy is dependent upon finding tests that are sufficiently sensitive and specific, using detection methods that identify cancer before it has spread and having curative treatments that are practical and consistent with maintenance of a normal lifestyle and quality of life.

Screening is provided to populations, e.g. for breast, cervical and colon cancer in the UK, and also to individuals via occupational exposure unless precautions are taken to minimize this using personal and environmental shielding and to record and limit the amount of personal exposure.

Therapeutic. Long-term survivors following radiotherapy, e.g. for Hodgkin’s lymphoma, have an increased incidence of cancer, particularly at the radiation field margins.

Diagnostic. Imaging procedures involving radiation exposure are associated with an increased risk of cancer. This risk is cumulative, dose dependent and time dependent, i.e. children are at higher risk than adults. The cancer risk of various common investigations is shown in Table 9.5. All doctors should strive to minimize diagnostic exposure to radiation where possible using alternative modalities such as ultrasound or MRI. Good documentation of radiation doses is required. This is particularly so in children and pregnant women.

Epidemiology

The incidence and mortality from cancer varies by tumour type and geographical region across the world.

Geographical distribution

The incidence of cancer across the world is dependent on the local environmental factors, the diet and the genetics of the population (see above) (Figs 9.3, 9.4). Age is also a factor as most cancers occur in those over the age of 65 who comprise 3.3% of the population in Africa compared with 15.2% in Europe. Reproductive patterns also influence breast cancer. Migrating individuals often take on the risks of the local environmental factors.

Other factors

Incidence and mortality are closely linked for cancers for which treatment has yet to make significant improvements such as lung, stomach and liver, while in countries with effective screening programmes, there is an increasing incidence and decreasing mortality for breast, cervix, bowel and prostate cancers.

THE CLINICAL PRESENTATION OF MALIGNANT DISEASE

Asymptomatic detection through screening

Most common cancers start as focal microscopic clones of transformed cells and diagnosis only becomes likely once

Figure 9.5 Lead time bias. Earlier diagnosis, at X, made by screening tests before the clinical diagnosis, at Y, suggests an increased survival time of A + B. The actual survival time (C) remains unchanged.

An effective screening procedure should:
- be affordable to the healthcare system
- be acceptable to all social groups so that they attend for screening
- have a good discriminatory index between benign and malignant lesions
- show a reduction in mortality from the cancer.

Cervical cancer. The smear test is cheap and safe but requires a well-trained cytologist to identify the early changes (dyskaryosis and cervical intraepithelial neoplasia, CIN). However, developments in liquid cytology and DNA testing for human papillomavirus (HPV) may overcome this. Effective treatment for high-risk preinvasive malignant changes reduces the incidence and mortality from cervical cancer, although there are no randomized trials. Screening will continue to be required despite the introduction of vaccination against HPV infection for women before they become sexually active because the lag time between infection and the appearance of disease can be in the order of 40–50 years.

Breast cancer. The UK NHS Breast Screening Programme (i.e. biplanar mammography every 3 years) for women aged 50–70 years has been shown to reduce mortality from breast cancer in randomized controlled studies. The test is acceptable to most women with 50–75% of women attending for screening when sufficiently educated about the benefits. In North America, there is continuing debate about whether annual mammography from a younger age is more effective. The cost is estimated to be between £250,000 and £1.3 million per life saved, money which, according to critics of screening, could be used more appropriately in better treatment.

Women from families with BRCA1, BRCA2 and p53 mutations require intensive screening starting at an earlier age when mammography is inaccurate due to greater breast density and MRI scanning is preferred.

Colorectal cancer (CRC). Faecal occult blood is a cheap test for the detection of CRC. Large randomized studies have shown a reduction in cancer-related mortality of 15–33%. However, the false-positive rates are high, meaning many unnecessary colonoscopies (see p. 291). The UK has recently introduced a national screening programme using faecal occult blood in patients aged 60–64 years, in which positive tests have identified that 10% have cancer and 40% adenomas. A randomized trial in Norway has found an increased number of early stage cancers in the screened population but a high incidence of interval cancers between biennial screens.

Colonoscopy is the ‘gold-standard’ technique for the examination of the colon and rectum and is the investigation of choice for high-risk patients. Universal screening strategies have been recommended in the USA, but the shortage of skilled endoscopists, the expense, the need for full bowel preparation and the small risk of perforation make colonoscopy impractical as a population screening tool at present and CT colonography (‘virtual colonoscopy’) (see Fig. 6.5) may become an alternative along with genetic testing and stool DNA tests.

Other population-based screening programmes that are being used or are in trials are:

Prostate cancer. Serum prostate-specific antigen (PSA) can be used for the detection of this cancer, which is on the increase. Many men over 70 have evidence of prostate cancer at post mortem with no symptoms of the disease and it has been suggested that over 75-year-olds should not have screening PSAs. The test must be interpreted with caution due to the natural increase in PSA with age, benign prostatic hypertrophy and with prostatitis. The early results of screening for prostate cancer have varied greatly from no benefit in a low-risk population to a halving of deaths from prostate cancer in a general population study but with no overall reduction in mortality. Currently national screening programmes are not recommended.

Epithelial ovarian cancer. Serum CA125 can be used for the early detection of this cancer and is the subject of ongoing trials. An improvement in survival of a screened population can be shown but at the cost of many unnecessary laparotomies so that further enhancements are being investigated by serial testing and in combination with transvaginal ultrasound scans.

The symptomatic patient with cancer

Patients may offer information of predisposing conditions and family history that alerts the clinician to the likelihood of a cancer diagnosis. Many present with a history of tumour site-specific symptoms, e.g. pain, and physical signs, e.g. a mass, which readily identify the primary site of the cancer. However, some only seek medical attention when more systemic and nonspecific symptoms occur such as weight loss, night sweats, fever, fatigue, recurrent infections and anorexia. These usually indicate a more advanced stage of the disease, except in some paraneoplastic and ectopic endocrine syndromes (see below). Other patients are only diagnosed upon the discovery of established metastases such as the abdominal distension of ovarian cancer, the back pain of metastatic prostatic cancer or the liver enlargement of metastatic gastrointestinal cancer (Table 9.6).

Paraneoplastic syndromes are indirect effects of cancer (Box 9.2, Fig. 9.6) that are often associated with specific types of cancer and may be reversible with treatment of the cancer. The effects and mechanisms can be very variable. For example in the Lambert–Eaton syndrome (see p. 1152), there is cross-reactivity between tumour antigens and the normal tissues, e.g. the acetylcholine receptors at neuromuscular junctions.

The coagulopathy of cancer may present with thrombophlebitis, deep venous thrombosis and pulmonary emboli, particularly in association with cancers of pancreas, stomach

and breast. Some 18% of patients with recurrent pulmonary embolus will be found to have an underlying cancer and many cancer patients are at increased risk of venous thromboembolism (VTE) following diagnosis. Trousseau’s syndrome – superficial thromboembolitis migrans – refers to this process in the superficial venous system. All patients with active cancer admitted to hospital are at high risk of VTE and should be given prophylaxis with subcutaneous LMW heparin in the absence of any contraindications (see p. 429). Dabigatran, an oral direct thrombin inhibitor, is an alternative therapy. Other symptoms are related to peptide or hormone release, e.g. carcinoid or Cushings’s syndrome.
Reactivated herpes zoster (Shingles).

Cachexia of advanced cancer is thought to be due to release of chemokines such as tumour necrosis factor (TNF), as well as the fact that patients have a loss of appetite. The unexplained loss of >10% of body weight in a patient should always stimulate a search for an explanation.

Cancer-associated immunosuppression can lead to reactivation of latent infections such as herpes zoster and tuberculosis.

Serum tumour markers

Tumour markers are intracellular proteins or cell surface glycoproteins released into the circulation and detected by immunoassays. Examples are given in Table 9.7. Values in the normal range do not necessarily equate with the absence of disease and a positive result must be corroborated by histology as these markers can be seen in many benign conditions. They are most useful in the serial monitoring of response to treatment. As discussed in subsequent sections, a proportion of low-grade B-cell lymphomas and a majority of cases of myeloma will produce a monoclonal paraprotein of intact immunoglobulin molecule or light chains. This acts as a valuable tumour marker in the diagnosis and assessment of response.

Cancer imaging

Radiological investigation by experts is required at various stages: at initial diagnosis and staging of the disease, during the monitoring of treatment efficacy, at the detection of recurrence and for the diagnosis and treatment of complications.

The choice of investigations needs to be guided by the patient’s symptoms and signs, site and histology of the cancer, the curative or palliative potential of treatment and the utility of the information in guiding treatment. The investigations are described under each tumour type.

Contrast agents are used for increased structural discrimination and can be further enhanced with functional specificity for metabolically active tissue with 19fluorodeoxy-glucose uptake and CT-positron emission tomography (CT-PET scan) as used extensively in head and neck cancer, lung cancer and lymphoma. Radionuclide imaging of sentinel lymph nodes is used to guide lymphatic surgery in breast cancer and melanoma. Tumour targeted contrast agents can improve detection rates such as the radiolabelled MAb rituximab for lymphoma or radiolabelled small molecules such as octreotide for neuroendocrine tumours. Research into the use of reporter agents which become visible only upon activation within the tumour environment holds the promise of greater sensitivity and specificity in the future.

Biopsy and histological examination

The diagnosis of cancer may be suspected by both patient and doctor but advice about treatment can usually only be given on the basis of a tissue diagnosis. This may be obtained by endoscopic, radiologically-guided or surgical biopsy or on the basis of cytology (e.g. lung cancer diagnosed by sputum cytology). Malignant lesions can be distinguished morphologically from benign ones by the pleiomorphic nature of the cells, increased numbers of mitoses, nuclear abnormalities of size, chromatin pattern and nucleolar organization and evidence of invasion into surrounding tissues, lymphatics or vessels. The degree of differentiation (or conversely of anaplasia) of the tumour has prognostic significance: generally speaking, more differentiated tumours have a better prognosis than poorly-differentiated ones. In some tumours where the surgical procedure will vary depending on the presence of malignancy, an intraoperative histological opinion can be rapidly obtained using a tissue sample processed using ‘frozen section’ techniques, which requires the availability of a histopathologist. This obviates the need for the sample to be paraffin embedded, which takes hours to days.

Tissue tumour markers. Immunocytochemistry, using monoclonal antibodies against tumour antigens, is very helpful in differentiating between lymphoid and epithelial tumours and between some subsets of these, for example T- and B-cell lymphomas, germ cell tumours, prostatic tumours, neuroendocrine tumours, melanomas and sarcomas. However, there is much overlap in the expression of many of the markers and some adenocarcinomas and squamous carcinomas do not bear any distinctive immunohistochemical markers that are diagnostic of their primary site of origin.

Molecular markers of genetic abnormalities have long been available in the haematological cancers and are increasingly available in solid cancers. For example, fluorescent in situ hybridization (FISH, see p. 40) can be used to look for characteristic chromosomal translocations, e.g. in lymphoma and leukaemia, as well as deletions or amplifications, e.g. in breast cancer (see genetic basis of cancer, p. 45). Cancer treatment

**Aims of treatment**

Optimal cancer treatment is delivered by a multidisciplinary team which coordinates the delivery of the appropriate anticancer treatment (surgery, chemotherapy, radiotherapy and biological/endocrine therapy), supportive and symptomatic care and psychosocial support. While all members will have the patient’s care as their central concern, someone, often the oncologist, has to take responsibility for the coordination of the many professionals involved.

The organization across multiple departments and coordination from primary to secondary and tertiary care has become known as a patient pathway. Establishment of agreed patient pathways has enabled more effective and timely delivery of care and post-treatment rehabilitation. The aim is to provide optimal treatment and for the patient to experience seamless and high quality care and to allow audit and continuing improvement against agreed standards. Central to this endeavour is the involvement of the patient, through education as to the nature of their disease and the treatment options available. An informed choice can then be made, even if in the end it is simply to abide by the decisions made by the professionals. Good communication embodies a humane approach which preserves hope at an appropriate level through empathy and understanding of the patient’s position (see p. 14).

**A curative approach**

For most solid tumours local control is necessary, but not sufficient, for cure because of the presence of systemic (microscopic) disease, while haematological cancers are usually disseminated from the outset. Improvement in the rate of cure of most cancers is thus dependent upon earlier detection to increase the success of local treatment and effective systemic treatment. The likelihood of cure of the systemic disease depends upon the type of cancer and its expression of appropriate treatment targets, its drug sensitivity and tumour bulk (microscopic or clinically detectable). A few rare cancers are so chemosensitive that even bulky metastases can be cured, e.g. leukaemia, lymphoma, gonadal germ cell tumours and choriocarcinoma. For most common solid tumours such as lung, breast and colorectal cancer, there is no current cure of bulky (clinically detectable) metastases, but micrometastatic disease treated by adjuvant systemic therapy (see below) after surgery can be cured in 10–20% of patients.

**Adjuvant therapy for solid tumours**

This is defined as treatment given, in the absence of macroscopic evidence of metastases, to patients at risk of recurrence from micrometastases, following treatment given for the primary lesion. ‘Neoadjuvant’ therapy, alternatively, is given before primary surgery, to both shrink the tumour to improve the local excision and treat any micrometastases as soon as possible.

Micrometastatic spread by lymphatic or haematological dissemination often occurs early in the development of the primary tumour and can be demonstrated by molecular biological methods capable of detecting the small numbers (1 in $10^7$) of circulating cells. Studies correlating prognosis with histological features of the primary cancer, e.g. differentiation, invasion of blood vessels or regional lymph nodes and molecular markers, e.g. Her2 in breast cancer, enable risk stratification and increasing individualization of therapy.

The success of adjuvant treatment across many tumour types relies upon careful selection of patients according to defined risk criteria and the reduction of treatment toxicity to reach a balanced risk/benefit ratio. Relative risk reductions in the order of 12–33% and absolute improvements in 5–10-year survival of 5–25% (dependent upon the pre-existing risk) have been achieved in common epithelial cancers such as lung, bowel, breast and prostate, with greater absolute improvements in the more sensitive germ cell tumours.

While these improvements currently translate into many lives saved from common diseases at a public health level, the majority who receive such treatment do not benefit because they were already cured, or because the cancer is resistant to the treatment. Better tests, e.g. gene arrays and circulating tumour cells, are being developed to identify those with the micrometastases who really need treatment.

On an individual patient basis the decision on whether adjuvant treatment will be worthwhile must include consideration of other factors such as the patient’s life expectancy, concurrent medical conditions and lifestyle priorities.

**A palliative approach**

When cure is no longer possible, palliation, i.e. relief of tumour symptoms, preservation of quality of life and prolongation of life, is possible in many cancers in proportion to their drug and radiation sensitivity. There is on average a 2–18-month prolongation in median life expectancy with treatments for solid tumours (see specific tumour types for details) and up to 5–8 years for some leukaemias and lymphomas, with those with the most responsive tumours experiencing the greatest benefit. The development of more effective chemotherapeutic drugs, targeted biological agents and better supportive care has done much to reduce the side-effects of systemic therapy and to improve the cost/benefit ratio for the patient receiving palliative treatment.

In addition, through early assessment during treatment, it is possible to stop if no evidence of benefit is demonstrable early on, so as to minimize exposure to toxic and unsuccessful treatment.

**Assessments before treatment**

**Staging**

Before a decision about treatment can be made, not only the type of tumour but also its extent and distribution need to be established. Various ‘staging investigations’ are therefore performed before a treatment decision is made. To be useful clinically the staging system must subdivide the patients into groups of different prognosis which can guide treatment selection.

The staging systems vary according to the type of tumour and may be site specific (see Hodgkin’s lymphoma, p. 461),
or the TNM (tumour, node, metastases) classification shown in Table 15.29, which can be adapted for application to most common cancers.

**Performance status**

In addition to anatomical staging, the person’s age and general state of health need to be taken into account when planning treatment. The latter has been called ‘performance status’ and is of great prognostic significance for all tumour types (Table 9.8). Performance status reflects the effects of the cancer on the patient’s functional capacity. An alternative performance rating scale is by Karnovsky. With a performance status of 2, response to and survival following treatment are greatly reduced for most tumour types.

**Assessing the benefits of treatment**

A measurable response to treatment can serve as a useful early surrogate marker when assessing whether to continue a given treatment for an individual patient. Trials to assess response to treatment in advanced disease have identified active agents for use in the more curative setting of adjuvant treatment of early stage disease.

Response to treatment can be subjective or objective. A **subjective response** is one perceived by the patient in terms of, for example, relief of pain and dyspnoea, or improvement in appetite, weight gain or energy. Such subjective response is a major aim of most palliative treatments. Quantitative measurements of these subjective symptoms (Patient Reported Outcome Measures, PROMs) form a part of the assessment of response to chemotherapy, especially in those situations where cure is not possible and where the aim of treatment is to provide prolongation of good-quality life. In these circumstances, measures of quality of life enable an estimate of the balance of benefit and side-effects to be made.

An **objective response** to treatment is assessed clinically and radiologically. The term ‘remission’ is often used synonymously with ‘response’, which, if complete, means an absence of detectable disease without necessarily implying a cure of the cancer. The terms used to evaluate the responses of tumours are given in Box 9.3. For a complete response all previous clinical abnormalities should have resolved and this needs to be confirmed by clinical examination or sampling of the primary disease site, e.g. by bone marrow examination in leukaemia. Where a tumour marker exists, such as a paraprotein in myeloma or β-hCG in testicular cancer, reductions in the level of tumour markers are useful surrogates for evidence of tumour response. They are also useful predictors for disease recurrence. Radiologically, a complete response, is the complete disappearance of all detectable disease and a partial response, defined since 1999 by the Response Evaluation Criteria in Solid Tumors (RECIST) convention, is a ≥30% reduction in the sum of all measurable lesion diameters.

The final assessment of treatment outcome is the impact of the therapy on remission duration and survival, i.e. the cure rate. Such survival figures are increasingly incorporating quality of life assessments and a health economic assessment to calculate the number of quality adjusted life years (QALY) gained for the cost of the treatment and judgements made about health system affordability.

When counselling, the individual patient’s interpretation of the trial evidence for benefit must be adjusted for the degree to which they resemble the population from which it is derived and the cost interpreted in view of their comorbidities and lifestyle choices.

**PRINCIPLES OF CHEMOTHERAPY**

Cytotoxic chemotherapy employs systemically administered drugs that directly damage cellular DNA (and RNA). It kills cells by promoting apoptosis and sometimes frank necrosis. Different cytotoxic drugs work at different stages in the cell cycle (Fig. 9.7; see also Fig. 2.13).

There is a narrow therapeutic window between effective treatment of the cancer and normal tissue toxicity, because cytotoxic drugs are not cancer specific (unlike some of the targeted biological agents) and the increased proliferation in cancers is not much greater than in normal tissues (see tumour growth and failure of apoptosis, p. 32, 33). The dose and schedule of the chemotherapy is limited by the normal tissue tolerance, especially in those more proliferative tissues of the bone marrow and gastrointestinal tract mucosa. All tissues can be affected, however, depending upon the

**Figure 9.7 Cell cycle** (see also Fig. 2.13) and chemotherapy drugs.

**Figure 9.8 Effects of multiple courses of cytotoxic chemotherapy,** showing the decrease in the number of cells with each course.

The therapeutic effect on the cancer is achieved by a variety of mechanisms which seek to exploit differences between normal and transformed cells. While most of the drugs have been derived in the past by empirical testing of many different compounds, e.g. alkylating agents, the new molecular biology is leading to targeting of particular genetic defects in the cancer (see tyrosine kinase inhibitors, p. 445).

Toxicity to normal tissue can be limited in some instances by supplying growth factors such as granulocyte colony-stimulating factor (G-CSF) or by the infusion of stem cell preparations to diminish myelotoxicity. The use of more specific targeted biological agents with relatively weak pro-apoptotic effects in combination with the general cytotoxics has also improved the therapeutic ratio (see trastuzumab and breast cancer, p. 475). Certain cytotoxic therapies may also be administered into the pleural space, the peritoneum, the CSF or into the arterial supply of a tumour.

Most tumours rapidly develop resistance to single agents given on their own through changes in membrane transport and DNA repair pathways. For this reason, the principle of intermittent combination chemotherapy was developed. Several drugs are combined together, chosen on the basis of differing mechanisms of action and non-overlapping toxicities. These drugs are given over a period of a few days, followed by a rest of a few weeks, during which time the normal tissues have the opportunity for regrowth. If the normal tissues are more proficient at DNA repair than the cancer cells, it may be possible to deplete the tumour while allowing the restoration of normal tissues between chemotherapy cycles (Fig. 9.8).

In many experimental tumours, it has been shown that there is a log–linear relationship between drug dose and number of cancer cells killed and that the maximum effective dose is very close to the maximum tolerated dose at which dose-limiting toxicity is reached. With a chemosensitive tumour, relatively small increases in dose may have a large effect on tumour cell kill. It is therefore apparent that where cure is a realistic option the dose administered is critical and may need to be maintained despite toxicity. In situations where cure is not a realistic possibility and palliation is the aim, a sufficient dose to exceed the therapeutic threshold, but not cause undue toxicity, is required as the short-term quality of life becomes a major consideration.

**Classification of cytotoxic drugs** (Table 9.9)

**DNA damaging drugs**

*Alkylating agents* act by covalently binding alkyl groups and their major effect is to cross-link DNA strands, interfering with DNA synthesis and causing strand breaks. Despite being among the earliest cytotoxic drugs developed, they maintain a central position in the treatment of cancer. Melphalan is one of the original nitrogen mustards and is used in multiple myeloma. Chlorambucil is used in Hodgkin’s lymphoma and chronic lymphocytic leukaemia. Other common alkylating agents include cyclophosphamide and ifosfamide,

as well as the nitrosoareas, carmustine (BCNU), bendamustine, lomustine (CCNU) and busulfan used in chronic myeloid leukaemia. Tetrazines also alkylate DNA; dacarbazine is used in Hodgkin’s lymphoma and temozolomide in malignant gliomas.

Platinum compounds. Cisplatin, carboplatin and oxaliplatin cause interstrand cross-links of DNA and are often regarded as non-classical alkylating agents. They have transformed the treatment of testicular cancer (cisplatin) and have a major role against many other tumours, including lung, ovarian and head and neck (cis or carboplatin) and gastrointestinal (oxaliplatin) cancer. Toxicity, as for other heavy metals, includes renal and peripheral nerve damage.

Antimetabolites

Antimetabolites are usually structural analogues of naturally occurring metabolites that interfere with normal synthesis of nucleic acids by falsely substituting purines and pyrimidines in metabolic pathways. Antimetabolites can be divided into:

Folic acid antagonists, e.g. methotrexate. This is structurally very similar to folic acid and binds preferentially to dihydrofolate reductase, the enzyme responsible for the conversion of folic acid to folinic acid. It is used widely in the treatment of solid tumours and haematological malignancies. Folinic acid is often given to ‘rescue’ normal tissues from the effects of high doses of methotrexate.

Pyrimidine antagonists. 5-Fluorouracil (5FU) consists of a uracil molecule with a substituted fluorine atom. It acts by blocking the enzyme thymidylate synthase, which is essential for pyrimidine synthesis. 5-Fluorouracil has a major role in the treatment of solid tumours, particularly gastrointestinal cancers. Oral capecitabine is metabolized to 5FU and tegafur for pyrimidine synthesis. 5-Fluorouracil has a major role against many other tumours, including lung, colon and rectal cancer.

Arabinosides inhibit DNA synthesis by inhibiting DNA polymerase. Cytosine arabinoside (cytarabine, Ara-C) is used almost exclusively in the treatment of acute myeloid leukaemia where it remains the backbone of therapy, while its analogue gemcitabine is proving useful in a number of solid cancers such as lung, breast, pancreas and ovary. Fludarabine is used in the treatment of B cell chronic lymphocytic leukaemia: it is also used in reduced intensity stem cell transplantation (see this chapter) because of its immunosuppressive effect. Other related drugs have found niche applications in acute leukaemia (cladribine, clofarabine, neltarabine/AraG) and myelodysplasia (azacytidine).

Purine antagonists, e.g. 6-mercaptopurine and 6-thioguanine, which are both used almost exclusively in the treatment of acute leukaemia.

DNA repair inhibitors

Epipodophyllotoxins. These are semisynthetic derivatives of podophyllotoxin which inhibit topoisomerase. Topoisomerase enzymes allow unwinding and uncoiling of supercoiled DNA. Etoposide is a drug used in a wide range of cancers and works by maintaining DNA strand breaks by inhibiting the enzyme topoisomerase II. Topoisomerase I inhibitors such as irinotecan and topotecan have also proved active against lung, colon, ovary and cervix cancer.

Cytotoxic antibiotics. The anthracyclines act by intercalating adjoining nucleotide pairs on the same strand of DNA and by inhibiting topoisomerase II DNA repair. They have a wide spectrum of activity in haematological and solid tumours. Doxorubicin and its congener epirubicin are two of the most widely used of all cytotoxic drugs but have cumulative toxicity to the myocardium. Pegylated liposomal doxorubicin is used for Kaposi’s sarcoma and as second-line treatment for advanced ovarian cancer with reduction of cardiac toxicity, but increased toxicity to the skin on the palms of the hands and soles of the feet. Amsacrine is a similar drug used occasionally in acute myeloid leukaemia. Bleomycin and mitomycin are also intercalating agents which promote the cleavage of DNA and RNA. Bleomycin has a particular toxicity to the lung causing interstitial fibrosis.

Antitubulin agents

Vinca alkaloids. Drugs such as vincristine, vinblastine and vinorelbine act by binding to tubulin and inhibiting microtubule formation during mitosis (see p. 20). They are used in the treatment of haematological (vincristine and vinblastine) and non-haematological cancers (vinorelbine). They are associated with neurotoxicity due to their anti-microtubule effect and must never be given intrathecally as this is lethal.

Taxanes. Paclitaxel and docetaxel bind to tubulin dimers and prevent their assembly into microtubules. They are active drugs against many cancers such as ovarian, breast and lung cancer. Taxanes can cause neurotoxicity and hypersensitivity reactions and patients should be premedicated with steroids, H1 and H2 histamine antagonists prior to treatment.

Side-effects of chemotherapy

Chemotherapy carries many potentially serious side-effects and should be used only by trained practitioners; however, an appreciation of its common potential side-effects is necessary for any general physician who is called to see a cancer patient on chemotherapy. The five most common side-effects are vomiting, hair loss, tiredness, myelosuppression and mucositis (Table 9.10). Side-effects are much more directly dose related than anticancer effects and it has been

Extravasation of intravenous drugs. Cytotoxic drugs should only be given by trained personnel. They cause severe local tissue necrosis if leakage occurs outside the vein. Stop the infusion immediately and institute local measures, e.g. aspirate as much of the drug from the cannula, infiltrate area with 0.9% saline and apply warm compresses. Antihistamines and corticosteroids may give symptomatic relief. Dexrazoxane is used for anthracycline extravasation.

Nausea and vomiting. The severity of this common side-effect varies with the cytotoxic and it can be eliminated in 75% of patients by using modern antiemetics. Nausea and vomiting are particular problems with platinum analogues. A stepped policy with antiemetics such as metoclopramide and domperidone followed by 5-HT3 serotonin antagonists (e.g. ondansetron, granisetron) combined with dexamethasone should be used to match the emetogenic potential of the chemotherapy. Aprepitant, a neurokinin receptor antagonist, is helpful in preventing acute and delayed nausea and vomiting. It is used with dexamethasone and a 5-HT3 antagonist. Drugs such as cyclizine, haloperidol and levomepromazine and benzodiazepines can be used to control persistent nausea.

Hair, skin and nails. Many but not all cytotoxic drugs are capable of causing hair loss. Scalp cooling can sometimes be used to reduce hair loss but in general this side-effect can only be avoided by selection of drugs where this is possible. Hair regrows on completion of chemotherapy. Nails will demonstrate banding reflecting periods of cessation of growth during each chemotherapy cycle and skin toxicity may be particularly pronounced with 5FU, capecitabine and docetaxel (Fig. 9.9).

Fatigue is often significant and may continue beyond completion of therapy. Other problems such as anaemia or depression may exacerbate this. Attention should be paid to nutrition, hydration, sleep hygiene, gentle exercise, task prioritization, pacing, realistic target setting and scheduling rest within the day.

Bone marrow suppression and immunosuppression. Suppression of the production of red blood cells, white blood cells and platelets occurs with most cytotoxic drugs and is a dose-related phenomenon (Fig. 9.10). Severely myelosuppressive chemotherapy may be required if treatment is to be given with curative intent despite the potential for rare but fatal infection or bleeding. Anaemia and thrombocytopenia are managed by red cell or platelet transfusions. (Neutropenic infection is discussed on p. 448.) The risk of infective problems can be ameliorated by the use of prophylactic antimicrobials, such as ciprofloxacin, or the use of GCSF as primary prophylaxis in those chemotherapy regimens with a significant risk of febrile neutropenia or those patients on less intensive therapies who are at higher risk due to age or co-morbidity.

Mucositis. This common side-effect of chemotherapy reflects the sensitivity of the mucosa to antimitotic agents. It causes severe pain in the oropharyngeal region and problems with swallowing and nutrition. Mucositis can be generalized throughout the intestinal tract when it can cause life-threatening diarrhoea. Treatment is with anti-septic and anti-candidal mouthwash and, if severe, fluid and antibiotic support, as the mucosa is a portal for entry of enteric organisms. Palifermin, a recombinant keratinocyte derived growth factor, may ameliorate severe chemotherapy and radiotherapy induced mucositis.

FURTHER READING

Other toxicities

**Cardiotoxicity.** This is a rare side-effect of chemotherapy, usually associated with anthracyclines such as doxorubicin, and can present as an acute arrhythmia during administration or cardiac failure due to cardiomyopathy after chronic exposure. This effect is dose-related and can largely be prevented by restricting the cumulative total dose of anthracyclines within the safe range (equivalent to 450 mg/m² body surface area cumulative doxorubicin dose). The risk of anthracycline cardiomyopathy is also dependent on other treatments such as trastuzumab or radiotherapy as well as other cardiac risk factors such as hypertension, smoking and hypercholesterolaemia. Cardiotoxicity can also be reduced by using the analogue epirubicin or by reducing peak drug concentrations through delayed release preparations such as liposomal doxorubicin. S-Fluorouracil and its prodrug capecitabine can cause cardiac ischaemia.

**Neurotoxicity.** This occurs predominantly with the vinca alkaloids, taxanes and platinum analogues (but not carboplatin). It is dose-related and cumulative. Chemotherapy is usually stopped before the development of a significant polyneuropathy, which once established is only partially reversible. Vinca alkaloids such as vincristine must never be given intrathecally as the neurological damage is progressive and fatal.

**Nephrotoxicity.** Cisplatin (but not oxaliplatin or carboplatin), methotrexate and ifosfamide can potentially cause renal damage. This can usually be prevented by maintaining an adequate diuresis during treatment to reduce drug concentration in the renal tubules and careful monitoring of renal function.

**Sterility and premature menopause.** Some anticancer drugs, particularly alkylating agents, but also anthracyclines and docetaxel, may cause gonadal damage resulting in sterility and in women the loss of ovarian oestrogen production, which may be irreversible.

In males, the storage of sperm prior to chemotherapy should be offered to the patient when chemotherapy is given with curative intent.

In females, collection of oocytes to be fertilized in vitro and cryopreserved as embryos for subsequent implantation is most successful; however it is also possible to collect and freeze by vitrification of unstimulated oocytes. Cryopreservation of ovarian tissue and retrieval of viable oocytes for subsequent fertilization is still experimental. The recovery of gonadal function is dependent upon the status before treatment and in women this is mostly related to age since menarche, with those under the age of 40 having significantly more ovarian reserve.

**Secondary malignancies.** Anticancer drugs have mutagenic potential and the development of secondary malignancies, predominantly acute leukaemia, is an uncommon but particularly unwelcome long-term side-effect in patients otherwise cured of their primary malignancies. The alkylating agents, anthracyclines and epipodophyllotoxins are particularly implicated in this complication.

**Haemopoietic stem cell transplantation (HSCT)**

HSCT is used in a range of malignancies and some nonmalignant disorders such as sickle cell disease. It relies on the ability of transfused haemopoietic stem cells to repopulate the marrow niche that has been rendered temporarily or permanently hypoplastic from chemotherapy with or without additional radiotherapy. Such procedures vary in the source of the stem cells and in the type and intensity of the preparatory conditioning regimen (Box 9.4).

**Autologous stem cell transplantation**

Most anticancer drugs have a sigmoid dose–response relationship which suggests that, up to a point, a higher dose of a cytotoxic drug will induce a greater response. However, increasing cytotoxic drug dose is often not possible, owing to toxicity. For those chemotherapeutic agents with a dose-limiting toxicity of bone marrow failure, infusion of previously harvested haemopoietic stem cells is able to ‘rescue’ the haemopoietic system and permits the use of higher doses to overcome tumour drug resistance. Haemopoietic stem cells are either collected from the patient’s bone marrow, or more commonly by leucopheresis from the peripheral blood following stem cell mobilization from the marrow niche by the administration of the growth factor granulocyte colony-stimulating factor (G-CSF) with or without chemotherapy. These stem cells are stored by cryopreservation and then reinfused intravenously after an intensive, chemotherapy regimen. This approach has been particularly effective in relapsed leukaemias, lymphomas, myeloma and germ cell tumours. However, tumour contamination of the reinfused stem cells remains a reality. Treatment-related mortality is in the region of 1–5%. Such an approach is also being evaluated for the treatment of severe autoimmune disease, such as Crohn’s.

**Allogeneic stem cell transplantation**

**Conventional ablative allogeneic transplants**

These combine the cytotoxic effect of high-dose therapy with a potent immunotherapy effect. Historically, the transplantation of donor haemopoietic cells has been combined with myeloablative chemotherapy with or without radiotherapy with the dual effects of treating the malignancy as well as causing temporary immunosuppression that allows the graft ‘to take’. Donors are usually fully matched at the major HLA antigens. Thus siblings are more likely to be found to be potential donors than unrelated volunteers. Allogeneic transplantation has been successfully used in acute and chronic leukaemias and myeloma. The engrafment of the donor immune system, with antitumour activity (graft-versus-tumour), is primarily responsible for the increased effectiveness of this approach. Complications include graft-versus-host disease (GVHD), an allo-immune reaction of the donor cells against normal host organs, which can affect 30–50% of transplant recipients and is potentially fatal in some cases. Immunosuppression, both from conditioning therapy and from the immunosuppressive drugs (cyclosporin or tacrolimus) given to prevent graft-versus-host disease, results in a high incidence of opportunistic infection and viral reactivation, e.g. CMV. All patients receiving prophylactic antibacterial, antifungal and antiviral drugs. Mortality therefore from conventional allogeneic stem cell transplantation is a major problem, with 20–40% at risk of dying from the procedure,
depending on the age and status of the recipient and the degree of HLA compatibility of the donor. The use of donor lymphocyte infusions following allogeneic bone marrow transplantation (BMT), while losing some of the specificity, has produced the strongest evidence for the efficacy of immunotherapy via graft-versus-tumour activity with clinical remissions observed, albeit with a risk of triggering GVHD.

Non-myeloablative allogeneic stem cell transplantation
This has been developed using conditioning therapy containing drugs such as fludarabine which are primarily immunosuppressive rather than myelosuppressive. This maintains the anticancer ‘graft-versus-leukaemia’ effect of the transplant without the toxicity of conventional allogeneic stem cell transplantation. Treatment-related mortality is lower and the technique can be used successfully particularly in the elderly and those with co-morbidities. GVHD remains an obstacle to success however.

PRINCIPLES OF ENDOCRINE THERAPY

Oestrogens are capable of stimulating the growth of breast and endometrial cancers and androgens the growth of prostate cancer. Removal of these growth factors by manipulation of the hormonal environment may result in apoptosis and regression of the cancer. Endocrine therapy can be curative in a proportion of patients treated for micrometastatic disease in the adjuvant setting for breast and prostate cancer and provides a minimally toxic non-curative (palliative) treatment in advanced/metastatic disease. The presence of detectable cellular receptors for the hormone is strongly predictive of response. However, this is also modified by the many molecular interactions between the activation pathways of, for example, EGFR and oestrogen receptor (ER). (See breast cancer p. 475 and prostate cancer p. 481.)

PRINCIPLES OF BIOLOGICAL AND TARGETED THERAPY

Biological therapies
Interferons
Interferons are naturally occurring cytokines that mediate the cellular immune response. They are both antiproliferative and stimulate humoral and cell-mediated immune responses to the tumour that can result in an antitumour effect if the host effector mechanisms are fully competent.

Alpha-interferon (IFN-α) has been used to treat advanced melanoma and renal cell carcinoma. Treatment with IFN has side-effects (see p. 321), most commonly flu-like symptoms, which tend to diminish with time, and fatigue, which generally does not, and can be treatment limiting. IFN was given as a daily subcutaneous injection, but conjugation with polyethylene glycol (PEG interferon) has led to a reduction in frequency of injection and severity of side-effects.

Interleukins
Interleukin 2, a recombinant protein, is used to activate T-cell responses, often in conjunction with interferon-stimulated B-cell activation. Antitumour activity has been observed in renal cell carcinoma and melanoma with responses in 10–20% of patients, occasionally for prolonged periods. Toxicity is common; acutely this includes the capillary leak syndrome with hypotension and pulmonary oedema, while autoimmune thyroiditis and vitiligo occur later.

Immunotherapy
While the most dramatic evidence for immunotherapy is seen in the allogeneic HSCT above, activation of the immune system using Bacille Calmette–Guérin (BCG) for bladder cancer induces responses in 60% of patients. Certain antigens that are specific to cancer cells, such as sequences of tumour immunoglobulin from B-cell lymphomas, or melanoma antigens, have been used as tumour vaccines together with manipulation of the immune system to overcome tolerance.

Immunomodulatory drugs (IMIDs)
thalidomide, lenalidomide
This family of immunomodulatory drugs are being increasingly used in a range of malignancies, such as myeloma, chronic lymphocytic leukaemia (CLL) and myelodysplastic syndrome (MDS) as well as some solid tumours. They have antiangiogenic functions as well as affecting cytokine production, tumour/stromal interactions and T-cell co-stimulatory functions. They are all considered teratogenic and should be avoided in women of reproductive potential unless extra precaution is taken against conceiving.

Proteasome inhibitors
The proteasome degrades redundant or damaged proteins that have been labelled by a process called ubiquitination. Such proteins include cyclins and cyclin-dependent kinases as well as factors in the NFκB pathway. Inhibition of the proteasome leads to apoptosis in cancer cells and is synergistic with other treatments such as steroids and chemotherapy. Bortezomib is the first of such inhibitors to reach clinical practice and is used in myeloma as well as some types of NHL.

Targeted therapies
Monoclonal antibodies
Monoclonal antibodies (MAB) directed against tumour cell surface antigens are ‘humanized’ by being genetically engineered and have a range of functions:

- As direct treatment for B cell lymphoid malignancy (e.g. rituximab anti-CD20 surface antigen). Tumour cell lysis occurs by both complement- and antibody-dependent cellular cytotoxicity.
- As a carrier molecule to target toxins or radioisotopes to the tumour cells, e.g. anti-CD20 conjugated to radioactive yttrium or iodine has been used as treatment for non-Hodgkin’s lymphoma.
- As anti-growth factor agents added to chemotherapy. They act by inhibiting dimerization of the extracellular receptor molecules, e.g. trastuzumab and pertuzumab target a member of the epidermal growth factor receptor (EGFR) family, the Her2/Neu or c-erbB2 antigen to increase the apoptotic response to cytotoxics in breast cancer. Others include bevacizumab anti-VEGF receptor in colorectal and breast cancer, cetuximab anti-EGFR for head and neck and colorectal cancers and ipilimumab for melanoma.

Side-effects are those of hypersensitivity to the foreign protein and specific cross-reactivities, e.g. trastuzumab for the myocardium, bevacizumab for the mucosa and renal tubule and cetuximab for the skin follicles.

**Intracellular signal inhibitors** (Table 9.12)

Many cancer cells are transformed by the activity of the protein products of oncogenes that signal growth by phosphorylation of tyrosine residues on the intracellular portion of growth factor receptors. Small molecule inhibitors have many pharmacokinetic advantages over the MAb inhibitors. The first example was the tyrosine kinase inhibitor (TKi) imatinib, which specifically inhibits the BCR-ABL fusion oncoprotein and c-Kit. This compound is an extremely effective treatment for chronic myeloid leukaemia and gastrointestinal stromal tumours (GIST), which are characterized by the presence of the c-Kit target. Lapatinib, which inhibits Her2, has increased survival in breast cancer. The less specific TKIs sunitinib and sorafenib which inhibit signalling by EGFR and VEGFR have proved effective in metastatic renal cancer, while erlotinib and gefitinib have shown activity in lung cancer. Vemurafenib is a kinase inhibitor and has a specificity for BRAF-V600 as used in malignant melanoma (p. 1226). Many other similar molecules are in preclinical or early clinical development but heterogeneity within a single tumour occurs and genomic anomalies may not all be represented in a single biopsy specimen.

**Gene therapy**

Antisense oligonucleotides are short sequences of DNA bases which specifically inhibit complementary sequences of either DNA or RNA. As a result, they can be generated against genetic sequences, which are specific for tumour cells. Their clinical development has been hampered by poor uptake by tumour cells and rapid degradation by natural endonucleases. However, one antisense sequence directed against the Bcl-2 oncogene has been shown to have an antitumour effect in patients with non-Hodgkin’s lymphoma. Viral vectors for the transfection of tumour cells in vivo are being tested as a way of delivering specific replacement gene therapy in head and neck cancers.
Theoretical background

Radiation delivers energy to tissues, causing ionization and excitation of atoms and molecules. The biological effect is exerted through the generation of single- and double-strand DNA breaks, inducing apoptosis of cells as they progress through the cell cycle and through the generation of short-lived free radicals, particularly from oxygen, which damage proteins and membranes. The generation of free radicals depends upon the degree of oxygenation/hypoxia in the target tissues. This can affect the biological effect by up to threefold and is the subject of continuing research for hypoxic cell sensitizers to overcome the reduced efficacy of radiation for hypoxic tumours. Hypoxia, however, may also drive a more malignant potential further, so reduced efficacy is only part of the solution to the hypoxia problem.

The radiation effect will also depend upon the intensity of the radiation source, measured as the linear energy transfer or frequency of ionizing events per unit of path, which is subject to the inverse square law as the energy diminishes with the distance from the source. The depth of penetration of biological tissues by the photons depends upon the energy of the beam. Low-energy photons from an 85 kV source are suitable for superficial treatments, while high-energy 35 MV sources produce a beam with deeper penetration, less dose at the initial skin boundary (skin sparing), sharper edges and less absorption by bone. Superficial radiation may be also delivered by electron beams from a linear accelerator that has had the target electrode that generates the X-rays removed.

The radiation dose is measured in Gray (Gy), where 1 Gray = 1 joule (J) absorbed per kilogram of absorbing tissue. The biological effect is dependent upon the dose rate, duration, volume irradiated and the tissue sensitivity. Sensitivity to photon damage is greatest during the G2–M phase of the cell cycle and is also dependent upon the DNA repair capacity of the cell.

Types of radiation therapy

External beam (or teletherapy) from a linear accelerator source produces X-rays. The energy is transmitted as photons and is the most commonly used form of radiotherapy. Cobalt-60 generators can also provide γ-rays and high-energy photons, but are being gradually phased out. Most external beam treatments that are given with curative intent are delivered in 1.5–2 Gy fractions daily for 5 days per week.

Fractionation is the delivery of the radiation dose in increments separated by at least 4–6 hours to try to exploit any advantage in DNA repair between normal and malignant cells.

Hyperfractionation is when more than one fraction per day is given and this approach has been shown to improve outcome in head and neck and lung cancer. The treatment can also be accelerated, i.e. the total dose is given in a shorter overall time. For example a standard curative treatment taking 6.5 weeks can be accelerated so that the same dose is delivered in 5.5 weeks. Radiation dose is thus described by three factors:

- Total dose in Gy
- Number of fractions
- Time for completion.

**Box 9.5 Palliative benefits of radiotherapy**

- Pain relief, e.g. bone metastases
- Reduction of headache and vomiting in raised intracranial pressure from CNS metastases
- Relief of obstruction of bronchus, oesophagus, ureter and lymphatics
- Preservation of skeletal integrity from metastases in weight-bearing bones
- Reversal of neurological impairment from spinal cord or optic nerve compression by metastases

**Principles of radiation therapy**

**Brachytherapy** is the use of radiation sources in close contact with the tissue to provide intense exposure over a short distance to a restricted volume. Such techniques have been used to treat localized breast, prostatic and cervical carcinoma.

**Systemic radionuclides**, e.g. iodine-131, or radioisotope-labelled monoclonal antibodies (e.g. anti-CD20 for lymphoma) and hormones (e.g. somatostatin for carcinoid tumours), can be administered by intravenous or intracavitary routes to provide radiation targeted to particular tissue uptake via surface antigens or receptors.

**Clinical application of radiation therapy**

Radiotherapy treatment planning involves both detailed physics of the applied dose and knowledge of the biology of the cancer and whether the intention is to treat the tumour site alone, or include the likely loco-regional patterns of spread. Normal tissue tolerance will determine the extent of the side-effects and therefore the total achievable dose. A balanced decision is made according to the curative or palliative intent of the treatment and the likely early or late side-effects.

The cancers for which radiotherapy is usually employed in a primary curative approach, when the tumour is anatomically localized, are listed in Table 9.13, along with those in which radiotherapy has curative potential when used in addition to surgery (adjuvant radiotherapy). Palliative treatments are frequently used to provide relief of symptoms to improve quality if not duration of survival (Box 9.5). Palliative treatment is usually given in as few fractions as possible over as short a time as possible. Radiotherapy planning, by the use of CT scanning guidance, has been complemented by the introduction of 3-dimensional planning and intensity modulated radiotherapy (IMRT) which can deliver curved dose distributions to enable an improved therapeutic ratio. This allows a greater differential in dose between the tumour and critical normal structures, in turn allowing dose escalation or a reduced risk of toxicity. 4D radiotherapy planning is also becoming widely used varying radiation dose over time, e.g. the respiratory cycle during lung cancer treatment. Stereotactic focused irradiation using the γ-knife or Cyberknife can concentrate gamma radiation from multiple sources onto...
a small volume to generate an ablative dose for treating tumours of the CNS and isolated metastases.

**Combination chemoradiotherapy**

The local efficacy of radiotherapy can be increased by the simultaneous but not serial addition of chemotherapy with agents such as cisplatin, mitomycin and 5FU for cancers of the head and neck, lung, oesophagus, stomach, rectum, anus and cervix. Reduced local recurrence rates have translated into survival benefits and further research is investigating the concurrent use of biological agents (e.g. epidermal growth factor receptor inhibitors) with radiation.

**Side-effects of radiotherapy**

- **Early radiotherapy side-effects** may occur within days to weeks of treatment when they are usually self-limiting but associated with general systemic disturbance (Table 9.14). The side-effects will depend upon tissue sensitivity, fraction size and treatment volume and are managed with supportive measures until normal tissue repair occurs. The toxicity may also be enhanced by exposure to other radiation-sensitizing agents, especially some cytotoxics, e.g. bleomycin, actinomycin, anthracyclines, cisplatin and 5-fluorouracil.

- **Later side-effects** occur from months to years later, unrelated to the severity of the acute effects because of their different mechanism. Late effects reflect both the loss of slowly proliferating cells and a local endarteritis which produces ischaemia and proliferative fibrosis. The risks of late side-effects are related to the fraction size and total dose delivered to the tissue.

- Growth may be arrested if bony epiphyses are not yet fused and are irradiated, leading to distorted skeletal growth in later life.

- **Secondary malignancies** following radiotherapy may appear 10–20 years after the cure of the primary cancer. Haematological malignancies tend to occur sooner than solid tumours from the irradiated tissues. The latter are very dependent upon the status of the tissue at the time of treatment, e.g. the pubertal breast is up to 300 times more sensitive to malignant transformation than the breast tissues of a woman in her thirties. Patients who smoke are more liable to develop lung cancer. Treatment of these secondary cancers can be successful providing there is normal bone marrow to reconstitute the haemopoietic system or the whole tissue at risk can be resected (e.g. thyroid after mantle radiotherapy for lymphoma).

**ACUTE ONCOLOGY**

The acute care of all patients admitted to hospital with a cancer diagnosis has become known as acute oncology, in order to ensure a co-ordinated patient care, with access to all facets of the multidisciplinary team and thus the most efficient use of high cost inpatient facilities. In addition, there are a number of common oncological emergencies for which urgent treatment is critical for success (Table 9.15).

**Neutropenic sepsis**

This is the most common cause of attendance in the emergency department for any cancer patient and must be always considered in any patient who is unwell within a month of chemotherapy. Neutropenic patients are at high risk of bacterial and fungal infection, most often from enteric bowel flora. Patients must be warned of the possibility of neutropenic fever occurring. Nonspecific symptoms are also common, e.g. nausea, diarrhoea, drowsiness, breathlessness. A fever >37.5°C may not always be present. The critical test is the full blood count and patients with neutrophils <1.0 × 10⁹/L are managed by the immediate introduction of broad-spectrum antibiotics and fluid resuscitation. Treatment can be risk stratified and low-risk patients managed with oral antibiotics such as co-amoxiclav. However, signs of systemic illness such as tachycardia, hypotension, oliguria mandate urgent admission and resuscitation with intravenous treatment (Box 9.6). Initial empirical therapy should be reviewed following microbiological results. All such patients need to be discussed with the appropriate specialist oncology team and hospitals should have clear protocols for the rapid institution of antibiotics in such patients within an hour of arrival in the A&E department. In units practised in the assessment of febrile neutropenia it is possible to follow

and as a side-effect of chemotherapy (Fig. 9.11). It often presents with unexplained breathlessness and episodic exacerbations from multiple small emboli, rather than chest pain. A high level of suspicion should be kept in any cancer patient with hypoxia or chest pain. CT pulmonary angiogram

**Figure 9.11 Pulmonary embolism.**

a more risk-stratified antibiotic policy and avoid or curtail admission with oral co-amoxiclav plus ciprofloxacin when low-risk features are present: i.e. absence of tachycardia, hypotension, hypoxia and mucositis and an expected short duration of myelosuppression.

**Pulmonary embolus**

This is a common complication of the coagulopathy of cancer and as a side-effect of chemotherapy (Fig. 9.11). It often presents with unexplained breathlessness and episodic exacerbations from multiple small emboli, rather than chest pain. A high level of suspicion should be kept in any cancer patient with hypoxia or chest pain. CT pulmonary angiogram

**Immediate intervention is essential**

- Resuscitation with intravenous fluids to restore circulatory function, monitor urine output, GCS and central venous pressure
- Cultures of blood, urine, sputum and stool
- Empirical antibiotics as per local policy and sensitivities
- Intensive care review and consideration for inotropic support at an early stage
  - Commonly used antibiotics should include activity against enteric Gram-negative bacteria and *Pseudomonas*, e.g. co-amoxiclav, ceftazidime or piperacillin-tazobactam with gentamicin; meropenem monotherapy
  - May require antibiotics against staphylococci, especially with indwelling venous access lines, e.g. vancomycin
- If the patient deteriorates clinically and/or temperature still elevated after 48 hours, change antibiotics according to culture results or empirically increase Gram-negative and consider adding Gram-positive cover. Discuss with Microbiology.
- If fever not responding to broad-spectrum antibiotics – consider imaging, e.g. chest CT to detect occult source for fever, and adding treatment for opportunistic infections
  - liposomal amphotericin B or voriconazole – *Candida* and *Aspergillus*
  - high-dose co-trimoxazole – *Pneumocystis*
  - clarithromycin – *Mycobacteria* and *Legionella*
  - antituberculous therapy – *Mycobacterium tuberculosis*

**Figure 9.12 Bulky anterior mediastinal mass** in a patient presenting with superior vena cava obstruction. T lymphoblastic lymphs.

is the investigation of choice. Prophylactic anticoagulation is given to all immobilized patients (see p. 429). Warfarin is ineffective in reversing the coagulopathy of cancer and heparin is required as long as treatment continues or the cancer is active.

**Superior vena caval obstruction**

**Superior vena caval obstruction** (Fig. 9.12) can arise from any upper mediastinal mass but is most commonly associated with lung cancer and lymphoma. The patient presents with difficulty breathing and/or swallowing, with stridor, swollen, oedematous facies and arms with venous congestion in the neck and dilated veins in the upper chest and arms. Treatment is with immediate steroids, vascular stents, anticoagulation and mediastinal radiotherapy or chemotherapy. Some tumours, e.g. lymphomas, small-cell lung cancers and germ cell tumours, are so sensitive to chemotherapy that this is preferred to radiotherapy, as the masses are likely to be both large and associated with more disseminated disease elsewhere. An early decision is necessary on the patient’s likely prognosis, as ventilatory support may be required until treatment has had time to relieve the obstruction.

**Spinal cord compression**

**Spinal cord compression** (see p. 1135) needs to be rapidly diagnosed and urgent treatment arranged within 24 hours of onset of paresis to salvage as much functional capacity as possible. Early neurological clinical features may be incomplete, more subjective than objective and gradual in onset. MR scanning is the investigation of choice. Treatment should begin with high-dose steroids and a joint neurosurgical and oncological consultation. Good prognosis patients with limited disease require surgical decompression and radiotherapy to the affected vertebrae to achieve the best disease control and palliation.

**Tumour lysis syndrome**

This occurs if treatment triggers a massive breakdown of tumour cells, leading to increased serum levels of urate, potassium and phosphate and a secondary hypocalcaemia. These biochemical changes can lead to cardiac arrhythmias and seizures. Urate deposition in the renal tubules can cause renal failure (hyperuricaemic nephropathy). Vigorous hydration, often with diuretics, is crucial to maintain high urine outputs in such patients; however, a proportion will require dialysis for uraemia, oliguria or severe electrolyte disturbances. The xanthine oxidase inhibitor allopurinol should be
given before treatment is started in low-risk patients. Intra-
venous rasburicase, a recombinant urate oxidase, is used for
prophylaxis in high-risk patients and in the treatment of
tumour lysis syndrome.

**Acute hypercalcaemia**

This presents with vomiting, confusion, constipation and
oliguria. Treatment is by resuscitation with intravenous fluids
to establish a saline diuresis and i.v. bisphosphonate, e.g.
pamidronate or the more potent zolendronic acid (see Emer-
gency Box 19.2). Treating the cause is crucial. Denosumab
and calcitonin can be used in intractable cases.

**Raised intracranial pressure**

**Raised intracranial pressure** due to intracerebral metas-
tases presents classically with headache, nausea and vomit-
ing. There are often no localizing neurological signs and
almost never papilloedema until very late in the disease.
However, for many there is a slower onset with nonspecific
symptoms such as drowsiness or mental deterioration. Treat-
ment is by high-dose steroids and investigation by MRI as to
whether surgery is appropriate if unifocal and/or threatening
the fourth ventricle, or whole brain or local stereotactic
Cyberknife radiotherapy are required.

**Hyperviscosity**

This can affect those with a very high haematocrit (Hb
>180 g/L), white cell count (>100 × 10⁹/L) or platelet cell count
(>1000 × 10⁹/L) from untreated leukaemia, or a myeloprolif-
erative disorder. Viscosity can also be increased by high
levels of monoclonal immunoglobulin molecules seen in
myeloma or Waldenström’s macroglobulinaemia. IgA and
IgM are more commonly implicated due to their respective
dimeric and pentameric structures. Clinical features include
hypoxia, pulmonary infiltrates, confusion, headache, visual
disturbances, papilloedema and retinal venous dilation as
well as rarely cardiac failure or priapism. Treatment is by
leucopheresis or plasmapheresis followed by urgent treat-
ment for the underlying malignancy.

**Malignant bile duct obstruction**

This will present with cholestatic jaundice. Lymphomatous
obstruction will respond very well to prompt initiation of
therapy. A small proportion of pancreatic and bile duct
tumours are surgically resectable, more commonly those in
the distal bile duct as compared to the hilar region. However,
in the greater proportion of patients the treatment is pallia-
tive. In recent years endoscopic techniques have allowed the
insertion of stents into the biliary tree to re-establish bile flow.
The initial use of plastic stents has largely been replaced by
self-expanding metal stents which have considerably longer
periods of patency though at the risk of ascending infection.
In the small proportion of patients in whom bile duct drainage
is not possible endoscopically, the percutaneous route offers
an alternative. Endoscopic photodynamic laser therapy with
a photoporphyrin sensitizer can also prolong patency.

## HAEMATOLOGICAL MALIGNANCIES

The leukaemias, the lymphomas and multiple myeloma are
an interrelated spectrum of malignancies of the myeloid and
lymphoid systems. They are uncommon but not rare, the
lymphomas alone being the fifth commonest cancer in the
UK. The aetiology of these diseases for the most part is
unknown, although viruses, irradiation, cytotoxic poisons and
immune suppression have been implicated in a small propor-
tion of cases (see p. 434). The pathogenesis involves at least
one or usually more molecular abnormalities and non-random
chromosomal abnormalities have been detected in several
lymphomas and lymphoid disorders. Classification has become
increasingly complex, with the universally applied WHO
scheme demanding morphological, cytogenetic and some-
times molecular criteria to be fulfilled. Transformation from
low-grade to high-grade pathologic subtype may occur.
Treatment options are multiple. Patients need to be sup-
ported through treatment involving prolonged myelosuppres-
sion and immunosuppression. These are potentially
life-threatening but can also be curative. This has given rise
to the need for highly skilled staff and specialist facilities;
patients should be referred to these centres for treatment.

Haematological malignancies can be divided on the basis
of the speed of evolution of the disease, according to the cell
of origin (myeloid or lymphoid) and according to whether the
presentation is primarily a marrow-based leukaemic presen-
tation or a nodal or extranodal lymphomatous presentation
where soft tissue masses predominate. This is summarized in
Table 9.16. This is an arbitrary division and there is move-
ment across the divisions, e.g. CML can transform to either
AML or ALL, myeloproliferative neoplasms (MPN) and MDS
can transform to AML, CLL and low-grade NHL can trans-
form to a high-grade form ‘Richter’s transformation’.

The myelodysplastic syndromes are considered pre-
leukaemias and are discussed on page 405. Similarly the
myeloproliferative disorders may also transform to acute leu-
kaemia and are discussed on page 402.

In the management of these diseases, it is critical that
patients are apprised of the natural history, its potential modi-
fication by treatment and the risks of both severe morbidity
and mortality. It must be made clear from the outset whether

a curative or palliative strategy is most appropriate and why. If cure is to be pursued, the patient must be apprised of the approximate probability of success and its potential price. The possibility of failure needs to be addressed at the outset.

## THE LEUKAEMIAS

There are four main subtypes, as discussed above:

1. Acute myeloid leukaemia (AML)
2. Acute lymphoblastic leukaemia (ALL)
3. Chronic myeloid leukaemia (CML)
4. Chronic lymphocytic leukaemia (CLL)

These are relatively uncommon diseases with an incidence of about 10/100,000 per year, which can occur at any age. The type of leukaemia varies with age; acute lymphoblastic leukaemia (ALL) is mainly seen in childhood and chronic lymphocytic leukaemia (CLL) is a disease of the elderly.

Leukaemia can be diagnosed by examination of a stained slide of peripheral blood and bone marrow, but immunophenotyping, cytogenetics and molecular genetics are essential for complete subclassification and prognostication. The lineage and degree of maturity of the leukaemic clone can be assessed by the expression of cytosolic enzymes and expression of surface antigens.

### Aetiology

In the majority of patients, this is unknown but several factors have been associated:

- **Radiation.** This can induce genetic damage to haemopoietic precursors and ALL, AML and CML have been seen in increased incidences in survivors of Hiroshima and Nagasaki and in patients treated with ionizing radiation.

- **Chemical and drugs.** Exposure to benzene used in industry may lead to marrow damage. AML occurs after treatment with alkylating agents (e.g. melphalan) and topoisomerase II inhibitors (e.g. etoposide).

- **Genetic.** Leukaemia risk is highly elevated in a number of germine conditions that result in genetic instability or bone marrow failure. These include Fanconi anaemia, ataxia telangiectasia and Li-Fraumeni syndrome. The risk is elevated some 30 times in people with trisomy 21. There is a high degree of concordance among monozygotic twins. Several genes have also been associated with familial AML such as CEBPA and RUNX1.

- **Viruses.** A type of leukaemia is associated with human T cell lymphotropic retrovirus type 1 (HTLV-1), which is found particularly in Japan and the Caribbean.

### Genetic abnormalities in leukaemia

Leukaemic cells often have a somatically acquired cytogenetic abnormality, which may be of prognostic, as well as diagnostic, significance.

These genetic alterations change the normal cell regulating process by interfering with the control of normal proliferation, blocking differentiation, maintaining an unlimited capacity for self-renewal and, lastly, promoting resistance to death signals, i.e. decreased apoptosis.

The first non-random chromosomal abnormality to be described was the Philadelphia (Ph) chromosome, which is associated with CML in 97% of cases (see Fig. 9.16a). The Ph chromosome is also found in ALL, the incidence in the latter illness increasing with age. The translocation is shown schematically in Figure 9.16a. The Ph chromosome is an abnormal chromosome 22, resulting from a reciprocal translocation between part of the long arm of chromosome 22 and chromosome 9. The resulting karyotype is described as t(9;22)(q34;q11). The molecular consequences of the translocation are that part of the Abelson proto-oncogene (c-ABL) normally present on chromosome 9 is translocated to chromosome 22, where it comes into juxtaposition with a region of chromosome 22 named the ‘breakpoint cluster region’ (BCR). The new ‘fusion’ gene BCR-ABL is capable of being expressed as a chimeric messenger RNA, which has been identified in cells from patients with CML. When translated, this produces a fusion protein that has tyrosine kinase activity and enhanced phosphorylating activity compared with the normal protein, resulting in altered cell growth, stromal attachment and apoptosis. The breakpoint differs in CML and Ph-positive ALL, leading to the production of two different tyrosine kinase proteins with molecular weights of 210 kDa and 190 kDa, respectively. It is unclear whether the presence of BCR-ABL is sufficient for the development of the disease. It has been shown that normal subjects can carry low levels of the BCR-ABL fusion gene in their blood without developing leukaemia. Other genetic and cytogenetic abnormalities are often seen in leukaemic cells (Table 9.17).

As well as cytogenetic and molecular aberrations, epigenetic modification via abnormal methylation patterns and chromatin modification due to histone acetylation is increasingly understood to be involved in oncogenesis and may represent potential therapeutic targets.

### Acute leukaemias

The acute leukaemias increase in incidence with advancing age. Acute myeloid (myeloblastic, myelogenous) leukaemia (AML) has a median age at presentation of 65 years and may arise de novo or against a background of myelodysplasia or prior cytotoxic chemotherapy (‘secondary’). Acute lymphoid (lymphoblastic) leukaemia (ALL) has a substantially lower median age at presentation and in addition is the commonest malignancy in childhood. The WHO classification is shown in Table 9.17.

### Clinical features

The majority of patients with acute leukaemia, regardless of subtype, present with symptoms reflecting inadequate haemopoiesis secondary to infiltration of the bone marrow by leukaemic cells, symptoms due to tissue infiltration by leukaemic cells, the consequences of a high WBC or substance release from the tumour cells (Table 9.18).

### Investigations

**Confirmation of diagnosis** (Fig. 9.13)

- **Blood count.** Hb low, WBC raised usually (sometimes low), platelets low.

- **Blood film.** Blast cells almost invariably seen (Fig. 9.13a), lineage may be identified morphologically, e.g. presence of Auer rods is consistent with a diagnosis of AML (Box 9.7).

- **Bone marrow aspirate.** Increased cellularity, reduced erythropoiesis, reduced megakaryocytes. Replacement by blast cells >20% (often approaching 100%) (Fig. 9.13b). Lineage confirmation by immunophenotyping, e.g. AML – CD33 or CD13, B lineage ALL – CD10 and CD19 and T lineage – CD3. Cytogenetic FISH analysis in real-time PCR and molecular genetics for prognostication.

*The entities included in this group are defined almost identically to the corresponding entity in the French–American–British (FAB) classification.

---

**Figure 9.13 Acute leukaemia.** (a) Peripheral blood film showing characteristic blast cells. The arrow points to the abnormal blast cell. (b) Bone marrow aspirate showing particle with increased cellularity. (Courtesy of Dr Manzoor Mangl.)

**Box 9.7 Characteristics of blast cells**
- A blast is an immature precursor of myeloid cells (myeloblasts) or lymphoid cells (lymphoblast).
- Bigger than normal counterpart.
- Immature nucleus (nucleolus, open chromatin).
- Cytoplasmic appearances often atypical.
- Rarely ever seen in normal individuals.
- If present, are highly suggestive of an acute leukaemia or a chronic disorder that is beginning to transform into an acute disease, e.g. transformed MPN, MDS-RAEB, CML blast crisis.

---

**Chest X-ray.** Mediastinal widening often present in T lymphoblastic leukaemia.

**Cerebrospinal fluid examination.** Performed in all patients with ALL, as the risk of CNS involvement is high. It is less critical in AML.

Coagulation profile to exclude presence of DIC (raised PT, APTT, reduced fibrinogen, increased fibrinogen degradation products, e.g. D-dimers).

**For planning therapy**
- Biochemistry, serum urate, renal and liver biochemistry.
- Cardiac function; ECG and direct tests of left ventricular function, e.g. echocardiogram (see p. 685).

**Principles of management**

Untreated acute leukaemia is invariably fatal, most often within a few months, though with judicious palliative care, it may be extended to perhaps a year. Treatment with curative intent may be successful, or may fail, either because the leukaemia does not respond (i.e. refractory to treatment), because the disease returns after an initial favourable response (relapse) or because the patient succumbs to complications of the therapy (treatment-related mortality). At initial presentation, acute leukaemias range from being probably curable (e.g. childhood 'good risk' ALL) through to probably incurable (e.g. AML with adverse cytogenetic features in the elderly). Since curative treatment carries considerable morbidity and potential mortality, it is essential that the ‘risk/benefit’ ratio is clearly understood by physician and patient alike.

**Palliative therapy**

Every attempt should be made to ensure that the patients are at home as much as possible, while making available the full range of supportive care. Palliation may well include both low-dose chemotherapy and irradiation in addition to blood product support and antimicrobials.

Curative therapy
The decision to treat with curative intent, particularly if successful, implies severe disruption of normality for the patient and family for at least 6 months and often up to a year. In the short term, it may demand transfer to another hospital, as acute leukaemia should only be treated in units seeing at least 10 such cases per year. It is highly likely to involve admission to hospital for up to a month in the first instance, with further, partly predictable, subsequent admissions of several days' to weeks' duration, requiring discussions and decisions about work or education.

The decision to treat with curative intent implies that cure is possible and that the chance of cure justifies the risks of the therapy. It does not imply that cure is guaranteed or even expected. The failure rate may be high and the patient must know that he or she will be told if cure becomes an unrealistic goal.

Active therapy
Supportive care
This forms the basis of treatment whether for cure or palliation:
- Avoidance of symptoms of anaemia (haemoglobin >80–100 g/L) – repeated transfusion of packed red cells (sometimes irradiation of cells is required)
- Prevention or control of bleeding (platelet count <10 x 10^9/L in the stable and <20 x 10^9/L in the septic patient or <50 if a procedure is planned, e.g. a lumbar puncture). Coagulation abnormalities should be corrected with FFP to keep APTR/INR <1.5 x normal and with cryoprecipitate to keep the fibrinogen level >1.5 g/dL. Norethisterone is given to women of menstrual age to avoid menorrhagia during their thrombocytopenic phase.
- Leucopheresis may be required to reduce the white cell count rapidly before the chemotherapy has started to be effective.

- Treatment of infection (see Box 9.6):
  - Prophylactically. Education of patients, relatives and staff about hand washing and isolation facilities. Selected antibiotics, antifungals, antivirals and *Pneumocystis jiroveci* prophylaxis may be required.

- Control of hyperuricaemia with hydration, prophylactic allopurinol and occasionally rasburicase (see p. 479).

Indwelling venous devices, e.g. Hickman line, are required to allow easy access to the blood for tests and administration of therapy. Sperm banking is offered to postpubertal men and oocyte collection to women, if there is time before treatment.

Specific treatment
The initial requirement of therapy is to return the peripheral blood and bone marrow to normal (complete remission; CR). This ‘induction chemotherapy’ is tailored to the particular leukaemia and the individual patient’s risk factors. Since this treatment is not leukaemia specific but also impairs normal bone marrow function, it leads to a major risk of life-threatening infection, which increases the risk of early death in the short term.

Successful remission induction is always followed by further treatment (consolidation). The details of this are determined by the type of leukaemia, the patient’s risk factors and the patient’s tolerance of treatment. Recurrence is almost invariable if ‘consolidation’ therapy is not given. This reflects the lack of sensitivity of the definition of ‘complete remission’, which has been solely morphological. Cytogenetics and molecular genetic techniques can however identify residual leukaemic cells not detected morphologically and they are highly predictive of recurrence. Recommendations have recently been made to modify the definition of remission to reflect this. Failure to achieve morphological CR with two cycles of therapy (‘refractory’) carries almost as bad a
prognosis as the untreated leukaemia. If CR can be achieved, e.g. by new experimental approaches, cure may still be possible with stem cell transplantation (see p. 444). A small proportion of patients with refractory disease may also be cured by a myeloablative allograft.

**Acute myeloid leukaemia (AML)**

In AML, the prognosis is dependent on a range of key variables, the two main ones being age and cytogenetics (Fig. 9.14; Table 9.19).

Treatment with curative intent is undertaken in the majority of adults below the age of 60 years, provided there is no significant co-morbidity. Treatment success reflects the cytogenetic pattern. Those at ‘low risk’ are treated with moderately intensive combination chemotherapy. This always includes an anthracycline such as daunorubicin and cytosine arabinoside (cytarabine) and consolidation with a minimum of four cycles of treatment given at 3–4-week intervals. Patients with low-risk disease do not benefit from allogeneic stem cell transplantation during their first complete remission because the risks outweigh benefits. Those at ‘intermediate risk’ are heterogeneous group. When possible, they should be given consolidation chemotherapy after an initial remission has been achieved followed by allogeneic transplantation only in those who are deemed at increased risk of relapse because of other risk factors, e.g. mutational data. Patients with high-risk disease should proceed to a stem cell transplant in CR1 because they respond poorly to conventional chemotherapy and have a high risk of relapse.

Complete remission (CR) will be achieved in about 80% of patients under the age of 60. Failure is due to either resistant leukaemia (10%) or death due to infection or bleeding (10%). Approximately 50% of those entering complete remission will be cured (i.e. approximately 40% overall) although this varies from 60–70% in the favourable cytogenetic group to 10–20% in the adverse cytogenetic group.

The initial treatment of the older patient is much more contentious. Older patients tolerate cytotoxic therapy less well than younger patients due to co-morbidities and their disease is often more aggressive in its biology, e.g. adverse cytogenetics are more common with increasing age. Reduced intensity allogeneic transplantation is increasingly being used for this group but is limited by the toxicity of this treatment.

The management of recurrence is undertaken on an individual basis, since the overall prognosis is very poor despite the fact that second remissions may be achieved. Long survival following recurrence is rarely achieved without allogeneic transplantation. Experimental therapy should be considered. The use of minimal residual disease monitoring may allow the detection of a subgroup of patients during initial therapy who require treatment intensification, e.g. allograft, as well as patients in CR who are at the early stages of relapse and need preemptive therapy before frank marrow relapse occurs.

Newer agents that target the FLT3 mutation, present in a significant proportion of cases of AML, are in clinical trials in conjunction with conventional chemotherapy. Other novel therapies that are being considered in AML include chemotherapy labelled monoclonal antibodies (gemtuzumab ozogamicin) and hypomethylating agents (azacytidine).

**Acute promyelocytic leukaemia (APML)**

This is a variant of AML, occurring in 10–15% of cases, that is characterized by the translocation t(15; 17) and with particular morphological features. There is an almost invariable coagulopathy, which was a major cause of early death. The empirical discovery that all-trans-retinoic acid (ATRA) causes differentiation of promyelocytes and rapid reversal of the bleeding tendency was a major breakthrough. APML is treated with ATRA combined with several courses of chemotherapy. Complete remission and molecular remission occur in at least 90% of younger adults with APML and at least 70% will expect to be cured. Transplantation may be necessary either if the leukaemia is not eliminated at the molecular level, or following recurrence and reinduction therapy. Arsenic trioxide, which induces apoptosis via activation of the caspase cascade (see p. 33), is used with resistant or relapsed disease and is under investigation as first-line therapy.

**Acute lymphoblastic leukaemia (ALL)**

This condition may present in leukaemic phase with significant marrow involvement (ALL) or may present as localized disease, typically a mediastinal mass (lymphoblastic lymphoma). The tumour cells in each condition are indistinguishable, and similar therapies are therefore used. The overall strategy for the treatment of ALL differs in detail from that for AML. Remission induction is undertaken with combination chemotherapy including vincristine, a glucocorticoid, an

**Figure 9.14 Prognosis related to cytogenetics and molecular data in AML** Outcome of younger adults with AML treated in the MRC AML10 and AML12 trials stratified according to cytogenetic and molecular abnormalities. (Reproduced with permission from Smith ML, Hills RK, Grimwade D. Independent prognostic variables in acute myeloid leukaemia. Blood Reviews 2011; 25(1):39–51.)
Prognosis of treatment response and survival in ALL (A number of clinical and laboratory features are determinants for this condition, including those with sibling donors and those high-risk patients with an available unrelated donor. Imatinib used in conjunction with chemotherapy increases response rate and quality of response in patients with the t(9;22) translocation and ALL. As with AML, most recurrences occur within the first 3 years and the outcome is extremely poor. Second remissions, though usually achieved, are rarely durable except following allogeneic transplantation. Isolated extramedullary recurrences, however, may be cured.

Chronic leukaemias

Chronic myeloid leukaemia (CML)

Chronic myeloid leukaemia (CML), which accounts for about 14% of all leukemias, is one of the family of myeloproliferative neoplasms (MPNs) and is almost exclusively a disease of adults with the peak of presentation being between 40 and 60 years. It is defined by the presence of the Philadelphia chromosome (Fig. 9.16), either demonstrated cytogenetically (95%) or molecularly (5%). Unlike the acute leukemias which are either rapidly reversed or rapidly fatal, CML has a more slowly progressive course, which if not initially cured, will be followed eventually by ‘blast crisis’ transformation to acute leukemia (75% myeloid, 25% lymphoid) or myelofibrosis with death in a median of 3–4 years.

Clinical features

CML usually presents in the chronic phase and some patients have no symptoms. Symptoms will include:

- Symptomatic anaemia (e.g. shortness of breath)
- Abdominal discomfort due to splenomegaly
- Weight loss
- Fever, sweats, in the absence of infection
- Headache (occasionally) or priapism due to hyperleucocytosis
- Bruising, bleeding (uncommon)

**Figure 9.15** Overall survival in 2628 children of different ages with newly diagnosed ALL participating in consecutive studies conducted at St Jude Children’s Research Hospital from 1982 to 2005. (From Pui C-M, Robinson LL, Look AT. Acute lymphoblastic leukaemia. Lancet 2008; 371: 1030–1043, Figure 3, with permission.)
Blood film showing blast cells in CML.

**Figure 9.16 The Philadelphia chromosome (Ph).** (a) The long arm (q) of chromosome 22 has been shortened by the reciprocal translocation with chromosome 9. (b) The Philadelphia chromosome is formed by a reciprocal translocation of part of the long arm (q) of chromosome 22 to chromosome 9. It is seen in 90–95% of patients with chronic myeloid leukaemia. The karyotype is expressed as 46XX, (9;22)(q34;q11).

**Signs** will include:

- Pallor
- Splenomegaly, often massive
- Lymphadenopathy (uncommon, suggests blast crisis)
- Extramedullary soft tissue leukaemic deposit ‘chloroma’ (= blast crisis)
- Retinal haemorrhage due to leucostasis.

**Investigations**

- **Blood count.** Hb low (normochromic and normocytic) or normal, WBC raised (usually >100x10^9/L), platelets low, normal or raised.
- **Blood film.** Neutrophilia with the whole spectrum of mature myeloid precursors. Elevated basophils and eosinophils. Increased numbers of blasts are suggestive of accelerated phase or blast crisis.

- **Bone marrow aspirate.** Increased cellularity, increased myeloid precursors. Cytogenetics reveals t(9;22) translocation (the Philadelphia chromosome) (Fig. 9.16b).
- **Fluorescence in situ hybridization (FISH) or reverse transcriptase polymerase chain reaction (RT-PCR)** are used to demonstrate the cytogenetic/molecular abnormality. These are also used to quantitatively monitor response to therapy.

**Management**

Treatment has been transformed by the advent of imatinib, a tyrosine kinase inhibitor that specifically blocks the enzymatic action of the BCR-ABL fusion protein, which is now first-line treatment for the chronic phase. Imatinib produces a complete haematological response in over 95% of patients and 70–80% of these have no cytogenetically detectable BCR-ABL translocation in the marrow (complete cytogenetic remission). A proportion will lose molecularly detectable BCR/ABL transcripts from the blood (complete molecular remission). Event-free and overall survival appear to be better than for other treatments. Side-effects of imatinib include nausea, headache, rashes and cytopenia. Imatinib can be continued indefinitely although it should be stopped before attempting to conceive. Resistance to imatinib as a single agent may develop as a result of secondary BCR/ABL kinase mutations beyond the t(9;22). The use of second-generation tyrosine kinase inhibitors, dasatinib and nilotinib, may restore haematological or molecular remissions in those patients in the chronic phase that have primary or acquired resistance to imatinib or who are intolerant to imatinib. Both dasatinib and nilotinib have demonstrated promise in the first-line setting although it remains to be seen whether any advantage over imatinib in speed or depth of response is sustained over time. Bosutinib and ponatinib are also under evaluation.

In the acute phase (blast transformation) most patients have only a short-lived response to imatinib and other chemotherapy, as for acute leukaemia, and stem cell transplantation is used in the hope of achieving a durable remission.

**Stem cell transplantation (SCT)**

Allogeneic haemopoietic stem cell transplantation can cure approximately 70% of chronic phase CML patients. It is now used in those with an inadequate response to imatinib or those that have disease progression on therapy.

**Chronic lymphocytic leukaemia (CLL)**

This is the most common leukaemia, occurring predominantly in later life and increasing in frequency with advancing years (median age of presentation between 65 and 67 years). It results from the clonal expansion of small lymphocytes and is almost invariably (95%) B cell in origin. The majority of patients are asymptomatic, identified as a chance finding on a blood count performed for another indication. Other patients, however, present with the features of marrow failure or immunosuppression. The median survival is about 10 years and prognosis correlates with clinical stage at presentation (Table 9.21). A number of cytogenetic and molecular abnormalities are now recognized as being of prognostic significance (see below). This condition may present in leukaemic phase with significant marrow involvement (CLL) or may present as localized disease (small lymphocytic lymphoma, SLL). The tumour cells in each condition are indistinguishable and a similar therapeutic approach is therefore used. A pre-malignant condition, monoclonal B cell lymphocytosis (MBL) exists where there are less than the 5x10^9/L B-cells required for a diagnosis of CLL. Some of these have CLL phenotype and may progress to CLL.
Clinical features
The majority of patients are asymptomatic at presentation. Common symptoms will be:
- Recurrent infection because of (functional) leucopenia and immune failure (reduced immunoglobulins)
- Anaemia due to haemolysis or marrow infiltration
- Painless lymphadenopathy
- Left upper quadrant discomfort (from splenomegaly)
- Anaemia
- Fever (due to infection)
- Lymphadenopathy (may involve single area or be generalized)
- Hepatosplenomegaly, sometimes massive
- Leukocytes and normal lymphocytes may also be present.

Investigations
- Blood count. Hb normal or low; WBC raised and may be very high; with lymphocytosis (criteria for diagnosis >5×10⁹/L), platelets normal or low.
- Blood film. Small or medium sized mature and normal appearing lymphocytes. May see smudge cells in vitro. No immature blasts are evident.
- Bone marrow. Reflects peripheral blood, often very heavily infiltrated with lymphocytes.
- Immunophenotyping shows mainly CD19+, CD5+, CD23+ B cells with weak expression of CD20, CD79b and surface immunoglobulin (kappa and lambda light chains).
- Cytogenetics/FISH analyses are not essential for diagnosis but help in the assessment of prognosis.
- Direct Coombs’ test. May be positive if there is haemolysis.
- Immunoglobulins. Low or normal.

Prognostic biomarkers
The clinical course of CLL is variable. Several markers are used to supplement clinical stage and have been shown to predict progression and survival. Variations in predictor cut-off levels have limited their widespread application.
- Cytogenetic abnormalities are detected in >90% of cases. Patients with an isolated deletion of 13q have an excellent prognosis, in contrast to those with either 11q deletion or 17p deletion (the sites of the tumour suppressor genes ATM and TP53, respectively) who tend to have a rapidly evolving clinical course. In those tumours that demonstrate a high level of mutation within the variable region of the rearranged immunoglobulin heavy chain (IgVH), the clinical course is more indolent than those where the IgVH sequence more closely resembles that of the germline. Expression of ZAP70, a 70 kDa tyrosine kinase protein, correlates well with mutational status. Patients with <20% expression of ZAP70 have median 10-year survival of >50%; in >20% expression the median survival was <5 years. High expression of CD38 on leukaemic cells may also indicate adverse prognosis.

Management
In CLL, the major consideration is when to treat, indeed 30% of patients will never require intervention. Treatment depends on the ‘stage’ (Table 9.21) of the disease. Choice of therapy will depend upon patient-related factors such as age and co-morbidity, adverse prognostic features and anticipated response and toxicities to therapy. Intervention, when indicated, usually causes improvement in symptoms and in the blood count. The effect on survival is unclear.
- Early-stage disease is usually managed expectantly, advanced-stage disease is always treated immediately and the approach to the intermediate stage is variable. The absolute indications for treatments are:
  - Marrow failure manifest by worsening anaemia and/or thrombocytopenia
  - Recurrent infection
  - Massive or progressive splenomegaly or lymphadenopathy
  - Progressive disease manifest by doubling of the lymphocyte count in 6 months
  - Systemic symptoms (fever, night sweats or weight loss)

Presence of haemolysis or other immune-mediated cytopenias.

**General/supportive treatment**

Anaemia due to haemolysis is treated with steroids. Anaemia and thrombocytopenia due to marrow infiltration is treated with chemotherapy and, when necessary, transfusion. Erythropoietin (see p. 374) may avoid the need for transfusions, particularly in patients receiving chemotherapy.

Infection is treated as indicated, with prophylactic antibiotic, antiviral, anti-PCP therapy and antifungal therapy potentially being given during periods of chemotherapy. Immunoglobulin replacement may be helpful.

Allopurinol is given to prevent hyperuricaemia.

**Specific treatment**

- Chlorambucil usually reduces the white cell count and decreases lymphadenopathy and splenomegaly and successfully palliates the disease. In asymptomatic patients without an indication for therapy, early use of chlorambucil does not provide a survival advantage over expectant management.

- Combination therapy with rituximab shows a dramatic improvement in the response rate and has become standard of care as first-line therapy – FCR (fludarabine, cyclophosphamide, rituximab).

- Purine analogues, fludarabine alone or in combination with cyclophosphamide or mitoxantrone (with or without steroids), have had a much greater impact on the bone marrow and can induce complete or molecular complete remission although they are not helpful in patients with 17p deletion or TP53 mutation.

- Alemtuzumab, a humanized monoclonal antibody targeting CD52 which is highly expressed on B-CLL, is used in those patients that progress after fludarabine or who have 17p deletion or TP53 mutation.

- Ofatumumab is a new generation anti-CD20 monoclonal antibody that binds to a different epitope to that of rituximab and is used for treatment of fludarabine or alemtuzumab refractory CLL.

- Allogeneic stem cell transplantation with non-myeloablative conditioning regimens is increasingly performed.

**Lymphomatous transformation**

CLL may undergo lymphomatous (Richter’s) transformation in 5–10% of cases, most typically to diffuse large B-cell lymphoma, although Hodgkin’s like transformation is recognized. In the main, response to cytotoxic chemotherapy is unsatisfactory and survival short.

**Hairy cell leukaemia (HCL)**

HCL is a clonal proliferation of abnormal B (or very rarely T) cells which, as in CLL, accumulate in the bone marrow and spleen. It is a rare disease, median age at presentation is 52 years old and the male to female ratio is 4:1. The bizarrenome relates to the appearance of the cells on a blood film and in the bone marrow – they have an irregular outline owing to the presence of filament-like cytoplasmic projections.

**Clinical features**

Clinical features include anaemia, fever and weight loss. Splenomegaly occurs in 80%, lymphadenopathy is uncommon. Anaemia, neutropenia, thrombocytopenia and low monocyte counts are found.

**Treatment**

The purine analogues 2-chloroadenosine acetate (2-CDA; cladribine) and pentostatin have specific activity in this condition; complete remission is achieved in 90% with just one cycle of treatment. The remissions can last for many years and patients can be successfully retreated. Rituximab is used in cases who do not respond to the above drugs.

**THE LYMPHOMAS**

The lymphomas are malignancies of the lymphoid system and hence may arise at any site where lymphoid tissue is present. Certain subtypes have increased in frequency over the past 50 years for reasons which are not clear, the overall incidence being 15–20 per 100,000 population making them the fifth most common malignancy in the Western world. Most commonly patients have peripheral lymphadenopathy or symptoms due to occult lymph nodes, although approximately 20% arise at primary extra-nodal sites. A relatively small proportion present with lymphoma-associated ‘B’ symptoms of weight loss, fever and sweats. The natural history and clinical course are determined by the pathological subtype, classified by histological, immunological and molecular criteria, the distribution of the disease (“Stage”), nonspecific prognostic features and general co-morbidity.

A significant proportion of patients are cured and many others are helped both in terms of quality and length of life.

The WHO classification of Tumours of Haematopoetic and Lymphoid Tissues primarily distinguishes Hodgkin’s lymphoma from non-Hodgkin’s lymphoma, an umbrella term covering a multiply subclassified spectrum of B- and T-cell malignancies, reflecting the stage of lymphoid development at which they arise. Thus, lymphoblastic lymphoma and lymphoblastic leukaemia are considered as a single entity, as are small lymphocytic lymphoma and chronic lymphatic leukaemia, both discussed in the section above.

**Overall management strategy common to all lymphomas**

A suspected diagnosis of lymphoma should always be confirmed by an excision biopsy of the relevant tissue large enough to allow histological, immunological and molecular analysis. Cutting needle biopsy is an acceptable substitute for biopsy of impalpable, ‘occult’ disease, but fine needle aspiration is inadequate. The opinion of an expert haematopathologist is essential.

**Investigation**

The diagnosis having been established, the treatment strategy and details will depend on the outcome of investigations that are common to all the lymphomas. These investigations are conducted to provide a basis for prognostication and treatment decisions, against which the outcome of treatment may be assessed (Table 9.22), ‘stage’ being assigned notionally to the modification of the Ann Arbor classification for all nodal lymphomas despite the fact it was planned only for Hodgkin’s disease.

The tests in Table 9.22 are essential for planning specific therapy. The serum uric acid is helpful, particularly in those lymphomas in which there is risk of tumour lysis syndrome (see p. 449), tests of cardiac function when potentially cardiotoxic chemotherapy is to be recommended, as well as HIV, hepatitis B and C status.

Upon completion of these investigations, within a maximum of 2 weeks, a treatment plan should be presented to the
Hodgkin’s lymphoma (HL)

HL occurs with an incidence of approximately 3 per 100 000 in the Western world; there is a male predominance of approximately 1.3:1. The majority of cases occur between the ages of 16 and 65, with a peak in the 3rd decade. The incidence is stable.

Aetiology

There is epidemiological evidence linking previous infectious mononucleosis with HL; up to 40% of patients with HL have increased EBV antibody titres at the time of diagnosis and EBV DNA has been demonstrated in tissue from patients with HL. These data suggest a role for EBV in pathogenesis. Other viruses have not been detected. Other environmental and occupational exposures to pathogens have been postulated.

Diagnosis

Hodgkin’s lymphoma is subclassified according to the WHO classification (Table 9.23) into:

1. Classical Hodgkin’s lymphoma (cHL), the hallmark of which is the Reed–Sternberg cell (Fig. 9.17), accounting for 90–95% of cases and which is further subdivided into four distinct categories
2. Nodular lymphocyte predominant HL (NLPHL), characterized by the Reed–Sternberg cell variant, the ‘popcorn cell’.

Figure 9.17 Histological appearance of Hodgkin’s lymphoma. Scattered mononuclear Hodgkin’s cells and a classical malignant binucleate Reed–Sternberg cell (arrow) are seen to the right of centre on a background of benign small lymphocytes and histiocytes. (Courtesy of Dr AJ Norton.)

Clinical features

The commonest presentation of HL is painless cervical lymphadenopathy, commonly described in examination as ‘rubbery’. Other causes of cervical lymphadenopathy are shown in Table 9.24. A smaller proportion present with disease localized to the mediastinum (often young women), with cough due to mediastinal lymphadenopathy...
(Fig. 9.18), others with ‘generalized disease’, including hepatosplenomegaly and constitutional ‘B’ symptoms. Other less common symptoms, undoubtedly associated with Hodgkin’s lymphoma, but not recognized in the staging classification, are pruritus and alcohol-related pain at the site of lymphadenopathy.

Investigation
This is summarized in Table 9.22. Bone marrow biopsy is only indicated in patients with clinically advanced disease (stage III, IV), those with ‘B’ symptoms and those who are HIV-positive. The clinical utility of the PET scan is becoming established in the management of Hodgkin’s lymphoma (Fig. 9.19).

‘Stage’ is currently assigned according to the Cotswolds modification of the Ann Arbor Classification, although this is under review (Table 9.25). The Hasenclever score is used for prognostication (Box 9.8); however its relevance to treatment planning is limited because of the very small number of patients at high risk of standard treatment failure. On the basis of ‘stage’ and other prognostic factors, patients with HL are divided into three groups (Table 9.26).

Initial management
Treatment is aimed towards a curative intent with expectation of success. However, in patients with NLPHL who usually present with stage I disease with longstanding lymphadenopathy, an expectant policy with close surveillance, is followed. Older patients, with or without co-morbidity,

require considerable modification of therapy and there is an expectation of success. Patients with HIV infection should be managed, in conjunction with their HIV clinicians, in the same way as those who are seronegative.

**Treatment**

**Early stage, ‘low risk’**

‘Moderate’ chemotherapy, comprising 2–4 cycles of doxorubicin, bleomycin, vinblastine and dacarbazine (ABVD), non-sterilizing and of a low second cancer risk, followed by involved field irradiation (20–30 Gy) has replaced large field irradiation (p. 435), with 90% being cured. Current trials are evaluating the role of PET scanning to see if patients who become ‘PET negative’ after chemotherapy can be spared irradiation altogether.

**Advanced disease (including locally advanced unfavourable early stage)**

This is also curable for a significant proportion of patients with a median survival well exceeding 5 years for 50–60% of patients. Cyclical chemotherapy with 6–8 cycles of ABVD with involved field irradiation to sites which were initially bulky, or at which there is ‘persistent disease’ after chemotherapy, is standard. Increasingly, the data from studies incorporating PET scanning both part way through and after planned chemotherapy have shown that PET-ve masses are likely to represent fibrous tissue and that in this situation irradiation may be omitted.

The major short-term toxicity relates to myelosuppression and mucositis, the mortality being no more than 1% and the long-term risks being to the heart and lungs. infertility and second malignancy are uncommon.

The above approach fails for about 25% of patients. More intensive treatment programmes, e.g. BEACOPP with additional etoposide (E) procarbazine (P) and prednisolone (P), have been tested with an overall increase in efficacy, but with greater toxicity profiles (and expense). It remains a challenge to identify those who will be ‘ABVD failures’ at initial presentation. An alternative is to develop ‘risk-adapted’ therapy, based on the response to the first two cycles of therapy, again with PET scanning and escalate to more intensive therapy in those in whom the response is deemed inadequate.

**Management of failure of initial therapy**

This has become a declining problem because of improvements in the outcome of first-line therapy. The median survival from first recurrence is more than 10 years, possibly being influenced by the duration of the first remission; it may not be so good if failure occurs after very intensive therapy. Second and third remissions may be achieved with ‘appropriate’ re-induction therapy, consolidated, if possible with an autograft. Registry data suggest this may be curative for up to 50%, but follow-up only extends to 15 years.

**Experimental approaches**

With such excellent results of first- and second-line conventional therapy, experimental treatment is seldom required. The antigen-targeted immunonjugate, anti-CD-30-auristatin (SGN-35, brentuximab) has shown such efficacy in phase II trials and the histone deacetylase inhibitor (HDAC) panobinostat also has potential. Allogenic haemopoietic stem cell transplantation (HSCT) following myeloablative conditioning has high treatment-related mortality and morbidity. Reduced intensity conditioning HSCT, followed if necessary by donor lymphocyte infusion, is being investigated.

**Long-term follow-up**

The risks of late effects of therapy, particularly second malignancy and cardiac and endocrine problems, require appropriate and indefinite surveillance of patients at ‘high risk’.

**Non-Hodgkin’s lymphomas (NHL)**

Defined by the WHO classification (Table 9.27), approximately 80% of NHL are of B-cell origin and 20% of T-cell origin, there being considerable geographical variation. The incidence has increased, not necessarily for all subtypes, from 5 to 15 per 100 000 per year in the last half century.

**Further reading**

FURTHER READING
terms. Certain inherited syndromes, e.g. ataxia-telangiectasia and Wiskott-Aldrich syndrome, are associated with an increased risk of lymphoma. The human T-cell leukaemia virus type 1 (HTLV-1) is causally related to adult T-cell leukaemia/lymphoma. Helicobacter pylori is known to ‘cause’ extranodal marginal zone lymphoma in the stomach. There is a very strong epidemiological relationship between EBV and endemic Burkitt’s lymphoma and a lesser one with sporadic Burkitt’s lymphoma and Hodgkin’s lymphoma.

Immune suppression, immunosuppressant drugs, particularly as used for solid organ transplantation, and HIV infection are all associated with an increased incidence of lymphoma. Agricultural work is associated with lymphoma, but no other data show any convincing evidence of an association between occupation or lifestyle. In the majority of individual cases, the cause is unknown.

Pathogenesis
Malignant clonal expansion of lymphocytes occurs at different stages of lymphocyte development, leading to the different subtypes of lymphoma (Fig. 9.20). In general, neoplasms of non-dividing mature lymphocytes are ‘indolent’, whereas those of proliferating cells (e.g. lymphoblastic) are much more ‘aggressive’. Malignant transformation is usually due to errors in gene rearrangements which occur during the class switch, or gene recombinations for immunoglobulin and T-cell receptors. Thus, many of the errors occur within immunoglobulin loci or T-cell receptor loci. For example, an abnormal gene translocation may lead to the activation of a proto-oncogene, by moving it next to a promoter sequence for the immunoglobulin heavy chains (lg-H).

Cytogenetic features
Burkitt’s lymphoma was the first tumour in which a cytogenetic change was shown to involve the translocation of a specific gene (Table 9.28). The most frequent change is a translocation between chromosomes 8 and 14 in which the MYC oncogene is translocated from chromosome 8 to a position near the constant region of the immunoglobulin heavy chain gene on chromosome 14, resulting in upregulation of myc. Similar rearrangements involving the light chain loci are seen in the alternative Burkitt’s lymphoma translocations between chromosome 8 and either chromosome 2 or 22. Other somatic cytogenetic abnormalities associated with human lymphoma are the t(14;18) in follicular lymphoma, involving upregulation of BCL2 or the upregulation of the cell cycle regulator cyclin D1, as a result of t(11;14) in mantle cell lymphoma. Gene expression profiling and other molecular techniques are identifying new molecular subclasses of lymphoma with prognostic significance.

NK, natural killer.

**Figure 9.20** Differentiation of T and B lymphocytes and their relationship to neoplasms. Top. T-cell differentiation. Progenitor T cells from the bone marrow enter the thymus and develop into different naive T cells. αβ T cells leave the thymus, are exposed to antigen (AG) and undergo blast transformation. They then develop into CD4+ and CD8+ effector and memory T cells. T regulatory cells are the major type of CD4+ effector cells. The other specific effector T cells are the follicular helper T cell (TFM) in the germinal centres (GC). Upon antigenic stimulation, T-cell responses to antigenic stimulation pathways of natural killer cells (NK) and γδ T cells is unknown.

Bottom. B cell differentiation. Precursor B cells mature in the bone marrow and undergo apoptosis or mature to naive B cells. Following exposure to antigen and blast transformation, they develop into short-lived plasma cells or enter the germinal centre (GC). Somatic hypermutation and heavy chain class switching occur here (not shown). The transformed cells of the GC (centroblasts) undergo apoptosis or develop into centrocytes. Post-GC cells include long-lived plasma cells and memory/marginal zone B cells. AG, antigen; DLBLC, diffuse large B-cell lymphoma; CLL/SLL, chronic lymphocytic leukaemia/small lymphocytic lymphoma. MALT, mucosal associated lymphoid tissue.
Figure 9.21 Relative frequencies of B-cell lymphoma subtypes in adults. (Reproduced with permission from the WHO. Swerdlow SH, Campo E, Harris NL et al. WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues, 4th edn. Geneva: WHO; 2008: Fig 8.06, p. 164.)

Clinical presentation

The commonest presentation overall is with painless lymphadenopathy or with symptoms caused by a lymph node mass. Primary extranodal lymphomas present with soft tissue masses and related symptoms at the relevant site.

Specific non-Hodgkin’s lymphomas

The more common subtypes of non-Hodgkin’s lymphomas are described below.

B-cell lymphomas (Fig. 9.21)

Follicular lymphoma

This is the second commonest non-Hodgkin’s lymphoma (comprising approximately 20% of the lymphomas in the world).

Clinical presentation and course

Follicular lymphoma occurs in middle to late life, being rare in childhood. The majority of patients will present with painless lymphadenopathy at more than one site, although a small proportion will be ill, some with ‘B’ symptoms. In the latter, there should be suspicion that the diagnostic biopsy was not representative. This may be the case when the presenting symptom relates to an abdominal mass, but a peripheral node is biopsied. Percutaneous needle biopsy of the abdominal mass may reveal transformation to diffuse large B-cell lymphoma, with potentially different management. Bone marrow infiltration is common in certain subtypes.

There have been dramatic improvements in the outcome of therapy since the introduction of antibody therapy (rituximab), targeting the CD20 antigen expressed on almost all B-cell lymphomas, leading to the development of chemoimmunotherapy, but to date, however, the proportion of patients cured has been small. The illness has been shown to regress spontaneously in some cases which has led to an expectant policy of treatment for many patients. The clinical course following initiation of treatment to date has been that of a remitting recurring disease, often with several biopsy-proven episodes of lymphadenopathy which are, albeit usually transiently, responsive to therapy. Transformation to diffuse large B-cell lymphoma occurs in up to 25% of patients over 15 years and usually heralds a grave prognosis, although this may be improving. Death occurs because of resistant disease, transformed or not, the complications of therapy, or unrelated causes. The median survival now exceeds 10 years. Prognostic factor are shown in Box 9.9.

Management

General management

Lymph node biopsy accompanied by appropriate further investigation should precede any treatment decision. The ‘well’ patient variously defined, but certainly without symptoms, organ impairment, ‘bulky disease’ or evidence of rapid progression or transformation should, after a careful explanation of the rationale, be managed expectantly. This approach is followed by progression mandating therapy in about two and a half years for half the patients, with 20% having had some spontaneous regression and 15% having had no treatment, more than 10 years since diagnosis. A large trial comparing expectant management with immunotherapy with rituximab, however, shows a very considerable delay to having the first treatment in the rituximab group. The implications of this are unclear. Indications for treatment of low-grade non-Hodgkin’s lymphoma are shown in Box 9.10.

Initial treatment: early disease

Stage I (possibly stage II): This is treated with involved field megavoltage irradiation, which almost always induces complete remission, with 50% being disease-free after 10–15 years. There are no randomized trials to show this is better in terms of overall survival than expectant management (i.e. observe and treat if progression occurs). Functional imaging, i.e. PET scanning, may identify patients who are in ‘surgical CR’ post-biopsy for whom no therapy is indicated.

Initial treatment: advanced disease (stages II–IV)

Chemoimmunotherapy incorporating rituximab is the treatment of choice having been shown in randomized trials to be superior to chemotherapy alone, in terms of disease-free, progression-free and overall survival. ‘CHOP-R’ (cyclophosphamide, doxorubicin, vincristine and prednisolone + rituximab) and the less intensive ‘R-CVP’ (rituximab + cyclophosphamide, vincristine and prednisolone) are both widely used and R-Bendamustine is gaining popularity. Over the next few years, it will become clear which chemotherapy is the best for which group of patients. It has been shown that continuing rituximab ‘maintenance’ for 2 years has a dramatic effect on progression-free survival, although as yet not on overall survival. If rituximab maintenance is not given, patients in complete or (‘good’) partial remission are managed
expectantly, until progression occurs. This is challenged by data showing that consolidation with radio-immunotherapy (¹⁹⁸yttrium anti-CD20) also prolongs disease-free survival. Trials are in progress to determine whether consolidation with myeloablative chemotherapy, with or without rituximab maintenance, improves outcome further.

Two studies have shown the efficacy of prolonged rituximab alone; the role of intensive therapy in standard practice is being questioned.

**Second therapy and beyond**

Patients are managed expectantly in the first instance, provided re-evaluation, including repeat biopsy, reveals no evidence of transformation. A number of options are available, including re-induction of remission with combined chemimmunotherapy, followed by rituximab maintenance in those not ‘rituximab resistant’. Myeloablative consolidation chemotherapy is used in younger patients, particularly those in whom the first remission was short. Reduced-intensity conditioning allogeneic haematopoetic stem cell transplantation (HSCT) has yielded very impressive results in selected patients that may be curative despite the toxicity of the treatment.

The biggest challenges lie in patients with ‘resistant disease’ and in the treatment of ‘transformation’. A number of experimental agents with new antibodies, immunomodulatory agents and drugs targeted to specific pathways are showing promise.

**Summary**

There has been a dramatic improvement in the overall survival pattern of follicular lymphoma as the result of introducing anti-CD20 (rituximab) in the treatment of advanced disease. The median survival has been extended, well beyond 10 years in several series, albeit possibly selected patients. Improvements in disease-free survival, both after initial and second-line therapy, are encouraging. It is reasonable to anticipate that further improvement will be seen with the selective use of allogeneic stem cell transplantation and the new targeted therapies under investigation.

**Diffuse large B-cell lymphoma (DLBCL)**

**Introduction**

This is the commonest lymphoma worldwide in the adult population (increasing in incidence with age) and the second commonest in childhood, accounting for approximately 30% of all cases. There is a slight male preponderance.

**Clinical presentation**

The majority of patients present with painless lymphadenopathy, clinically at one or several sites. Intra-abdominal disease presents with bowel symptoms due to compression or infiltration of the gastrointestinal tract. In a small proportion there is a primary mediastinal presentation, most often in men, with symptoms and signs akin to those of Hodgkin’s lymphoma. There may be ‘B symptoms’, which should not be confused with symptoms related to the site of involvement. Investigation will lead to the demonstration of either locally or systematically advanced disease in the majority of cases. The illness is itself rapidly progressive, without intervention, death occurring within months rather than years. Approximately 30% present at an extranodal site as opposed to having nodal disease with extranodal spread.

**Initial treatment**

Treatment should be initiated immediately after the diagnosis is confirmed and in younger patients without co-morbidity there is a high expectation of cure. Treatment is assigned on the basis of the International Prognostic Index (Box 9.9, Fig. 9.22).

Although this was constructed in the pre-rituximab era, it remains broadly applicable. Further refinement using gene expression profiling has identified at least two distinct subtypes of DLBCL (Fig. 9.23). Allopurinol is given routinely and also in some cases with different prognoses – germinal centre cell (GC) and activated B-cell (AB). A high proliferative index, aggressive prophylaxis against tumour lysis is indicated.

**Low-risk (IPI score 0–1) with anatomically localized disease**

At present, ‘R-CHOP’ followed by involved field irradiation, or ‘more R-CHOP’, are both used. Interim PET scanning may be used to inform individualization of therapy.

Two studies conducted in France suggest that the prognosis is better with chemotherapy alone provided ‘enough’ is given, with more than 80% of younger patients being alive 10 years after therapy. A trial comparing ‘R-chemo’ with ‘chemo’ in all patients with low-risk disease showed a marked advantage for those receiving chemoimmunotherapy. Further studies are awaited (Fig. 9.24).

**Intermediate and poor-risk (IPI score 2+)**

The age of the patient and co-morbidity are critical for both the selection of treatment and the prognosis. Recognition of this fact has led to the use of an age-adjusted prognostic index for patients over the age of 60. Chemoimmunotherapy...
was established to be superior to chemotherapy alone for older patients in this category. ‘R-CHOP’, to a total of 6 or 8 cycles, has become standard care for the large majority of patients of all ages with DLBCL.

Many trials of increasing intensity of therapy for selected patients have yet to yield convincing results. However, there is an increasing consensus that the small group of patients having DLBCL with ‘Burkitt-like features’ should be treated as for Burkitt’s lymphoma. The ability to distinguish between the molecularly distinct, ‘germinal centre’ and ‘activated B cell’; DLBCL with immunohistochemistry, has made it possible to explore different therapeutic approaches in the two groups, with appropriate targeted agents.

Involvement of the central nervous system, most often meningeal, is an uncommon but devastating complication, confirming a very poor prognosis overall. Patients with a high IPI score and particularly those with specific extranodal sites of involvement (testis, paranasal sinuses, bone marrow) and those who are HIV-positive should receive intrathecal methotrexate with each cycle of therapy. The management of overt leptomeningeal or parenchymal involvement, often in the context of generalized lymphoma, is difficult and usually unsuccessful in the long term. Most strategies involve high doses of systemic methotrexate and cytosine arabinoside, both of which cross the blood-brain barrier. Cranial or craniospinal irradiation is also used.

Second (and subsequent) therapy

Although there may be responsiveness initially to alternative chemotherapy, after failure of initial therapy or subsequent progression, the prognosis is very poor. Patients entering a partial remission do better than those who recur after entering an initial complete remission.

The major issues to be addressed are whether treatment is to be undertaken with palliative or curative intent and if the latter, the expectations of success. The palliative approach involves both chemotherapy and irradiation. The curative approach involves complete re-evaluation followed by second-line chemotherapy, with a proven response rate of approximately 50%. If at least a further partial remission is achieved, in the younger, fitter patient, peripheral blood stem cell harvest is undertaken, followed, if successful, by an autograft. Overwhelmingly, the best results are achieved in those entering an unequivocal second complete remission. Even so, the proportion of patients in a prolonged second remission does not exceed 25%.

Prognosis

The outlook for patients with diffuse large B-cell lymphoma has improved by at least 15% in terms of cure, with the incorporation of rituximab into the initial therapy, the expectation of cure now being between 40% and 80% depending on the presenting features. The challenge of progressive disease following initial treatment is great, with overall less than 20% of patients alive long term.

Burkitt’s lymphoma

Introduction

This is the most rapidly proliferating lymphoma with a doubling time approaching 100% and a very rapid evolution. The commonest childhood malignancy worldwide, it has a male:female preponderance of approximately 3:1 and occurs in all ages. There are three types:

- **Endemic**
  - always EBV-associated
  - occurring in equatorial Africa
  - corresponds to the distribution of malaria
- **Sporadic**
  - 30% EBV-related
- **AIDS-related**

A similar picture to AIDS-related lymphoma may appear post-transplant.

The commonest presenting feature in the endemic type is a rapidly growing jaw tumour in a young child (Fig. 9.25). Otherwise, the next commonest is an abdominal mass often associated with bone marrow involvement. Other common sites are the central nervous system, the kidney and the testis. Investigation is along conventional lines for lymphoma, at least in the Western world, but must be conducted as a matter of urgency. A different staging classification is applied to children.

Management

Burkitt’s lymphoma should be treated with curative intent whenever feasible, regardless of HIV status. Investigation having been completed, it is essential that the patient is
haemodynamically and metabolically stable prior to the initiation of specific therapy. Particular attention must be paid to the risk of the tumour lysis syndrome. Whenever possible, rasburicase prophylaxis should be given. If this is not available, other standard measures based on fluids and allopurinol to minimize the risk of tumour lysis syndrome should be pursued. Very frequent monitoring of electrolyte balance is essential for at least 72 hours after treatment is commenced, with particular attention to potassium and phosphate levels.

Standard treatment comprises if possible, intensive, cyclical combination chemotherapy, including cyclophosphamide, methotrexate and cytosine arabinoside in high doses. Rituximab is now included, although the evidence base for this is minimal. The details and number of cycles administered will be determined by the perceived level of ‘risk’. Prophylactic central nervous system therapy is essential, intrathecal methotrexate or cytosine arabinoside often being given in addition to high-dose systemic administration. The chances of cure are very high for ‘low-risk’ patients and exceed 50% for ‘poor-risk’ patients as well, provided all treatment can be administered.

Failure to achieve complete remission is a very poor prognostic factor as is recurrence, which does so within the first year after completion of initial therapy if it is to happen. Although there may be further chemo-responsiveness, it is rare for second-line therapy to be more than transiently beneficial, regardless of whether it is followed by consolidation, with either myeloablative chemotherapy or allogeneic haematopoietic stem cell transplantation.

Summary
In the Western world, the prognosis of Burkitt’s lymphoma has improved markedly over the past 10 years, with cure being the probability for the large majority at low risk and being substantial for those at high risk, including the HIV-positive cases.

Mantle cell lymphoma
This is one of the less common B-cell lymphomas, presenting usually in later life, with a male to female preponderance of 3:1. The commonest presentation is with painless lymphadenopathy, often generalized. There may be nonspecific symptoms of tiredness, or those related to the gastrointestinal tract. ‘B’ symptoms occur in <50%. Examination and standard investigation usually confirm generalized lymphadenopathy with or without hepatosplenomegaly (Fig. 9.26).

Patients with bowel symptoms frequently have multiple lesions found on endoscopy. The bone marrow is usually involved and there may well be lymphoma cells in the peripheral blood.

Treatment
In the majority of patients, therapy is started after investigation has been completed. It is usual for there to be regression of disease with chemotherapy, although it is not often that complete remission is achieved. A prognostic index is used to help determine whether more or less ‘aggressive’ treatment is best employed. In reality, the major determining factors are the age of the patient and the presence or absence of co-morbidities. The outcome is likely to be best when ‘more’ treatment is given. Hence, younger, fitter patients are now treated with relatively intensive chemomunotherapy, incorporating rituximab, followed by, depending on its efficacy, myeloablative chemotherapy, with autologous stem cell rescue. Older, less fit patients are treated with less intensive therapy. In general, the strategy is to stop treatment after the planned initial course of treatment, provided the patient is well and at least a partial remission has been achieved. Almost inevitable progression for both older and younger patients occurs; palliation being the expectation for most. Experimental approaches include reduced intensity allogeneic haematopoietic stem cell transplantation and novel drugs targeting both the NFκB and mTOR pathways.

Summary
Mantle cell lymphoma is a lymphoma with a natural history untreated which lies between that of diffuse large B-cell lymphoma and follicular lymphoma. The prognosis has improved in recent years with the introduction of new strategies which have prolonged the period of remission without curing the patient and with the discovery of new ‘effective’ agents, making the overall median survival nearer 5 years.

Lymphoplasmacytic lymphoma
This is an uncommon, B-cell malignancy, which when associated with an IgM paraprotein and bone marrow infiltration is known as Waldenström’s macroglobulinaemia. It usually occurs in later life, the incidence being approximately the same in men and women. It may be preceded by a pre-lymphomatous phase, in which a small, monoclonal IgM band is present, often an incidental finding, for many years. The presentation is with lymphadenopathy or alternatively with symptoms of anaemia or hyperviscosity due to the paraprotein (e.g. headaches, visual disturbance). Examination and investigation usually reveal little beyond minimal adenopathy and commonly splenomegaly.

Management
Following completion of investigation, the critical decision is whether to initiate specific therapy or not. A prognostic score is assigned, the critical decision being whether to initiate specific therapy or not. In an emergency, with severe symptoms of hyperviscosity, it is most appropriate to lower the paraprotein by plasmapheresis. In some circumstances, particularly in the otherwise less fit, it may be best to use maintenance pheresis and blood transfusion as the primary therapy. ‘Responses’ occur in about 50% of cases, with a fall in the paraprotein to 50% of the baseline level with single agent therapy and higher with combination chemotherapy and rituximab. The general strategy is to treat when it is clinically indicated and to stop after a conventional course of
treatment. Treatment, either repeating the initial therapy or changing, is re-instated only when progression is clearly documented, most often by fall in the haemoglobin or significant rise in the M-band and the illness is a threat to quality and quantity of life. In the very small proportion of younger patients for whom complete remission is achieved, consolidation with a bone marrow transplant is used. Similarly, in the same group of patients who have recurrent disease, which is again responsive, allogeneic haematopoietic stem cell transplantation is also used.

**Prognosis**

Lymphoplasmacytic lymphoma is a relatively rare chemotherapy- and immunotherapy-sensitive disease, which may have an indolent course for some years without therapy. Although the median survival is only 5 years, as it presents in later life, 10–20% of patients die of unrelated causes.

**Primary extranodal lymphoma**

Lymphoma may arise anywhere in the body where there is lymphoid tissue and therefore the clinical presentation is that of a lesion or mass at the relevant site. In practice the majority occur in the central nervous system, the stomach, or the skin.

**Primary central nervous system lymphoma**

This diffuse large B-cell lymphoma occurs in both the immunocompetent (predominantly the elderly) and the immune-suppressed, in the context of post-solid organ transplant or HIV infection. It presents with symptoms relating to single or multiple parenchymal mass lesions. The diagnosis needs to be made on the basis of a biopsy, particularly in the immunocompromised, in whom an infectious aetiology of the symptoms is possible, e.g. toxoplasmosis. MRI scan is the first choice investigation; cerebrospinal fluid is usually normal. Further investigation is necessary to exclude the cerebral lesion being a manifestation of generalized disease.

**Treatment**

In some patients in the post-transplant setting, reduction of immune suppression may be beneficial. Chemotherapy alone, with high-dose methotrexate and cytosine arabinoside, is used. Possibly, the best ‘disease-free’ results have been obtained by the use of chemotherapy and irradiation but toxicity is greater, with a risk of irreversible loss of cerebral function. The overall results are disappointing with only a small proportion of patients alive long-term without disability. The situation in the HIV-positive patient with cerebral lymphoma (fortuitously a declining problem) is much worse and palliative irradiation is the best option.

**Primary gastric lymphoma**

This B-cell lymphoma, either extranodal marginal zone lymphoma of mucosa-associated tissue (MALT), or diffuse large B-cell lymphoma arising on a background of MALT lymphoma, is closely related to Helicobacter infection. It presents with symptoms of gastric ulceration or a mass, indigestion or bleeding and the diagnosis is made by endoscopic biopsy to include both the confirmation of lymphoma and H. pylori status. This is followed by investigation as for nodal lymphoma, which reveals local nodal involvement in a proportion of patients and distant spread in only a small number. Treatment is entirely dependent on whether or not there is any evidence of diffuse large B-cell lymphoma. If only ‘low-grade’ gastric ‘MALT’ lymphoma is present, Helicobacter eradication therapy is the treatment of choice (p. 249). This almost invariably alleviates the symptoms. Re-evaluation after 3 months with endoscopy, repeat biopsy and in some circumstances, endoscopic ultrasound is carried out. In general, a conservative approach is followed, as responses may take many months to achieve and rapid progression is very unlikely. Regular endoscopy 6-monthly should be continued for at least 2 years. Failure is not common and if it occurs, it is rarely rapid. If it occurs, the biopsy should be repeated. If the histology is unchanged after further Helicobacter eradication therapy (if necessary) either irradiation to the gastric bed or chemoimmunotherapy is likely to be effective or possibly curative. Overall, the prognosis is very good, the very large proportion of patients being alive 10 years after diagnosis.

Any evidence of diffuse large B-cell lymphoma is an indication for chemoimmunotherapy. Helicobacter eradication therapy should also be given, but should not be considered definitive treatment. The potential risk of gastric perforation or haemorrhage because of therapy is not a contraindication to treatment. Surgery is rarely needed, but irradiation is used for persistent disease. The prognosis is approximately the same as for nodal DLBCL of equivalent extent.

**Primary cutaneous lymphoma (T or B cell)**

Lymphomas of both B- or T-cell type may arise singly and multiply in the skin and pursue a very long natural history even though they may give rise to considerable discomfort.

**Mycosis fungoides, Sézary syndrome**

This is the commonest cutaneous lymphoma, predominantly arising in and confined to the skin, although later in the disease spreading to other organs. It has a long natural history, being sometimes preceded by a scaly ‘pre-mycotic phase’. This T-cell lymphoma presents with multiple erythematous lesions, plaques and tumours, which when associated with spread to the blood, become the Sézary syndrome. Generalized erythema may occur (erythroderma). The likelihood over time of disease extending beyond the skin is highest in patients with tumours.

Treatment is palliative and there is little indication that the disease is ever eradicated. Many treatments result in regression of disease. Antibiotics are used for infection. Phototherapy (PUVA), topical steroids and topical chemotherapy all lead to response. Radiation is effective and total skin electron beam therapy particularly so, although attention must be given to potential side-effects including erythroderma. Systemic chemotherapy, either at conventional or high doses, has been disappointing. Newer approaches include anti-T-cell antibodies and histone deacetylase inhibitors. The median survival is approximately 10 years, there being close correlation with the extent of disease at presentation. Interaction between oncologist and dermatologist is essential.

**Cutaneous B-cell lymphoma**

The two major subtypes are extranodal marginal zone and follicle centre in origin. Both usually present with either single or clustered cutaneous lesions, biopsy of which confirms the diagnosis. All conventional staging investigations are negative. Treatment is either expectant, surgical excision or irradiation, which may be used repeatedly over time. Antibiotics are used for marginal zone lymphoma if there is evidence of *Borrelia burgdorferi* infection. Only if there are lesions at multiple sites should systemic chemotherapy be used. The long-term prognosis is excellent.

**T and natural killer (NK) cell lymphomas**

(Fig. 9.27)

**Introduction**

These are much less common than their B-cell counterparts, although they are relatively more frequent in the East than...
the West. The commonest presentations are nodal or cutaneous (p. 1226) and specific subtypes involve the liver and subcutaneous tissue. Peripheral T-cell lymphomas with nodal presentation have a poor prognosis. They are treated as for DLBCL without rituximab.

The two ‘commonest subtypes’ of nodal T-cell lymphoma are peripheral T-cell lymphoma, ‘not otherwise specified’ (NOS) and angioimmunoblastic T-cell lymphoma, which together account for about 50% of T-cell lymphomas. Both occur in the middle-aged to elderly population, the primary presentation being lymphadenopathy. In contrast to the B-cell lymphomas, ‘B symptoms’ are common. Patients with angioimmunoblastic T-cell lymphoma also present with features akin to inflammatory disease, with fevers, rashes and electrolyte abnormalities, which in the first instance may be rapidly responsive to corticosteroids or low doses of alkylating agents.

Management

Following standard investigation, which usually reveals widespread disease, patients are treated with cyclical combination chemotherapy as used for diffuse large B-cell lymphoma. CD20 is not expressed on T cells so rituximab is not used and, as yet, there is no equivalent drug for T-cell lymphoma. Resolution of symptoms almost invariably occurs, although they may recur between cycles. Overall, the outcome of treatment is worse than for DLBCL, in terms of quality of response, duration of response and overall survival. Second-line therapy is rarely satisfactory, although a small proportion of patients may benefit from myeloablative therapy to consolidate a second response.

**MYELOMA**

Myeloma is a malignant disease of bone marrow plasma cells, accounting for 1% of all malignant disease. There is a clonal expansion of abnormal, proliferating plasma cells producing a monoclonal paraprotein, mainly IgG (55%) or IgA (20%) and rarely IgM and IgD. The paraproteinaemia may be associated with excretion of light chains in the urine (Bence Jones protein), which are either kappa or lambda. In approximately 20%, there is no paraproteinaemia, only light chains – ‘non-secretory myeloma’ (<5%).

Clinicopathological features

Myeloma is a disease of the elderly, the median age at presentation being over 60 years. It is rare under 40 years of age. The annual incidence is 4 per 100,000 and it is commoner in males and in black Africans but less common in Asians. The clinical features include:

- Bone destruction, often causing fractures of long bones or vertebral collapse (which can cause spinal cord compression) and hypercalcaemia. Soft tissue plasmacytomas also occurs and they are the usual cause of spinal cord compression in myeloma.
- Bone marrow infiltration with plasma cells, resulting in anaemia, neutropenia, thrombocytopenia, together with production of the paraprotein which may (rarely) result in symptoms of hyperviscosity.
- Kidney injury (see p. 1043) owing to a combination of factors – deposition of light chains in the renal tubules, hypercalcaemia, hyperuricaemia, use of NSAIDs and rarely the deposition of AL amyloid.

In addition, there is a reduction in the normal immunoglobulin levels (immune paresis), contributing to the tendency for patients with myeloma to have recurrent infections, particularly of the respiratory tract. The WHO classification (2008) of plasma cell neoplasms is shown in Table 9.29.

**Cytogenetics**

With fluorescence in situ hybridization and microarray techniques abnormalities are found in most cases of myeloma. Abnormalities of chromosome 13 and hypodiploidy (<45 chromosomes) have been shown to be associated with poor survival, as have t(4; 14), t(14; 16) and p53 (17p) deletions; t(11; 14) and hyperdiploidy (>50 chromosomes) are associated with a better prognosis.

**Bone disease**

There is dysregulation of bone remodelling, which leads to the typical lytic lesions, usually seen in the spine, skull, long bones and ribs. In myeloma there is increased osteoclastic activity with no increased osteoblast formation of bone. Bisphosphonates that inhibit osteoclast activity are useful in myeloma but surprisingly there is no increase in bone deposition (see below).

Adhesion of stromal cells to myeloma cells stimulates the production of RANKL, IL-6 and also VEGF, which plays a role in angiogenesis. RANKL also stimulates osteoclast formation and the lytic lesions. Myeloma cells also produce dikkopf-1 (DKK1), which inhibits osteoblast activity and therefore production of new bone. This occurs because DKK1 binds to the Wnt co-receptor, lipoprotein receptor-related protein 5

FURTHER READING

Malignant disease

(LRP5), inhibiting Wnt signalling (see p. 26) and osteoblast differentiation.

Symptoms
- Bone pain – most commonly backache owing to vertebral involvement (60%)
- Symptoms of anaemia
- Recurrent infections
- Symptoms of renal failure (20–30%)
- Symptoms of hypercalcaemia
- Rarely symptoms of hyperviscosity and bleeding due to thrombocytopenia.

Patients can be asymptomatic, the diagnosis being suspected by ‘routine’ abnormal blood tests. Life-threatening complications are shown in Box 9.11.

Investigations

General
- Full blood count. Hb, WCC and platelet count are normal or low.
- ESR. This is often high.
- Blood film. There may be rouleaux formation as a consequence of the paraprotein and circulating plasma cells in the aggressive plasma cell leukaemia variant of myeloma.
- Urea and electrolytes. There may be evidence of kidney injury (see above).
- Serum calcium is normal or raised. Serum alkaline phosphatase is usually normal.

Immunological
- Total protein is normal or raised.
- Serum protein electrophoresis and immunofixation characteristically shows a monoclonal band and immune paresis (Fig. 9.28). The serum free light chain assay, more sensitive than urine electrophoresis, may show an abnormal ratio and an increased total amount of free kappa or lambda chains and is often abnormal earlier than routine electrophoresis.
- 24-hour urine electrophoresis and immunofixation is used for assessment of light-chain excretion.

Radiological
- Skeletal survey. This may show characteristic lytic lesions, most easily seen in the skull (Fig. 9.29). CT, MRI and PET are used in plasmacytomas (bone or soft tissue deposits). MRI spine is useful if there is back pain – may show imminent compression/collapse.

Other
Bone marrow aspirate or trephine shows characteristic infiltration by plasma cells (Fig. 9.30). Amyloid may be found (see p. 1043).

Box 9.11 Life-threatening complications of myeloma
- Renal impairment – often a consequence of hypercalcaemia – requires urgent attention and patients may need to be referred for long-term peritoneal or haemodialysis
- Hypercalcaemia should be treated by rehydration and use of bisphosphonates such as pamidronate
- Spinal cord compression due to myeloma is treated with dexamethasone, followed by radiotherapy to the lesion delineated by a magnetic resonance imaging (MRI) scan
- Hyperviscosity due to high circulating levels of paraprotein may be corrected by plasmapheresis.

Figure 9.28 Immunofixation and electrophoresis. (a) Immunofixation IgG kappa monoclonal paraprotein. (b) Quantitation and serum electrophoresis IgG paraprotein. Serum electrophoresis and immunofixation of a patient with an IgG K paraprotein (left). The column on the far left is the total serum electrophoresis stained with anti-protein reagents. Albumin is at the top with the increased immunoglobulins at the bottom. These are shown to stain with anti-IgG and anti-kappa light chain reagents. The paraprotein is quantified (right) by calculating the area under the paraprotein spike and comparing it with the albumin concentration.

Figure 9.29 Myeloma affecting the skull. Note the rounded lytic translucencies produced by infiltration of the skull with myeloma cells.

Figure 9.30 Multiple myeloma. Histology shows replacement of the medullary cavity by abnormal plasma cells with some binucleate forms (arrow). A residual bony trabeculum is present towards the right. (Courtesy of Dr AJ Norton.)
Prognostic factors
Reduced serum albumin, increased serum β2-microglobulin and increased serum lactate dehydrogenase (LDH).

Diagnosis
Symptomatic myeloma (SMM) can be diagnosed if either of the following are present:
- Significant paraproteinaemia
- Increased bone marrow plasma cells (>10%); with evidence of end organ failure, i.e. hypercalcaemia, renal impairment, anaemia, lytic bone lesions (CRAB).

An international prognostic index based on serum albumin + β2 microglobulin (β2M) at diagnosis is used for prognostic information (Box 9.12).

Asymptomatic myeloma (AMM) (10% cases) has a significant paraprotein (IgG or IgA >30 g/dL or urinary light chain excretion >1 g/day) and/or a marrow plasmacytosis >10% but no end organ damage. The median time to progression for these patients is 2–3 years. The risk is highest for those with IgA isotype and light chains in the urine

Monoclonal gammopathy of unknown significance (MGUS). MGUS describes an isolated finding of a monoclonal paraprotein in the serum, usually in the elderly, that does not fulfil the diagnostic criteria for SMM or AMM. 20–30% go on to develop multiple myeloma over a 25-year period. Low-risk MGUS is characterized by those with an IgG subtype, a paraprotein <15 g/dL and a normal serum free light chain ratio.

Plasmacytoma. Patients may present with an isolated tumour of neoplastic plasma cells called a plasmacytoma and no evidence of multiple myeloma. This may be a solitary plasmacytoma of bone within the skeleton or an ‘extramedullary plasmacytoma’ outside the marrow cavity typically in the upper aerodigestive tract.

For paraprotein associated neuropathy and POEMS, see page 1079.

Supportive therapy
- Anaemia should be corrected; blood transfusion may be required. Erythropoietin often helps. Transfusion should be undertaken slowly in patients with hyperviscosity.
- Hypercalcaemia, kidney injury and hyperviscosity should be treated as indicated (see Acute oncology p. 448 and Acute kidney injury p. 609).
- Infection should be treated promptly with antibiotics. Give yearly flu vaccinations.
- Bone pain can be helped most quickly by radiotherapy and systemic chemotherapy or high-dose dexamethasone. NSAIDs are usually avoided because of the risk of acute kidney injury. Bisphosphonates, e.g. zoledronate, which inhibit osteoclast activity, help ensure rapid normocalcaemia and, given long term, reduce skeletal events such as pathological fracture, cord compression and bone pain.
- Pathological fractures may also be prevented by prompt orthopaedic surgery with pinning of lytic bone lesions at critical sites seen on the skeletal survey, e.g. femoral shaft. Kyphoplasty and vertebroplasty may be useful in treating vertebral fractures (p. 505).

Specific therapy
Myeloma remains incurable. Therapy is aimed at treatment of specific complications, prevention of these and prolongation of overall survival. Thalidomide has activity as a single agent and is widely used in first-line and relapsed settings. It is teratogenic and associated with neuropathy, somnolence, constipation and an increased risk of venous thrombosis.

In younger patients (<65–70 years), an orally active cyclophosphamide, thalidomide and dexamethasone-based induction (CTD), followed by a high-dose melphalan autograft, has a significantly higher response rate with 40% of patients achieving a CR with median survival increasing to 6 years. The role of allogeneic transplant is currently unclear. In older or less fit patients, melphalan and prednisolone was used, with a median survival of 29–37 months; complete remissions are rare. Recent phase III studies have suggested that this, combined with thalidomide, results in improved response rates and overall survival, albeit with increased toxicity.

For relapsed patients, a second autograft may be considered if there was a favourable response duration to the first (>12–18 months). Bortezomib is a proteasome inhibitor, which is licensed for relapsed myeloma. Thalidomide, lenalidomide and bortezomib all show synergy with dexamethasone and chemotherapy and several phase II studies have shown very promising activity in newly diagnosed patients. One phase III study has shown that bortezomib plus melphalan and prednisolone (VMP) is superior to the latter two alone. Lenalidomide is a thalidomide analogue, which is also used for relapsed myeloma. It has greater potency than thalidomide with less toxicity.

Common solid tumour treatment
Common solid cancer mortality is listed in Table 9.1; the improvements in survival over the past 10 years have come from advances in both prevention, diagnosis and treatment (Fig. 9.31). The presentation, diagnosis, natural history and systemic treatment of the common cancers are described in the relevant chapters. The decision to treat and the aim of that treatment, whether for palliation or cure, require knowledge of the natural history of the disease, prognostic and predictive factors, the patient’s performance status and the potential efficacy of treatment. Management should be carried out by multidisciplinary teams, usually led by an oncologist.

Lung cancer
The presentation and diagnosis of lung cancer (Fig. 9.32) are more fully covered in the chapter on respiratory disease (see p. 856). The current treatment reflects the fact that the

Lung cancer histology is divided into two main types: small-cell (neuroendocrine) lung cancers (SCLC), which tend to disseminate early in their development, and non-small-cell lung cancers (NSCLC), which are more likely to be diagnosed in a localized form. Tumour stage and patient performance status are used in selecting treatment and predicting response and prognosis. While overall 5-year survival has remained approximately 15%, treatment is beginning to have an impact in selected groups and the multidisciplinary team can greatly aid in the appropriate application of treatment and the avoidance of nihilism.

Non-small-cell lung cancer

The staging has been improved by CT and PET scanning and is classified according to the TNM system (see Table 15.29; Fig. 15.44), by which the disease can be divided into local, locally advanced and advanced stages with 5-year survival varying from 55–67%, to 23–40%, to 1–3%, respectively.

Treatment

Surgery can be curative in non-small-cell lung cancer (T1, N0, M0) but only 5–10% of all cases are suitable for resection; about 70% of these survive for 5 years. Surgery is rarely appropriate in patients over 65 years, as the operative mortality rate exceeds the 5-year survival rate. Trial data suggest that neoadjuvant chemotherapy may downstage tumours to render them operable and may also improve 5-year survival in patients whose tumours are operable at presentation. Preoperative assessment: lung function tests, including walking oximetry, are used to predict postoperative potential. An active life after pneumonectomy is unlikely if the gas transfer is reduced below 50%.

In operable disease stages T1N0 to T3N2 (stage I to IIIa), adjuvant radiotherapy and chemotherapy following surgery can improve prognosis in patients of good performance status as shown by the international adjuvant lung cancer trial and a meta-analysis of 12 randomized controlled trials. Cisplatin-based combination chemotherapy induced a response in 60% and produced a relative risk reduction of 11% with an absolute improvement in 5-year survival for stage II and IIIa disease of 4% from 40.4% to 44.5%.

A practical molecular assay to predict survival in resected non-squamous lung cancer is becoming available.

Radiation therapy for cure

In patients who are fit and who have a stage 1 NSCLC, high-dose radiotherapy (65 Gy or 6500 rads) can result in a 27-month median survival and a 22% 5-year survival. It is the treatment of choice if surgery is not appropriate; however, poor lung function can also be a relative contraindication to radiotherapy. Radiation pneumonitis (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10–15% of cases. Radiation fibrosis, a fibrotic change occurring within a year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all cases but is usually asymptomatic.

For unresectable disease, the combination of concurrent cisplatin with radiotherapy (chemoradiation) when compared with radiotherapy alone has increased the resection rate and 3-year survival from 11% to 23%, at the expense of greater oesophageal toxicity.

In advanced disease, cisplatin or carboplatin in combination with one other drug such as paclitaxel or gemcitabine for 12 weeks, produces a symptomatic improvement in 40% and increases median survival from 6 to 10 months, compared with best supportive care, with 10–20% alive at 1 year.

In the future, molecularly targeted treatment for lung cancer is becoming a possibility. Activating mutations (del exon 19 and L858R point mutation) in EGFR in 10% of adenocarcinomas confer sensitivity to erlotinib and gefitinib and 5% of NSCLC (mostly non-smoking associated adenocarcinoma) carry mutated anaplastic lymphoma kinase (ALK) genes conferring sensitivity to the receptor tyrosine kinase inhibitor crizotinib.
Small-cell lung cancer

Prognostic factors

The staging of small-cell lung cancer is divided into limited and extensive disease according to whether or not it is confined to a single anatomical area or radiation field. Systemic therapy is the primary therapeutic modality because of the usually disseminated nature of the disease.

Treatment

Limited disease is present in approximately 30% of patients and is best treated with concurrent chemo- and radiotherapy using a co-mibration of cisplatin and etoposide or irinotecan, which increases the survival at 5 years from 15% to 25%, compared with radiotherapy alone. A similar degree of improvement can also be achieved with hyperfractionated radiotherapy. Prophylactic whole-brain radiation to prevent cerebral metastases can reduce symptomatic CNS disease and improve overall survival by 5%.

Extensive disease can be palliated with the combination of carboplatin and etoposide or irinotecan, which when compared with best supportive care, can increase median survival from 6 months to 9–13 months and the 2-year survival to 20%.

Symptomatic care for lung cancer patients

The prognosis for the majority of patients remains poor because the disease is diagnosed in an advanced stage and the co-morbidity from other smoking-related disease compromises treatment. Therefore, much of the treatment whether symptomatic or anticancer is delivered with palliative intent. (General palliative care is discussed in Chapter 10.) Specific issues for lung cancer are the relief of bronchial obstruction and breathlessness and the relief of local pain for which radiotherapy is often employed alongside appropriate opiate analgesia. Laser therapy, endobronchial irradiation and tracheobronchial stents are used (see p. 862).

Metastases in the lung

Metastases are very common and usually present as round shadows (1.5–3.0 cm diameter). They are usually detected on chest X-ray in patients already diagnosed as having carcinoma, but may be the first presentation. Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix or ovary.

Metastases develop in the parenchyma or pleura usually and are often relatively asymptomatic even when the chest X-ray shows extensive disease. Rarely, metastases may develop within the bronchi and present with haemoptysis.

Carcinoma, particularly of the stomach, pancreas and breast, can involve mediastinal glands and spread along the lymphatics of both lungs (lymphangitis carcinomatosa), leading to progressive and severe breathlessness. Chest X-ray signs of hilar lymphadenopathy and basal shadowing are unreliable compared with the characteristic signs on CT scan of irregular thickening of the interlobular septa in a polygonal pattern around a thick-walled central vessel.

Occasionally, a pulmonary metastasis may be detected as a solitary round shadow on chest X-ray in an asymptomatic patient. The most common primary tumour to do this is a renal cell carcinoma.

The differential diagnosis includes:

- Primary bronchial carcinoma
- Tuberculosis
- Benign tumour of the lung
- Hydatid cyst.

Single pulmonary metastases can be removed surgically, but, as CT scans usually show the presence of small metastases undetected on chest X-ray, detailed imaging including PET scanning and assessment is essential before undertaking surgery.

Breast cancer

Breast cancer is the most common cancer in women who do not smoke. The screening programme in the UK, with biplanar digital mammography every 3 years in women aged 50–70, and improvements in multimodality treatment have improved overall survival and rates of cure, while breast-conserving surgery has greatly ameliorated the psychosexual impact of the disease.

Aetiology and pathology

The majority of breast cancers arise from the epithelial cells of the milk ducts and reproduce their histological features in a variety of patterns (Table 9.30), of which the most common is an infiltrating ductal carcinoma. The molecular biology of breast cancer has revealed that further subdivision based on resemblance to basal, luminal A, or luminal B type ductal cells is associated with differing behaviour. For example the oestrogen receptor (ER), negative, progesterone receptor (PR) negative, mutated EGFR (Her2) negative, triple negative phenotype corresponds to a portion of the basal cell population and is associated with a worse prognosis than the luminal types. Some triple negative cancers also resemble the BRCA1 mutated cancers with an associated DNA repair deficiency which has been targeted with new drugs such as PARP inhibitors. For many cancers it is thought that there is an identifiable precursor in situ stage which is confined within the basement membrane and is still truly localized and detectable by its trademark microcalcification on a screening mammogram. For others, this stage may be so brief or non-existent as to not be detectable and invasive disease is present from very early in development with a consequently worse prognosis. Approximately 10% of women have familial breast carcinoma (Table 9.31) and 3% have detectable mutations in the BRCa1 and 2 genes and TP53. The hormonal environment exerts a major effect on the expression of the breast cancer potential and is related to reproductive behaviour, diet, exercise, weight and exogenous hormones from oral contraception and postmenopausal hormone replacement therapy.

Symptoms and signs

Most women with symptomatic rather than screen-detected breast cancer present with a painless increasing mass which may also be associated with nipple discharge, skin tethering,
ulceration and, in inflammatory cancers, oedema and erythema. In developing countries, 80% are likely to present with advanced disease and metastases.

**Investigations**

The triple assessment of any symptomatic breast mass by palpation, radiology (mammography, ultrasound and MRI scan) and fine-needle aspiration cytology is the most reliable way to differentiate breast cancer from the 15 times more common benign breast masses. Large bore core needle biopsy should follow to provide histological confirmation and predictive factors such as grade, Ki-67 proliferation index and oestrogen, progesterone and Her2 receptor status to inform the subsequent decision-making process. Assessment should be carried out in a dedicated one-stop clinic able to provide the appropriate support and referral. Staging is both surgical with respect to tumour size and axillary lymph node status and, in advanced disease, by investigation of common sites of metastasis by chest X-ray and CT scan of lungs and liver and bone scan. At present, only 20% of patients are diagnosed with no evidence of microscopic nodal metastases.

**Prognostic factors**

The following are all significant independent predictors of risk of recurrence: size of the primary tumour; the histological subtype (most are infiltrating ductal carcinoma); histological grade/differentiation; oestrogen and progesterone receptor (ER, PR) status; patient age and menopausal status. Expression of Her2 is an adverse factor for small otherwise good prognosis tumours and like ER and PR is a predictor of treatment response.

Gene expression profiles have identified sets of between 20 and 70 genes, the expression pattern of which can identify low-and high-risk subsets independent of the clinical risk factors. Clinical trials are in progress to test whether this leads to better decision-making and outcome than the traditional clinical factors.

**Early breast cancer**

Survival probability and benefit from adjuvant treatment can be calculated using the website: www.adjuvantonline.com, which is based on the American Surveillance Epidemiology and End Results (SEER) database and has been validated on independent datasets from British Columbia and Finland. The estimated 10-year survival probability following surgery alone will vary from 93–99% for small (<1 cm) low-grade node-negative tumours to only 10% for large high-grade tumours with more than nine axillary nodes involved.

**Local treatment**

Surgery may vary from wide local excision or segmental mastectomy and breast conservation for masses <3 cm in diameter, to simple mastectomy with or without reconstruction. The choice is dictated by the location and extent of the breast mass in relation to the breast size and patient preferences. In the absence of clinical or radiological (usually ultrasound) evidence of lymphadenopathy, surgery of the axilla can be minimized by sentinel lymph node guided sampling (after dye or radioactive tracer injection); otherwise dissection to level 3 is required if there are clinically involved nodes in order to gain local control and provide prognostic information to guide adjuvant treatment. The greater the amount of axillary surgery, the greater the risk of postoperative lymphoedema.

Radiotherapy is given to the conserved breast after wide local excision to reduce local recurrence and to the chest wall after mastectomy if there are risk factors for local recurrence to complete the local control measures. The indications for breast cancer adjuvant radiotherapy are:

- Breast conserving surgery
- Large high-grade primary tumour
- Proximity to surgical margins
- >2 Lymph node metastases.

Radiotherapy to the axilla can be added after sampling but not after full dissection of the axilla because the combination raises the risk of severe lymphoedema to 30%. Adjuvant radiotherapy reduces the risk of local recurrence by 25% and improves 10-year survival by 3%.

Recent data suggest that women over 70 years with oestrogen receptor positive cancers up to 2 cm diameter may be offered surgery and tamoxifen alone without radiotherapy, without compromising outcome.

**Endocrine treatment**

**Premenopausal women**

In premenopausal women, a reduction in oestrogens can be achieved by oophorectomy or via pituitary downregulation using a gonadotrophin-releasing hormone (GnRH) analogue such as goserelin or leuprolrelin.

Tamoxifen is a mixed agonist and antagonist of oestrogen action on the ER while the more recent drug fulvestrant is a more selective oestrogen receptor modulator (SERM).

Synthetic progestogens, e.g. medroxyprogesterone acetate and megestrol acetate, have a direct effect on breast tumour cells through progesterone receptors, as well as effects on the pituitary/ovarian (premenopausal) and adrenal/pituitary axis (postmenopausal). They can be as effective as tamoxifen in metastatic breast cancer.

**Postmenopausal women**

In postmenopausal women, androgens are synthesized by the adrenal glands and converted in subcutaneous fat to estrone by the enzyme aromatase. The aromatase inhibitors, anastrozole, letrozole and exemestane, reduce circulating oestrogen levels and oestrogen synthesis in tumour cells and have shown greater efficacy than tamoxifen in the treatment of metastatic breast cancer and equivalence in the adjuvant setting.

Side-effects (Table 9.32) are those of oestrogen deprivation and women need support in managing them if they are to be able to complete the standard 5-year course.
**Adjuvant systemic treatment**

**Endocrine**

In about one-third of patients, the breast cancer will express receptors for oestrogen and progesterone. For premenopausal women tamoxifen adjuvant therapy immediately following surgery for receptor-positive disease reduces the 10-year relative risk of women dying from breast cancer by about 25% and the absolute 10-year death rate by an average of 12% for all stages.

For postmenopausal women with oestrogen and/or progesterone receptor-positive disease, adjuvant tamoxifen or aromatase inhibitors (AIs) such as anastrozole, letrozole, or exemestane all given for 5 years, reduce the risk of death from breast cancer by a similar 25%.

Aromatase inhibitors, however, are the treatment of choice for postmenopausal women because they avoid the adverse effects of tamoxifen on the uterus and venous thromboembolism and achieve a greater reduction in contralateral breast cancers and in distant metastases contributing to an overall improvement in relapse-free survival though not an overall survival advantage. Both tamoxifen and aromatase inhibitors cause symptoms of oestrogen deprivation (see above), but whereas tamoxifen has a beneficial effect upon serum lipid profiles the reverse is true of AIs leading to concerns over their long-term effects on women’s cardiovascular health. It is recommended that the choice should be discussed for each patient taking the individual co-morbidities into account. The effects of endocrine therapy are additive to those of chemotherapy and most effective given following, not concurrently with, the chemotherapy.

**Chemotherapy and targeted therapy**

A meta-analysis of all randomized trials of adjuvant therapy in breast cancer has shown that for women with high-risk features (Box 9.13), adjuvant chemotherapy with first generation regimens such as CMF (cyclophosphamide, 5-fluorouracil, and methotrexate) for 6 months, reduces the absolute 10-year death rate by about 10% and the relative risk of death by 20%. Ovarian ablation by a GnRH analogue for 2 years is equally as effective as CMF chemotherapy in pre-menopausal women. More effective second generation regimens with an anthracycline such as epirubicin (Epi-CMF) or FEC100 (5-fluorouracil, epirubicin 100 mg/m², cyclophosphamide) increase this to 25%. A third generation regimen with a taxane, e.g. FEC-D (fluorouracil, epirubicin, cyclophosphamide followed by docetaxel) (Table 9.11), gives a 33% relative risk reduction but has increased toxicity.

Chemotherapy is less effective in hormone receptor positive disease and although menopausal status does not affect the relative efficacy of chemotherapy the risk of recurrence is lower after the menopause and thus the absolute improvement in survival is less. Toxicity may also be higher in this age group, especially over the age of 70, so that treatment decisions may need to be more individualized in discussion between the patient and her doctors. The combined effect of radiotherapy, chemotherapy and tamoxifen or aromatase inhibitor approximately halves the risk of dying of breast cancer for appropriately selected patients.

**Her2/c-erbB2 targeted therapy**

The addition of adjuvant i.v. trastuzumab for a further year to chemotherapy for the treatment of the 15–20% of patients in whom the breast cancer overexpresses Her2 further reduces the risk of mortality by 25% for trastuzumab alone and by 33% when administered concurrently with a taxane. Trastuzumab is the standard of care for these patients but has a direct toxic effect upon the myocardium that is additive to pre-existing myocardial damage, especially that caused by anthracyclines, and should not be given concurrently. An alternative regimen with docetaxel, carboplatin and trastuzumab is equally as effective and can avoid much of the myocardial toxicity. Left ventricular ejection fraction must be monitored before and during treatment to avoid potentially severe congestive heart failure.

Alternative approaches which block the Her2 signalling with a different monoclonal antibody pertuzumab or the receptor tyrosine kinase inhibitor lapatinib are also proving successful and dual combination with trastuzumab holds promise for preventing the development of resistance to these targeted therapies.

**Neoadjuvant and primary systemic treatment**

There is no survival advantage for preoperative endocrine or chemotherapy treatment when compared with postoperative treatment, i.e. the advantage over surgery alone is the same; however, there is a significant benefit from either rendering inoperable tumours operable (called primary systemic therapy) or large tumours smaller and suitable for breast conserving surgery in about one-third of such patients (called neoadjuvant therapy), in addition to the reduction in risk of death from distant metastases.

**Advanced breast cancer**

Patients with established metastatic disease may require endocrine therapy, chemotherapy and radiotherapy. The treatment is not curative but is of great palliative benefit and consistent often with many years of good-quality life. Little additional benefit has been gained by adding endocrine and chemotherapy together, although the addition of anti-HER2 (antibodies) to chemotherapy has produced a survival advantage. Prolonging treatment can delay relapse but at the expense of treatment toxicity and, therefore, the serial use of intermittent courses of the different endocrine and chemotherapies starting with the least toxic, most effective treat-

**Endocrine therapy**

Women who have high levels of oestrogen receptors (ER) and progesterone receptors (PR) in their tumour have a greater chance of responding to endocrine treatments (i.e. 60%
versus 10% for ER negative disease). Endocrine responsive disease characteristics are:
- Expression of ER and/or PR
- Disease-free interval >1 year
- Skin, lymph node or bone disease
- Absence of life-threatening visceral disease.

Endocrine therapy is usually tried first in those patients who have characteristics suggesting they are likely to respond and who do not have immediately life-threatening organ failure. Remission lasts on average 2 years and is consistent with an excellent quality of life. When relapse occurs, further treatment with different agents may produce another remission.

Chemotherapy

Chemotherapy is used for patients who lack the above features of hormone responsive disease or who fail to respond to endocrine therapy or who require a rapid response if at risk of, e.g. liver or respiratory failure. Chemotherapy can provide good-quality palliation and prolongation of life. The drugs listed below are all able to induce objective responses in metastatic disease and patients in whom the disease responds are likely to experience further serial responses to subsequent treatment at relapse. There is no advantage in combining more than two drugs at a time and considerable uncertainty over the advantages of combinations with higher response rates but only rarely better survival compared with single agent regimens which have the advantage of preserving more options for future use. There is very little difference in efficacy between the different regimens for metastatic disease, with response rates varying from 40% to 60% for median duration of 8–10 months. The most common regimens with either single agents or doublet combinations include:
- MM: mitoxantrone and methotrexate
- AC/EC: doxorubicin or epirubicin and cyclophosphamide
- DC: docetaxel and capecitabine
- PG: paclitaxel and gemcitabine
- Vinorelbine, carboplatin, mitomycin and eribulin.

The multiple regimens provide the possibility of avoiding drug resistance over several episodes of treatment interspersed with treatment-free periods so that the disease can be palliated, often for several years.

The addition of trastuzumab and more recently lapatinib to the cytotoxic drugs (except the anthracyclines, see above) has significantly improved survival for those women whose tumour overexpresses the c-erbB2/Her2 onc gene. Inhibition of VEGFR by bevacizumab may be effective in a small proportion of patients but it is without as yet a predictive biomarker. Markers of DNA repair deficiency such as BRCA1 mutations render the breast cancer especially sensitive to the PARP inhibitor olaparib.

Bisphosphonate therapy

Bone metastases are a common problem in the management of breast cancer and the bisphosphonates have a major role in reducing the incidence of osteolytic deposits, bone pain and fracture when used preductively and in treating pain and hypercalcaemia from established metastases. Second generation bisphosphonates pamidronate and oral clodronate are often sufficient. The more potent third generation drugs such as zoledronate and oral ibandronate may require less frequent administration but can be associated with impaired bone healing and osteonecrosis of the jaw (see Chapter 11).

Denosumab is a MAb to the RANK ligand that inhibits osteolysis and is equally effective as bisphosphonates.

Gastrointestinal cancer

Presentation and diagnosis are described in Gastrointestinal disease, see Chapter 6.

Upper gastrointestinal

Oesophageal cancer

Early diagnosis as pioneered in Japan, where there is a particularly high incidence, has shown that it is possible to improve the prognosis of a disease otherwise typically only diagnosed when local metastases have already occurred.

Treatment and prognostic factors

Histology, stage, age and performance status are critical prognostic factors for treatment decisions, which should be made by a multidisciplinary team in designated units with the surgical expertise to avoid treatment mortality. The prognosis for the majority of symptomatic patients is poor, 50% have distant metastases at the time of diagnosis and the majority of the remainder will have loco-regional spread into adjacent mediastinal structures. Staging with endoscopic ultrasound and CT-PET scans has improved the selection of patients of good performance status with truly localized disease for whom curative treatment may be attempted.

Surgery provides the best chance of a cure and should be used only when imaging (see above) has shown that the tumour has not infiltrated outside the oesophageal wall (stage 1). Five-year survival following surgery for stage 1 is 80% (T1/T2, N0, M0). For those with stage 2 it is 30%, stage 3, 18% and stage 4, 4%. Some 70% of patients present with stage ≥3 disease, so overall survival is 27% at 1 year and around 10% at 5 years.

Neoadjuvant therapy for potentially resectable squamous carcinomas with cisplatin, 5-fluorouracil and concurrent radiotherapy achieves complete remission in 20–40% with a median survival of 19 months and 25–35% of patients alive 5 years after surgery. There is an increased perioperative mortality. Pre- and postoperative chemotherapy with epirubicin, cisplatin and 5FU for adenocarcinomas at the oesophagogastric junction has improved overall survival for those patients with resectable disease and good performance status with a relative risk reduction of 25% and absolute improvement in 5-year survival by 13%, from 23% to 36%.

Locally advanced or metastatic disease can be palliated with 5-fluorouracil or capecitabine chemotherapy in approximately 30%, increasing to 45–55% with the addition of oxaliplatin or irinotecan for a median duration of 6–8 months. Distressing symptomatic problems with dysphagia can be partially relieved by endoscopic insertion of expanding metal stents or percutaneous endoscopic gastrostomy tubes to support liquid enteral feeding and endoscopic ablation to help control bleeding. In deciding upon nutritional measures the patient and their family need considerable support and explanation to understand that feeding including parenteral feeding does not improve survival beyond that dictated by the underlying cancer and may introduce its own complications with adverse effects upon quality of life.

Gastric cancer

Presentation and diagnosis of gastric cancer are described in Chapter 6.

Prognostic factors

The majority of patients are still diagnosed at an advanced stage except in Japan, which has an active surveillance
policy. Thus, in the West, the overall prognosis has not improved above 10% survival at 5 years. Selected groups may do much better and the histological grade and staging with respect to the presence of serosal involvement (T3), nodal involvement (N1–2) and performance status are the main factors in determining prognosis and selecting treatment.

**Treatment**

Early non-ulcerated mucosal lesions can be removed endoscopically, but suitable lesions are rare outside Japan.

Surgery remains the most effective form of treatment if the patient is operable. Careful selection has reduced the numbers undergoing surgery and has improved the overall surgical 5-year survival rates from 20% to 30%. Five-year survival rates in 'curative' operations are as high as 50%.

Adjuvant treatment trials of perioperative chemotherapy with epirubicin, cisplatin and infusional 5-fluorouracil (ECF) improved 5-year survival in operable gastric and lower oesophageal adenocarcinomas from 23% to 36%. Adjuvant postoperative treatment with cisplatin, 5-fluorouracil and radiotherapy compared with surgery alone significantly increased median survival from 28 to 35 months and 3-year survival from 41% to 50%. This was achieved mainly through improvement in loco-regional control but is suitable only for good performance status patients.

Advanced disease may be palliated with chemotherapy such as epirubicin or docetaxel combined with cisplatin and infusional 5-fluorouracil, or oxaliplatin and capecitabine with response in 40–50% of patients for a median of 8–10 months in good performance status patients. The addition of trastuzumab for tumours overexpressing Her2 has improved response as in breast cancer.

Supportive care for patients with upper GI cancers more than any other must include careful attention to nutrition with the use of endoscopic stents to relieve obstruction, nasojejunal and percutaneous gastrostomy feeding tubes and occasionally parenteral nutrition with the same caveats as above. When the disease progresses beyond active anticancer treatment, management of the same caveats as above. When the disease progresses beyond active anticancer treatment, management of the same caveats as above. Treatment with further responses to dasatinib.

**Gastrointestinal stromal tumours (GIST)**

These rare slow growing tumours may arise in the stomach, small or large intestine and carry a mutation of the cKit oncoprotein, which renders them sensitive to the receptor tyrosine kinase inhibitor imatinib (see Ch. 6). Surgery is potentially curative for localized disease and Imitinib can induce remissions in 50–80% by PET-CT criteria for a median of 2 years with further responses to dasatinib.

**Lower gastrointestinal**

**Small intestine cancer**

Predisposing factors of small intestine presentation and treatment are described in Chapter 6.

**Colorectal cancer**

Presentation and diagnosis of colorectal cancer are described in Chapter 6.

**Prevention**

- **Diet.** A low-fat, high-fibre diet for the prevention of sporadic colorectal cancer and endoscopic screening is recommended for at-risk patients with a strong family history and for inherited syndromes (e.g. FAP, HNPCC).
- **NSAIDs or aspirin may play a role in prevention and after 5 years daily aspirin, there is a 35% reduction in all GI cancers (used for those not at risk of gastric erosions).**

**Screening**

See page 436.

**Treatment**

Treatment should be undertaken by multidisciplinary teams working in specialist units. About 80% of patients with colorectal cancer undergo surgery, though fewer than half of these survive more than 5 years. The operative procedure depends on the cancer site. Long-term survival is determined by the stage of the primary tumour, the achievement of clear surgical margins and the presence of metastatic disease (Table 9.33). There has been a gradual move from using Dukes’ classification to using the TNM classification system.

**Prognostic factors**

The site of the disease, above or below the pelvic peritoneal reflection, surgical margins, TNM stage and performance status are the main clinical prognostic factors. Gene profiles are being developed to identify patients at risk of recurrence and who may benefit from adjuvant chemotherapy.

**Surgery**

- **Rectal cancer.** Total mesorectal excision (TME) is used to carefully remove the entire package of mesorectal tissue surrounding the cancer. A low rectal anastomosis is then performed. Abdomino-perineal excision which requires a permanent colostomy is reserved for very low tumours within 5 cm of the anal margin. TME combined with preoperative radiotherapy reduces local recurrence rates in rectal cancer to around 8% and improves survival. Local transanal surgery is very occasionally used for early superficial rectal cancers.
- **Colon cancer.** A segmental resection and restorative anastomosis with removal of the draining lymph nodes

Malignant disease

as far as the root of the mesentery, is used for cancer elsewhere in the colon. Surgery in patients with obstruction carries greater morbidity and mortality. Where technically possible, preoperative decompression by endoscopic stenting with a mesh-metal stent relieves obstruction so surgery can be elective rather than emergency and is probably associated with a decrease in morbidity and mortality.

Adjuvant chemotherapy and radiotherapy

Neoadjuvant chemo-radiation treatment of rectal cancers using cisplatin and 5-fluorouracil with radiotherapy has increased the proportion of locally advanced tumours able to be resected with clear surgical margins (long course radiotherapy) and reduced local relapse rate (both short and long course radiotherapy) but has not improved distant metastatic relapse and overall survival. Preoperative rather than postoperative treatment has reduced toxicity to the other pelvic structures due to the preservation of the normal anatomical relations.

Adjuvant chemotherapy with 6 months of infusional 5-fluorouracil and folinic acid or oral capcitabine for rectal and colonic adenocarcinoma reduces the risk of death by 30% and significantly increases 5-year survival for node-positive disease stage III (Dukes’ C) by 10–15%, from 40% to 55%. A further 4% improvement in one trial was achieved by the addition of oxaliplatin but with additional toxicity. Less benefit is seen for stage II node-negative patients. The initial promising results from the addition of biological agents such as bevacizumab have yet to be demonstrated in adjuvant studies and remain experimental.

Follow-up

All patients who have surgery should have a total colonoscopy performed before surgery to look for additional lesions. If total colonoscopy cannot be achieved before surgery, a second ‘clearance’ colonoscopy within 6 months of surgery is essential. Patients with stage II or III disease should be followed up with regular colonoscopy and CEA measurements; rising levels of CEA suggest recurrence. CT scanning to detect operable liver metastases should be performed for up to 5 years post-surgery.

Metastatic colorectal cancer

Advanced colorectal cancer is successfully palliated with little toxicity by 5-fluorouracil and folinic acid regimens or oral capcitabine in approximately 30% of patients for a median of 12–14 months. The addition of irinotecan or oxaliplatin increases the proportion who benefit to 55% and extended median survival to 18 months but with increased toxicity. The anti-VEGFR monoclonal antibody bevacizumab and anti-EGFR cetuximab or panitumumab (for those with wild type KRAS and BRAF genes) increase the response rate with chemotherapy to 68% and the median survival from 14 to 24 months.

Liver and lung metastases are a common problem with colorectal cancers. With appropriate selection of patients with a good performance status and in whom MRI and PET-CT scans do not demonstrate extrahepatic disease, local treatment can prolong good quality survival. This can be accomplished with a variety of methods from surgical resection to gamma knife irradiation, radiofrequency, or cryoablation, or hepatic artery embolization. Small lesions can be ablated, larger lesions are best managed by partial hepatectomy or a combination approach so that embolization is followed by hepatic regeneration before final resection. Long-term survival without recurrence is reported in up to 20% of patients at 5 years with a single <4 cm lesion amenable to resection presenting more than a year from initial diagnosis and may be further extended by perioperative chemotherapy.

Anal cancer

Treatment is, where possible, with surgery or if locally advanced by downstaging with chemoradiotherapy with mitomycin-C (MMC) and 5FU followed by surgery.

Hepatobiliary and pancreatic cancers

Liver

Hepatocellular carcinoma (HCC)

Treatment and prognosis

HCC arises in a cirrhotic liver in 95% of cases and can be screened and detected by cross-sectional imaging and a rise in serum α-fetoprotein. Surgical resection of isolated lesions <5 cm diameter or up to three lesions <3 cm diameter is associated with a median survival of 5 years although the remaining liver remains at risk of further recurrence. Liver transplantation offers the only opportunity for cure for patients with a small primary but is limited often by the underlying cause of the hepatitis and cirrhosis. Conventional chemotheraphy and radiotherapy are unsuccessful, but transarterial embolization or radiofrequency ablation in patients with small primaries as above and adequate liver function prolongs survival though less successfully than surgery. Antiangiogenic compounds are being evaluated; sorafenib prolongs survival in patients with non-resectable tumours to 10 months.

Biliary tract cholangiocarcinoma

Cancer of the biliary tree may be intra- or extrahepatic. These malignancies represent approximately 1% of all cancers. A number of associations have been identified such as that with cholelithiasis and chronic infection of the biliary tree with, for example, Clonorchis sinensis. There are also associations with autoimmune disease processes such as primary sclerosing cholangitis.

Cholangiocarcinoma of the gall bladder

represents 1% of all cancers. The mean age of occurrence is in the early 60s with a ratio of 3 women to 1 man. Gallstones have been suggested as an aetiological factor but this relationship remains unproven. Diffuse calcification of the gall bladder (porcelain gall bladder), considered to be the end stage of chronic cholecystitis, has also been associated with cancer of the gall bladder and is an indication for early cholecystectomy. Adenomatous polyps of the gall bladder in excess of 1 cm in diameter are also recognized as premalignant lesions.

Carcinoma of the gall bladder

is often detected at the time of planned cholecystectomy for gallstones and in such circumstances resection of an early lesion may be curative. Early lymphatic spread to the liver and adjacent biliary tract precludes curative resection in more advanced lesions.

Cholangiocarcinoma of the bile ducts

usually presents with jaundice and is detected by imaging, initially ultrasound and thereafter CT and in particular magnetic resonance cholangiopancreatography (MRCP). The disease spread is usually by local lymphatics or local extension. Cholangiocarcinoma of the common bile duct may be resectable at presentation but local extension precludes such management in the majority of more proximal lesions. Localized disease justifies an aggressive surgical approach including partial hepatic...
resection. Hepatic transplantation for selected stage 1 and 2 disease has achieved 80% 5-year survival.

Palliative chemotherapy for good performance status patients with advanced disease with gemcitabine and cisplatin achieves a response in 50% with a median survival of 12 months. Chemoradiation has been used to treat localized small hilar cholangiocarcinoma and radiotherapy can provide good analgesia.

Pancreas
Pancreatic adenocarcinoma

Prognosis
The 5-year survival rate for carcinoma of the pancreas is approximately 2–5%, with surgical intervention representing the only chance of long-term survival. Approximately 20% of all cases have a localized tumour suitable for resection and a median survival of 2 years but in an elderly population, many of these have co-morbid factors that preclude such major surgery.

Treatment
There is no proven adjuvant therapy for pancreatic cancer following surgery. To optimize the percentage of patients undergoing possible surgical resection it is necessary to review each case in a multidisciplinary meeting. This approach also allows formulation of treatment strategies for those considered unsuitable for surgery.

In the majority of cases, the management is palliative. Obstruction of the biliary tree and jaundice is a debilitating complication, often associated with severe pruritus but also the cause of non-specific malaise, lethargy and anorexia. Endoscopic placement of endoprostheses (stents) offers excellent palliation.

Palliative surgery has a role in duodenal obstruction (a complication seen in 10% of cases) but in advanced disease self-expanding metal stents can be placed across the duodenal obstruction with excellent short-term results.

Chemoradiotherapy with gemcitabine for small locally advanced disease can achieve response in 30% and a median survival of 17 months. Palliative chemotherapy for advanced disease with gemcitabine and cisplatin can achieve a response in approximately 20% of patients with advanced disease with an improvement in median survival from 6 to 12 months.

With disease progression, abdominal pain is a frequent complicating factor which may prove extremely difficult to treat but can be helped sometimes by radiotherapy.

Neuroendocrine tumours of the pancreas

Treatment options for pancreatic neuroendocrine tumours require a multidisciplinary approach and depend upon the presence or absence of metastatic (usually hepatic) disease. Surgical resection of the pancreatic lesion is the only potential curative approach. Aggressive surgical intervention including a resection of the primary lesion as well as liver resection for metastasis has been used in selected cases. Somatostatin analogues such as octreotide and lanreotide have been used specifically for the control of symptoms secondary to the hormonal secretion. Radionuclide labelled octreotide can also be used to induce responses in 23% for a median of 17 months.

The chemotherapeutic agents streptozotocin, 5-fluorouracil and cisplatin produce partial remission in 33% for a median of 9 months, while median survival was 31 months reflecting their indolent natural history. Sunitinib, the VEGFR inhibitor, can provide palliative benefit with prolongation of progression-free survival from 5.5 to 11 months and increased survival.

In patients with extensive liver metastasis, occlusion of the arterial blood flow by hepatic arterial embolization may control hormone-related symptoms. In most cases the tumours are slowly progressive and may allow a reasonable quality of life for several years.

Epithelial ovarian cancer

Aetiology and pathology
There is uncertainty over the tissue of origin that gives rise to the 80% of all ovarian cancers that are epithelial (Table 9.34). The ovarian surface epithelium of the serosal peritoneum or the epithelial lining of the fallopian tubes are most likely. There is a consistent relationship between the risk of epithelial ovarian cancer (EOC) and the frequency and duration of ovulation. While not mechanistically explained this has provided a successful rationale for reducing risk of EOC by up to one-third through early pregnancy and the use of the oral contraceptive pill. The non-epithelial cancers are of germ cell or stromal origin although molecular biological markers have shown that the category of mixed Mullerian sarcoma is an entirely epithelial tumour with metaplastic stromal elements.

Symptoms and signs
Ovarian cancer typically causes few specific symptoms, often leading to late diagnosis. However, the following are most often associated and need investigation:

- Persistent abdominal distension (women often refer to this as bloating)
- Feeling full when eating or early satiety and loss of appetite
- Pelvic or abdominal pain
- Increased urinary urgency or frequency.

Sometimes, there is a sensation of a pelvic mass, which may become (acutely) painful, often there is only vague abdominal distension and epigastric discomfort. Symptoms of irritable bowel syndrome can be confused with those of ovarian cancer but rarely present for the first time over the age of 50 when they should stimulate investigation for ovarian cancer.

On examination, the majority of patients present with a pelvic mass and advanced stage III (spread within the peritoneal cavity) or IV (extraperitoneal) disease. Screening (see p. 436) by serum CA125 tumour marker and transvaginal ultrasound scan does detect some early cancers with improved survival but is being further refined with serial tests to avoid

**Additional Reading**

**FURTHER READING**

**FURTHER READING**

too many negative laparotomies and is thus still considered a research tool.

**Investigation**

Pelvic examination should be complemented by a serum CA125 tumour marker in primary care and transvaginal ultrasound. MRI is the definitive imaging technique for the pelvis while CT-PET scans assist in staging the patient.

An RMI >250 (risk of malignancy index, Table 9.35) should trigger investigation by a specialist gynaecological cancer team.

**Prognostic factors**

Histological subtype (clear cell and mucinous are worse), grade/differentiation, stage, extent of residual disease following surgery (macroscopic versus microscopic or none) and performance status are all significant independent prognostic factors for survival (Table 9.36).

**Treatment**

Surgery (with total abdominal hysterectomy, bilateral salpingo-oophorectomy and omentectomy) has a major role in the treatment of ovarian cancer. For patients in whom the disease is confined to the ovari, i.e. stage I, the surgery can be curative in 80–90% if the histology is well to moderately differentiated. For patients with poorly differentiated or more advanced disease, with spread throughout the peritoneal cavity, surgery still has a major role in staging the patient and improving survival when it is possible to debulk optimally to no visible residual disease. Primary chemotherapy and delayed surgery is an alternative approach when the disease is too advanced to permit primary debulking surgery and is able to render approximately one-third of inoperable patients fit for optimal debulking surgery. Survival of patients with such advanced disease is equal whether chemotherapy is given before or after surgery but preoperative downstaging can avoid much surgical morbidity.

Carboplatin, which is associated with fewer side-effects than cisplatin, has become the mainstay of epithelial ovarian cancer chemotherapy. Response is achieved in approximately two-thirds of patients. Paclitaxel has been shown to increase the response rate and improve the survival of many patients when added to a platinum-based treatment. Adjutant treatment with carboplatin and paclitaxel for stage I high-risk disease increases the absolute 5-year survival by 9%, from 70% to 79% and for combined stages I–III completely debulked disease by 19%, from 60% to 79%, a relative risk reduction of 29%.

In more advanced disease, 75% of patients will respond to combination chemotherapy and the median survival is approximately 3 years. Treatment at recurrence can be delayed until the disease is symptomatic. Further palliative responses can be achieved with carboplatin and paclitaxel if the treatment-free interval is >6 months, or liposomal doxorubicin, etoposide, gemcitabine and trabectedin are all active drugs for the palliation of recurrent disease. Up to 30% of those with metastatic disease may be alive after 5 years, although this falls to 5–10% if the cancer is not able to be debulked at operation or has spread outside the peritoneal cavity. It has proven difficult to develop more targeted biological agents for ovarian cancer. Bevacizumab when added to chemotherapy has increased disease-free survival by a few months and BRCA-positive tumours are sensitive to PARP inhibitors such as olaparib.

Epithelial ovarian cancer tends to remain within the peritoneal cavity often exclusively which has led to new intra-peritoneal routes of administration of treatment with potentially improved survival. However, at recurrence bulk disease in the peritoneum commonly causes progressive bowel obstruction which may require palliative operation or expert palliative care support to manage the terminal phases of the illness.

**Urological cancers**

**Renal cell carcinoma**

**Presentation and diagnosis**

See Chapter 12.

**Investigation and treatment**

At diagnosis, renal cancers are staged using CT and/or MRI scans to assess operability and the presence of distant metastases. Prognosis depends upon the TNM stage, histological subtype and grade, performance status and serum LDH, calcium and haemoglobin levels.

A nephrectomy is performed unless bilateral tumours are present or the contralateral kidney functions poorly, in which case conservative surgery such as partial nephrectomy may be indicated. If metastases are present, nephrectomy may still be warranted when the primary tumour constitutes the main bulk of disease since regression of metastases has been reported after removal of the main tumour mass. Adjunct treatments are unproven and being investigated. The 5-year survival rate is 60–70% with tumours confined to the renal parenchyma, 15–35% with lymph node involvement and only approximately 5% in those who have distant metastases.

**Metastatic disease**

Metastases are present in 20–30% of patients at diagnosis and are likely to develop in 40% of patients following surgery.
for apparently localized disease. Prognosis without treatment depends upon the extent of the disease as measured by the Memorial Sloan-Kettering Cancer Center (MSKCC) index comprising: performance status, high LDH, low haemoglobin, high calcium and primary in situ. Patients with no metastases and a score of 0 have a median survival of 20 months, those with a score of 1–2 have median survival 10 months and those with a score of >2 have median survival of 4 months.

Immunotherapy for renal cancer has been pursued since the observation of the occasional regression of metastases either spontaneously or following nephrectomy. In good performance status patients interferon-α produces a response in 16% with a median survival of 15 months. Interleukin-2 and interferon with 5FU is associated with a higher response rate (23%) but no longer survival. Other approaches such as tumour cell vaccines and stem cell transplants continue to be investigated.

Agents that target the VEGF (and other) receptors have been investigated because the inactivation of the VHL pathway in renal cancers leads to an increase in VEGF and PDGF production which is inversely associated with prognosis. The tyrosine kinase inhibitors sunitinib and sorafenib, the monoclonal antibody bevacizumab and the mTOR inhibitor temsirolimus have all demonstrated an ability to delay progression of disease and temsirolimus an improvement in survival. However, the incidence of cardiovascular and cerebrovascular toxicity may limit their use.

Urothelial cancers

Presentation and diagnosis

Prognosis depends upon the performance status of the patient, the TNM stage of the tumour (in particular in the bladder whether it has penetrated the bladder muscle) and its degree of differentiation. After surgery, the surgical margins, lymphovascular invasion and nodal involvement are further prognostic factors.

Treatment

Renal pelvis and ureteric tumours

Early stage tumours are treated by nephroureterectomy. Adjuvant radiotherapy and chemotherapy appear to be of little or no value. The remainder of the urethrium is at risk of further primary transitional cell cancers (TCC) in about half the patients and requires surveillance cystoscopy. Metastatic TCC is treated as for bladder below.

Bladder tumours

Superficial bladder TCC within the basement membrane are treated by transurethral resection or local diathermy. The risk of recurrence varies with the differentiation and follow-up check cystoscopies and cytological examination of the urine are required. Recurrent superficial TCC can be treated with bladder instillation of BCG (bacille Calmette-Guérin) or alternatively with chemotherapy agents such as doxorubicin, or mitomycin to delay further recurrence for on average 18 months.

Patients with muscle invasive bladder tumours are treated with radical cystectomy in patients under 70 years and radical radiotherapy in those over 70 years with salvage cystectomy for recurrences. The prognosis ranges from a 5-year survival rate of 80–90% for lesions not involving bladder muscle to 5% for those presenting with metastases.

Alternatively, those with T1 grade 3 to T4 tumours can be offered the chance of bladder preservation with chemotherapy and cisplatin and 5FU. This can achieve complete response at subsequent transurethral resection in 66%, bladder preservation and a good quality of life in 67% and a comparable long-term survival (30–50% 5 years) to cystectomy. Cystectomy requires a new bladder to be made out of small bowel, joining this to the urethra if possible, or an ileal conduit.

Prostate cancer

Early prostate cancer

Presentation and diagnosis are described on page 635.

Prognostic factors

Diagnosis is usually made on a raised serum PSA (prostate-specific antigen) followed by a transrectal ultrasound-guided needle biopsy. The histological appearances are graded and accorded a Gleason Score, which together with the height of the serum PSA plus accurate staging of the local extent of disease with pelvic MRI and transrectal ultrasound can identify prognostic groups (Table 9.37). Treatment decisions must balance the age and performance status of the patient with the predicted behaviour of the cancer, which is becoming more objectively identifiable with advances in gene profiling. This allows the selection of patients with good prognosis for no active treatment who may reasonably choose to be kept under surveillance and, like 75% of men over the age of 80, die with, but not because of, their prostate cancer.

Treatment (Chapter 12)

Patients with disease localized to the prostate requiring treatment can be managed by curative surgery (radical prostatectomy), or external beam radiotherapy, or brachytherapy implants which can achieve equivalent survival rates but differ in the spectrum of unwanted side-effects with respect to incontinence and sexual dysfunction. Radiotherapy tends to be more used in older patients who wish to avoid surgery. In appropriately selected series of patients a 5-year survival of 85% can be achieved. Adjuvant radiotherapy after radical prostatectomy can reduce PSA relapse but has not increased overall survival. Discussion between patient and clinician is vital to enable a treatment choice that is most appropriate to the patient’s circumstances; many of the patients are elderly and the side-effects of treatment are significant with often no improvement in mortality.

Androgen deprivation

- GnRH agonists, e.g. goserelin and leuprolin, and orchidectomy are equally effective in lowering circulating androgens and inducing responses in prostate cancer. However, in the first week GnRH agonists produce a rise in LH and testosterone which can result in a tumour flare in metastatic disease and require combination with an antiandrogen, e.g. flutamide, in the initial phases.

FURTHER READING

Gynaecomastia

Androgen receptor blockers such as flutamide and abiraterone, an inhibitor of CYP17 which is necessary for androgen production, are also effective and abiraterone has been effective after failure of androgen suppression.

Adjuvant androgen deprivation treatment such as monthly depot goserelin has not improved the survival following surgery but when given before and during radiotherapy can improve the overall survival at 3 years for T1–T3 tumours from 62% to 78%.

Advanced prostate cancer

Treatment

Locally advanced prostate cancer (T3 N0) without distant metastases is best treated with combined androgen deprivation and radiotherapy, which improves 10-year survival compared with endocrine treatment alone from 61% to 71%.

Metastatic prostate cancer with either local or most often osteoblastic skeletal spread, is rapidly and effectively palliated in 70% of patients by androgen deprivation through orchidectomy, monthly depot injection of GnRH analogues, or androgen receptor blockade with oral flutamide. The median duration of response is 2 years. However, on progression despite androgen suppression, prostate cancer management must be further tailored to the patient’s age, performance status and bone marrow function. These measures include simple steroids and bisphosphonates, or docetaxel chemotherapy which can be guided by PSA response to provide some further palliation. Abiraterone is an inhibitor of adrenal androgen synthesis which has achieved responses in 50% of castration-resistant post docetaxel patients for a median duration of 6 months. Radiotherapy provides very effective palliation for the common problem of painful skeletal metastases and can be delivered by external beam therapy or systemically by intravenous bone-seeking strontium-labelled bisphosphonate for patients with multiple affected sites.

Bone pain can also be reduced with bisphosphonates such as zoledronate, as the metastatic sites comprise a combination of increased osteoclastic and osteoblastic activity.

Testicular and ovarian germ cell tumours

Germ cell tumours are the most common cancers in men aged 15–35 years but comprise only 1–2% of all cancers. They are much less common in women. There are two main histological types, seminoma (dysgerminoma in women) and teratoma. Teratomas may comprise varying proportions of mature and immature elements. Mature teratomas in women present as dermoid cysts with low malignant potential. Germ cell tumours may rarely occur in extragonadal sites in the midline from pituitary, mediastinum or retroperitoneum but should be treated in a similar manner (Table 9.38).

Symptoms and signs

Most men present with a testicular mass which is often painful, some with symptoms of metastases to the para-aortic lymph nodes with back pain and gynaecomastia if hCG secreting. In women, the mass presents with vague pelvic symptoms but at a younger age than the more common epithelial ovarian cancers.

Investigations and surgery

- Ultrasound or MRI scanning of the testicle or ovary is required.
- Assay of serum tumour markers, α-fetoprotein (AFP) and beta-human chorionic gonadotrophin (β-hCG) and lactate dehydrogenase (LDH).

A urinary pregnancy test for hCG in A&E has saved the lives of young men with metastatic germ cell cancer.

- CT or MRI scan for distant metastases.
- Surgery for men is by the inguinal approach to avoid spillage of highly metastatic tumour in the scrotum.
- Surgery in women for diagnosis and staging should always be conservative compared to the approach in epithelial ovarian cancer with preservation of fertility because of the efficacy of chemotherapy.

Treatment

Seminomas

Seminomas are the least common of these tumours and are very radiosensitive and chemosensitive. Seminomas are associated with a raised serum LDH but only rarely a mildly raised β-hCG and never a raised AFP. Stage I disease limited to the gonad is associated with a 30% 5-year risk of recurrence with surgery alone. Adjuvant therapy with either chemotherapy or radiotherapy to the para-aortic lymph nodes leads to greater than 95% cure in early-stage disease but chemotherapy with single-agent cisplatin or carboplatin does not have the long-term risks of secondary malignancy associated with radiotherapy. Alternatively, intensive surveillance can be undertaken with treatment reserved for those who relapse with an equally high cure rate since combination chemotherapy (e.g. cisplatin, etoposide and bleomycin) will cure 90% of those with visible metastatic disease.

Teratomas

The risk of relapse with stage I disease varies from 5% to 40% depending upon the prognostic factors of histological differentiation and extent of local invasion.

Adjuvant chemotherapy for those at moderate to high risk with cisplatin, etoposide and bleomycin leads to a 95% cure rate. In those without vascular invasion a single cycle of treatment can be given instead of retroperitoneal lymph node dissection.

Metastatic disease commonly involves para-aortic lymph nodes and lungs but may spread rapidly (especially if there are trophoblastic (β-hCG-producing) elements present) and cause life-threatening respiratory or other organ failure. A rapid diagnosis can be made in the presence of gynaecomastia and a positive urinary pregnancy test before the institution of potentially life-saving treatment. About 80% of teratomas will express either β-hCG or AFP and almost all metastatic disease will be associated with an elevation of the less-specific serum marker LDH.

Chemotherapy for metastatic teratoma varies from over 90% for those with small-volume to 40% for those with large-volume metastases and associated rises of AFP >10,000 and β-hCG >100,000 IU/L.

Although approximately 20% of men will be infertile due to azoospermia at the time of diagnosis, the majority of the remainder will retain their fertility after chemotherapy and be able to father normal children. Similarly, most women retain
their fertility, although less is known about the association with infertility at presentation owing to the much lower frequency of germ cell tumours in women.

**Metastatic cancer of unknown primary**

Patients presenting with symptoms of their metastases or with an incidental finding on imaging without a clinically obvious primary after investigation represent a common clinical problem and comprise 5–10% of patients in a specialist oncological centre. As a result of several systematic studies, some with post-mortem follow-up, the following guidance should aid the choice of appropriate investigation and treatment. Poor prognosis patients identified by performance status, histology, site and extent of disease on the other hand can be spared the discomfort of intensive investigation and given more appropriate palliative care.

**Diagnosis**

Diagnosis requires histology first and foremost, as it will lead to the identification of several distinct groups.

- **Squamous cancers**: mostly presenting in the lymph nodes of the cervical region, 80% will be associated with an occult head and neck primary, the remainder arising from the lung. Inguinal nodes point usually to a primary of the genital tract or anal canal. Treatment with radiotherapy and chemotherapy may have curative potential especially in the head and neck area even in the absence of an identifiable primary on pan-endoscopy.

- **Poorly differentiated or anaplastic cancers**: this group will contain the majority of the curable cancers such as high-grade lymphomas and germ cell tumours and should be suspected in all young patients with midline masses. They are identifiable by their immunocytochemistry and tumour markers. Gene markers such as ip12 for germ cell tumours and Bcl-2 for lymphomas are increasingly available to aid this diagnosis. Treatment and prognosis are as outlined for lymphoma and germ cell tumours.

- **Adenocarcinomas** form the majority of cases and their investigation should be guided by the desire to identify the most treatable options and the knowledge that the largest proportion will have arisen from the lung or pancreas, with relatively poor treatment prospects.

Tissue tumour markers can be helpful (Table 9.39) and increasingly, gene profiles can identify the primary site of origin by gene expression microarray and RT-PCR.

Investigations should therefore always start with a review of the histology, a chest X-ray and CT scan of chest, abdomen and pelvis, with, in men, serum PSA and rectal ultrasound to identify prostate cancers and in women, mammography and breast MRI to identify occult breast cancer and pelvic MRI to identify ovarian cancer.

For good prognosis patients wishing to have palliative chemotherapy, investigations such as endoscopy to identify lung, colon or stomach primaries are indicated to guide the choice of chemotherapy agents, although the diagnostic yield of 4–5% must be set against the discomfort and risks. Serum tumour markers for other solid cancers, although highly sensitive, are too nonspecific and unreliable to be useful as diagnostic aids in this situation.

Further investigation may require PET-CT for head and neck, lung and possibly other primaries and radioisotope scans for thyroid and carcinoid tumours. PET-CT may also be used to seek other metastatic sites if considering surgery for unifocal disease.

Prognosis
The histological type and extent of the disease and performance status of the patient are the key factors. Most large series report an overall median survival of 12 weeks but considerably better survival amongst the special subgroups such as patients presenting with isolated nodal metastases who have a significantly better prognosis than the majority with visceral and/or bone metastases and may warrant more extensive investigation.

Treatment
If investigations have not identified a primary site, surgery may be considered for unifocal ACUP metastases in lymph nodes, lung, liver and brain especially if due to melanoma with potential for long-term survival.

In women, an isolated axillary lymph node metastasis should be treated as for lymph-node-positive breast cancer with a similar prospect for long-term cure though without the need for breast surgery. Malignant ascites in women should have a trial of chemotherapy as for primary peritoneal, fallopian tube or epithelial ovarian cancer. The prognosis for those responding to the therapeutic trial is similar to the disease of known primary origin. Primary chemotherapy that achieves an excellent response by imaging and CA125 criteria should be followed by debulking surgery with, if successful, a median survival in excess of 4 years.

For men, the occasional occult prostatic cancer found from a raised serum PSA offers some palliative treatment prospects (Box 9.14).

For the patient presenting with hepatic metastases most commonly associated with an occult gastrointestinal primary there is an increasing choice and efficacy of chemotherapy agents for gastrointestinal cancers that have the potential to improve their palliation.

If there is an excellent response, suitable patients may even be considered for hepatic ablation or resection. If after all efforts no primary has been identified, palliative chemotherapy treatment can achieve responses in 20–40% in highly selected series, with median survivals of 9–10 months and 5–10% surviving to 5 years.

INTRODUCTION AND GENERAL ASPECTS

Palliative care is the active total care of patients who have advanced, progressive life-shortening disease. It is now recognized that palliative care should be based on needs not diagnosis: it is needed in many non-malignant diseases as well as in cancer (Box 10.1).

The goal of palliative care is to achieve the best possible quality of life for patients and their carers by managing not only physical symptoms, but also psychological, social and spiritual problems. When life-prolonging treatments are no longer improving or maintaining quality of life, death is accepted as a normal process. The aim is to enable the patient to be cared for and to die in the place of their choice, with excellent symptom control and an opportunity to say goodbye and bring closure.

Who provides palliative care?

A hallmark of palliative care is the multiprofessional team, as single professionals cannot provide the breadth of necessary expertise, and the emotional demands of working in this area require team support to enable balanced, compassionate but dispassionate care.

All healthcare providers should have basic palliative care skills and access to a specialist palliative care (SPC) team. They should be aware of the services that the local SPC teams can offer and recognize when referral is appropriate. A problem-based approach to disease management will ensure that patients and carers obtain access to appropriate support services, including SPC and will avoid an either/or approach (‘either curative treatment or palliative care’).

Good communication between members of the healthcare team, and the patient and carer underpins the successful management of advanced disease and end-of-life care. Good liaison between the hospital, primary care and hospice is also essential.

Importance of early assessment

Early assessment of needs, with SPC referral if required, is crucial to obtaining the best outcome for rehabilitation and for maintaining or improving quality of life for both patient and carer. Palliative care is most effective when it is given as soon as possible after diagnosis and is given alongside disease-specific therapy, such as radio/chemotherapy for cancer or cardiac medication for heart failure. Early referral links palliative care with quality of life improvements; positive associations increase the likelihood that patients and families continue to use palliative care services when they need them. Furthermore, in malignant disease, there is good evidence that integrating palliative care and anti-tumour treatment soon after diagnosis reduces long-term distress and increases survival in selected cases.

If palliative care is seen only as relevant for the end-of-life phase, patients who have non-malignant disease are denied expert help for complex symptoms. Timely management of physical and psychosocial issues earlier in the course of disease prevents intractable problems later (Box 10.2).

Assessment of patient’s needs and understanding

The causes of a patient’s symptoms are often multifactorial, and a holistic assessment is central to optimum management. Assessment of the patient’s understanding of the disease, understanding their future wishes and acknowledging their concerns, will help the team plan and implement effective support. Patients will have differing needs for information, and will deal with ‘bad news’ in different ways. A sensitive approach, respecting individual requirements, is crucial.

Recent changes in provision of palliative care

An increase in the number of patients who survive malignant disease and a recognition of the needs of patients who have non-malignant disease have led to changes in the provision of SPC services. Many patients will use SPC services for a limited period (weeks to months) whilst complex problems are addressed, and then are discharged with the opportunity for re-referral if help is required later.

SYMPTOM CONTROL

This section outlines the medical aspects of symptom control. Good palliative care integrates these with appropriate non-pharmacological approaches, including anxiety management and rehabilitation (see p. 489).
Pain

Pain is a feared symptom in cancer and at least two-thirds of people with cancer suffer significant pain. Pain has a number of causes, and not all pains respond equally well to opioid analgesics (Fig. 10.1). The pain is either related directly to the tumour (e.g. pressure on a nerve) or indirectly, for example due to weight loss or pressure sores. It may result from a co-morbidity such as arthritis. Emotional and spiritual distress may be expressed as physical pain (termed ‘opioid irrelevant pain’) or will exacerbate physical pain.

The term ‘total pain’ encompasses a variety of influences that contribute to pain:

- **Biological**: the cancer itself, cancer therapy (drugs, surgery, radiotherapy)
- **Social**: family distress, loss of independence, financial problems from job loss
- **Psychological**: fear of dying, pain, or being in hospital; anger at dying or at the process of diagnosis and delays; depression from all above
- **Spiritual**: fear of death, questions about life’s meaning, guilt.

The WHO analgesic ladder

Most cancer pain can be managed with oral or commonly used transdermal preparations. The World Health Organization (WHO) cancer pain relief ladder guides the choice of analgesic according to pain severity (Fig. 10.2, Table 10.1).

If regular use of optimum dosing (e.g. paracetamol 1 g × 4 daily for step 1) does not control the pain, then an analgesic from the next step of the ladder is prescribed. As pain is due to different physical aetiologies, an adjuvant analgesic may be needed in addition or instead, such as the tricyclic antidepressant amitriptyline for neuropathic pain (Table 10.1).

### Strong opioid drugs

**Dose titration and route**

Morphine is the drug of choice and, in most circumstances, should be given regularly by mouth. The dose should be tailored to the individual’s needs by allowing ‘as required’ doses; morphine does not have a ‘ceiling’ effect. If a patient has needed further doses in addition to the regular daily dose, then the amount in the additional doses can be added to the following day’s regular dose until the daily requirement becomes stable; a process called ‘titration’. When the stable daily dose requirement has been established, the morphine can be changed to a sustained-release preparation. For example:

- 20 mg morphine elixir 4-hourly
  - = 120 mg morphine per day
- 60 mg twice-daily of a 12-hour preparation
  - or 120 mg daily of a 24-hour preparation.

Symptom control

Introduction and general aspects

Symptom control

### Adjuvant analgesics

The most commonly used adjuvant analgesics are described in Table 10.1. Other treatments such as radio/chemotherapy, anaesthetic or neurosurgical interventions, acupuncture and TENS may be useful in selected patients.

Regular review is necessary to achieve optimal pain control, including regular assessment to distinguish pain severity from pain distress.

### Gastrointestinal symptoms

Anorexia, weight loss, malaise and weakness

These result from the cancer-cachexia syndrome of advanced disease and carry a poor prognosis. Although attention to nutrition is necessary, the syndrome is mediated through chronic stimulation of the acute phase response, and tumour-secreted substances (e.g. lipid mobilizing factor and proteolysis inducing factor). Thus, calorie-protein support alone gives limited benefit: parenteral feeding has been shown to make no difference to patient survival or quality of life.

There is a small and evolving evidence base for specific therapies such as eicosapentaenoic acid (EPA) fish oil, cyclooxygenase (COX) inhibition with an NSAID and antioxidant treatment, but currently, unless the patient is fit enough for, and responds to, anti-tumour therapy, management is supportive. Some patients benefit from a trial of a food supplement that contains EPA and antioxidants. Megestrol may help appetite, but weight gain is usually fluid or fat. It is also thrombogenic and is of little benefit.

Until recently, corticosteroids were recommended and they are still commonly used as an appetite stimulant; however, the weight gained is usually fluid and muscle catabolism is accelerated. Also, any benefit in appetite stimulation tends to be short-lived. Thus, their use should be limited to short term only.

---

</table>

The most common side-effects are:

- **Nausea and vomiting:** this can usually be managed or prevented with antiemetics (such as metoclopramide). Some antiemetics can be combined with an opioid, e.g. haloperidol or metoclopramide; always check compatibility data.
- **Constipation** is common and should be anticipated with administration of a combination of stool softener (e.g. macrogols) and stimulants either separately or in one preparation. Methyl naltrexone is a peripherally acting opioid receptor antagonist which is used if response to other laxatives is poor.

If side-effects are intractable, a change of opioid is often helpful.

**Toxicity**

Confusion, persistent and undue drowsiness, myoclonus, nightmares and hallucinations indicate opioid toxicity. This may follow rapid dose escalation and responds to dose reduction and slower re-titration. It may indicate poorly opioid responsive pain and the need for adjuvant analgesics.

Antipsychotics such as haloperidol may help settle the patient’s distress whilst waiting for resolution of toxicity. Some patients will tolerate an alternative opioid better, e.g. oxycodone, or, an alternative route, e.g. subcutaneous injection.

---

**FURTHER READING**

Breathlessness remains one of the most distressing and common symptoms in palliative care; causing the patient serious discomfort, it is highly distressing for carers to witness. Full assessment and active treatment of all reversible conditions, such as drainage of pleural effusions, or optimization of treatment of heart failure or chronic pulmonary disease is mandatory. In advanced cancer, breathlessness is often multifactorial in origin and many of the contributory factors are irreversible (e.g. cachexia), so a ‘complex intervention’ combining a number of different treatment strategies has the greatest impact. Aspects of breathlessness management are summarized in Box 10.3.

**Breathlessness with panic and anxiety**

Patients often experience a panic-breathlessness cycle and fear dying during an acute episode of breathlessness. This is extremely unlikely in chronic disease, unless there is an acute complication, and reassurance will help. The perception of breathlessness is mediated by the central nervous system and can be modulated by thoughts and feelings about the sensation. Education about breathlessness and exploration of psychological precipitators or maintainers can reduce its impact.

Non-pharmacological approaches such as using a hand-held fan, pacing, prioritizing activities to avoid over-exertion, breathing training and anxiety management are helpful (Table 10.2). There is no evidence to suggest that oxygen therapy reduces the sensation of breathlessness in advanced disease and the hand-held fan should be used before oxygen for this purpose. Opioids, used orally or parenterally, can palliate breathlessness. If panic/anxiety is significant, a quick-acting benzodiazepine such as lorazepam (used sublingually for rapid absorption) may be useful.

**Cough**

Persistent unproductive cough is another troublesome symptom that can be helped by the antitussive effect of opioids (e.g. morphine). Excessive respiratory secretions can be treated with hyoscine hydrobromide 400–600 μg every 4–8 hours but does give a dry mouth. Glycopyrronium is also useful by subcutaneous infusion of 0.6–1.2 mg in 24 hours.

**Other physical symptoms**

People with cancer may develop other physical symptoms caused directly by the tumour (e.g. hemiplegia due to brain secondaries) or indirectly (e.g. bleeding or venous thromboembolism due to disturbances in coagulation). Symptoms may also result from treatment, such as lymphoedema following treatment for breast or vulval cancer, or heart failure secondary to anthracycline or trastuzumab therapy. The principles of holistic assessment, reversal of reversible factors and appropriate involvement of the multiprofessional team should be applied.

**Lymphoedema**

The pain and disabling swelling associated with lymphoedema can be alleviated through complete decongestive therapy (CDT), a treatment which is a massage-like technique and comprises manual lymphatic drainage, compression bandaging and gentle exercise. Diuretics should not be used. Referral to a specialist lymphoedema therapist or nurse is useful.

**Fatigue**

Fatigue is a significant and debilitating problem for palliative patients. It has physical, cognitive and affective components; unlike normal tiredness, it is not relieved by usual sleep or rest. An assessment for reversible contributory factors such as anaemia, hypokalaemia or over-sedation due to poorly
Other symptoms. Rehabilitation can: not routinely assessed, and not as well managed as pain and on others. Evidence suggests that functional problems are physical frailty, loss of independence, and perceived burden increasing. Some of the most pressing concerns include increasing and rehabilitation.

Loss of function, disability and rehabilitation

Some of the most pressing concerns include increasing physical frailty, loss of independence, and perceived burden on others. Evidence suggests that functional problems are not routinely assessed, and not as well managed as pain and other symptoms. Rehabilitation can:

- contribute to patients’ quality of life by providing strategies for managing declining physical function and fatigue, and by offering resources that might make life easier for patients and carers (e.g. equipment or a wheelchair)
- support patients’ adaptation to disability, helping them to increase social participation and find fulfilment in everyday living
- minimize carer stress and distress.

A referral to physiotherapy or occupational therapy is helpful for patients whose ability to carry out daily activities is compromised by illness or its treatment. However, remember that effective rehabilitation is a team effort and is not solely the domain of nursing and allied health professionals. Doctors also have a major role to play in attending to functional problems and fatigue; they should not see these as inevitable, unavoidable and insoluble.

There is a need to take into account changing performance status as well as changes in goals and priorities. It can be helpful to identify short-term, achievable goals and focus on these. Most patients wish to remain at home for as long as possible, and to die at home, given adequate support. Patients’ community rehabilitation needs should not be neglected.

Psychosocial issues

Depression is a common feature of life-limiting and disabling illness and is often missed or dismissed as ‘understandable’. However, it may well respond to the usual drugs and/or to non-pharmacological measures such as cognitive behavioural therapy, increased social support (e.g. day therapy) and support for family relationships. Such interventions can make a big difference to the patient’s quality of life and the ability to cope with the situation.

</table>

CBT, cognitive behavioural therapy; SOB, short of breath (breathlessness).

optimized medication should be undertaken. Management strategies are:

- **Non-pharmacological**: relaxation, sleep hygiene, resting ‘pro-actively’ rather than collapsing when exhausted, and planning, pacing and prioritizing daily activities
- **Pharmacological**: low dose methylphenidate or modafinil (central nervous system stimulants), done in conjunction with the specialist palliative care team, may help.

**General wellbeing**

Corticosteroids are commonly given as a non-specific ‘boost’ for general wellbeing, but benefits are short-lived and the adverse effects, which include proximal myopathy, are significant. If corticosteroids are to be given, then a short-term course (up to 3 weeks) to cover particular goals, with clear prescribing responsibility, is the best way to ensure net benefit.
Box 10.4 Key points in palliative care

- Patients should always be involved in decisions about their care.
- Quality of life is increased when treatment goals are clearly understood by everyone, including patient and carer.
- The multidisciplinary team can provide a high standard of care but there must be realism and honesty about what can be achieved.
- Hospitalization is sometimes necessary but end-of-life care is often delivered in hospices or the home.
- Care at home should be encouraged for as long as possible, even if the patient’s preferred place of death is elsewhere.
- Discussions about end-of-life care planning are best held outside times of crisis, when the patient feels as well as possible, with clinicians with whom they have a good relationship. The results of these discussions must be recorded and made known to everyone involved in the patient’s care.

EXTENDING PALLIATIVE CARE TO PEOPLE WITH NON-MALIGNANT DISEASE

The principles of palliative care can be applied throughout medical practice so that all patients, irrespective of care setting (home, hospital or hospice) receive appropriate care from the staff looking after them and have access to SPC services for complex issues. Some principles are outlined in Box 10.4. Patients who have chronic non-malignant disease such as organ failures (heart, lung and kidney), degenerative neurological disease and HIV infection:

- have a similar or greater symptom burden than people with cancer
- may live longer with these difficulties
- benefit from a palliative care approach with access to SPC for complex problems.

There may be a less clear end-stage of disease, but the principles of symptom control are the same: holistic assessment, reversal of reversible factors and multiprofessional support.

Patients who have non-malignant disease may have very close relationships with their usual team, and an integrated approach is essential to allow optimization of disease-directed medication as well as palliation. People with non-malignant disease may live for years with a difficult illness and so their palliative care needs to differ in some respects from those of cancer patients (Table 10.3). However, symptom management is largely transferable, with some exceptions and extra complexities as outlined below.

Throughout the course of the illness, careful open discussion of possible future options is essential. Early discussion of difficult choices is as helpful for patients who have non-malignant disease as it is for those with cancer and these discussions are ideally held when the patient is relatively well and outside an acute episode. Discussions delayed until the crisis of acute admission may lead to acceptance of an invasive treatment that is later regretted by the patient.

Heart failure

There are special considerations with respect to cardiac medication in advanced disease:

- Drugs that are commonly used in palliative care but usually contraindicated in heart failure, such as amitriptyline and NSAIDs, may be appropriate at the very end-of-life.

- Sudden death is more common than in patients who have malignancy and a patient may have an implanted defibrillator in place. If present, these devices should be re-programmed to pacemaker mode in advanced disease because they have not been shown to improve survival in severe heart failure and it will be distressing for patient, carer and staff if they discharge as the patient is dying.

- Peripheral oedema can become a major problem and more resistant to diuretic therapy, therefore careful balancing of medication regimens is required. Ultimately symptom relief is prioritized over renal function.

- Medications should be rationalized to reduce polypharmacy, e.g. ceasing drugs prescribed to reduce long-term secondary risk (e.g. statins) and continuing drugs that help symptom control (including angiotensin converting enzyme inhibitors, which benefit symptoms as well as survival). Beta blockers may have to be stopped if the patient can no longer maintain non-symptomatic hypotension.

Chronic respiratory disease

Chronic obstructive pulmonary disease (COPD)

COPD is the most common chronic respiratory disease. Patients may live increasingly restricted lives for years, rather...
than the months or weeks that are common once someone with cancer becomes breathless. Patients usually reach late middle age or old age before becoming very disabled, and an elderly spouse often has to carry significant physical burdens.

Because of the risk of dependency, falls and memory problems, non-pharmacological approaches to anxiety are more appropriate than benzodiazepines (Table 10.2). Short-acting benzodiazepines should be reserved for severe panic episodes.

Palliative care breathlessness services can be very helpful for those unable to comply with pulmonary rehabilitation. Emergency admissions to hospital for non-medical reasons are often due to anxiety and the support offered by community palliative care services working with respiratory teams can help prevent these.

Ventilatory support

For many patients who have respiratory failure, non-invasive ventilation has superseded the use of intermittent positive pressure ventilation (IPPV) on intensive therapy units. However, there are patients who are likely to need IPPV during admission for an acute exacerbation. For some of this group, life has become burdensome rendering the net benefit for this procedure less, or negligible. These patients should be put in contact with hospice services when they are relatively stable (not during acute exacerbations), anticipating an alternative place of admission in the event of subsequent deteriorating health.

Other chronic respiratory diseases

Other chronic respiratory illnesses that often require palliative care include:

- **Diffuse parenchymal lung disorders (interstitial lung disease) (ILD):** this has a trajectory similar to cancer with rapidly developing breathlessness and cough. The breathlessness of ILD is particularly frightening but may respond well to opioids: early access to hospice services is particularly relevant to help with symptom control and anxiety.
- **Cystic fibrosis:** patients are teenagers or young adults who usually have known their respiratory team all their lives. An integrated team involving SPC clinicians ensures good symptom control and provides useful support when difficult decisions have to be made about treatments (e.g. lung transplant), as well as offering psychosocial care to the family.
- **Primary pulmonary hypertension:** patients are often young and treated far from home in specialist centres. They require symptom control in close consultation with the medical team, and it is essential that any dependent children receive the care they need.

Opioid titration in non-malignant respiratory disease

In non-malignant respiratory disease, opioid titration may need to follow a different pattern from that used in malignant disease, in which many patients are already on opioids for pain control before they develop breathlessness. The evidence is not clear but some clinicians recommend a cautious approach for these chronically breathless patients who have non-malignant disease, rather than immediately starting a daily dose of 10 mg of modified release morphine.

Renal disease

All care for patients who have end-stage chronic kidney disease (CKD) is directed toward maintenance or improvement of renal function. Prescribing is complicated, particularly if patients are receiving dialysis. Care must be taken not to inadvertently cause renal damage with potentially nephrotoxic medication, and close liaison with the renal team is mandatory.

In patients who have CKD, co-morbidities such as cardiovascular disease, diabetes or osteoporosis may cause greater problems than the renal disease. Those with a fluctuant course of symptoms, such as the 25–33% who have co-existing cardiac disease, bear disproportionately greater physical and psychological burdens.

Patients who are on dialysis

Patients attend three times per week (and receive social support from this). Thus additional attendance at hospice day therapy service may be too tiring. If further support from SPC services is needed, then outpatient clinics, community support (for patient and/or carer) or even admission may be more suitable.

Withdrawal of dialysis

Withdrawal of dialysis is necessary if the effort of attendance becomes too great when there is little improvement in quality of life and the impact of other co-morbidities becomes intrusive.

If there is no residual renal function, survival after withdrawal of dialysis is likely to be a few days at most. In contrast, patients who have some residual function (usually those who have had dialysis for only a few weeks or months) may live for months or even a year after withdrawal. Patients and carers need to understand these differences in order to make informed choices.

Patients who are not on dialysis

Maximizing and preserving remaining renal function is a critical consideration in deciding which medications can or should be prescribed:

- Medication that accelerates loss of renal function may markedly reduce survival in those patients who are able to live months or years with very little remaining renal function.
- The renal impact of both dose and drug choice must be taken into account, e.g. morphine and diamorphine metabolites accumulate in end-stage renal dysfunction, thus strong opioids such as alfentanil or fentanyl should be used instead.
- Close liaison with the medical team is essential for drug prescribing.

Neurological disease

People who suffer from chronic degenerative neurological diseases have considerable burden of palliative care needs including:

- Difficulties in swallowing (e.g. in motor neurone disease)
- Loss of mental capacity – the ability to understand, weigh up, come to a decision and communicate that decision.
- Ideally, discussions regarding the patient’s wishes should take place in advance, if the patient is able to do this, so that these can be supported.
Motor neurone disease

Motor neurone disease is usually rapidly progressive, often requiring hospice support. Percutaneous endoscopic gastrostomy (p. 222) feeding may be required. In addition, if ventilatory failure develops, nocturnal non-invasive ventilation may be offered. Patients and their carers need to understand:

- why this treatment has been offered (to prevent hypercapnia and morning headache and confusion)
- when this treatment will be withdrawn (when it is no longer helping to maintain or improve quality of life in the face of advancing disease).

Patients need to be given a clear understanding of what alternative symptom control will be offered at withdrawal.

Multiple sclerosis

Pain is often prominent in multiple sclerosis because of muscle spasm: patients may become too disabled to attend outpatient clinics and then receive very little surveillance. Hospice day therapy service, rehabilitation and support for the family can make a huge impact on quality of life.

Dementia

Dementia-related palliative care needs arise in the context of:

- neurological conditions that tend to occur in older people (Alzheimer’s disease and multi-infarct dementia)
- neurological conditions that also affect younger people (e.g. Parkinson’s disease, multiple sclerosis, Huntington’s disease).

Dementia poses special problems with respect to inpatient palliative care. For example, in the UK, many hospice inpatient units will not accept mobile patients who have dementia because the patient’s safety cannot be guaranteed. However, they will care for those at the end-of-life with other SPC needs, for example a distressed young family or pain, and will often support other services by providing advice on symptom control.

Care of the dying

Most people express a wish to die in their own homes, provided their symptoms are controlled and their carers are supported. However, patients die in any setting and so all healthcare professionals should be proficient in end-of-life care.

Reports of inadequate hospital care have led to the development of integrated pathways of care for the dying. Pathways act as prompts of care, including psychological, social, spiritual and carer concerns in those who are diagnosed as dying. The latter is a decision reached by a multiprofessional team through careful assessment of the patient and exclusion of reversible causes of deterioration.

Do not attempt resuscitation (DNAR) orders

- The resuscitation status of every patient should be discussed by senior doctors at the time of admission and the decision documented in the notes.
- Many hospitals have specific DNAR forms. Deciding a person’s resuscitation status is a careful balance of risk versus benefit. The patient’s co-morbidities and pre-morbid quality of life should be taken into account.
- Involve the patient and family in this discussion, and explain the medical reasoning behind the decision. If the patient requests that CPR is not performed in the event of cardio-pulmonary arrest, those wishes should be respected.

Remember that a decision not to resuscitate a patient is not the same as the decision to withhold other treatment. A patient who is not for resuscitation may still be eligible for antibiotics, fluids, endoscopy and even surgery. Management should remain positive, allowing the patient to die free of distress and with dignity.

An end-of-life tool: the Liverpool Care Pathway

The Liverpool Care Pathway (LCP) is a four-stage end-of-life tool designed to transfer the standard of hospice care of the dying into the hospital (Box 10.5). Now adapted for any setting, it is the most commonly used pathway for care of the dying in the UK and in several other countries. There have been no trials comparing effectiveness of any end-of-life care pathways against usual care without a pathway, but serial UK national hospital audits have been able to assess and monitor the level of care documented against the standards set in the LCP.

The LCP has provision for departures from the ‘prompts of care’, e.g. discontinuation of intravenous antibiotics or parenteral fluids, if a clinical need can be demonstrated. The patient is reviewed regularly (at least daily). Occasionally, the patient improves whilst on the pathway and can be returned to usual care if this is deemed more appropriate by the clinical team. For those who do not improve, the LCP prompts advanced prescription of medication to ease the symptoms most likely to arise in the dying phase (pain, breathlessness, nausea, agitation and excess respiratory secretions) to allow timely action.

Engagement with family and carers is vital, and it should not be assumed that they will recognize or understand signs of imminent death. The LCP has supportive information leaflets that carers should find useful.

Box 10.5 Stages in the Liverpool Care Pathway – an end-of-life tool

- Recognition of the dying phase
- Initial assessment (which includes the patient’s and carers’ understanding and psychological state)
- Ongoing assessment and monitoring
- Care of the carers after the patient’s death (see Table 10.2)
Many common locomotor problems are short-lived and self-limiting or settle with a course of simple analgesia and/or physical treatment; e.g. physiotherapy or osteopathy. However, they represent 20–30% of the workload of the primary care physician, where non-inflammatory problems predominate. Recognition and appropriate early treatment of many painful rheumatic conditions may help reduce the incidence of chronic pain disorders. Early recognition and subsequent treatment of inflammatory arthritis by specialist multidisciplinary teams leads to better symptom control and prevents long-term joint damage and disability. The patient should always be included when decisions about treatment are being discussed. Pamphlets and websites offer helpful advice for patients, and their use should be encouraged.

## THE NORMAL JOINT

There are three types of joints: fibrous, fibrocartilaginous and synovial.

### Fibrous and fibrocartilaginous joints

These include the intervertebral discs, the sacroiliac joints, the pubic symphysis and the costochondral joints. Skull sutures are fibrous joints.

### Synovial joints

These (Fig. 11.1) include the ball-and-socket joints (e.g. hip) and the hinge joints (e.g. interphalangeal).

They possess a cavity and permit the opposed cartilaginous articular surfaces to move painlessly over each other. Movement is restricted to a required range, and stability is maintained during use. The load is distributed across the surface, thus preventing damage by overloading or disuse.  

**Synovium and synovial fluid.** The joint capsule, which is connected to the periosteum, is lined with synovium, which is a few cells thick and vascular. Its surface is smooth and non-adherent and is permeable to proteins and crystalloids. As there are no macroscopic gaps, it is able to retain normal joint fluid even under pressure. Macrophages and fibroblast-like synoviocytes form the synovial layer by cell-to-cell interactions mediated by cadherin-II. The synoviocytes release hyaluronan into the joint space, which helps to retain fluid in the joint. Synovial fluid is a highly viscous fluid secreted by the synovial cells and has a similar consistency to plasma. Glycoproteins ensure a low coefficient of friction between the cartilaginous surfaces. Tendon sheaths and bursae are also lined by synovium.

### Juxta-articular bone

The bone which abuts a joint (epiphyseal bone) differs structurally from the shaft (metaphysis) (see Fig. 11.32). It is highly vascular and comprises a light framework of mineralized
collagen enclosed in a thin coating of tougher, cortical bone. The ability of this structure to withstand pressure is low and it collapses and fractures when the normal intra-articular covering of hyaline cartilage is worn away as in osteoarthritis (OA; see p. 512). Loss of surface cartilage also leads to the abnormalities of bone growth and remodelling typical of OA (see p. 512).

Bone structure and physiology
Bone structure and physiology is discussed on page 549.

Hyaline cartilage
Hyaline cartilage forms the articular surface and is avascular. It relies on diffusion from synovial fluid for its nutrition. It is rich in type II collagen that forms a meshwork enclosing giant macromolecular aggregates of proteoglycan. These heterogeneous macromolecules comprise protein chains with side-chains of the carbohydrates keratan and chondroitin sulphate (aggrecans). These molecules have a negative charge and retain water in the structure by producing a dynamic tension between the retaining force of the collagen matrix and the expansive effect of osmotic pressure. Intermittent pressure from ‘loading’ of the joint is essential to normal cartilage function and encourages movement of water, minerals and nutrients between cartilage and synovial fluid. Chondrocytes secrete collagen and proteoglycans and are embedded in the cartilage. They migrate towards the joint surface along with the matrix they produce.

Ligaments and tendons
These structures stabilize joints. Ligaments are variably elastic and this contributes to the stiffness or laxity of joints (see p. 559). Tendons are inelastic and transmit muscle power to bones. The joint capsule is formed by intermeshing tendons and ligaments. The point where a tendon or ligament joins a bone is called an enthesis and may be the site of inflammation.

Components of extracellular matrix
All connective tissues contain an extracellular matrix of macromolecules: collagens, elastins, non-collagenous glycoproteins and proteoglycans, in addition to cells, e.g. synoviocytes. There are several different types of cell surface receptors that bind extracellular matrix proteins including the integrins, CD44 and the proteoglycan family of receptors, e.g. syndecans.

Collagens. Collagens consist of three polypeptide \((\alpha)\) chains wound into a triple helix. These alpha chains contain repeating sequences of Gly-x-y triplets, where \(x\) and \(y\) are often prolyl and hydroxypropyl residues. Collagen fibres show genetic heterogeneity, with genes on at least 12 chromosomes. Hyaline cartilage is 90% type II (COL2A1). There are several classes of collagen genes, based on their protein structures, and abnormalities of these may lead to specific diseases (see p. 560).

Elastin, secreted as tropoelastin, is an insoluble protein polymer and is the main component of elastic fibres.

Glycoproteins. Fibronectin is the major non-collagenous glycoprotein in the extracellular matrix. Its molecule contains a number of functional domains, or cell recognition sites that bind ligands and are involved in cellular adhesion. Fibronectin plays a major role in tissue remodelling. Its production is stimulated by interferon-gamma (IFN-\(\gamma\)) and by transforming growth factor-beta and inhibited by tumour necrosis factor and interleukin-1.

Proteoglycans. These proteins contain glycosaminoglycan (GAG) side-chains and are of variable form and size. Many different molecules have been identified at different sites in connective tissue. Their function is to bind extracellular matrix together, retain soluble molecules in the matrix and assist with cell binding. Abnormalities of any of these structures may lead to periaricular or articular symptoms and/or predispose to the development of arthritis.

Joint sensation
The ligaments, periosteum, synovial tissue and capsule of the joint are richly supplied by blood vessels and nerves. Pain usually derives from inflammation of these sites because the synovial membrane is relatively insensitive.

Connective tissue degradation
Connective tissue constantly undergoes repair and remodelling. Degradation is mediated by enzymes such as aggrecanase and matrix metalloproteinases (MMPs) which require zinc and act at a neutral pH. There are several MMPs which act on different collagens, e.g. the gelatinases (MMP-2 and -9), which degrade denatured collagen. MMPs also act on non-collagen proteins, e.g. the stromelysins (MMP-3, -10, -11), which degrade proteoglycans and fibronectin.

The turnover of normal collagen is initiated by cytokines, e.g. interleukin-1 synthesized by chondrocytes. Activation of latent MMPs and tissue plasminogen activator then occurs. Two inhibitors, TIMP (Tissue Inhibitor of Metalloproteinase) and plasminogen activator inhibitor-1 (PAI-1), inhibit degradation during matrix remodelling.

Skeletal muscle
This consists of bundles of myocytes containing actin and myosin molecules. These molecules interdigitate and form myofibrils which cause muscle contraction in a similar way to myocardial muscle (p. 671). Bundles of myofibrils (fasciculi) are covered by connective tissue, the perimysium, which merges with the epimysium (covering the muscle) and forms the tendon which attaches to the bone surface (enthesis).
CLINICAL APPROACH TO THE PATIENT

Taking a musculoskeletal history

The following questions are helpful in assessing the problem and making a diagnosis. A history can often lead to a diagnosis as pattern recognition is the key to diagnosis in rheumatic diseases.

- **Has there been recent trauma?**

**Pain**

- **Where is it? Is it localized or generalized?** The pattern of joint involvement is a useful clue to the diagnosis (e.g. distal interphalangeal joints in nodal osteoarthritis).
- **Is it arising from joints, the spine, muscles or bone, with local tenderness?** Soft tissue lesions and inflamed joints are locally tender.
- **Could it be referred from another site?** Joint pain is localized but may radiate distally – shoulder to upper arm; hip to thigh and knee.
- **Is it constant, intermittent or episodic?** How severe is it – aching or agonizing?
- **Are there aggravating or precipitating factors?** Is it made worse by activity and eased by rest (mechanical) or worse after rest (inflammatory).
- **Are there any associated neurological features?** Numbness, pins and needles and/or loss of power suggest ‘nerve’ involvement. The distribution of symptoms is a useful clue to the nerve or nerve root affected.

**Stiffness**

- **Is it generalized or localized?** Spine or joint stiffness is common after injury.
- **Does it affect the limb girdles or periphery?**
  - **Is it worse in the morning and relieved by activity?**
    - Morning joint stiffness for more than 15 min each morning – think of inflammatory arthritis.
    - Morning spinal stiffness in younger adults – think of ankylosing spondylitis (p. 527).
    - Morning shoulder and pelvic girdle stiffness and pain in a patient over 55 years may be polymyalgia rheumatica (p. 542).

**Swelling**

- **Is it of one joint, or of several?** Look for symmetry or asymmetry, and/or a peripheral or proximal pattern. An acute monoarthritis may be due to trauma, gout (in a middle-aged male) or sepsis (fever or immunosuppression).
- **Is it constant or does it come in short-lived or longer episodes?**
- **Is there associated inflammation** (redness and warmth)?

**Gender**

Gout (see p. 530), reactive arthritis (p. 529) and ankylosing spondylitis (p. 527) are more common in men. Rheumatoid arthritis and other autoimmune rheumatic diseases are more common in women.

**Age**

- **Is the person young, middle-aged or older?**
- **How old was the patient when the problem first started?** Osteoarthritis (see p. 512) and polymyalgia rheumatica (p. 542) rarely affect the under-50s. Rheumatoid arthritis starts most commonly in women aged 30–50 years.

**General health**

- **Is there any associated ill-health or other worrying feature, such as weight loss or fever?**
- **Are there other associated medical conditions that may be relevant?** Psoriasis (see p. 1207) or inflammatory bowel disease is associated with spondyloarthritis (see p. 1004). Charcot’s joints (p. 547) are seen in diabetics.

**Medication**

- **Could a drug be a cause?** Diuretics may precipitate gout in men and older women. Hormone replacement therapy or the oral contraceptive pill may precipitate systemic lupus erythematosus (SLE) (p. 535). Steroids can cause avascular necrosis. Some drugs cause a lupus-like syndrome (p. 535).

**Race**

- **Is this relevant?** Sickle cell disease causes joint pain in young black Africans, but osteoporosis (see p. 552) is uncommon in older black Africans.

**Past history**

- **Have there been any similar episodes or is this the first?** Are there any clues from previous medical conditions? Gout is recurrent; the episodes settle without treatment in 7–10 days. Acute episodes of palindromic rheumatism may predate the onset of rheumatoid arthritis (see p. 519).

**Family history**

- **Does anyone in the family have a similar problem or another related disorder?**

**Occupational history**

- **What job does the patient do?** This can be a factor in soft tissue problems and osteoarthritis (e.g. in heavy labourers and dancers). Work-related problems, particularly in those who use a keyboard, are becoming more common and are complained of more.

**Psychosocial history**

The biopsychosocial model of disease is highly relevant to many rheumatic disorders:

- **Has there been any recent major stress in family or working life? Could this be relevant?** Stress rarely causes rheumatic disease but may precipitate a flare-up of inflammatory arthritis. It reduces a person’s ability to cope with pain or disability.

**Extent of disability**

The World Health Organization describes the impact of disease on an individual in terms of:

- **Impairment:** any loss or abnormality of psychological or anatomical structure or function.
**Disability** (activity limitation): any restriction or lack of ability to perform an activity in the manner or within the range considered normal for a human being

**Handicap** (participation restriction): a disadvantage for an individual resulting from an impairment or disability that limits or prevents the fulfillment of a role that is normal for that individual.

The patient’s own perception of limitation must be taken into account during assessment, as well as the impact of physical causes due to disease. Subjective and objective assessments must be made. Quality of life (QoL) involves physical and psychosocial factors. The aim of treatment is to reduce or cure physical and/or psychological disease and to reduce the impact of any impairment or disability on the individual. A variety of different standard questionnaires is used to assess pain, disease impact and outcome (e.g. Health Assessment Questionnaire, HAQ; Arthritis Impact Measurement Scale, AIMS).

### Examination of the joints

Always observe a patient, looking for disabilities, as he or she walks into the room and sits down. General and neurological examinations are often necessary. Guidelines for rapid examinations of the limbs and spine are shown in **Practical Box 11.1**.

Examination of an individual joint involves three stages: looking, feeling and moving (Table 11.1). A screening examination of the locomotor system, known by the acronym GALS (Global Assessment of the Locomotor System) has been devised. X-ray or ultrasound of the joint often forms an integral part of the examination.

### Investigations

Investigations are unnecessary in many of the common musculoskeletal problems; the diagnosis is clear from the history and examination findings. Tests help to exclude another condition and to reassure the patient or their primary care physician.

#### Useful blood screening tests

- **Full blood count**
  - **Haemoglobin**. Normochromic, normocytic anaemia suggests chronic inflammatory and autoimmune diseases. Hypochromic, microcytic anaemia indicates iron deficiency, sometimes due to non-steroidal anti-inflammatory drug (NSAID) induced gastrointestinal bleeding.
  - **White cell count**. Neutrophilia is seen in bacterial infection (e.g. septic arthritis). It also occurs with corticosteroid treatment. Lymphopenia occurs with viral illnesses or active systemic lupus erythematosus (SLE). Neutropenia may reflect drug-induced bone marrow suppression. Eosinophilia is seen in the Churg–Strauss syndrome (p. 847).
  - **Platelets**. Raised platelets occur with any chronic inflammation. Thrombocytopenia is seen in drug-induced bone marrow suppression.

- **Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)**. An increase of these reflects inflammation. Plasma viscosity is also raised in inflammatory disease.

- **Bone and liver biochemistry**. A raised serum alkaline phosphatase may indicate liver or bone disease. A rise in liver enzymes is seen with drug-induced toxicity. For other investigations of bone, see page 550.

### Other blood and urine tests

- Protein electrophoretic strip (and/or immunofixation), serum free light chain testing and urinary Bence Jones protein – to exclude myeloma as a cause of a raised ESR.
- Serum uric acid – for gout.
- Antistreptolysin-O titre – in rheumatic fever.

### Serum autoantibody studies

- **Rheumatoid factors (RFs)** (see also p. 518). Rheumatoid factors are detected by enzyme linked immunoabsorbent assay (ELISA). RFs are antibodies...
### Table 11.1 Examination of the joint

<table>
<thead>
<tr>
<th>LOOK at the appearance of the joint</th>
<th>MOVE</th>
<th>FEEL</th>
</tr>
</thead>
<tbody>
<tr>
<td>Swelling – could be bony, fluid or synovial</td>
<td>Active movement – is the range full and pain-free? Is the movement fluid? In the hands – can the patient perform fine movements? In the legs – can the patient walk properly? Compare movements on the right and left side – are they symmetrical? Is there crepitus when the joint is moved? If active movement is limited try passive movement. In a joint problem both will usually be affected. If it is a muscle or nerve problem passive movement may remain full.</td>
<td>Swelling – fluid swelling (effusion) usually represents increased synovial fluid in inflammatory arthritis, but can be due to blood or pus Synovial swelling is rubbery or boggy and usually occurs in inflammatory arthritis Bony swelling, such as Heberden’s nodes in the fingers is usually seen in osteoarthritis Warmth – a warm joint may be inflamed or infected Tenderness – may represent joint inflammation, but many people have chronic tenderness all over the body (e.g. in fibromyalgia)</td>
</tr>

(usually IgM, but also IgG or IgA) against the Fc portion of IgG. They are detected in 70% of people with rheumatoid arthritis (RA), but are not diagnostic. RFs are detected in many autoimmune rheumatic disorders (e.g. SLE), in chronic infections, and in asymptomatic older people (Table 11.2).

#### Anti-citrullinated peptide antibodies (ACPAs)

These antibodies are directed against citrullinated antigens, vimentin, fibrinogen, alpha enolase and type II collagen. They are measured by an ELISA technique and are present in up to 80% of people with RA. They have a high specificity for RA (90% with a sensitivity of 60%). They are helpful in early disease when the RF is negative to distinguish it from acute transient synovitis (see Box 11.6, p. 519). Positivity for RF and/or ACPA is associated with a worse prognosis and an increase in the likelihood of bony erosions in people with RA.

#### Normal population

| 8 |

#### Antinuclear antibodies (ANAs)

These are detected by indirect immunofluorescent staining of fresh-frozen sections of rat liver or kidney or Hep-2 cell lines. Different patterns reflect a variety of antigenic specificities that occur with different clinical pictures (see Box 11.16, p. 537). ANA is used as a screening test for systemic lupus erythematosus (SLE) and systemic sclerosis (SSc) – a negative ANA makes either condition highly unlikely – but low titres occur in RA and chronic infections and in normal individuals, especially the elderly (Table 11.3).

#### Anti-double-stranded DNA (dsDNA) antibodies

These are usually detected by a precipitation test (Farr assay), by ELISA, or by an immunofluorescent test using Crithidia luciliae (which contains double-stranded DNA). Raised anti-dsDNA is highly specific for SLE and the levels usually rise and fall in parallel with disease activity so can be used to monitor the level of treatment required.

#### Anti-extractable nuclear antigen (ENA) antibodies

(see Box 11.16, p. 537). These produce a speckled ANA fluorescent pattern, and can be identified by ELISA. The most commonly measured ENAs are:
Joint aspiration

Examination of joint (or bursa) fluid is used mainly to diagnose septic, reactive or crystal arthritis. The appearance of the fluid is an indicator of the level of inflammation. The procedure is often undertaken in combination with injection of a corticosteroid. Aspiration alone is therapeutic in crystal synovitis.

Examination of synovial fluid

Aspiration and analysis of synovial fluid are always indicated when an infected or crystal induced arthritis is suspected, particularly a monoarthritis. Normal fluid is clear and straw coloured and contains <3000 WBC/mm³. Inflammatory fluid is cloudy and contains >3000 WBC/mm³. Septic fluid is opaque and less viscous and contains up to 75,000 WCC/mm³. There is much overlap.

Polarized light microscopy is performed for crystals.

- **Gout**: negatively birefringent, needle-shaped crystals of sodium urate
- **Pyrophosphate arthropathy (pseudogout)**: rhomboidal, weakly positively birefringent crystals of calcium pyrophosphate.

**Gram staining** is essential if septic arthritis is suspected and may identify the organism immediately. Joint fluid should be cultured and antibiotic sensitivities requested.

Diagnostic imaging and visualization

- **X-rays** can be diagnostic in certain conditions (e.g. established rheumatoid arthritis) and are the first investigation in many cases of trauma. X-rays can detect joint space narrowing, erosions in rheumatoid arthritis, calcification in soft tissue, new bone formation, e.g. osteophytes and decreased bone density (osteopenia) or increased bone density (osteosclerosis):
  1. In acute low back pain (see p. 503), X-rays are indicated only if the pain is persistent, recurrent, associated with neurological symptoms or signs, or worse at night or associated with symptoms such as fever or weight loss.
  2. Radiological changes are common in older people and may not indicate symptomatic osteoarthritis or spondylosis.
  3. X-rays are of little diagnostic value in early inflammatory arthritis but are useful as a baseline from which to judge later change.

- **Ultrasound (US)** is particularly useful for periarticular structures, soft tissue swellings and tendons and for detecting active synovitis in inflammatory arthritis. It is increasingly used to examine the shoulder and other structures during movement, e.g. shoulder impingement syndrome (see p. 500). Doppler US measures blood flow and hence inflammation. US is used to guide local injections.

- **Magnetic resonance imaging (MRI)** shows bone changes and intra-articular structures in striking detail. Visualization of particular structures can be enhanced with different resonance sequences. T₁-weighted is used for anatomical detail, T₂-weighted for fluid detection and short tau inversion recovery (STIR) for the presence of bone marrow oedema. It is more sensitive than X-rays in the early detection of articular and periarticular disease. It is the investigation of choice for most spinal disorders but is inappropriate in uncomplicated mechanical low back pain. Gadolinium injection enhances inflamed tissue. MRI can also detect muscle changes, e.g. myositis.

- **Computerized axial tomography (CT)** is useful for detecting changes in calcified structures but dose of irradiation is high.

- **Bone scintigraphy** utilizes radionuclides, usually ⁹⁹ᵐ⁹⁹Tc, and detects abnormal bone turnover and blood circulation and, although nonspecific, helps in detecting areas of inflammation, infection or malignancy. It is best used in combination with other anatomical imaging techniques.

- **DXA scanning** uses very low doses of X-irradiation to measure bone density and is used in the screening and monitoring of osteoporosis.

- **Positron emission tomography (PET) scanning** uses radionuclides, which decay by emission of positrons. ¹⁸F-Fluorodeoxyglucose uptake indicates areas of increased glucose metabolism. It is used to locate tumours and demonstrate large vessel vasculitis, e.g. Takayasu’s arteritis (see p. 789). PET scans are combined with CT to improve anatomical details.

- **Arthroscopy** is a direct means of visualizing a joint, particularly the knee or shoulder. Biopsies can be taken, surgery performed in certain conditions (e.g. repair or trimming of meniscal tears), and loose bodies removed.

---

**Anti-neutrophil cytoplasmic antibodies (ANCAs)**

These are predominantly IgG autoantibodies directed against the primary granules of neutrophil and macrophage lysosomes. They are strongly associated with small-vessel vasculitis. Two major clinically relevant ANCA patterns are recognized on immunofluorescence:

- **Proteinase 3 (PR3-ANCA)**, also called cytoplasmic or cANCA, producing a granular immunofluorescence and seen in Wegener’s granulomatosis.
- **Myeloperoxidase (MPO-ANCA)**, also called perinuclear or pANCA, producing a perinuclear stain and seen in microscopic polyarteritis (polyangiitis) and Churg–Strauss syndrome.

**Antiphospholipid antibodies**

These are detected in the antiphospholipid syndrome (see p. 538). These are a direct means of visualizing a joint, particularly a monoarthritis. Normal fluid is clear and straw coloured and contains <3000 WBC/mm³. Inflammatory fluid is cloudy and contains >3000 WBC/mm³. Septic fluid is opaque and less viscous and contains up to 75,000 WCC/mm³. There is much overlap.

**Complement.** Low complement levels indicate consumption and suggest an active disease process in SLE.
Common regional musculoskeletal problems

Pain in the neck and shoulder (Table 11.4)

Mechanical or muscular neck pain (shoulder girdle pain)

Unilateral or bilateral muscular-pattern neck pain is common and usually self-limiting. It can follow injury, falling asleep in an awkward position, or prolonged keyboard working. Chronic burning neck pain occurs because of muscle tension from anxiety and stress.

Spondylosis seen on X-ray increases after the age of 40 years, but it is not always causal. Spondylosis can, however, cause stiffness and increases the risk of mechanical or muscular neck pain. Muscle spasm is palpable and tender and may lead to abnormal neck posture (e.g. acute torticollis). Muscular-pattern neck pain is not localized but affects the trapezius muscle, the C7 spinous process and the paracervical musculature (shoulder girdle pain). Pain often radiates upwards to the occiput and is commonly associated with tension headaches. These features are also seen in chronic widespread pain (see p. 509).

Treatment

Patients are given short courses of analgesic therapy along with reassurance and explanation. Physiotherapists can help to relieve spasm and pain, teach exercises and relaxation techniques, and improve posture. An occupational therapist can advise about the ergonomics of the workplace if the problem is work-related (see p. 510).

Nerve root entrapment

This is caused by an acute cervical disc prolapse or pressure on the root from spondylotic osteophytes narrowing the root canal.

Acute cervical disc prolapse presents with unilateral pain in the neck, radiating to the interscapular and shoulder regions. This diffuse, aching dural pain is followed by sharp, electric shock-like pain down the arm, in a nerve root distribution, often with pins and needles, numbness, weakness and loss of reflexes (Table 11.5).

Cervical spondylosis occurs in the older patient with posterolateral osteophytes compressing the nerve root and causing root pain (see Fig. 22.58, p. 1148), commonly at C5/C6 or C6/C7; it is seen on oblique radiographs of the neck. An MRI scan clearly distinguishes facet joint OA, root canal narrowing and disc prolapse.

Treatment

A support collar, rest, analgesia and sedation are used initially as necessary. Patients should be advised not to carry heavy items. It usually recovers in 6–12 weeks. MRI is the investigation of choice if surgery is being considered or the diagnosis is uncertain (Fig. 11.3). A cervical root block administered under direct vision by an experienced pain specialist may relieve pain while the disc recovers. Neurosurgical referral is essential if the pain persists or if the neurological signs of weakness or numbness are severe or bilateral.
Pain may take a few weeks or months to settle and the patient should be warned of this.

Pain in the shoulder

The shoulder is a shallow joint with a large range of movement. The humeral head is held in place by the rotator cuff (Fig. 11.4) which is part of the joint capsule. It comprises the tendons of infraspinatus and teres minor posteriorly, supraspinatus superiorly and teres major and subscapularis anteriorly. The rotator cuff (particularly supraspinatus) prevents the humeral head blocking against the acromion during abduction; the deltoid pulls up and the supraspinatus pulls in to produce a turning movement and the greater tuberosity glides under the acromion without impingement. Shoulder pathology restricts or is made worse by shoulder movement. Specific diagnoses are difficult to make clinically but this may not matter for pain management.

Pain in the shoulder can sometimes be due to problems in the neck. The differential diagnosis of this is shown in Box 11.1. Adhesive capsulitis (true frozen shoulder) is uncommon (see below). Early inflammatory arthritis and polymyalgia rheumatica in the elderly may present with shoulder pain. Shoulder pain is more common in diabetic patients than in the general population.

Rotator cuff (supraspinatus) tendonosis

This is a common cause of shoulder pain at all ages. It follows trauma in 30% of cases and is bilateral in under 5%. The pain radiates to the upper arm and is made worse by arm abduction and elevation, which are often limited. The pain is often worse during the middle of the range of abduction, reducing as the arm is raised fully; a so-called ‘painful arc
syndrome’. When examined from behind, the scapula rotates earlier than usual during elevation. Passive elevation reduces impingement and is less painful. Severe pain virtually immobilizes the joint, although some rotation is retained (cf. adhesive capsulitis, see below). There is also painful spasm of the trapezius. There may be an associated subacromial bursitis. Isolated subacromial bursitis occurs after direct trauma, falling on to the outstretched arm or elbow. Acromioclavicular osteophytes increase the risk of impingement and may need to be removed surgically.

X-rays or ultrasound are necessary only when rotator cuff tendoson is persistent or the diagnosis is uncertain.

**Treatment**

Analgesics, NSAIDs and/or physiotherapy may suffice, but severe pain responds to an injection of corticosteroid into the subacromial bursa (Fig. 11.4). Patients should be warned that 10% will develop worse pain for 24–48 hours after injection. Some 70% improve over 5–20 days and mobilize the joint themselves. Physiotherapy helps persistent stiffness. Further ultrasound-guided corticosteroid injections may be needed but the long-term benefit is unclear.

**Torn rotator cuff**

This is caused by trauma but also occurs spontaneously in the elderly and in rheumatoid arthritis (RA). It prevents active abduction of the arm, but patients learn to initiate elevation using the unaffected arm. Once elevated, the arm can be held in place by the deltoid muscle. In younger people, the tear is repaired surgically but this is rarely possible in the elderly or in RA. Some patients require arthroscopic surgery.

**Calcific tendonosis and bursitis**

Calcium pyrophosphate deposits in the tendon are visible on X-ray, but they are not always symptomatic. The pathogenesis is unclear, although ischaemia may play a part. The deposit is usually just proximal to the greater tuberosity. It may lead to acute or chronic recurrent shoulder pain and restriction of movement. A local corticosteroid injection may relieve the pain. The calcification may persist or resolve. Aspiration or breaking up of the deposit under ultrasound control may be required for persistent pain. Rarely, arthroscopic removal is necessary.

Shedding of crystals into the subacromial bursa causes a bursitis with severe pain and shoulder restriction. The shoulder feels hot and is swollen, and an X-ray shows a diffuse opacity in the bursa. The differential diagnosis of calcific bursitis is gout, pseudogout or septic arthritis. Aspiration and injection with corticosteroid can help.

**Adhesive capsulitis (true ‘frozen’ shoulder)**

This is uncommon but can develop with rotator cuff lesions, or following hemiplegia, chest or breast surgery or myocardial infarction. It causes severe shoulder pain and complete loss of all shoulder movements, including rotation. High doses of NSAIDs and intra-articular injections of local anaesthetic and corticosteroids are helpful. Once the pain settles, arthroscopic release speeds functional recovery.

**Pain in the elbow**

Pain in the elbow can be due to epicondylitis, inflammatory arthritis or occasionally osteoarthritis.

**Epicondylitis**

Two common sites where the insertions of tendons into bone become inflamed (enthesitis) are the insertions of the wrist extensor tendon into the lateral epicondyle (‘tennis elbow’) and the wrist flexor tendon into the medial epicondyle (‘golfer’s elbow’). Both are usually unrelated to either sporting activity.

There is local tenderness. Pain radiates into the forearm on using the affected muscles – typically, gripping or holding a heavy bag in tennis elbow or carrying a tray in golfer’s elbow. Pain at rest also occurs.

**Treatment**

Advise rest and arrange review by a physiotherapist. A local injection of corticosteroid at the point of maximum tenderness is helpful when the pain is severe but needs physiotherapy follow-up to prevent recurrences (Fig. 11.5). Avoid the ulnar nerve when injecting golfer’s elbow. Both conditions settle spontaneously eventually, but occasionally persist and require surgical release.

**Pain in the hand and wrist (Table 11.6)**

Hand pain is commonly caused by injury or repetitive work-related activities. When associated with pins and needles or numbness it suggests a neurological cause arising at the wrist, elbow or neck. Pain and stiffness that are worse in the morning are due to tenosynovitis or inflammatory arthritis. The distribution of hand pain often indicates the diagnosis.

**Figure 11.5 Injection for tennis elbow.**

DIPs, PIPs, distal and proximal interphalangeal joints.
**Tenosynovitis**

The finger flexor tendons run through synovial sheaths and under loops which hold them in place. Inflammation occurs with repeated or unaccustomed use, or in inflammatory arthritis. The thickened sheaths are often palpable.

**Flexor tenosynovitis** causes finger pain when gripping and stiffness of the fingers in the morning. Occasionally a tendon causes a trigger finger, when the finger remains flexed in the morning or after gripping and has to be pulled straight. A tender tendon nodule is palpable, usually in the distal palm. Trigger finger or thumb is commoner in diabetic patients.

**Dorsal tenosynovitis** is less common except in rheumatoid arthritis. The hourglass swelling extends from the back of the hand and under the extensor retinaculum.

**De Quervain’s tenosynovitis** causes pain and swelling around the radial styloid where the abductor pollicis longus tendon is held in place by a retaining band. There is local tenderness, and the pain at the styloid is worsened by flexing the thumb into the palm.

**Treatment**

Resting, splinting and NSAIDs may help. Local corticosteroids injected alongside the tendon under low pressure (not into the tendon itself) are helpful. Occasionally surgery is needed if symptoms persist.

**Carpal tunnel syndrome**

This is due to median nerve compression in the limited space of the carpal tunnel. Thickened ligaments, tendon sheaths or bone enlargement can cause it, but it is usually idiopathic. (Causes are discussed on p. 1144.) The history is usually typical and diagnostic with the patient waking with numbness, tingling and pain in a median nerve distribution. The pain radiates to the forearm. The fingers feel swollen but usually are not. Wasting of the abductor pollicis brevis develops with sensory loss in the radial three and a half fingers. The pain may be produced by tapping the nerve in the carpal tunnel (Tinel’s sign) or by holding the wrist in flexion (Phalen’s test).

**Treatment** is with a splint to hold the wrist in dorsiflexion overnight. This relieves the symptoms and is diagnostic; used nightly for several weeks it may produce full recovery. If it does not, a corticosteroid injection into the carpal tunnel (avoid the nerve!) helps in about 70% of cases, although it may recur. Persistent symptoms or nerve damage produce prolonged latency across the carpal tunnel on nerve conduction studies and require surgical decompression.

**Other conditions causing pain**

**Inflammatory arthritis.** This may present with pain, swelling and stiffness of the hands. In RA the wrists, proximal interphalangeal (PIP) joints and metacarpophalangeal (MCP) joints are affected symmetrically. In psoriatic arthritis and reactive arthritis a finger may be swollen (dactylitis) or the distal interphalangeal (DIP) joints and nails are affected asymmetrically.

**Nodal osteoarthritis.** This affects the DIP and less commonly PIP joints, which are initially swollen and red. The inflammation and pain settle but bony swellings remain (p. 514).

**First carpometacarpal osteoarthritis.** This causes pain at the base of the thumb when gripping, or painless stiffness at the base of the thumb, often in persons with nodal osteoarthritis.

**Scaphoid fractures.** These cause pain in the anatomical snuffbox. They are not seen immediately on X-ray. A cast is necessary. Untreated scaphoid fractures can eventually cause pain because of failed union.

**Ganglion.** A ganglion is a jelly-filled, often painless swelling caused by a partial tear of the joint capsule or tendon sheath. The wrist is a common site. Treatment is not essential as many resolve or cause little trouble, otherwise surgical excision is the best option.

**Dupuytren’s contracture**

This is a painless, palpable fibrosis of the palmar aponeurosis, with fibroblasts invading the dermis due to abnormal signalling in the Wnt pathway. It causes puckering of the skin and gradual flexion, usually of the ring and little fingers. It is more common in males, Caucasians, in diabetes mellitus and in those who overuse alcohol. A similar fibrosis occurs in the feet and is often more aggressive. It is also associated with Peyronie’s disease of the penis – a painful inflammatory disorder of the corpora cavernosa, leading eventually to painless fibrosis and angulation of the penis during erection. Intraliesional steroid injections may help in early disease and some advocate transcutaneous needle aponeurotomy. Collagenase injection into the collagen contracted cord improved the amount of movement in one randomized study. Plastic surgical release of the contracture is restricted to those with severe deformity of the fingers.

---

**Pain in the lower back**

Low back pain is a common symptom. It is often traumatic and work-related, although lifting apparatus and other mechanical devices and improved office seating help to avoid it. Episodes are generally short-lived and self-limiting, and patients attend a physiotherapist or osteopath more often than a doctor. Chronic back pain is the cause of 14% of long-term disability in the UK. The causes are listed in Table 11.7, and the management of back pain is summarized in Box 11.2.

**Investigations**

- **Spinal X-rays** are required only if the pain is associated with certain ‘red flag’ symptoms or signs, which indicate a high risk of more serious underlying problems:
  a. starts before the age of 20 or after 50 years
  b. is persistent and a serious cause is suspected
  c. is worse at night or in the morning, when an inflammatory arthritis (e.g. ankylosing spondylitis), infection or a spinal tumour may be the cause
  d. is associated with a systemic illness, fever or weight loss
  e. is associated with neurological symptoms or signs.
- **MRI** is preferable to CT scanning when neurological signs and symptoms are present. CT scans demonstrate bony pathology better. Interpretation of the relevance of the findings may require a specialist opinion.
- **Bone scans** are useful in infective and malignant lesions but are also positive in degenerative lesions.
- **Full blood count, ESR and biochemical tests** are required only when the pain is likely to be due to malignancy, infection or a metabolic cause. Normal
Mechanical low back pain

Mechanical low back pain starts suddenly, may be recurrent and is helped by rest. It is often precipitated by an injury and may be unilateral or bilateral. It is usually short-lived.

Examination and management

The back is stiff and a scoliosis may be present when the patient is standing. Muscular spasm is visible and palpable and causes local pain and tenderness. It lessens when sitting or lying. Pain relief and physiotherapy are helpful. Acupuncture helps some. Excessive rest should be avoided. Re-education in lifting and exercises help to prevent recurrent attacks of pain. Once a patient develops low back pain, although the episode itself is usually self-limiting, there is a significantly increased risk of further back pain episodes. Risk factors for recurrent back pain include:

- female sex
- increasing age
- pre-existing chronic widespread pain (fibromyalgia)
- psychosocial factors such as high levels of psychological distress, poor self-rated health and dissatisfaction with employment.

Chronic low back pain is a major cause of disability and time off work and is reduced by appropriate early management. Spinal movement occurs at the disc and the posterior facet joints, and stability is normally achieved by a complex mechanism of spinal ligaments and muscles. Any of these structures may be a source of pain. An exact anatomical diagnosis is difficult, but some typical syndromes are recognized (see below). They are often associated with but not necessarily caused by radiological spondylosis (see p. 1148).

Postural back pain develops in individuals who sit in poorly designed, unsupportive chairs. Lumbar spondylosis. The fundamental lesion in spondylosis occurs in an intervertebral disc, a fibrous joint whose tough capsule inserts into the rim of the adjacent vertebrae. This capsule encloses a fibrous outer zone and a gel-like inner zone. The disc allows rotation and bending.

Changes in the discs occasionally start in teenage years or early 20s and often increase with age. The gel changes chemically, breaks up, shrinks and loses its compliance. The surrounding fibrous zones develop circumferential or radial fissures. In the majority this is initially asymptomatic but visible on MRI as decreased hydration. Later the discs become thinner and less compliant. These changes cause circumferential bulging of the intervertebral ligaments.

Reactive changes develop in adjacent vertebrae; the bone becomes sclerotic and osteophytes form around the rim of the vertebra (Fig. 11.6). The most common sites of lumbar spondylosis are L5/S1 and L4/L5.

ESR and CRP distinguish mechanical back pain from polymyalgia rheumatica, a likely differential in the elderly.

Box 11.2 Management of back pain

- Most back pain presenting to a primary care physician needs no investigation.
- Pain between the ages of 20 and 55 years is likely to be mechanical and is managed with analgesia, brief rest if necessary and physiotherapy.
- Patients should stay active within the limits of their pain.
- Early treatment of the acute episode, advice and exercise programmes reduce long-term problems and prevent chronic pain syndromes.
- Physical manipulation of uncomplicated back pain produces short-term relief and enjoys high patient satisfaction ratings.
- Psychological and social factors may influence the time of presentation.
- Appropriate early management reduces long-term disability.

Further reading

In young people, disc prolapse through an adjacent vertebral endplate produces a Schmorl's node on X-ray. This is painless but may accelerate disc degeneration. Spondylosis may be symptomless, but it can cause:

- Episodic mechanical spinal pain
- Progressive spinal stiffening
- Facet joint pain
- Acute disc prolapse, with or without nerve root irritation
- Spinal stenosis
- Spondylolysis

**Facet joint syndrome.** Lumbar spondylosis also causes secondary osteoarthritis of the misaligned facet joints. Pain is typically worse on bending backwards and when straightening from flexion. It is lumbar in site, unilateral or bilateral and radiates to the buttock. The facet joints are well seen on MRI and may show osteoarthritis, an effusion or a ganglion cyst. Direct corticosteroid injections into the joints under imaging may help but their long-term value is unclear. Physiotherapy to reduce hyperlordosis and reducing weight are helpful.

**Fibrositic nodulosis.** This causes unilateral or bilateral low back and buttock pain. There are tender nodules in the upper buttock and along the iliac crest. Such nodules are relevant only if they are tender. They are probably traumatic. Local, intralesional corticosteroid injections help.

**Postural back pain and sway back of pregnancy.** Low back pain is common in pregnancy and reflects altered spinal posture and increased ligamentous laxity. There is usually a hyperlordosis on examining the patient standing. Weight control and pre- and postnatal exercises are helpful, and the pain usually settles after delivery. Analgesics and NSAIDs are best avoided during pregnancy and breast-feeding. Epidurals during delivery are not associated with an increased incidence of subsequent back pain. Poor posture causes a similar syndrome in the non-pregnant, owing to obesity or muscular weakness. Poor sitting posture at work is a frequent cause of chronic low back pain.

### Treatment of mechanical back pain
Adequate analgesia to allow normal mobility and avoid bed rest is best, combined with physical treatments such as physiotherapy, back muscle training regimens and manipulation. Manipulation produces more rapid pain relief in some patients. Acupuncture may help. Most episodes recover irrespective of the treatment given. A positive approach probably reduces the development of chronic pain. A comfortable sleeping position should be adopted using a mattress of medium (not hard) firmness.

**Acute lumbar disc prolapse**
The central disc gel may extrude into a fissure in the surrounding fibrous zone and cause acute pain and muscle spasm. These events are often self-limiting. A disc prolapse occurs when the extrusion extends beyond the limits of the fibrous zone (Fig. 11.6). The weakest point is posterolateral, where the disc may impinge on emerging spinal nerve roots in the root canal.

The episode often starts dramatically during lifting, twisting or bending and produces a typical combination of low back pain and muscle spasm, and severe, lancinating pains, paraesthesia, numbness and neurological signs in one leg (rarely both). The back pain is diffuse, usually unilateral and radiates into the buttock. The muscle spasm leads to a scoliosis that reduces when lying down. The nerve root pain develops with, or soon after, the onset. The site of the pain and other symptoms is determined by the root affected (Table 11.8). A central high lumbar disc prolapse may cause spinal cord compression and long tract signs (i.e. upper motor neurone). Below L2/L3 it produces lower motor neurone lesions.

On examination, the back often shows a marked scoliosis and muscle spasm. The straight-leg-raising test, whilst lying, is positive in a lower lumbar disc prolapse – raising the straight leg beyond 30° produces pain in the leg. Slight limitation or pain in the back limiting this movement is seen with mechanical back pain. Pain in the affected leg produced by a straight raise of the other leg suggests a large or central disc prolapse. Look for perianal sensory loss and urinary retention, which indicate a cauda equina lesion – a neurosurgical emergency (see p. 1135). An upper lumbar disc prolapse produces a positive femoral stretch test; pain in the anterior thigh when the knee is flexed in the prone position.

**Treatment**
Advise a short period (2–3 days) of bed rest, lying flat for a lower disc but semi-reclining for a high lumbar disc, and prescribe analgesia and muscle relaxants. Once the pain is tolerable, encourage the patient to mobilize and refer to a physiotherapist for exercises and preventative advice. An imaging-guided epidural or nerve root canal injection reduces pain rapidly, although the evidence that it speeds resolution or prevents surgery is unclear. Caudal epidural injections are less effective than lumbar ones. Resuscitation equipment must be available for these procedures. Referral to a surgeon for possible microdiscectomy or hemilaminectomy is necessary if the neurological signs are severe, if the pain persists and is severe for more than 6–10 weeks, or if the disc is central. If bladder or anal sphincter tone is affected it becomes a neurosurgical emergency.

**FURTHER READING**
Spinal and root canal stenosis

Progressive loss of disc height, OA of the facet joints, posterolateral osteophytes and buckling of the ligamentum flavum all contribute to root canal stenosis. This causes nerve root pain or spinal root claudication – pain and paraesthesiae in a root distribution brought on by walking and relieved slowly by rest. The associated sensory symptoms, slower recovery when the patient rests, and presence of normal foot pulses distinguish this from peripheral arterial claudication. Severe cervical spondylosis may also produce spinal claudication, often with arm symptoms and signs.

Spinal canal stenosis at more than one level is often associated with severe spondylosis and/or a congenitally narrow spinal canal. It causes buttock and bilateral leg pain, ‘heaviness’, paraesthesiae and numbness when walking. Rest helps, as does bending forwards, a manoeuvre that opens the spinal canal. Specialist surgical advice is necessary.

Treatment

Advise bed rest and analgesia until the severe pain subsides over a few weeks, then gradual mobilization. It may warrant hospitalization, and intravenous bisphosphonates or subcutaneous or nasal calcitonin are given to relieve pain. There may be some residual pain and deformity.

The role of percutaneous vertebroplasty and balloon kyphoplasty remains unclear: there are no randomized controlled trials showing any benefit. Both involve inserting a needle through a pedicle into the affected vertebral body under CT guidance with the aim of stabilizing the fracture. Kyphoplasty involves inflating a balloon filled with methyl methacrylate cement in order to restore vertebral shape. Vertebroplasty is the injection of cement alone, without restoring vertebral shape. Pain relief is usual with both but the risks are higher with vertebroplasty. Deciding when to intervene is complicated by the spontaneous recovery that many experience.

Bone density measurement and preventative treatment of osteoporosis are essential (see p. 555).

Septic discitis

Septic discitis may cause severe pain and rapid adjacent vertebral destruction. It is seen on MRI and requires urgent neurosurgical referral.

Ankylosing spondylitis (see p. 527)

Buttok pain and low back stiffness in a young adult suggests ankylosing spondylitis, especially if it is worse at night and in the morning.

Osteoarthritis (OA)

OA (see p. 512) is the most common cause of hip joint pain in a person over the age of 50 years. It causes pain in the

</tbody>
</table>
buttock and groin on standing and walking. Stiff hip movements cause difficulty in putting on a sock and may produce a limp. Sudden onset pain may be associated with an effusion on MRI and can be treated by an ultrasound guided steroid injection.

**Lateral hip pain syndrome:** trochanteric bursitis and gluteus medius tendonopathy

This may be due to *trochanteric bursitis* and caused by trauma or unaccustomed exercise. It also occurs in inflammatory arthritis. The pain over the trochanter is worse going up stairs, and the trochanter is tender to lie on. Its best management is unclear but exercises help, as may a local corticosteroid injection, although the evidence base for treatment is poor. Surgery is occasionally necessary. Lateral hip pain may be referred from the upper lumbar spine. A tear of the gluteus medius tendon at its insertion into the trochanter causes a similar syndrome but does not respond to injection. MRI scans have demonstrated this new syndrome.

**Meralgia paraesthetica**

This causes numbness and burning dysesthesia (increased sensitivity to light touch) over the anterolateral thigh and may be precipitated by a sudden increase in weight, an injury or during pelvic surgery. It is usually self-limiting but can be helped by amitriptyline or gabapentin at night.

**Fracture of the femoral neck**

This usually occurs after a fall, occasionally spontaneously. There is pain in the groin and thigh, weight-bearing is painful or impossible, and the leg is shortened and externally rotated. Occasionally, a fracture is not displaced and remains undetected. X-rays are diagnostic. Anyone with a hip fracture, especially after minimal trauma, should be reviewed for osteoporosis (see p. 553).

**Avascular necrosis (osteonecrosis) of the femoral head**

This is uncommon but occurs at any age. (Risk factors are discussed on p. 556.) There is severe hip pain. X-rays are diagnostic after a few weeks, when a well-demarcated area of increased bone density is visible at the upper pole of the femoral head. The affected bone may collapse. Early, the X-ray is normal but bone scintigraphy or MRI demonstrates the lesion and shows bone marrow oedema.

**Inflammatory arthritis of the hip**

This produces pain in the groin and stiffness, which are worse in the morning. Rheumatoid arthritis (RA) rarely presents with hip pain, although the hip is involved eventually in severe RA. Ankylosing spondylitis and other seronegative spondyloarthopathies cause inflammatory hip arthritis in younger people.

**Polymyalgia rheumatica**

Bilateral hip, buttock and thigh pain and stiffness that are worse in the morning in an elderly patient may be attributable to polymyalgia rheumatica (see p. 542). Neck and shoulder pain and stiffness are usually also present.

**Pain in the knee** *(Table 11.10)*

The knee depends on ligaments and quadriceps muscle strength for stability. It is frequently injured, particularly during sports. Trauma or overuse of the knee leads to a variety of peri- and intra-articular problems. Some are self-limiting; others require physiotherapy, local corticosteroid injections or surgery.

The knee is also a common site of inflammatory arthritis and osteoarthritis. Minor radiographic changes of osteoarthritis (see Fig. 11.11) are common in the over-50s and often coincidental, the cause of the pain being periarticular. Symptomatic osteoarthritis of the knee correlates poorly with the severity of the radiological changes.

**Common periarticular knee lesions**

**Medial knee pain**

There may be medial or lateral ligament strain, but the medial ligament is more commonly affected. There is pain at the ligament’s insertion into the upper medial tibia, which is worsened by standing or stressing the affected ligament.

Anserine bursitis causes pain and localized tenderness 2–3 cm below the posteromedial joint line in the upper part of the tibia at the site of the bursa. It occurs in obese women, often with valgus deformities, and in breast-stroke swimmers.

*Treatment* is with physiotherapy and a local corticosteroid injection.

**Anterior knee pain**

Anterior knee pain is common in adolescence. In many cases, no specific cause is found, despite investigation. This is called ‘anterior knee pain syndrome’ and settles with time. Isometric quadriceps exercises and avoidance of high heels both help the condition. Patient and parents often need firm reassurance. Abnormal patellar tracking may be a cause and need surgical treatment. Hypermobility of joints causes joint pain, maltracking and rarely recurrent patellar dislocation (see also p. 546).

*Pre- and infrapatellar bursitis* are caused by unaccustomed kneeling (‘housemaid’s knee’). There is local pain, tenderness and fluctuant swelling. Avoidance of kneeling and a local corticosteroid injection are helpful. Septic bursitis can occur.
**Osgood–Schlatter disease** (p. 546) causes pain and swelling over the tibial tubercle. It is a traction apophysitis of the patellar tendon and occurs in enthusiastic teenage sports players.

**Enthesitis** may occur at the patellar end of the tendon (jumper’s knee).

**Common intra-articular traumatic lesions of the knee**

**Chondromalacia patellae**
This is diagnosed arthroscopically. The retropatellar cartilage is fibrillated. In most cases the pain settles eventually. When there is patellar misalignment it may need surgery, as does recurrent patellar dislocation in adolescent girls.

**Torn meniscus**
The menisci are partially attached fibrocartilages that stabilize the rounded femoral condyles on the flat tibial plateaux. In the young they are resilient but this decreases with age. They can be torn by an injury, commonly in sports that involve twisting and bending. The history is usually diagnostic. There is immediate medial or lateral knee pain and swelling within a few hours. The affected side is tender. If the tear is large the knee may lock flexed. The immediate treatment is to apply ice. MRI demonstrates the tear (Fig. 11.7). In most circumstances, especially in active sportsmen, early arthroscopic repair or trimming of the torn meniscus is essential. Surgical intervention reduces recurrent pain, swelling and locking but not the risk of secondary osteoarthritis. The long-term benefit of early repair of tears is not yet known. Post-surgical quadriceps exercises aid a return to sport and other activities.

**Torn cruciate ligaments**
Torn cruciate ligaments account for around 70% of knee haemarthroses in young people. They often co-exist with a meniscal tear. Partial cruciate tears are difficult to diagnose clinically. On flexing the knee to 90°, a torn anterior cruciate allows the tibia to be pulled forwards on the femur. MRI is the investigation of choice. Such injuries need urgent orthopaedic referral, reconstructive surgery usually being necessary in young active adults. There is a significant incidence of secondary OA.

**Osteochondritis dissecans**
This occasionally causes knee pain and swelling in adolescents and young adults, more commonly males. It is probably traumatic, possibly with hereditary predisposing factors. A fragment of bone and its attached cartilage detach by shearing, most commonly from the lateral aspect of the medial femoral condyle.

There is aching pain after activity and, if the fragment becomes loose, locking or ‘giving way’ occurs. The lesion is seen on a tunnel-view X-ray, but MRI is more sensitive, especially if the fragment is undisplaced. Undisplaced lesions are treated with rest, then isometric quadriceps exercises. Loose fragments can be fixed arthroscopically or removed. A similar lesion affecting the lateral femoral condyle occurs in older people.

**Spontaneous osteonecrosis of the knee (SONK)**
This may occur spontaneously or after injury. There is local pain and there are marked bone marrow changes on MRI or SPECT-CT. Weight-bearing must be avoided. Pamidronate by infusion is sometimes used. It may progress to bone infarction and require replacement surgery.

Occasionally, spontaneously or after trauma, osteonecrosis of the knee is associated with severe pain and striking findings on MRI, which is often called SONK (spontaneous osteonecrosis of the knee).

**Knee joint effusions**
An effusion of the knee causes swelling, stiffness and pain. The pain is more severe with an acute onset and with increasing inflammation, because of stretching of the capsule that contains the pain receptors. A full clinical history must include past medical, family and drug history.

Inflammatory arthritis affects the knees and causes warmth and swelling. An acute inflammatory monoarthritis of the knee is a common presentation of a spondyloarthritis and occasionally is the first sign of RA.

Monoarthritis of the knee, associated with severe pain and marked redness, may be due to septic arthritis, or gout in the middle-aged male, or to gout or pseudogout in an older male or female. A cool, clear, viscous effusion is seen in elderly people with moderate or severe symptomatic OA (see p. 512).

**Examination**
A large and tense effusion is easily seen and felt on each side of the patella and in the suprapatellar pouch, and is fluctuant. The effusion delays the patella tapping against the femur when it is pressed firmly and quickly (the ‘patellar tap’ sign) with the knee held straight and relaxed. Small effusions also demonstrate the ‘bulge’ sign when the patient is lying with the quadriceps relaxed. For this, apply a gentle sweeping pressure, first to the medial side of the joint and then, watching the medial dimple, to the lateral side. Slightly delayed bulging of the medial dimple indicates fluid in the joint.

**Investigations**
These are (a) blood tests, and (b) aspiration (Fig. 11.8) and examination of the knee effusion. The basic technique of aspiration is described in Practical Box 11.2.
In approximately 5% of people with a knee effusion, a swollen, painful popliteal cyst develops. The semimembranosus bursa in some individuals has a valve-like connection to the knee. This allows the effusion to flow into the bursa but not back. The cyst is best seen on MRI as it advances and, if a joint effusion is suspected, attempt to aspirate as you advance it. If fluid is obtained, change syringes and aspirate fully. Examine the fluid in the syringe and decide whether or not to proceed with a corticosteroid injection (if fluid clear or slightly cloudy) or send for microbiological tests. Cover the injection site and advise the patient to rest the affected area for a few days. Warn the patient that the pain may increase initially but to report urgently if this persists beyond a few days, if the swelling worsens, or if they become febrile, since this might indicate an infected joint.

Haemarthrosis of the knee

This is caused by:
- Trauma: meniscal, cruciate or synovial lining tear
- Clotting or bleeding disorders: such as haemophilia, sickle cell disease or von Willebrand’s disease.

Popliteal cyst (Baker’s cyst). In approximately 5% of people with a knee effusion, a swollen, painful popliteal cyst develops. The seminembranosus bursa in some individuals has a valve-like connection to the knee. This allows the effusion to flow into the bursa but not back. The cyst is best seen and felt in the popliteal fossa with the patient standing.

Ruptured popliteal cyst. A popliteal cyst may rupture if the patient is mobile. Fluid escapes into the soft tissue of the popliteal fossa and upper calf, causing sudden and severe pain, swelling and tenderness of the upper calf. Dependent oedema of the ankle develops and the knee effusion reduces dramatically in size and may be undetectable.

A history of previous knee problems and the sudden onset of pain and tenderness high in the calf suggest a ruptured cyst rather than a deep vein thrombosis (DVT). However, the diagnosis is often missed and treated inappropriately with anticoagulants. A diagnostic ultrasound examination distinguishes a ruptured cyst from a DVT (see p. 789). Analgesics or NSAIDs, rest with the leg elevated, and aspiration and injection with corticosteroids into the knee joint are required.

Pain in the foot and heel (Table 11.11)

The feet are subjected to extreme pressures by weight-bearing and inappropriate shoes. They are commonly painful. Broad, deep, thick-soled shoes are essential for sporting activities, prolonged walking or standing, and in people with congenitally flat or arthritic feet.

There are two common types of foot deformity:
- Flat feet: stress the ankle and throw the hindfoot into a valgus (everted) position. A flat foot is rigid and inflexible.
- High-arched feet: place pressure on the lateral border and ball of the foot.

The foot is affected by a variety of inflammatory arthritic conditions. After the hand, the foot joints are the most commonly affected by rheumatoid arthritis. The diagnosis depends upon careful assessment of the distribution of the joints affected, the pattern of other joint problems or by finding the associated condition (e.g. psoriasis, see p. 1207).

Hallux valgus

The great toe migrates laterally. In the congenital form, the first metatarsal bone is displaced medially (metatarsus primus varus). The shape of modern shoes causes later onset of hallux valgus. It is a common complication of RA.

Hallux rigidus

Osteoarthritis of the first metatarsophalangeal (MTP) joint in a normally aligned or valgus joint causes hallux rigidus: a stiff, dorsiflexed and painful great toe. Careful choice of footwear and the help of a podiatrist suffice for most cases, but some require surgery.

Metatarsalgia

This is common, especially in women who wear high heels, after trauma and in those with hammer toes. The ball of the foot is painful to walk and stand on. Callosities and pressure-induced bursae develop under the metatarsal heads. Rheumatoid arthritis causes misalignment of the metatarsal bones and severe metatarsalgia.

Treatment is with podiatry and the wearing of appropriate shoes. Surgery is occasionally needed, particularly in the rheumatoid forefoot.
Morton’s metatarsalgia is due to a neuroma, usually between the third and fourth metatarsal heads. It causes pain, burning and numbness in the adjacent surfaces of the affected toes when walking. It is helped by wearing wider, cushioned-soled shoes. Occasionally a steroid injection or excision is necessary.

Stress (march) fractures
These cause sudden, severe, weight-bearing pain in the distal shaft of the fractured metatarsal bone. They occur after unaccustomed walking or with new shoes. There is local tenderness and swelling, but initially X-rays are normal and diagnosis delayed. A radioisotope bone scan or MRI reveals the fracture earlier than X-rays. Reduced weight-bearing for a few weeks usually suffices. There is a possibility of osteoporosis.

Tarsal tunnel syndrome
This is an entrapment neuropathy of the posterior tibial nerve at the medial malleolus. It produces burning, tingling and numbness of the toes, sole and medial arch. The nerve is tender below the malleolus and, when tapped, produces a shock-like pain (Tinel’s sign). A local steroid injection under the retinaculum, between the medial malleolus and calcaneum, is helpful.

Pain under the heel
Plantar fasciitis is an enthesitis at the insertion of the tendon into the calcaneum. It produces localized pain under the heel when standing and walking, and local tenderness. It occurs alone or in spondyloarthritides.

Plantar spurs are traction lesions at the insertion of the plantar fascia in older people and are usually asymptomatic. They become painful after trauma.

Calcaneal bursitis is a pressure-induced (adventitious) bursa that produces diffuse pain and tenderness under the heel. Compression of the heel pad from the sides is painful, which distinguishes it from plantar fascia pain.

Whatever the cause, the pain is always worse in the morning as soon as weight is placed on the foot.

All of these lesions are treated with heel pads, and reduced walking; they are often self-limiting. A dorsiflexion splint at night to stretch the plantar fascia is worth trying. When an injection is necessary, a medial approach is used, rather than through the heel pad, often under ultrasound guidance.

Pain behind the heel and leg
Sever’s disease is a traction apophysitis of the Achilles tendon in young people (cf. Osgood–Schlatter disease, p. 546).

Pain at the insertion of the Achilles tendon into the calcaneum is an enthesitis. This is traumatic or it can complicate spondyloarthritides. Raising the shoe heel reduces pain. Occasionally a steroid injection or excision is necessary.

Achilles tendonosis causes a painful, tender swelling a few centimetres above the tendon’s insertion. Advise against walking barefoot and jumping. Tendon damage or rupture can occur with quinolone, e.g. ciprofloxacin therapy. Therapeutic ultrasound is helpful. (Caution: a local injection may cause the tendon to rupture.) Autologous platelet concentrates are used but evidence for efficacy is poor.

Achilles bursitis lies clearly anterior to the tendon and can be safely injected with corticosteroid.

Compartment syndromes
The muscles of the lower leg are enclosed in fascial compartments, with little room for expansion to occur. Compartment syndromes can be acute and severe, such as following exercise.

In the anterior tibial syndrome there is severe pain in the front of the shin, occasionally with foot drop. Immediate surgical decompression to prevent muscle necrosis is sometimes required.

Chronic compartment syndrome produces pain in the lower leg that is aggravated by exercise and may therefore be mistaken for a vascular or neurological disorder.

Pain in the chest
Musculoskeletal conditions are sometimes a cause of chest pain. An example is Tietze's disease. In this condition, pain arises from the costosternal junctions. It is usually unilateral and affects one, two or three ribs. There is local tenderness, which helps to make the diagnosis. The condition is benign and self-limiting. It often responds well to anti-inflammatory drugs. Other causes of chest wall pain include rib fractures due to trauma or osteoporosis or a malignant deposit. Costochondral pain occurs in ankylosing spondylitis (see p. 527). In people with heart disease, costochondral pain may cause severe anxiety but it is not like angina and the patient should be reassured.

CHRONIC PAIN SYNDROMES
Chronic pain syndromes (see p. 1163) are difficult to manage. Psychological factors are at least as relevant as inflammation or damage in determining the patient’s perception of pain. It is essential to be objective and non-judgemental when assessing physical, psychological and social factors without assuming which is primary. Chronic pain syndromes are difficult to explain scientifically. It is all too easy for a doctor to respond to this lack of a clear scientific cause by seeming to ‘blame’ the patient for the symptoms. Many chronic pain states are post-traumatic and some may be exaggerated partly by the process of litigation that may follow an injury.

Any chronic painful condition can change the way a person copes. Some people with chronic diseases or chronic pain cope well, but others adopt coping strategies and patterns of behaviour which make things worse. They become anxious, depressed or socially isolated, and their QoL is reduced. In chronic pain syndromes patients need help to lead a more normal life despite their pain, and are best referred to a specialist, multidisciplinary pain service.

Psychological states such as depression and anxiety produce physical symptoms, of which one is pain, while people with frank physical diseases are often understandably anxious and depressed. A biopsychosocial approach is best.

Chronic widespread pain (fibromyalgia)
Chronic widespread pain is defined as pain for more than three months both above and below the waist (p. 1163). It is a diagnosis of exclusion although it is still not universally accepted as a diagnosis. Multiple trigger points are reported by people with fibromyalgia (see p. 1163; Fig. 11.9). The pain is widespread, with unremitting, aching discomfort. Many patients have sleep disturbances, so they awake unfreshened and have poor concentration. Multiple other symptoms, e.g. irritable bowel syndrome (IBS), tension headaches, dysmenorrhoea, atypical facial or chest pain, often co-exist. It occurs at any age and affects women more than men (7:1).

Doctors sometimes inappropriately label these patients ‘heart sink’ patients and patients sense this. The patient’s
The predominant symptoms are pain in all or part of one or both arms. A specific lesion, such as tennis elbow or carpal tunnel syndrome, or muscular-pattern neck pain often develops first, and early recognition and treatment may prevent chronicity. After a variable period, the pain becomes more diffuse and no longer simply work-related, and there is often severe distress. It is seen in keyboard workers and in musicians. When it arises at work, it is often at a time of changing work practices, shortage of staff or disharmony. Middle managers find it difficult to deal with and this compounds the stress.

It is seen throughout the developed world. It peaked in incidence in Australia in the 1970s and 1980s but has largely disappeared there, apparently because of changes in work practices, improvements in early medical management, changes in workers’ compensation legislation, and reduced media discussion of the problem.

**Treatment**

If possible, there should be a brief period off work and a gradual return to activity as the pain settles. Use of analgesics and NSAIDs, with physiotherapy, is helpful during the initial phase to prevent a vicious circle developing. Amitriptyline or pregabalin is helpful for some patients.

A review of working practices and the positioning of screen, keyboard and chair are essential, as is support of the patient by their manager. Musicians are helped by expert advice on playing technique and should reduce playing times temporarily, but not stop completely.

**Temporomandibular pain dysfunction syndrome**

This is a disorder of the temporomandibular joint associated with nocturnal tooth grinding or abnormalities of bite. It occurs in anxious people. It gives rise to pain in one or both temporomandibular joints.

Dental correction of the bite helps a few but when no dental cause is found, low-dose tricyclic antidepressant therapy is used. Many patients are made worse by unnecessary dental treatment.

**Hypermobility and hypermobility syndrome**

Many people in the adult population have hypermobile joints (see p. 546). A small proportion are more prone to joint pains, joint instability and autonomic disturbances. This sometimes causes extreme anxiety and manifests as a chronic pain syndrome. Specific exercises to stabilize the joints, recognition of the problem and, sometimes, cognitive behavioral therapy all help. Surgery is best avoided because of problems with healing.

**Chronic regional pain syndrome type I (previously called reflex sympathetic dystrophy or Sudeck’s atrophy)**

This is defined as ‘a complex disorder or group of disorders that may develop as a consequence of trauma affecting the limbs, with or without obvious nerve lesions’. It may also develop after central nervous system lesions (e.g. strokes) or without cause. Its features are pain and other sensory abnormalities, including hyperaesthesia, autonomic vasomotor dysfunction, leading to abnormal blood flow and sweating, and motor system abnormalities. This leads to structural changes of superficial and deep tissues (trophic changes). Not all components need be present. The sensory, motor and
sympathetic nerve changes are not restricted to the distribution of a single nerve and may be remote from the site of injury. The early phase, with pain, swelling and increased skin temperature, is difficult to diagnose but potentially reversible.

After a period of weeks or months, a second, still painful, dystrophic phase develops, characterized by articular stiffness, cold skin and trophic changes, often with localized osteoporosis.

A late phase involves continued pain, skin and muscle atrophy, and muscle contractures, and is extremely disabling.

Diagnosis is initially clinical – a high index of suspicion and recognizing the unusual distribution of the pain. A three-phase bone scan shows diffuse or patchy increase in uptake in the affected limb in all three phases. MRI also shows these early changes. Demineralization on X-ray occurs later.

**Treatment**

Management is difficult and the problem often very disabling. The evidence base for treatment is poor. Early diagnosis, effective pain relief and general care of the patient are essential. NSAIDs, corticosteroids and pregabalin or gabapentin are used in the early phase, together with active exercise of the limb encouraged by a physiotherapist. Intravenous disodium pamidronate can be used at this stage. Referral to a specialist pain clinic is essential. A stellate ganglion block may help upper limb involvement and a sympathetic chain block for the lower limb. Guanethidine (an alpha-blocking agent) or lidocaine administered to the limb under tourniquet are also used.

**Chronic regional pain syndrome type II**

This is discussed on page 1067.

**Analgesic and anti-inflammatory drugs for musculoskeletal problems**

The key to using drugs, particularly in chronic disorders and the elderly, is to balance risk and benefit and constantly to review their appropriateness. Box 11.3 shows the main drugs available.

**Simple and compound analgesic agents**

Simple agents such as paracetamol, aspirin, or codeine compounds (or combination preparations), used when necessary or regularly, relieve pain and improve function. Sleep may also be improved. Side-effects are relatively infrequent, although drowsiness and constipation occur with codeine preparations, especially in the elderly.

Stronger analgesics, such as dihydrocodeine or morphine derivatives, should be used only with severe pain.

**Non-steroidal anti-inflammatory drugs (NSAIDs)**

NSAIDs have anti-inflammatory and centrally acting analgesic properties. They inhibit cyclo-oxygenase (COX), a key enzyme in the formation of prostaglandins, prostacyclins and thromboxanes (see Fig. 15.30). There are two specific cyclo-oxygenase enzymes:

- **COX-1** is the constitutive form present in many normal tissues.
- **COX-2** is the form mainly induced in response to pro-inflammatory cytokines and not found in most normal tissues (except the kidney). It is associated with oedema and the nociceptive and pyretic effects of inflammation.

**Effects and side-effects**

Most of the older NSAIDs are nonspecific and block both enzymes but with variable specificity (‘nonspecific NSAIDs’ or nsNSAIDs). Their therapeutic effect depends on blocking COX-2 and their side-effects mainly on blocking COX-1. COX-1 protects the gastric mucosa and blocking it accounts for the majority of upper gastrointestinal side-effects.

The most common side-effects with nonspecific NSAIDs are indigestion or skin rashes. More serious upper gastrointestinal side-effects are gastric erosions and peptic ulceration with perforation and bleeding. These occur more frequently in the elderly, in whom mortality is higher, in long-term use, and in those with high risk factors: a history of ulcers, *Helicobacter pylori*, and concurrent corticosteroids or anticoagulant therapy. Ibuprofen, in combination with low-dose aspirin, significantly increases the risk of severe gastrointestinal bleeding. Practice guidelines recommend proton pump inhibitors in high-GI-risk patients on nonspecific NSAIDs. 

H₂ blockers are less effective as gastroprotective agents. Prostaglandin E₂ analogues, e.g. misoprostol, reduce ulcer complications and are popular but may cause nausea and diarrhoea. Lower gastrointestinal (Gl) side-effects of nonspecific NSAIDs are becoming more common.

COX-2 inhibitors (‘Coxibs’) produce fewer gastrointestinal side-effects but they still occur. Coxibs are used in patients who have a high risk of gastrointestinal disease and with no cardiovascular risk. People with a high risk of both may be better off taking an NSAID (ibuprofen or naproxen) or a Coxib with a proton pump inhibitor.

Coxibs and NSAIDs may reduce renal function, especially in the elderly (see Box 12.3, p. 608) and rarely cause cardiovascular events.

**Uses**

- **Short courses** of NSAIDs or coxibs are used in musculoskeletal pain and in osteoarthritis and

*COX-2-specific NSAID (coxib).
spontaneous but simple analgesia is often more appropriate.

- In crystal synovitis, NSAIDs and coxibs have a true anti-inflammatory effect (see p. 511).
- In chronic inflammatory synovitis, NSAIDs and coxibs do not alter the chronic inflammatory process, or decrease the risk of joint damage, but they do reduce pain and stiffness.
- Slow-release preparations are useful for inflammatory arthritis and when more constant pain control is needed.
- Be aware of the patient’s gastrointestinal and cardiac risks before prescribing NSAIDs or coxibs.
- NSAID gels have some value in chronic arthritis.

**OSTEOARTHRITIS (OA)**

Osteoarthritis is the most common type of arthritis. It occurs with a variety of patterns in synovial joints and is characterized by cartilage loss with an accompanying periaricular bone response. It is probably not a single disease entity but a multifactorial process in which mechanical factors have a central role. The whole joint structure including cartilage, subchondral bone, ligaments, menisci, synovium and capsule is involved. Pathologically, there is significant inflammation of articular and periaricular structures and alteration in cartilage structure. Osteoarthritis is the subject of intense investigation but no drugs which halt or reverse this process have yet been developed.

**Epidemiology**

The prevalence of OA increases with age; it is uncommon below the age of 50 years and most people over 60 years will have some radiological evidence of it, although only a quarter of these will be symptomatic. It occurs worldwide, but with a variable distribution, e.g. in Asians, hip OA is less common and knee OA is more common than in Europeans. Women over 55 years are affected more commonly than men of a similar age. There is a familial pattern of inheritance in nodal OA and in primary generalized OA. OA has a variable distribution (Fig. 11.10). The resulting disabilities have major socioeconomic resource implications, particularly in the developed world. OA is the most common cause of disability in the Western world in older adults.

**Aetiology** (Box 11.4)

The gene that encodes collagen type II (COL2A1) is a candidate gene for familial OA but there is no single gene that associates with all patterns of OA. Abnormal local mechanical factors which affect loading and wear, such as prior injury, instability, hypermobility and joint dysplasia, play a role in most types of OA. Inflammation starting at periaricular entheses is seen during the inflammatory phase on MRI in nodal OA. Osteoarthritis is the result of active, sometimes inflammatory but potentially reparative processes rather than the inevitable result of trauma and ageing. Focal destruction of the articular cartilage is the common pathological feature. The spectrum of OA ranges from atrophic disease in which cartilage destruction occurs without any subchondral bone response, to hypertrophic disease in which there is massive new bone formation at the joint margins.

Cartilage is a matrix of collagen fibres, which enclose a mixture of proteoglycans and water (see p. 494). The gene for human aggrecan has been cloned, and polymorphisms of the gene have been correlated with OA of the hand in older men.

**Box 11.4 Factors predisposing to osteoarthritis**

- Obesity: Predicts later risk of radiological and symptomatic OA of the hip and hand in population studies
- Heredity: Familial tendency to develop nodal and generalized OA
- Gender: Polyarticular OA is more common in women; a higher prevalence after the menopause suggests a role for sex hormones
- Hypermobility (see p. 546): Increased range of joint motion and reduced stability lead to OA
- Osteoporosis: There is a reduced risk of OA
- Diseases: See Table 11.12
- Trauma: A fracture through any joint. Meniscal and cruciate ligament tears cause OA of the knee
- Congenital joint dysplasia: Alters joint biomechanics and leads to OA. Mild acetabular dysplasia is common and leads to earlier onset of hip OA
- Joint congruity: Congenital dislocation of the hip or a slipped femoral epiphysis or Perthes’ disease; osteonecrosis of the femoral head (see p. 556) in children and adolescents causes early-onset OA
- Occupation: Miners develop OA of the hip, knee and shoulder, cotton workers OA of the hand, and farmers OA of the hip
- Sport: Repetitive use and injury in some sports causes a high incidence of lower-limb OA.

Cartilage is smooth-surfaced and shock-absorbing. Under normal circumstances, there is a dynamic balance between cartilage degradation by wear and its production by chondrocytes. Early in the development of OA, this balance is lost and, despite increased synthesis of extracellular matrix, the cartilage becomes oedematous. Focal erosion of cartilage develops. Chondrocytes die and, although repair is attempted from adjacent cartilage, the process is disordered. Eventually
Pathogenesis

Several mechanisms have been suggested:

- **Abnormal stress and loading** leading to mechanical cartilage damage play a role in secondary OA.
- **Obesity** is a risk factor for developing OA of the hand and knee, but not the hip in later life. Increased skeletal mass increases cartilage volume.
- **Collagenases** (MMP-1 and MMP-13) cleave collagen, and other metalloproteinases such as stromelysin (MMP-3) and gelatinases (MMP-2 and MMP-9) are also present in the extracellular matrix. MMPs are secreted by chondrocytes in an inactive form. Extracellular activation then leads to the degradation of both collagen and proteoglycans around chondrocytes.
- **Tissue inhibitors of metalloproteinases** (TIMPs) regulate the MMPs. Disturbance of this regulation may lead to an increase in cartilage degradation over synthesis and contribute to the development of OA. TIMPs have not yet proven to be of therapeutic value.

- **Osteoprotegerin (OPG), RANK and RANK ligand** (RANKL) control the remodelling of subchondral bone remodelling. Their levels are significantly different in OA chondrocytes. Inhibiting RANKL may prove a new therapeutic approach in OA.
- **Aggrecanase** production is stimulated by pro-inflammatory cytokines and aggrecan (the major proteoglycan) levels fall.
- **Synovial inflammation** is present in OA, and CRP in the serum may be raised. Interleukin-1 (IL-1) and tumour necrosis factor (TNF-α) release stimulates metalloproteinase production and IL-1 inhibits type II collagen production. IL-6 and IL-8 may also be involved.

- **Anticytokine therapy** has not yet been tested in OA. The production of cytokines by macrophages and of MMPs by chondrocytes in OA are dependent on the transcription factor NF-κB. Inhibition of NF-κB may have a therapeutic role in OA.
- **IL-1 receptor antagonist** genes are associated with radiographic severity of knee OA.
- **Growth factors**, including insulin-like growth factor (IGF-1) and transforming growth factor (TGF-β), are involved in collagen synthesis, and their deficiency may play a role in impairing matrix repair. However, increased TGF-β may cause increased subchondral bone density.
- **Cartilage breakdown products** lead to macrophage infiltration and vascular hyperplasia and IL1-β and TNF-α may contribute to further cartilage degradation.
- **Vascular endothelial growth factor** (VEGF) from macrophages is a potent stimulator of angiogenesis and may contribute to inflammation and neovascularization in OA. Innervation can accompany vascularization of the articular cartilage.
- **Mutations** in the gene for type II collagen (COL2A1) have been associated with early polyarticular OA.
- **A strong hereditary element** underlying OA is suggested by twin studies. Further studies may reveal genetic markers for the disease. The influence of genetic factors is estimated at 35–65%.
- **In the Caucasian population** there is an inverse relationship between the risk of developing OA and osteoporosis.
- **Gender**. In women, weight-bearing sports produce a two- to three-fold increase in risk of OA of the hip and knee. In men, there is an association between hip OA and certain occupations: farming and labouring. OA may flare after the female menopause or after stopping hormone replacement therapy.

- **Periarticular enthesitis** has been proposed as a factor in the pathogenesis of nodal generalized OA (NGOA; p. 515) and is the subject of investigation.

The term primary OA is sometimes used when there is no obvious known predisposing factor.

Box 11.4 shows some of the predisposing factors for the development of OA, and Table 11.12 shows other conditions that sometimes cause secondary arthritis.

**Clinical features**

Osteoarthritis affects many joints, with diverse clinical patterns. Hip and knee OA are major causes of disability. Early OA is rarely symptomatic unless accompanied by a joint
effusion, whilst advanced radiological and pathological OA is not always symptomatic.

Some flare-ups are due to inflammation and there may be a slight rise in ESR or CRP. Focal synovitis is caused by fragments of shed bone or cartilage. Radiological OA is usually, but not inevitably, progressive. This progression may be stepwise or continual. Radiological improvement is uncommon but has been observed, suggesting that repair is possible.

**Symptoms**
- Joint pain
- Short-lived morning joint stiffness
- Functional limitation.

**Signs**
- Crepitus
- Restricted movement
- Bony enlargement
- Joint effusion and variable levels of inflammation
- Bony instability and muscle wasting.

**Clinical subsets**

**Localized OA**

**Nodal OA** (Table 11.13)

Joints of the hand are usually affected one at a time over several years, with the distal interphalangeal joints (DIPs) being more often involved than the proximal interphalangeal joints (PIP s). Nodal OA often starts around the female menopause. The onset may be painful and associated with tenderness, swelling and inflammation and impairment of hand function. At this stage, enthesitis can be seen on MRI. An intra-articular corticosteroid injection can be used at this stage, if deemed necessary. The inflammatory phase settles after some months or years, leaving painless bony swellings posterolaterally: Heberden’s nodes (DIPs) and Bouchard’s nodes (PIPs), along with stiffness and deformity (Fig. 11.12). Functional impairment is slight for most, although PIP osteoarthritis restricts gripping more than DIP involvement. On X-ray, the nodes are marginal osteophytes and there is joint space loss.

Thumb base OA co-exists with nodal OA and causes pain and disability, which decrease as the joint stiffens. The ‘squared’ hand in OA (Fig. 11.12) is caused by bony swelling of the carpometacarpal joint and fixed adduction of the thumb. Function is rarely severely compromised.

Polyarticular hand OA is associated with a slightly increased frequency of OA at other sites.

**Hip OA**

Hip OA (see p. 494) affects 7–25% of adult Caucasians but is significantly less common in black African and Asian populations. There are two major subgroups defined by the radiological appearance. The most common is **superior-pole hip OA**, where joint space narrowing and sclerosis predominantly affect the weight-bearing upper surface of the femoral head and adjacent acetabulum. This is most common in men and unilateral at presentation, although both hips may become involved because the disease is progressive. Early onset of hip OA is associated with acetabular dysplasia or labral tears. Less commonly, **medial cartilage** loss occurs. This is most common in women and associated with hand involvement (nodal generalized OA – NGOA), and is usually bilateral. It is more rapidly disabling.

**Knee OA**

The prevalence of symptomatic knee OA is 40% in individuals aged over 75 years. It is commoner in women than in men. There is a strong relationship with obesity. The disease is generally bilateral and strongly associated with nodal OA.
of the hand in elderly women, or as part of generalized OA. The medial compartment is most commonly affected and leads to a varus (bow-legged) deformity. There is often also retropatellar OA. Previous trauma, meniscal and cruciate ligament tears are risk factors for developing knee OA. Bone marrow lesions seen on MRI predict disease progression and eventual joint replacement.

**Primary generalized OA**
This is rare but is usually seen in combination with nodal OA – NGOA. The other joints affected are the knees, first MTP, hip, and intervertebral (spondylosis). Its onset is often sudden and severe. There is a female preponderance and a strong familial tendency. Periarticular ligamentous pathology may have an important role in the phenotypic expression of NGOA.

**Erosive OA**
This is rare. The DIPs and PIPs are inflamed and equally affected and the functional outcome is poor. Radiologically, there is marked osteolysis. Destructive phases are followed by phases of remodelling.

**Crystal-associated OA**
This is most commonly seen with calcium pyrophosphate deposition in the cartilage (chondrocalcinosis). **Chondrocalcinosis** increases in frequency with age and is seen on over 40% of knee X-rays in the over-80s, but is usually asymptomatic. The joints most commonly affected are the knees (hyaline cartilage and fibrocartilage) and wrists (triangular fibrocartilage, see Fig. 11.10). There is patchy linear calcification on X-ray (Fig. 11.13).

A chronic arthropathy (pseudo-OA) occurs, predominantly in elderly women with severe chondrocalcinosis. There is a florid inflammatory component and marked osteophyte and cyst formation visible on X-rays. The joints affected differ from NGOA, being predominantly the knees, then wrists and shoulders. Chondrocalcinosis is associated with pseudogout, an acute crystal-induced arthritis (see p. 532).

A rare, rapidly destructive arthritis in elderly women, affecting shoulders, hips, and knees, is associated with finding crystals of calcium apatite in a bloody joint effusion. The outlook is poor and joints require early surgical replacement.

**Investigations in OA**
- **Blood tests.** There is no specific test; the ESR is normal although high sensitivity CRP may be slightly raised. Rheumatoid factor and antinuclear antibodies are negative.
- **X-rays** are abnormal only when the damage is advanced. They are useful in preoperative assessments. For knees, a standing X-ray (stressed) is used to assess cartilage loss and ‘skyline’ views in flexion for patellofemoral OA.
- **MRI** demonstrates meniscal tears, early cartilage injury and subchondral bone marrow changes (osteochondral lesions).
- **Arthroscopy** reveals early fissuring and surface erosion of the cartilage.
- **Aspiration of synovial fluid** (if there is a painful effusion) shows a viscous fluid with few leucocytes (p. 498).

**Management**
The guiding principle is to treat the symptoms and disability, not the radiological appearances; depression and poor quadriceps strength are better predictors of pain than is radiological severity in OA of the knee. Education of the individual about the disease and its effects reduces pain, distress and disability and increases compliance with treatment. Psychological or social factors alter the impact of the disease.

**Physical measures**
Weight loss and exercises for strength and stability are useful. Hydrotherapy helps, especially in lower-limb OA. Local heat, ice packs, massage and rubefacients or local NSAID gels are all used. Insoles for flat feet and a walking stick held on the contralateral side to the affected lower limb joint are useful.

There is increasing evidence that acupuncture helps knee OA. Other forms of complementary medicine are commonly used and, despite lack of scientific evidence, little is lost in trying it since a number of patients do seem to be helped.

**Medication**
Balance the potential benefit against potential side-effects, especially in the elderly. Paracetamol is effective and should be prescribed before NSAIDs (Box 11.3). NSAIDs or coxibs should be used intermittently when possible. Opioids should be used cautiously in older patients.

Intra-articular corticosteroid injections produce short-term improvement when there is a painful joint effusion. Frequent injections into the same joint should be avoided. The role of intra-articular hyaluronan preparations is unclear.

Glucosamine and chondroitin (sold as food supplements) have no clinically relevant effect on joint pain or joint space narrowing.

There are no proven agents which halt or reverse OA, although they are greatly needed. The role of bisphosphonates in reducing bone changes is unclear. The role of drugs which block tissue metalloproteinases or cytokines (see pathogenesis, below) is also unclear.

**Surgery**
Arthroscopy for knee OA is not beneficial. However, replacement arthroplasty has transformed the management of severe OA. The safety of hip and knee replacements is now equal, with a complication rate of about 1%; loosening, and late blood-borne infection are the most serious. The slight but definite risks make it essential that the patient

---

**Figure 11.13 Chondrocalcinosis of the knee.** Note the linear calcification in the hyaline cartilage and calcification of the lateral meniscus (plus mild secondary OA).
is certain that surgery is necessary. Resurfacing hip surgery has become popular but may have higher complication rates in women. Unicompartmental knee replacement is a less major procedure and appropriate for some patients. For the vast majority, a total hip or knee replacement reduces pain and stiffness, greatly increases function and mobility, and – particularly significant for the elderly – independence.

Other surgical procedures include realignment osteotomy of the knee or hip, excision arthroplasty of the first MTP and base of the thumb, and fusion of a first MTP joint.

**INFLAMMATORY ARTHRITIS**

Inflammatory arthritis (Table 11.14) includes a large number of arthritic conditions in which the predominant feature is synovial inflammation (Box 11.5). This disparate group includes post-viral arthritis, rheumatoid arthritis, spondyloarthrisis, crystal arthritis, and Lyme arthritis. The diagnosis of these conditions is helped by the pattern of joint involve ment (symmetrical or asymmetrical; large or small) (Table 11.14), along with any non-articular disease; a past and family history is helpful. The periodicity of the arthritis (single acute, relapsing, chronic and progressive) also helps in the diagnosis.

Certain non-articular diseases, e.g. psoriasis, iritis, inflammatory bowel disease, nonspecific urethritis or recent dysentery, suggest spondyloarthrisis. There may be evidence of recent viral illness (rubella, hepatitis B or erythrovirus), of rheumatic fever, or a tick bite and skin rash (Lyme disease). In early arthritis, it may not be possible to make a specific diagnosis until the disease has evolved from an undifferenti ated arthritis into a chronic form.

There is a distinct genetic separation of rheumatoid-pattern synovitis and spondyloarthrisis; RA (see below) is associated with a genetic marker in the class II major histocompatibility genes, whilst spondyloarthrisis shares certain alleles in the B locus of class I MHC genes, usually B27 (see p. 526).

In general, the pain and stiffness of inflammatory arthritis are worse in the morning often for several hours, in contrast to the much shorter morning stiffness of OA. Inflammatory markers (ESR and CRP) are often raised in inflammatory arthritis, and there is often a normochromic, normocytic anaemia. Specific types of arthritis are discussed below.

**Early inflammatory polyarthritis**

Undifferentiated polyarthritis requires urgent referral to a rheumatologist for diagnosis and treatment, including the early introduction of disease-modifying agents when indicated (see p. 523). In persistent inflammatory arthritis sustained remission depends on rapid diagnosis and intensive treatment. Poor prognostic features for undifferentiated polyarthritis are:

- Polyarticular onset
- Positive anticyclic citrullinated peptide antibodies
- Positive rheumatoid factor
- Joint erosion on X-ray at presentation
- Disease >3–6 months

**RHEUMATOID ARTHRITIS (RA)**

Rheumatoid arthritis is an autoimmune disease associated with autoantibodies to the Fc portion of immunoglobulin G (rheumatoid factor) and to citrullinated cyclic peptide. There is persistent synovitis, causing chronic symmetrical polyarthritis and systemic inflammation. Genetic studies suggest that RA is a heterogeneous group of diseases. Before the modern drug era it was rapidly disabling for most patients.

**Epidemiology**

RA has a worldwide distribution and affects 0.5–1% (with a female preponderance of 3:1) of the population. The prevalence is low in black Africans and Chinese people. The incidence in first-degree relatives and a high socio economic cost. It presents from early childhood (when it is rare) to late old age. The most common age of onset is between 30 and 50 years.

**Aetiology and pathogenesis**

The cause is multifactorial and genetic and environmental factors play a part.

- **Gender.** Women before the menopause are affected three times more often than men. After the menopause, the frequency of onset is similar between the sexes, suggesting an aetiological role for sex hormones. A meta-analysis of the use of the oral contraceptive pill has shown no effect on RA overall, but it may delay the onset of disease.

- **Familial.** The disease is familial with an increased incidence in first-degree relatives and a high concordance amongst monozygotic twins (up to 15%) and dizygotic twins (3.5%). In occasional families it affects several generations.

- **Genetic** factors account for about 60% of disease susceptibility. There is a strong association between susceptibility to RA and certain HLA haplotypes: HLA-DR4, which occurs in 50–75% of patients and
correlates with a poor prognosis, as does possession of certain shared alleles of HLA-DRB1*04. The possession of these shared epitope alleles in HLA-DRB1 (S2 and S3p) increases susceptibility to RA and may predispose to anti-citrullinated peptide antibodies (ACPA).

Citrullination is a process which modifies antigens, allowing them to fit into the shared epitope on HLA alleles. In a genome-wide association study in ACPA-positive RA, an association was found with loci near HLA-DRB1 and PTPN22 in people of European descent. These genes affect the presentation of autoantigens (HLA-DRB1), T cell receptor signal transduction (PTPN22) and targets of ACPA (PAD14).

- **Smoking** is an environmental risk factor for seropositive RA, possibly by activation of the innate immune system.

### Immunology

RA is primarily a synovial disease which invades local tissues and rheumatoid synovitis results when chemoattractants produced in the joint recruit circulating inflammatory cells. Overproduction and overexpression of tumour necrosis factors (TNF-α) is a key inflammatory element in RA, leading to synovitis and joint destruction. Interaction of macrophages and T and B lymphocytes drives this overproduction. TNF-α stimulates overproduction of interleukin-6 and other cytokines. Antibodies to TNF-α and IL-6 or specific blocking agents produce marked short-term improvement in synovitis, indicating the pivotal role of these cytokines in the chronic synovitis (see p. 523). These antibodies also reduce the malaise and tiredness felt in active RA. Interleukin-1 plays a bigger role in certain subsets, such as systemic juvenile idiopathic arthritis (see p. 545) and adult-onset Still’s disease (see p. 545).

An imbalance in the number of certain cell types appears to be central to immune regulation and its dysfunction.

- **Synovial cells** in chronic rheumatoid synovitis are predominantly abnormally behaving fibroblast-like synoviocytes, and macrophage-like synoviocytes which produce pro-inflammatory cytokines.
- **Abnormal fibroblast-like synoviocytes** appear to circulate between joints and may be the trigger for the polyarticular.
- **Osteoclasts** play an active role in bone and cartilage destruction.
- **B cells** in the synovium, activated by cytokine-activated macrophages and T cells produce autoantibodies of which IgM and IgA RF is the most typical in RA. As RFs have the Fc portion of IgG as their antigen they have the potential for self-aggregation and immune complex formation in the synovium. These may then trigger macrophages via IgGFc receptors to produce even more cytokines including IL-1, IL-8, TNF-α and granulocyte-macrophage colony-stimulating factor, and fibroblasts to produce IL-6.
- **CD20 positive B cell ablation** (a technique used for treating B cell lymphomas) induces temporary remission, reinforcing the central role of B cells in the chronic inflammation of RA. As the B cells return, the CRP rises and the disease flares again.
- **Synovial fibroblasts** have high levels of the adhesion molecule, vascular cell adhesion molecule (VCAM-1: a molecule which supports B lymphocyte survival and differentiation), decay accelerating factor (DAF: a factor that prevents complement-induced cell lysis) and cadherin-II (which mediates cell to cell interactions). These molecules may facilitate the formation of ectopic lymphoid tissue in synovium. Recent studies have shown that mice deficient in cadherin-II are resistant to a form of inflammatory arthritis. High-affinity antibodies are not a feature of RA, unlike other autoimmune diseases.

- **T cells** can be a part of the destructive process but other subsets reduce its severity. T cell-associated cytokines such as IL-2 and IL-4 are not present in high amounts and, when CD4-specific antibodies were used therapeutically to produce a specific helper T cell lymphopenia, they did not significantly alter the disease, suggesting that T cells play a lesser role. This treatment is no longer used. T17 helper cells (see p. 61), which produce IL-17A, 17F, 21 and 22 and TNF-α, may cause inflammation. The normal regulatory T cells are suppressed by TGF-β and interleukins (produced by macrophages and dendritic cells), allowing the T17 helper cells to increase.

- **The role of innate immunity** in RA pathogenesis and in predisposing the joint to inflammation are the subjects of increasing interest (see p. 51).

The triggering antigen, which leads to self-maintained inflammation in RA, remains unclear. Triggers for ACPA production include flaggrin, type II collagen and vimentin. There is little evidence that collagen type II is the triggering antigen, although it is a cause of arthritis in animal models of RA. Smoking is a potential trigger, particularly in ACPA-positive RA.

### Pathology

Rheumatoid arthritis is typified by widespread persistent synovitis (inflammation of the synovial lining of joints, tendon sheaths or bursae). The normal synovium is thin and comprises a lining layer a few cells thick containing fibroblast-like synoviocytes and macrophage-like synoviocytes which produce pro-inflammatory cytokines.

- **Abnormal fibroblast-like synoviocytes** appear to circulate between joints and may be the trigger for the polyarticular.
- **Osteoclasts** play an active role in bone and cartilage destruction.
- **B cells** in the synovium, activated by cytokine-activated macrophages and T cells produce autoantibodies of which IgM and IgA RF is the most typical in RA. As RFs have the Fc portion of IgG as their antigen they have the potential for self-aggregation and immune complex formation in the synovium. These may then trigger macrophages via IgGFc receptors to produce even more cytokines including IL-1, IL-8, TNF-α and granulocyte-macrophage colony-stimulating factor, and fibroblasts to produce IL-6.
- **CD20 positive B cell ablation** (a technique used for treating B cell lymphomas) induces temporary remission, reinforcing the central role of B cells in the chronic inflammation of RA. As the B cells return, the CRP rises and the disease flares again.
- **Synovial fibroblasts** have high levels of the adhesion molecule, vascular cell adhesion molecule (VCAM-1: a molecule which supports B lymphocyte survival and differentiation), decay accelerating factor (DAF: a factor that prevents complement-induced cell lysis) and cadherin-II (which mediates cell to cell interactions).
occasionally reverse erosion formation. Erosions lead to a variety of deformities and contribute to long-term disability.

**Rheumatoid factors (RFs) and anti-citrullinated peptide antibodies (ACPAs)**

RFs (see p. 496) are circulating autoantibodies that have the Fc portion of IgG as their antigen. Transient production of RF is an essential part of the body’s normal mechanism for removing immune complexes, but in RA they show a much higher affinity and their production is persistent and occurs in the joints. They are of any immunoglobulin class (IgM, IgG or IgA), but the most common tests employed clinically detect IgM rheumatoid factor. Around 70% of people with polyarticular RA have IgM rheumatoid factor in the serum. Positive titres can predate the onset of RA.

The term ‘seronegative RA’ is used for patients in whom the standard tests for IgM rheumatoid factor are persistently negative. They tend to have a more limited pattern of synovitis.

*IgM rheumatoid factor* is not diagnostic of RA and its absence does not rule the disease out; however, it is a useful predictor of prognosis. A persistently high titre in early disease implies more persistently active synovitis, more joint damage and greater disability eventually, and justifies earlier use of DMARDs.

Anti-CCP antibodies (ACPA) (p. 497) are usually present with RF in RA. They are better predictors of a transition from early transient inflammatory arthritis to persistent synovitis and early RA. RF and the ACPA together are even more specific.

**Clinical features of RA**

**Typical presentation**

The most typical presentation of rheumatoid arthritis (approximately 70% of cases) begins as a slowly progressive, symmetrical, peripheral polyarthritis, evolving over a period of a few weeks or months. The patient is usually between 30 and 50 years of age, but the disease can occur at any age. Less commonly (15%) a rapid onset can occur over a few days (or explosively overnight) with a severe symmetrical polyarticular involvement, especially in the elderly. Factors which indicate a poor prognosis are listed in Box 11.6. The differential diagnosis of early RA is shown in Box 11.7.

Older classification criteria used to distinguish RA from other forms of arthritis (American College of Rheumatology, ACR criteria 1987) are now mainly used to ensure matched groups for research. The newer criteria that have replaced them are more suitable for assessing early arthritis because they do not rely on later changes such as erosions and extra-articular disease (Box 11.8).

In early RA, the combination of at least one swollen joint for more than 6 weeks with no prior injury and no associated history or family history of spondyloarthritis or associated conditions such as psoriasis (see p. 1207) and a positive ACPA test is the best way to select patients for earlier treatment to avoid joint damage. This earlier treatment is evidence based and has been shown to reduce the risk of the development of damage and thus reduce permanent joint deformities.
### Box 11.6 Factors predicting poor prognosis for progression in early RA

- Age
- Female sex
- Symmetrical small joint involvement
- Morning stiffness >30 min
- >4 swollen joints
- CRP >20
- Positive RF and ACPA

### Box 11.7 Differential diagnosis of early rheumatoid arthritis

- Post-viral arthritis: rubella, hepatitis B or erythrovirus
- Seronegative spondyloarthropathies
- Polymyalgia rheumatica
- Acute nodal osteoarthritis (PIP and DIP involved)

The cut-off point for RA is at 6 or more points. Patients can also be classified as having RA if they have both typical erosions and longstanding disease previously satisfying the classification criteria. (Adapted from Scott DL, Wolfe F, Huizinga TW. Rheumatoid arthritis. Lancet 2010; 376(9744–9745.)

ACR, American College of Rheumatology

### Box 11.9 Presentations of rheumatoid arthritis

- **Palindromic:** Palindromic monoarticular attacks lasting 24–48 hours; 50% progress to other types of RA.
- **Transient:** A self-limiting disease, lasting less than 12 months and leaving no permanent joint damage. Usually seronegative for IgM rheumatoid factor and ACPA. Some of these may be undetected post-viral arthritis.
- **Remitting:** There is a period of several years during which the arthritis is active but then remits, leaving minimal damage.
- **Chronic, persistent:** The most typical form, it may be seropositive or seronegative for IgM rheumatoid factor. The disease follows a relapsing and remitting course over many years. Seropositive (plus ACPA) patients tend to develop greater joint damage and long-term disability. They warrant earlier and more aggressive treatment with disease-modifying agents.
- **Rapidly progressive:** The disease progresses remorselessly over a few years and leads rapidly to severe joint damage and disability. It is usually seropositive (plus ACPA), has a high incidence of systemic complications and is difficult to treat.

### Other presentations

The presentation and progression of RA is variable. Presentations are shown in Box 11.9. Relapses and remissions occur either spontaneously or on drug therapy. In some patients, the disease remains active, producing progressive joint damage. Rarely, the process may cease (‘burnt-out RA’). **Seronegative RA** initially affects the wrists more often than the fingers and has a less symmetrical joint involvement. It has a better long-term prognosis, but some cases progress to severe disability. This form can be confused with psoriatic arthropathy, which has a similar distribution (p. 528).

**Palindromic rheumatism** is unusual (5%) and consists of short-lived (24–72 hours) episodes of acute monoarthritis. The joint becomes acutely painful, swollen and red, but resolves completely. Further attacks occur in the same or other joints. About 50% go on to develop typical chronic rheumatoid synovitis after a delay of months or years. The rest remit or continue to have acute episodic arthritis. The detection of RF or ACPA predicts conversion to chronic, destructive synovitis.

### Complications (Table 11.15)

#### Septic arthritis

This is a serious complication with significant morbidity and mortality. In immunosuppressed patients, the affected joints may not be hot and inflamed with accompanying fever. There is usually a neutrophil leucocytosis. Any effusion, particularly of sudden onset, should be aspirated. Staphylococcus aureus is the most common organism. Blood cultures are often positive. Treatment is with systemic antibiotics (see p. 533) and drainage.

**Side-effects of therapy**

See Table 11.16
Shoulders
RA commonly affects the shoulders. Initially, the symptoms mimic rotator cuff tendinosis (see p. 500) with a painful arc syndrome and pain in the upper arms at night. As the joints become more damaged, global stiffening occurs. Late in the disease rotator cuff tears are common (see p. 501) and interfere with dressing, feeding and personal toilet.

Elbows
Synovitis of the elbows causes swelling and a painful fixed flexion deformity. In late disease, flexion may be lost and severe difficulties with feeding result, especially combined with shoulder, hand and wrist deformities.

Feet
One of the earliest manifestations of RA is painful swelling of the MTP joints. The foot becomes broader and a hammer-toe deformity develops.

A combination of ulnar drift and palmar subluxation of the MCPs (Fig. 11.16). This leads to unsightly deformity, but function may be remarkably good once the patient has learned to adapt, and pain is controlled

Fixed flexion (buttonhole or boutonnière deformity) or fixed hyperextension (swan-neck deformity) of the PIP joints, which impairs hand function

Swelling and dorsal subluxation of the ulnar styloid. which leads to wrist pain and may cause rupture of the finger extensor tendons, leading in turn to a sudden onset of finger drop of the little and ring fingers predominantly, which needs urgent surgical repair.

Knees
Massive synovitis and knee effusions occur, but respond well to aspiration and steroid injection (see p. 507). A persistent effusion increases the risk of popliteal cyst formation and rupture (see p. 508). In later disease, erosion of cartilage and bone causes loss of joint space on X-ray and damage to the medial and/or lateral and/or retropatellar compartments of the knees. Depending on the pattern of involvement, the knees may develop a varus or valgus deformity. Secondary

Figure 11.16  Rheumatoid arthritis. (a) Characteristic hand deformities in RA. (b) Early rheumatoid arthritis – dorsal tenosynovitis of the right wrist and small joints of both hands with spindling of the fingers.

Figure 11.17 The toes in RA, showing exposure of the metatarsal heads with forward migration of the soft tissue pad.

Joint involvement in RA
The changes described below are seen in established disease or when early drug treatment has been ineffective.

Hands and wrists
The impact of RA on the hands is severe. In early disease, the fingers are swollen, painful and stiff. Inflamed flexor tendon sheaths increase functional impairment and may cause a carpal tunnel syndrome. Joint damage causes:

- A combination of ulnar drift and palmar subluxation of the MCPs (Fig. 11.16). This leads to unsightly deformity, but function may be remarkably good once the patient has learned to adapt, and pain is controlled
- Fixed flexion (buttonhole or boutonnière deformity) or fixed hyperextension (swan-neck deformity) of the PIP joints, which impairs hand function
- Swelling and dorsal subluxation of the ulnar styloid, which leads to wrist pain and may cause rupture of the finger extensor tendons, leading in turn to a sudden onset of finger drop of the little and ring fingers predominantly, which needs urgent surgical repair.

Figure 11.16 Rheumatoid arthritis. (a) Characteristic hand deformities in RA. (b) Early rheumatoid arthritis – dorsal tenosynovitis of the right wrist and small joints of both hands with spindling of the fingers.

Figure 11.17 The toes in RA, showing exposure of the metatarsal heads with forward migration of the soft tissue pad.

Rheumatoid arthritis

Amyloidosis
Amyloidosis (see p. 1042) is found in a very small number of people with uncontrolled rheumatoid arthritis. RA is the most common cause of secondary AA amyloidosis. AL amyloidosis causes a polyarthritis that resembles RA in distribution and is also often associated with carpal tunnel syndrome and subcutaneous nodules.

Joint involvement in RA
The changes described below are seen in established disease or when early drug treatment has been ineffective.

Hand involvement
The impact of RA on the hands is severe. In early disease, the fingers are swollen, painful and stiff. Inflamed flexor tendon sheaths increase functional impairment and may cause a carpal tunnel syndrome. Joint damage causes:

- A combination of ulnar drift and palmar subluxation of the MCPs. This leads to unsightly deformity, but function may be remarkably good once the patient has learned to adapt, and pain is controlled
- Fixed flexion (buttonhole or boutonnière deformity) or fixed hyperextension (swan-neck deformity) of the PIP joints, which impairs hand function
- Swelling and dorsal subluxation of the ulnar styloid, which leads to wrist pain and may cause rupture of the finger extensor tendons, leading in turn to a sudden onset of finger drop of the little and ring fingers predominantly, which needs urgent surgical repair.

Knees
Massive synovitis and knee effusions occur, but respond well to aspiration and steroid injection (see p. 507). A persistent effusion increases the risk of popliteal cyst formation and rupture (see p. 508). In later disease, erosion of cartilage and bone causes loss of joint space on X-ray and damage to the medial and/or lateral and/or retropatellar compartments of the knees. Depending on the pattern of involvement, the knees may develop a varus or valgus deformity. Secondary

Knees
Massive synovitis and knee effusions occur, but respond well to aspiration and steroid injection (see p. 507). A persistent effusion increases the risk of popliteal cyst formation and rupture (see p. 508). In later disease, erosion of cartilage and bone causes loss of joint space on X-ray and damage to the medial and/or lateral and/or retropatellar compartments of the knees. Depending on the pattern of involvement, the knees may develop a varus or valgus deformity. Secondary
OA follows. Total knee replacement is often the only way to restore mobility and relieve pain.

**Hips**

The hips are occasionally affected in early RA but are less commonly affected than the knees at all stages of the disease. Pain and stiffness are accompanied by radiological loss of joint space and juxta-articular osteoporosis. The latter may permit medial migration of the acetabulum (protrusio acetabulae). Later, secondary OA develops. Hip replacement is usually necessary.

**Cervical spine**

Painful stiffness of the neck in RA is often muscular, but it may be due to rheumatoid synovitis affecting the synovial joints of the upper cervical spine and the bursae which separate the odontoid peg from the anterior arch of the atlas and from its retaining ligaments. This synovitis leads to bone destruction, damages the ligaments and causes atlantoaxial or upper cervical vertebral instability. Subluxation and local synovial swelling may damage the spinal cord, producing pyramidal and sensory signs. MRI is the best way of visualizing this, but lateral flexed and extended neck X-rays can demonstrate instability. In late RA, difficulty walking which cannot be explained by articular disease, weakness of the legs or loss of control of bowel or bladder may be due to spinal cord compression and is a neurological emergency.

Image the cervical spine in flexion and extension in people with RA before surgery or upper gastrointestinal endoscopy to check for instability and reduce the risk of cord injury during intubation.

**Other joints**

The temporomandibular, acromioclavicular, sternoclavicular, cricoarytenoid and any other synovial joint can be affected.

**Non-articular manifestations** (Fig. 11.18)

**Soft tissue surrounding joints**

Subcutaneous nodules are firm, intradermal and generally occur over pressure points, typically the elbows, the finger joints and the Achilles tendon. Histologically, there is a necrotic centre surrounded by rows of activated macrophages, which resembles synovitis without a synovial space. The nodules may ulcerate and become infected. They may resolve when the disease comes under control. The nodules can be removed surgically but they tend to recur.

Tenosynovitis of flexor tendons in the hand can cause stiffness and occasionally a trigger finger. Swelling of the extensor tendon sheath over the dorsum of the wrist is common. Muscle wasting around joints is common. Corticosteroid-induced myopathy occurs. Osteoporosis is more common in poorly controlled RA.

**Less common non-articular manifestations**

Non-articular complications are becoming less common, probably because of more effective disease control.

**Lungs** (see p. 792)

- Airways disease: a spectrum from predominant bronchiectasis (cough and daily sputum) to predominant oblitative bronchiolitis (progressive breathlessness)
- Disease of the pleura: pleural effusion (asymptomatic to mildly breathless) and thickening
- Fibrosing alveolitis: a combination of inflammation and basal lung fibrosis
- Peripheral, intrapulmonary nodules: these are asymptomatic but may cavitate, especially with pneumoconiosis (Caplan’s syndrome)
- Infective lesions, e.g. TB in patients on biological DMARDs.

**Vasculitis**

Vasculitis (see p. 542) is caused by immune complex deposition in arterial walls. It is uncommon. Smoking is a risk factor. Findings are:

- Nail-fold infarcts due to cutaneous vasculitis
- Widespread cutaneous vasculitis with necrosis of the skin (seen in people with very active, strongly seropositive disease)
- Mononeuritis multiplex (p. 1145)
- Necrotizing arteritis of the mesenteric vessels causing bowel infarction.

**The heart and peripheral vessels**

Poorly controlled RA with a persistently raised CRP and high cholesterol is a risk factor for premature coronary artery and cerebrovascular atherosclerosis independent of traditional risk factors (i.e. high cholesterol and hypertension). Other cardiovascular problems include:

- Pericarditis is rarely symptomatic.
- Endocarditis and myocardial disease, rarely symptomatic, are found at post-mortem in approximately 20% of cases.
- Raynaud’s syndrome occurs (see p. 788).

**The nervous system**

- Peripheral sensory neuropathies: mononeuritis multiplex or symmetrical, peripheral – due to vasculitis of the vasa nervorum
- Compression neuropathies: carpal or tarsal tunnel syndrome – due to synovitis
- Cord compression: due to atlantoaxial subluxation (see above).
The eyes
- Sjögren’s syndrome causes dry mouth and eyes (see Sjögren’s syndrome, p. 541).
- Scleritis and episcleritis occur in severe, seropositive disease, resulting in painful red eye.
- Scleromalacia perforans (rare).

The kidneys
Amyloidosis causes proteinuria, nephrotic syndrome and chronic kidney disease. It occurs rarely in severe, longstanding rheumatoid disease and is due to the deposition of highly stable serum amyloid A protein (SAP) in the intercellular matrix of a variety of organs. SAP is an acute-phase reactant, produced normally in the liver.

The spleen, lymph nodes and blood
Felty’s syndrome is splenomegaly and neutropenia in a patient with RA. Leg ulcers or sepsis are complications. HLA-DR4 is found in 95% of patients, compared with 50–75% of people with RA alone.

The lymph nodes may be palpable, usually proximal to affected joints. There may be peripheral lymphoedema of the arm or leg.

Anaemia is almost universal and is usually normochromic and normocytic. It may be iron-deficient owing to gastrointestinal blood loss from NSAID ingestion, or rarely haemolytic (Coombs positive). There may be a pancytopenia due to hypersplenism in Felty’s syndrome or as a complication of DMARD treatment. A high platelet count occurs with active disease.

Diagnosis and investigations
The diagnosis relies on the clinical features described above. The predictors of poor prognosis arthritis are listed in Box 11.6. Initial investigations include:

- Blood count. Normochromic, normocytic anaemia may be present.
- The ESR and/or CRP are raised in proportion to the activity of the inflammatory process and are useful in monitoring treatment.
- Serology. ACPA (see p. 497) is present earlier in the disease (and may predate it by many years), and in early inflammatory arthritis indicates the likelihood of progressing to RA. Rheumatoid factor is present in approximately 70% of cases and ANA at low titre in 30%.
- X-rays show soft tissue swelling in early disease but MRI demonstrates synovitis and early erosions.
- Aspiration of the joint if an effusion is present. The aspirate looks cloudy owing to white cells. In a suddenly painful joint septic arthritis should be suspected (see p. 532).
- Doppler ultrasound is a very effective way of demonstrating persistent synovitis when deciding on the need for DMARDs or assessing their efficacy.

Other investigations will depend on the clinical picture as outlined above. In severe disease, extensive imaging of joints may be required. MRI is the technique of choice, especially for the knee and cervical spine.

Management of RA (Box 11.10)
The diagnosis of RA inevitably causes concern and fear in the patient and requires a lot of explanation and reassurance. Most guidelines suggest that anyone with early inflammatory arthritis should be referred to a specialist arthritis clinic within 3 months of onset, whenever possible.

The doctor should have a positive approach and remind the patient that with the help of drugs most people continue to lead a more or less normal life, despite their arthritis; 25% will recover completely. The earliest years are often the most difficult and people should be helped and encouraged to stay at work during this phase if possible. Uncertainty about remissions and flares and the impact of drug treatment makes planning difficult. However, patients adjust remarkably with time and support; the specialist team in a rheumatology unit (including doctors, nurses, physiotherapists, podiatrists and psychologists) helps patients learn to cope. Leaflets, websites and local patient groups also provide helpful advice.

Patients from socially deprived backgrounds and smokers have a worse prognosis. Statins have been shown to be of benefit in reducing cardiovascular risk and possibly inflammation whatever the cholesterol level; more studies are required.

Drug therapy
There is no curative agent available for RA but drugs are now available that prevent disease deterioration. Symptoms are controlled with analgesia and NSAIDs. Data now support the use of DMARDs early in the disease to prevent the long-term irreversible damaging effects of inflammation of the joints, and drugs that block TNF-α and IL-1 and the use of B cell ablation with rituximab are revolutionizing the management of RA. Searching for persistent synovitis in patients in apparent remission using Doppler ultrasound is leading to more intensive therapeutic regimes which will potentially reduce longer-term disability.

Non-steroidal anti-inflammatory drugs (NSAIDs) and coxibs
Most people with RA are unable to cope without an NSAID to relieve night pain and morning stiffness. NSAIDs do not reduce the underlying inflammatory process. They all act on the cyclo-oxygenase (COX) pathway (see Fig. 15.30). The individual response to NSAIDs varies greatly. It is desirable therefore to try several different drugs for a particular patient in order to find the best (Box 11.13). Each compound should be given for at least a week. Start with an inexpensive NSAID and coxibs are discussed on page 511. If gastrointestinal side-effects are prominent, or the patient is...
over 65 years of age, add a proton pump inhibitor. Slow-release preparations (e.g. slow-release diclofenac, 75 mg, taken after supper), or a suppository at bedtime, usually work well. For additional relief, a simple analgesic is taken as required (e.g. paracetamol or a combination of codeine or dihydrocodeine and paracetamol). Many patients need night sedation.

**Corticosteroids**

There is evidence to suggest that the early use of corticosteroids slows down the course of the disease but intensive short courses in very early arthritis do not appear to stop progressive disease. Corticosteroids are the commonest cause of secondary osteoporosis. Treatment for more than 3 months or with repeated courses is a risk, and concomitant calcium with vitamin D and bisphosphonates is necessary.

**Intra-articular injections** with semicrystalline steroid preparations have a powerful but sometimes only short-lived effect.

**Intramuscular depot injections** (40–120 mg depot methylprednisolone) help whilst waiting for DMARDs to work and to control severe disease flares, or they can be used before a holiday or other life event. They should be used infrequently.

**Oral corticosteroids** have a number of problems (Boxes 11.11 and 19.11). They are powerful disease-controlling drugs, but are avoided in the long term because side-effects are inevitable. Early intensive short-term regimens are often used. Doses of 5–7.5 mg daily as maintenance therapy are used in some centres. Corticosteroids are invaluable to people with severe disease with extra-articular manifestations such as vasculitis.

**Disease-modifying anti-rheumatic drugs (DMARDs)**

DMARDs, prescribed by a rheumatologist, are listed in Table 11.16 (see also Fig. 11.19).

- Traditional DMARDs, which mainly act through cytokine inhibition, reduce inflammation, with a reduction of joint swelling, a fall in the plasma acute-phase reactants and slowing of the development of joint erosions and irreversible damage. Their beneficial effect is not immediate (hence ‘slow-acting agents’) and may be partial or transient.

- DMARDs often only have a partial effect, achieving between 20% and 50% improvement by ACR criteria for disease remission (Box 11.12).

**Box 11.11 Problems associated with the use of corticosteroids**

- Patients are increasingly anxious about the use of corticosteroids because of adverse publicity about their potential side-effects. This must be discussed frankly and the risks of not using corticosteroids in treatment should be described and balanced against the risks of the drugs themselves.

- Patients must be warned to avoid sugars and saturated fats and to eat less because of the risk of weight gain.

- The skin becomes thin and easily damaged.

- Monitor for diabetes and hypertension.

- Cataract formation may be accelerated.

- Osteoporosis develops within 6 months on doses above 7.5 mg daily. Monitor with DXA scan and treat with calcium and vitamin D and bisphosphonate (see this chapter).

DMARDs are used as early as possible once RA has been diagnosed. Studies suggest that early intervention with DMARDs at 6 weeks to 6 months improves the outcome. Combinations of three or four drugs (steroids, sulfasalazine, methotrexate and hydroxychloroquine) in early RA are increasingly common, reducing the number of agents once remission has been achieved. Most DMARDs are contraindicated in pregnancy (Box 11.13). Effective treatment with DMARDs reduces the increased cardiovascular risk seen in people with RA.

**Sulfasalazine**

This is a combination of sulfapyridine and 5-amino-salicylic acid. Sulfapyridine is probably the active component. It is well tolerated and can be used during pregnancy. Around 50% of patients respond in the first 3–6 months, but efficacy can be lost. Blood monitoring is obligatory because of the risk of leukopenia and thrombocytopenia.

**Methotrexate**

This is considered by many to be the ‘gold standard’ drug in RA. It should not be used in pregnancy. Conception should be delayed for 3–6 months off the drug for either partner. A chest X-ray is taken to exclude tuberculosis. An initial pneumococcal and annual influenza vaccination are given. The starting weekly dose of 2.5–7.5 mg orally is increased up to 15–25 mg if necessary. It is well tolerated and this therapy can be introduced early in the disease. Nausea or poor absorption may limit its efficacy, in which case it is given by subcutaneous injection. Oral folic acid reduces side-effects but may also reduce efficacy. Full blood counts and liver biochemistry should be monitored. It usually works within 1–2 months. More patients remain on this agent than on most other DMARDs, indicating that it is effective and has relatively few side-effects.

**Hydroxychloroquine**

A dose of 200–400 g daily is well tolerated. It is used alone in mild disease or as an adjunct to other DMARDs. Retinopathy is extremely rare (occurring in about 1 in 2000 patients on this drug). Some rheumatologists arrange an initial check of macular function with an Amsler chart and further reviews annually, as retinopathy is irreversible.

**Leflunomide**

This DMARD exerts an immunomodulatory effect by preventing pyrimidine production in proliferating lymphocytes through blockade of the enzyme dihydroorotate dehydrogenase, thus blocking clonal expansion of T cells. Most other cells are able to bypass this blockade. It has a long half-life of 4–28 days. A dose of 20 mg daily (10 mg if diarrhoea is a problem) is used. Diarrhoea diminishes with time. Blood monitoring is obligatory (full blood count, platelets, liver biochemistry). The onset of action is 4 weeks with some further improvement sustained at 2 years. Leflunomide works in some patients who have failed to respond to methotrexate. Its long half-life means that it is best avoided in women planning a family.

**Cytokine modulators**

**TNF-α blockers.** The availability of agents that block TNF-α has significantly changed the traditional use of DMARDs. Because of their cost they are used after at least two DMARDs (usually sulfasalazine and methotrexate) have been tried. They represent a major therapeutic advance, although not all patients respond and there is loss of efficacy in some responders. They are usually given in combination with
Rheumatology and bone disease

Complement-dependent and antibody-dependent cytotoxicity. It is useful with or without methotrexate for severe active RA.

**Golimumab** is a human IgG1-κ monoclonal antibody against TNF which is awaiting approval in some countries. It is given by subcutaneous injection once monthly for severe RA.

These products slow or halt erosion formation in up to 70% of people with RA and produce healing in a few. Malaise and tiredness improve in a manner that is not seen with other DMARDs. Secondary failure occurs with all in the first year and changing to another anti-TNF agent is justified and often regains control of the disease. Potential biomarkers for responsiveness are being studied. Failure to respond to one does not predict failure to others.

**Side-effects.** Many patients on cytokine modulators are entered into a long-term observational study in the UK and other countries to monitor for potential side-effects. To date,
lung disease. Reactivation of old TB may occur but is
vasculitis, some extracutaneous involvement or interstitial
develop a reversible lupus-like syndrome, leucocytoclastic
risk of other cancers. A few people become ANA positive and
the results are reassuring. People with severe RA are at
probably less common with etanercept. A pre-treatment
chest X-ray is recommended, with a specialist review for
high-risk groups. TB should be treated before using these
agents and a course of prophylaxis is used in latent disease.
There is an increased risk of chest infections which requires
close monitoring. Hepatitis B and C infection requires careful
risk analysis and regular aminotransferase monitoring if anti-
TNF agents are prescribed. They should not be used in
patients who have severe cardiac failure.
These agents are extremely expensive when compared with
traditional DMARDs but they may save costs in the
longer term by reducing disability and the need for hospitali-
Zation. Their use should be restricted to specialist centres.
To date there is no evidence of an adverse effect on preg-
nancy outcome but care is essential.
Other cytokine modulators
Rituximab is a genetically engineered chimeric monoclonal
antibody (p. 72) that causes lysis of CD20-positive B cells.
CD20 is a pan-B cell surface antigenic phosphoprotein. Its
expression is restricted to pre-B and mature B cells but it is
not present on stem cells and is lost before differentiation
into plasma cells. Rituximab produces significant improve-
ment in RF-factor positive RA for 8 months to several years
when used alone or in combination with corticosteroids and/
or methotrexate. This is associated with a 6–9-month B cell
lymphopenia with little change in circulating immunoglobu-
ins. A re-flare is often accompanied by a return of peripheral
lymphocytes and a rise in CRP. Rituximab can be reused as
the disease flares. Repeated courses over up to 5 years are
acceptable and well tolerated and around 80% of RF-positive
patients respond with 50–60% showing persistent disease
control. It is worth trying in patients who have failed to
respond to anti-TNF agents. There may be an increased risk
of chest infections, and immunoglobulin levels may fall pro-
gressively and need to be monitored.
Abatacept is a recombinant fusion protein of CTLA4 and
the Fc portion of IgG1, which selectively modulates T cell

\[ \text{Relative risk of ACR50} \]

(a) ACR50 response in trials of DMARDs and biological agents.

(b) Impact of treatment duration, disease stage and prior treatment on ACR50 response. The difference between patients
treated with active drug and placebo is greatest in people with late rheumatoid arthritis who have failed biological treatment and
whose disease is managed for short periods. The difference is smallest in individuals with early arthritis who have not
previously received DMARDs and are treated for a long time.

Figure 11.19 American College of Radiology ACR50 responses in trials of DMARDs and biological agents (50% improvement in five of seven measures in the ACR 1987 criteria).a,b

Paracetamol – the oral analgesic of choice

- Oral NSAIDs and selective COX-2 inhibitors: can be used after implantation up until the last trimester if symptoms justify their use.
- Corticosteroids: may be used to control disease flares (main maternal risks are hypertension, glucose intolerance and osteoporosis).
- DMARDs:
  - May be used: sulfasalazine, hydroxychloroquine, azathioprine or ciclosporin if required to control inflammation.
  - Must be avoided: methotrexate, leflunomide, cyclophosphamide, gold and penicillamine. Women should not conceive while taking methotrexate or leflunomide.
- Cytokine modulators: safety during pregnancy is currently unclear.

Contraindicated in breast-feeding: methotrexate, leflunomide, ciclosporin, azathioprine, sulfasalazine, hydroxychloroquine.

Box 11.12 ACR criteria for disease remission in rheumatoid arthritis

- Morning stiffness <15 min
- No fatigue, joint pain, joint tenderness or soft tissue swelling
- ESR <30 in women, <20 in men

Box 11.13 Drug use during pregnancy in treatment of rheumatoid arthritis

- Paracetamol – the oral analgesic of choice
  - Oral NSAIDs and selective COX-2 inhibitors: can be used after implantation up until the last trimester if symptoms justify their use.
  - Corticosteroids: may be used to control disease flares (main maternal risks are hypertension, glucose intolerance and osteoporosis).
  - DMARDs:
    - May be used: sulfasalazine, hydroxychloroquine, azathioprine or ciclosporin if required to control inflammation.
    - Must be avoided: methotrexate, leflunomide, cyclophosphamide, gold and penicillamine. Women should not conceive while taking methotrexate or leflunomide.
  - Cytokine modulators: safety during pregnancy is currently unclear.

Contraindicated in breast-feeding: methotrexate, leflunomide, ciclosporin, azathioprine, sulfasalazine, hydroxychloroquine.

the results are reassuring. People with severe RA are at
slightly increased risk of lymphoma and this is being carefully
monitored. There is no convincing evidence of any increased
risk of other cancers. A few people become ANA positive and
develop a reversible lupus-like syndrome, leucocytoclastic
vasculitis, some extracutaneous involvement or interstitial
lung disease. Reactivation of old TB may occur but is
activation by costimulation blockade. It may have an important role in patients who do not respond to anti-TNF regimens.

**Tocilizumab** is a humanized monoclonal anti-IL-6 receptor antibody and is used with methotrexate for moderate to severe RA after at least one other cytokine modulator has failed.

**Anakinra** is a human recombinant IL-1 receptor antagonist which is used in combination with methotrexate. It has been used after anti-TNF agents have been unsuccessful, but is now only recommended for clinical studies.

**Spleen tyrosine kinase (SYK) inhibitor** given orally has been effective in RA in phase 2 studies.

**Drugs used less commonly**

**Gold (sodium aurothiomalate)** is given by deep intramuscular injection. A response (occasionally remission) is seen in about 3 months. Side-effects or lack of effect mean that few patients remain on it beyond 2 years. Blood and urine testing are mandatory.

**D-Penicillamine** is given before food for at least 3 months before improvement occurs. If proteinuria exceeds 2 g/24 hours the drug must be stopped. Loss of taste is reversible. Other rare side-effects include a lupus erythematosus-like syndrome and a myasthenia gravis-like syndrome.

**Azathioprine** at a maximum dose of 2.5 mg/kg and cyclophosphamide 1–2 mg/kg have been used, usually when other DMARDs have been ineffective. They are often used when extra-articular features are severe, particularly with vasculitis. There is a high risk of neutropenia and possibly liver toxicity from azathioprine in patients who have low levels of the enzyme thiopurine methyltransferase (TPMT) which metabolizes azathioprine into its active metabolites. Pretesting is a wise precaution.

**Ciclosporin** 2.5–4 mg/kg is used for active rheumatoid arthritis when conventional therapy has been ineffective. Side-effects include a rise in creatinine level and hypertension.

**Physical measures**

People with RA need constant advice and support from physiotherapists and nurse specialists, especially while they are learning to adjust. A combination of rest for active arthritis and exercises to maintain joint range and muscle power is essential. Exercise in a hydrotherapy pool is popular and effective. Exercises to maintain joint range and muscle power is essential. Learning to adjust. Advice about managing activities of daily living despite the arthritis, and about gadgets, seating or structural changes in the home or at work are helpful. Family and friends should be involved. Podiatry, shoe wear advice and psychological support should be offered to all people with RA.

**Surgery**

Surgery has a useful role in the long-term approach to patient management but is less frequently needed as therapeutic disease control becomes more effective. Its main objectives are prophylactic, to prevent joint destruction and deformity, and reconstructive, to restore function.

Single-joint disease can be treated by surgical synovectomy to reduce the bulk of inflamed tissue and prevent damage. Excision arthroplasty of the ulnar styloid reduces pain and the risk of extensor tendon damage. Excision arthroplasties of the metatarsal heads reduce metatarsal pain and relieve pressure points. The major surgical advance has been the development of total replacement arthroplasty of the hip, knee, finger joints, elbow and shoulder. Such procedures need careful planning and preparation, and the expected outcomes and risks should be explained to the patient.

### Prognosis

A poor prognosis is indicated by:

- **A clinical picture** of an insidious rather than an explosive onset of RA, female sex, increasing number of peripheral joints involved and the level of disability at the onset
- **Blood tests** showing a high CRP/ESR, normocytic normochromic anaemia and high titres of ACPA antibodies and of rheumatoid factor
- **X-rays** with early erosive damage (note: ultrasound and MRI can show cartilage and bone damage prior to conventional X-rays).

Prognosis can be altered dramatically with early DMARD therapy under expert supervision.

### SPONDYLOARTHRITIS

This is a group of conditions affecting the spine and peripheral joints which cluster in families and are linked to certain HLA antigens (Table 11.17).

The joint involvement is usually more limited than that seen in RA and its distribution is different. There are associated extra-articular and genetic features. These diseases occasionally present in childhood.

Histologically, the synovitis itself is similar to that of RA, but there is no production of rheumatoid factors – hence ‘seronegative’. ACPA is also usually negative. Inflammation of the enthesis (junction of ligament or tendon and bone) and joint ankylosis develop more commonly than in RA. All are associated with an increased frequency of sacroiliitis and an increased frequency of HLA-B27.

**Aetiology**

The common aetiological thread of these disorders is their striking association with HLA-B27, particularly ankylosing spondylitis (AS). HLA type B27 is present in >90% of Caucasians with AS but only 8% of controls. HLA-B27 exhibits a number of unusual characteristics including a high tendency to mis-fold but its aetiological relevance remains unclear. The role of class I HLA antigens in pathogenesis is supported by the fact that HLA-B27 transgenic mice spontaneously develop arthritis, skin, gut and genitourinary lesions.

There are clues that infections play a role, possibly by molecular mimicry, with parts of the organism which are structurally similar to the HLA molecule triggering cross-reactive antibody formation. This is unproven. AIDS is increasing the prevalence of reactive arthritis and spondylitis in sub-Saharan Africa even in the absence of HLA-B27. The explanation for this changing epidemiology is unclear.

The types of arthritis that follow a precipitating infection are called reactive arthritis (p. 529).

The specialized immune systems of the gut and genitourinary mucous membranes may also play a causal role,

Ankylosing spondylitis (AS)  

This is an inflammatory disorder of the spine affecting mainly young adults (late teens to early 30s). It occurs worldwide, with a male to female ratio of 5:1. Women present later and are underdiagnosed. The frequency of AS in different populations is roughly paralleled by the incidence of both HLA-B27; Africans and Japanese have a low incidence of both HLA-B27 and ankylosing spondylitis, while the North American Haida Indians have a high incidence of both. There are at least 24 subtypes of HLA-B27 (B*2701-B*2724). Some appear to increase risk; others have a protective role. Twin studies indicate a much higher disease concordance in HLA-B27-positive monozygotic (up to 70%) twins than in dizygotic twins (about 20–25%). There are also other genes lying within the major histocompatibility complex (interleukin-1 gene cluster and the gene CYP2D6) which also influence susceptibility to AS but the disease is polygenic.

Epidemiology and pathogenesis  

Environmental factors may also be involved but although Gram-negative organisms, e.g. *Yersinia*, *Klebsiella*, *Salmonella*, *Shigella*, can cause a reactive arthropathy, there is no conclusive evidence for their involvement in the pathogenesis of AS.

There is lymphocyte and plasma cell infiltration and local erosion of bone at the attachments of the intervertebral and other ligaments (enthesitis). This heals with new bone (syndesmophyte) formation.

Clinical features  

Episodic inflammation of the sacroiliac joints in the late teenage years or early 20s is the first manifestation of AS. Pain in one or both buttocks and low back pain and stiffness are typically worse in the morning and relieved by exercise. Initially the diagnosis is often missed because the patient is asymptomatic between episodes and radiological abnormalities are absent. Retention of the lumbar lordosis during spinal flexion is an early sign. Later, paraspinal muscle wasting develops.

Criteria for classifying inflammatory back pain as ankylosing spondylitis are shown in Box 11.14.

Spinal stiffness can be measured by Schober’s test: a tape measure is placed in the midline 10 cm above the dimples of Venus. Any movement of a marker at 15 cm during flexion is recorded. A reading of <5 cm implies spinal stiffness. Individuals may be able to touch the floor with a stiff back if they have good hip movements but serial measurement of the finger tip to floor distance highlights any change.

Non-spinal complications (uveitis or costochondritis) suggest the diagnosis of spondyloarthritis (Box 11.15).

Investigations  

- **Blood.** The ESR and CRP are usually raised.
- **HLA testing** is rarely of value because of the high frequency of HLA-B27 in the population, but may give supporting evidence in a difficult case.
- **X-rays.** The medial and lateral cortical margins of both sacroiliac joints lose definition owing to erosions and eventually become sclerotic (Fig. 11.20). The earliest radiological appearances in the spine are blurring of the costochondral junction inflammation causes anterior chest pain. Measurable reduction of chest expansion is due to costovertebral joint involvement.

Peripheral joint involvement is asymmetrical and affects a few, predominantly large joints. Hip involvement leads to fixed flexion deformities of the hips and further deterioration of the posture. Young teenage boys occasionally present with a lower-limb monoarthritis (see p. 546), which later develops into AS.

Acute anterior uveitis is strongly associated with HLA-B27 in AS and related diseases and is occasionally the presenting complaint. Severe eye pain, photophobia and blurred vision are an emergency (see p. 1062).

Overall clinical assessment is based on pain, tenderness, stiffness and fatigue using, e.g. the Bath Ankylosing Spondylitis Disease Activity Index.

Box 11.15 Non-articular problems in spondyloarthritis  

- Uveitis, in all types
- Cutaneous lesions in reactive arthritis (keratoderma blennorrhagica), histologically identical to pustular psoriasis
- Nail dystrophy, in psoriasis and reactive arthritis
- Aortitis, occasionally in AS and reactive arthritis

Figure 11.20 X-ray of ankylosing spondylitis. The sacroiliac joints are eroded and show marginal sclerosis (white arrows). There is bridging syndesmophyte formation at the thoracolumbar junction (black arrows).
upper or lower vertebral rims at the thoracolumbar junction (best seen on a lateral X-ray) caused by an enthesitis at the insertion of the intervertebral ligaments. These changes may eventually affect the whole spine. Persistent inflammatory enthesitis causes bony spurs (syndesmophytes). Syndesmophytes are more vertically oriented than the beak-like osteophytes of spondylosis and the disc is preserved, unlike in spondylosis (see p. 503). Syndesmophytes cause bony ankylosis and permanent stiffening. The sacroiliac joints eventually fuse, as may the costovertebral joints, reducing chest expansion. Calcification of the intervertebral ligaments and fusion of the spinal facet joints and syndesmophytes leads to what is often called a ‘bamboo’ spine (Fig. 11.21).

MRI with gadolinium demonstrates sacroiliitis before it is seen on X-rays, and persistent enthesitis.

Treatment

- The key to effective management of AS is early diagnosis so that a regimen of preventative exercises is started before syndesmophytes have formed. Morning exercises aim to maintain spinal mobility, posture and chest expansion.
- Failure to control pain and to encourage regular spinal and chest exercises leads to an irreversible dorsal kyphosis and wasted paraspinal muscles. This, along with stiffening of the cervical spine, makes forward vision difficult.
- When the inflammation is active and the morning pain and stiffness are too severe to permit effective exercise, an evening dose of a long-acting or slow-release NSAID or an NSAID suppository improves sleep, pain control and exercise compliance. Peripheral arthritis and enthesitis are managed with NSAIDs or local steroid injections.
- Methotrexate is effective for peripheral arthritis but not for spinal disease.
- The TNF-α blocking drugs adalimumab and etanercept (Table 11.16) have revolutionized the lives of people with AS. They produce a rapid, dramatic and sustained reduction of symptoms and of spinal and peripheral joint inflammation. Around half the patients are able to stop NSAIDs. Relapse occurs on stopping therapy but may be delayed by several months making intermittent treatment feasible. Golimumab is also available for severe active disease unresponsive to conventional therapy. Rituximab does not help spondyloarthritis.

Prognosis

With exercise and pain relief, the prognosis is excellent and over 80% of patients are fully employed. Anti-TNF therapies are likely to reduce the morbidity of severe disease, reducing the risk of permanent spinal stiffness and progressive peripheral joint disease.

Patients should be made aware that they risk passing the HLA-B27 gene to 50% of their children. HLA-B27 positive offspring then have a 30% risk of developing AS.

Psoriatic arthritis

The prevalence of psoriasis is 2–3% worldwide, and in this population around 10% have arthritis (see p. 506). A family history of psoriasis may be a clue to the diagnosis. The aetiology and pathogenesis is described on page 509.

Clinical features

Patterns of psoriatic arthritis include:

- Mono- or oligoarthritis
- Polyarthritis virtually indistinguishable from RA
- Ankylosing spondylitis: uni- or bilateral sacroiliitis and early cervical spine involvement; only 50% are HLA-B27 positive
- Distal interphalangeal arthritis, which is the most typical pattern of joint involvement in psoriasis, often with adjacent nail dystrophy (see p. 1209) reflecting enthesitis extending into the nail root
- Arthritis mutilans, which affects about 5% of patients who have psoriatic arthritis and causes marked periarticular osteolysis and bone shortening (‘telescopic’ fingers) (Fig. 11.22).

Radiologically, psoriatic arthritis is erosive but the erosions are central in the joint, not juxta-articular, and produce a ‘pencil in cup’ appearance (Fig. 11.23). The skin and nail disease can be mild and may develop after the arthritis.

Treatment and prognosis

NSAIDs and/or analgesics help the pain but they can occasionally worsen the skin lesions. Local synovitis responds to intra-articular corticosteroid injections.
Spondyloarthritis

Mode of presentation of bacteria-derived peptides to T lymphocytes.

These are not mutually exclusive. There are other organisms that also trigger reactive arthritis but have a different genetic basis; see post-streptococcal arthritis (p. 533), gonococcal arthritis (p. 546) and brucellosis (p. 533). In these, the borderline between reactive arthritis and septic arthritis is more indistinct and they can cause both.

Clinical features (Fig. 11.24)

The arthritis is typically an acute, asymmetrical, lower-limb arthritis, occurring a few days to a couple of weeks after the infection. The arthritis may be the presenting complaint if the infection is mild or asymptomatic. Enthesitis is common, causing plantar fasciitis or Achilles tendon enthesisitis (see p. 509). Seventy per cent recover fully within 6 months but many have a relapse.

In susceptible individuals with reactive arthritis, sacroiliitis and spondylitis may also develop. Sterile conjunctivitis occurs in 30%. Acute anterior uveitis complicates more severe or relapsing disease but is not synchronous with the arthritis.

The skin lesions resemble psoriasis:

- Circinate balanitis in the uncircumcised male causes painless superficial ulceration of the glans penis. In the circumcised male the lesion is raised, red and scaly. Both heal without scarring.
- Keratoderma blennorrhagica – the skin of the feet and hands develops painless, red and often confluent raised plaques and pustules histologically similar to pustular psoriasis.
- Nail dystrophy occurs.

Treatment

Treating persisting infection with antibiotics alters the course of the arthritis, once it has developed. Cultures should be taken and any infection treated. Sexual partners must be screened.

Pain responds well to NSAIDs and locally injected or oral corticosteroids. The majority of individuals with reactive arthritis have a single attack which settles, but a few develop...
a disabling relapsing and remitting arthritis. Relapsing cases are sometimes treated with sulfasalazine or methotrexate (Table 11.16). TNF-\(\alpha\) blocking agents remain the drugs of next choice in severe and persistent disease but are rarely necessary.

**Enteropathic arthritis associated with inflammatory bowel disease**

Enteropathic synovitis occurs in up to 10–15% of patients who have ulcerative colitis and Crohn’s disease (see p. 275). The link between the bowel disease and the inflammatory arthritis is not clear. Selective mucosal leakiness may expose the individual to antigens that trigger synovitis.

The arthritis is asymmetrical and predominantly affects lower-limb joints. An HLA-B27-associated sacroiliitis or spondylitis also occurs. The joint symptoms may predate the development of bowel disease and lead to its diagnosis.

Remission of ulcerative colitis or total colectomy usually leads to remission of the joint disease, but arthritis can persist even in well-controlled Crohn’s disease.

**Treatment**

The inflammatory bowel disease should be treated (see p. 272). In all cases of enteropathic arthritis, the symptoms are helped by NSAIDs, although they may make diarrhoea worse. A monoarthritis is best treated by intra-articular corticosteroids. Sulfasalazine is more frequently prescribed than mesalazine as it may help both bowel and joint disease. The TNF-\(\alpha\) blocking drug infliximab is used in inflammatory bowel disease (p. 272) and can help the arthritis.

**CRYSTAL ARTHRITIS**

**Aetiology**

Two main types of crystal account for the majority of crystal-induced arthritis. They are sodium urate and calcium pyrophosphate and are distinguished by their different shapes and refringence properties under polarized light with a red filter. Rarely, crystals of calcium apatite (see p. 515) or cholesterol cause acute synovitis.

**Gout and hyperuricaemia**

Gout is an inflammatory arthritis associated with hyperuricaemia and intra-articular sodium urate crystals.

**Epidemiology**

The prevalence of gout is increasing mainly in developed countries, due to changing diets – purine rich foods, high saturated fats, fructose containing drinks and alcohol. The prevalence is 1.4% in the UK (increasing with age to 3% in women and 7% in men) and 2.7% in the USA. Asian populations are more at risk as their diet becomes more Western. Gout develops in men more than women (10 : 1) and rarely occurs before young adulthood (when it suggests a specific genetic defect), and seldom in premenopausal females. Some 85–90% of cases are idiopathic. The prevalence in older females is increasing with increased diuretic use. Hyperuricaemia is common in certain ethnic groups (e.g. Maoris).

The last two steps of purine metabolism in humans are the conversion of hypoxanthine to xanthine and of xanthine to uric acid, catalysed by the enzyme xanthine oxidase. Primates lost the gene for uricase during their evolution about 10–20 million years ago. Hyperuricaemia possibly offered an evolutionary advantage.

Uric acid levels are higher in men than in women. There is a normal distribution of serum uric acid in the population with a skewed distribution at the upper end of the range. Hyperuricaemia is defined as a serum uric acid level greater than two standard deviations from the mean (420 \(\mu\)mol/L in males; 360 \(\mu\)mol/L in females). This is close to the limit of solubility – 360 \(\mu\)mol/L at 35°C and 300 \(\mu\)mol/L at 30°C.

Most people with hyperuricaemia are asymptomatic. Osteoarthritic joints are more prone to gouty attacks. The range for gouty individuals is higher than for normals, but the curves overlap (Fig. 11.25). Serum uric acid levels increase with age, obesity, a ‘Western’ diet (see above) and combined hyperlipidaemia, diabetes mellitus, ischaemic heart disease and hypertension (metabolic syndrome, p. 218). There is often a family history of gout.

**Pathogenesis of hyperuricaemia and gout**

Uric acid is the final product of endogenous and dietary purine metabolism in humans and levels in the blood depend on the balance between purine synthesis and the ingestion of dietary purines, and the elimination of urate by the kidney and intestine. Some 90% of people with gout have impaired excretion of uric acid (10% have increased production due to high cell turnover and <1% due to an inborn error of metabolism). Renal excretion is coordinated by a group of renal tubular urate transport molecules and a complex process of glomerular filtration, proximal tubule reabsorption via the urate transporter-1 (URAT-1) and active resecretion (Fig. 11.26). GLUT9 transports uric acid along with glucose and fructose into the cell from the tubule and back into circulation. Both the entry of uric acid via the URAT-1 mechanism and the exit into circulation by GLUT9 can be blocked by uricosuric drugs such as probenecid. The body pool is about 1000 mg and 60% is turned over daily. Low-dose aspirin blocks uric acid secretion. Insulin resistance enhances uric acid resorption. Causes of hyperuricaemia are shown in Table 11.18.
Glomerular filtration (98%), tubular reabsorption (40–45%), secretion, pre-secretory reabsorption.

**Figure 11.26 Urate renal transport.** The net result is that about 5–10% of the glomerular load is excreted in the urine under normal circumstances.

**Table 11.18 Causes of hyperuricaemia**

**Gout as an autoinflammatory disease**

The roles of innate immunity and of the inflammasome suggest that crystal arthritis is an autoinflammatory disease, similar to the hereditary periodic fevers (p. 548). A series of receptors recognize bacteria and viruses as 'foreign' and eliminate them by activating the cytokine cascade. One such receptor (NLRP3) has recently been implicated in crystal-triggered inflammation. The activation of the inflammasome (p. 63) activates interleukin-1β, which in turn activates more cells and triggers an IL-8 mediated influx of neutrophils. Ingestion by polymorphonuclear leucocytes of sodium urate crystals causes the release of pro-inflammatory cytokines, particularly interleukin-1β and complement. Colchicine works by inhibition of microtubule formation necessary for this to occur. The involvement of IL-1β indicates a potential role for the IL-1β blocking agent anakinra in gout, in patients resistant to usual treatments.

**Clinical features**

Hyperuricaemia may be asymptomatic. It also causes:

- **Acute gout**, followed by an asymptomatic intercritical phase; a second acute attack likely within 2 years
- **Chronic interval gout**, with acute attacks superimposed on low grade inflammation and potential joint damage
- **Chronic polyarticular gout** is rare, except in elderly people on longstanding diuretic treatment, in renal

**Failure, or when allopurinol is started too soon after an acute attack**

- **Tophaceous gout**
- **Urate renal stone** formation (p. 600).

**Acute gout** presents typically in a middle-aged male with sudden onset of agonizing pain, swelling and redness of the first MTP joint. The attack occurs at any time, but may be precipitated by too much food or alcohol, by dehydration or by starting a diuretic. Untreated attacks last about 7 days. Recovery is typically associated with desquamation of the overlying skin. In 25% of attacks, a joint other than the great toe is affected.

In severe attacks, overlying crystal cellulitis makes gout difficult to distinguish clinically from infective cellulitis. A family or personal history of gout and the finding of a raised serum urate suggest the diagnosis but, if in doubt, blood and joint fluid cultures should be taken.

**Chronic tophaceous gout** (see below).

**Investigations**

The clinical picture is often diagnostic, as is the rapid response to NSAIDs or colchicine.

- **Joint fluid microscopy** is the most specific and diagnostic test but is technically difficult.
- **Serum uric acid** is usually raised (>600 μmol/L). If it is not, recheck it several weeks after the attack, as the level falls immediately after an acute attack. Acute gout rarely occurs with a serum uric acid in the lower half of the normal range below the saturation point of 360 μmol/L.
- **Serum urea, creatinine** and eGFR are monitored for signs of renal impairment.

**Treatment**

The use of NSAIDs or coxibs in high doses rapidly reduces the pain and swelling. The first dose should be taken at the first indication of an attack:

- **Naproxen**: 750 mg immediately, then 500 mg every 8–12 hours
- **Diclofenac**: 75–100 mg immediately, then 50 mg every 6–8 hours
- **Indomethacin**: 75 mg immediately, then 50 mg every 6–8 hours. For some, the frequency of side-effects is unacceptably high with indometacin. After 24–48 hours, reduced doses are given for a further week. Caution: NSAIDs may cause renal impairment. In individuals with renal impairment or a history of peptic ulceration, alternative treatments include:
  - **Colchicine**: 1000 μg immediately, then 500 μg every 6–12 hours, but this causes diarrhoea or colicky abdominal pain
  - **Corticosteroids**: oral prednisolone or intramuscular or intra-articular depot methylprednisolone.

**Dietary advice**

The first attacks may be separated by up to 2 years and are managed symptomatically. Individuals should be advised to reduce their alcohol intake, especially beer, which is high in purines and fructose. Non-diet carbonated soft drinks are also high in fructose. A diet which reduces total calorie and cholesterol intake and avoids such foods as offal, some fish and shellfish and spinach, all of which are rich sources of purines, is advised. This can reduce serum urate by 15% and
delay the need for drugs that reduce serum urate levels. Dietary advice is readily available on the internet.

**Treatment with agents that reduce serum uric acid levels**

The aim of treatment is to reduce the uric acid level below the 360 μmol/L level; some guidelines recommend below 300 μmol/L.

**Allopurinol** should only be used when the attacks are frequent and severe (despite dietary changes), associated with renal impairment or tophi, or when the patient finds NSAIDs or colchicine difficult to tolerate. Allopurinol (300–600 mg) blocks the enzyme xanthine oxidase, which converts xanthine into uric acid (see Fig. 16.20). It reduces serum uric acid levels rapidly and is relatively non-toxic but should be used at low doses (50–100 mg) in renal impairment. It should never be started within a month of an acute attack and always be started under cover of a course of NSAID or colchicine for the first 2–4 weeks before and 4 weeks after starting allopurinol, as it may induce acute gout. The dose can be increased gradually from 100 mg every few weeks until the uric acid level is below the 360 μmol/L level. Skin rashes and gastrointestinal intolerance are the most common side-effects. A hypersensitivity reaction is the most serious adverse event. This is rare, as is bone marrow suppression.

**Febuxostat** (80–120 mg) is a non-purine analogue inhibitor of xanthine oxidase but not other enzymes in the purine and pyrimidine pathway. It is well tolerated and as effective as allopurinol in trials and is safer in renal impairment as it is metabolized in the liver and not renally excreted. It has been approved by the FDA and is helpful in patients who cannot tolerate allopurinol but there are anxieties that it may increase cardiovascular risks. At time of writing, most doctors advise trying allopurinol first unless there are strong contraindications to its use.

**Pegloticase**, a pegylated recombinant uricase given intravenously, lowers urate levels dramatically but its place in therapy is unclear.

**Uricosuric agents** also lower the serum uric acid but their use is restricted throughout Europe by the very rare occurrence of serious hepatotoxicity. **Benzbromarone** acts on the URAT-1 transporter and is well tolerated. Sulphinpyrazone and **probenecid** are best avoided in renal impairment. Availability of these drugs varies between countries – in the UK benzbromarone and probenecid can be obtained for treating named patients.

**Losartan** is an angiotensin I-receptor antagonist and is uricosuric in hypertensive patients with gout. It may reduce the risk of gout in patients with the metabolic syndrome.

**Anakinra** blocks IL-1β and **canakinumab** is a human monoclonal antibody with specific cross-reactivity for IL-1β but not other members of the IL-1 family. Their role in treatment-resistant gout is still subject to trials to establish when their use is justified in gout which has not responded to the more conventional agents.

**Chronic tophaceous gout**

Individuals with very high levels of uric acid can present with chronic tophaceous gout, as sodium urate forms smooth white deposits (tophi) in skin and around joints. They occur on the ear, the fingers (Fig. 11.27) or the Achilles tendon. Large deposits are unsightly and ulcerate. There is chronic joint pain and sometimes superimposed acute gouty attacks.

Periarticular deposits lead to a halo of radio-opacity and clearly defined (‘punched-out’) bone cysts on X-ray.

Tophaceous gout is often associated with renal impairment and/or the long-term use of diuretics. There may be acute or chronic urate nephropathy or renal stone formation. Whenever possible, stop the diuretics or change to less urate-retaining ones, such as bumetanide. Treat with allopurinol and/or uricosuric agents (see above). Pegylated uricase (Pegloticase), a pegylated recombinant uricase given intravenously, is used preventatively in people undergoing chemotherapy for malignancies (tumour lysis syndrome). Pegloticase has an important but, as yet, unproven role in those rare individuals who have refractory tophaceous gout.

**Pseudogout (pyrophosphate arthropathy)**

Calcium pyrophosphate deposits in hyaline and fibrocartilage produce the radiological appearance of chondrocalcinosis (see p. 515). Shedding of crystals into a joint precipitates acute synovitis which resembles gout, except that it is more common in elderly women and usually affects the knee or wrist. The attacks are often very painful. In young people it may be associated with haemochromatosis, hyperparathyroidism, Wilson’s disease or alkaptonuria.

**Diagnosis**

The diagnosis is made by detecting rhomboidal, weakly birefringent crystals in joint fluid, or deduced from the presence of chondrocalcinosis on X-ray. The joint fluid looks purulent. Septic arthritis must be excluded and joint fluid should be sent for culture. The attacks may be associated with fever and a raised white blood cell count.

**Treatment**

Aspiration of the joint reduces the pain dramatically but it is usually necessary to use an NSAID or colchicine, as for gout. If infection can be excluded, an intra-articular injection of a corticosteroid helps.

**INFECTIONS OF JOINTS AND BONES**

Joints become infected by direct injury or by blood-borne infection from an infected skin lesion or other site. Chronic inflamed joints (e.g. in rheumatoid arthritis) are more prone to infection than are normal joints. Individuals who are immunosuppressed, by AIDS or by immunosuppressive agents, are particularly at risk, as are infants, the elderly and those who use excess alcohol. Artificial joints are also potential sites for infection.

**Septic arthritis**

The organism that most commonly causes septic arthritis is *Staphylococcus aureus*. Other organisms include streptococci, other species of staphylococcus, *Neisseria gonorrhoeae*, *Haemophilus influenzae* in children, and these
and other Gram-negative organisms in the elderly or complicating RA.

**Clinical features**

Suspected septic arthritis is a medical emergency. In young and previously fit people, the joint is hot, red, swollen and agonizingly painful and held immobile by muscle spasm. In the elderly and immunosuppressed and in RA the clinical picture is less dramatic, so a high index of suspicion is needed to avoid missing treatable but potentially severely destructive and occasionally fatal septic arthritis.

In 20% of patients, the sepsis affects more than one joint. Chronic destructive arthritis due to tuberculosis is rare.

**Investigations**

- **Aspirate** the joint and send the fluid for urgent Gram-staining and culture. The fluid is usually frankly purulent. The culture techniques should include those for gonococci and anaerobes.
- **Blood cultures** are often positive.
- **Leucocytosis** is usual, unless the person is severely immunosuppressed.
- **X-rays** are of no value in diagnosis in acute septic arthritis.
- **Skin wound swabs, sputum and throat swab or urine** may be positive and indicate the source of infection.

**Treatment**

This should be started immediately on diagnosis because joint destruction may occur within weeks. The joint should be immobilized initially and then physiotherapy started early to prevent stiffness and muscle wasting. Intravenous antibiotics should be given for 1–2 weeks. It is usual to give two antibiotics to which the organism is sensitive for 6 weeks, then one for a further 6 weeks, orally. Monitor clinically and with the ESR and CRP.

**Empirical treatment in septic arthritis**

This is started before the results of culture are obtained. Discuss the case with a microbiologist. Intravenous flucloxacillin 1–2 g is given 6-hourly, plus fusidic acid 500 mg orally 8-hourly. If the patient is allergic to penicillin, replace flucloxacillin with erythromycin 1 g i.v. 6-hourly or clindamycin 600 mg i.v. 8-hourly. In immunosuppressed patients, flucloxacillin 1–2 g i.v. 6-hourly plus gentamicin (to cover Gram-negative organisms) should be used. Telcocaplanin i.v. should replace flucloxacillin if MRSA is likely. Change the antibiotics if the organism is not sensitive. Drainage of the joint and arthroscopic joint washouts are helpful in relieving pain.

**Management of infected prostheses**

If chronically infected, the prosthesis is removed and the joint space filled with an antibiotic-impregnated spacer for 3–6 weeks before a new prosthesis is inserted. The whole process is covered by antibiotics, e.g. teicoplanin i.v. and oral sodium fusidate.

**Gonococcal arthritis**

This is the most common cause of a septic arthritis in previously fit young adults; more commonly affecting women and men who have sex with men.

Initially the patient becomes febrile and develops characteristic pustules on the distal limbs. Polyarthralgia and tenosynovitis are common at this stage and about 40% have a gonococcaemia. This phase settles and blood cultures usually become negative. Nucleic acid amplification tests are a useful adjunct to cultures and may be positive even when cultures are negative. Later, large-joint mono- or pauciarticular arthritis may follow. Culture is usually positive from the genital tract, although the joint fluid may be sterile. It is not clear whether this is simply a septic arthritis — although it responds rapidly to antibiotics, or whether there is also a reactive element to bacterial lipopolysaccharide.

**Treatment** consists of oral penicillin, ciprofloxacin or doxycycline for 2 weeks, and joint rest. Resistance to antibiotics is increasing.

**Tuberculous arthritis**

Around 1% of people with tuberculosis develop joint and/or bone involvement. It occurs as the primary disease in children. In adults, it is usually due to haematogenous spread from secondary pulmonary or renal lesions. The onset is insidious and diagnosis often delayed.

The organism invades the synovium or intervertebral disc. There are caseating granulomas and rapid destruction of cartilage and adjacent bone. Some patients develop a reactive polyarthritis (Poncet’s disease).

The hip or knee (30%) is quite commonly affected, but around 50% develop spinal disease. The patient is febrile, has night sweats, is anorexic and loses weight. The usual risk factors for tuberculosis apply — debility, excess alcohol use or immunosuppression. HIV-positive/AIDS patients are at particular risk.

**Investigations** should include culture of fluid, and culture and biopsy of the synovium. M. tuberculosis is the usual organism, but atypical mycobacteria are occasionally implicated. A chest X-ray should be performed. Initially joint or spinal X-rays may be normal but joint-space reduction and bone destruction develop rapidly if treatment is delayed. MRI shows the abnormality earlier in the spine and CT-guided biopsy from the affected disc is often necessary to obtain cultures.

**Treatment** is as for pulmonary tuberculosis with therapy for 9 months (see p. 820). The joint should be rested and the spine immobilized in the acute phase.

**Meningococcal arthritis**

This may complicate a meningococcal septicemia and presents as a migratory polyarthritis. Organisms can only rarely be cultured from the joint and most cases are due to immune complex deposition. Treatment is urgent with immediate penicillin therapy (p. 75).

**Infective endocarditis**

This may present with arthralgia, polymyalgia rheumatica-like symptoms or an infective arthritis. It is discussed on page 687.

**Lyme arthritis**

About 25% of people with Lyme disease develop arthralgia, less commonly an acute pauciarticular arthritis (see p. 130). This usually resolves but 10% of untreated cases go on to develop a chronic arthritis. There are no positive markers in these patients of an ongoing infection (p. 130).

**Diagnosis** is by the detection of IgM antibodies against the spirochaete *Borrelia burgdorferi*.

**Treatment** with antibiotics (amoxicillin or doxycycline) is highly effective in early disease. The response of chronic arthritis to antibiotic treatment is discussed on page 130.

**Brucellosis**

Brucellosis (see p. 129) has a worldwide distribution. The most common cause of chronic brucellosis and of arthritis is...
**Brucella melitensis.** There is usually a migratory large joint mono- or oligoarticular arthritis, which is septic or reactive. Arthritis is more common in chronic infections of more than 6 months.

**Syphilitic arthritis**

Congenital syphilis (see p. 166) can cause an acute painful epithymitis or osteochondritis sometimes associated with para-articular swelling in the first few weeks of life. Later, at age 8–16 years, painless effusion of the knees may occur (Clutton’s joints).

In acquired syphilis, arthralgia and arthritis occur in the secondary stage. Charcot’s (neuropathic) joints usually involve the knees in tabes dorsalis (see p. 1129).

**Leprosy** (p. 130)

Acute or chronic symmetrical polyarthritis resembling RA, swollen hands and feet due to lepra reactions, tenosynovitis and thickened nerves with or without cutaneous manifestations are seen in leprosy.

**Actinomycetaceae infection**

Actinomycetaceae can affect the mandible or vertebrae.

**Arthritis in viral disease**

A transient polyarthritis or arthralgia can occur before, during or after many viral illnesses. These include infectious mononucleosis, chickenpox, mumps, adenovirus, rubella, erythrovirus B19, hepatitis B and C, arboviral infections and HIV. In most of these it is due to a direct toxic effect or immune complex deposition.

In *rubella* (see p. 104) the virus can occasionally be isolated from the joint. This arthritis is rare in countries where rubella vaccination is routine. It occurs most commonly in up to 50% of young adult females a few days after rubella infection (6% of men). It is a symmetrical polyarthritis involving the MCP or PIP joints most commonly, but many joints can be affected. It closely resembles rheumatoid arthritis. IgM rubella antibodies are present. It resolves within a few weeks in most cases. A mild arthritis occurs rarely 2–4 weeks after rubella vaccination.

**Erythrovirus** B19 (p. 101) causes an acute, self-limiting arthritis and is associated with erythema infectiosum (‘slapped cheek disease’).

In *hepatitis B* infection (see p. 318), a sudden symmetrical polyarticular arthritis of the small joints of the hands occurs in approximately one-third of patients, often in the prodromal phase and mostly resolving before the onset of jaundice. Hepatitis C infection causes type II mixed cryoglobulinaemia (see p. 323).

**Arbovirus infections** (see p. 104) which are endemic in many parts of the world, give rise to an arthralgia and/or arthritis. For example, the Ross River virus causes an epidemic polyarthritis in Australia and the South Pacific; it involves the small joints of the hands and clears in 2–4 weeks. Other viral infections causing epidemic arthritis include chikungunya (p. 105) and O’nyong-nyong.

**Musculoskeletal aspects of infection with human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS)**

The clinical features seen in these patients are due to a number of causes such as opportunistic infections and drug therapy and are not usually caused directly by HIV. Infective arthritis seen in these immunosuppressed patients often has minimal symptoms and signs. Some of the antiviral agents cause an acute arthritis, possibly because of crystallization in the joint.

Arthralgia is common in AIDS. There is a *seronegative, predominantly lower-limb arthritis*, similar to psoriasis or Reiter’s disease. *Spondylitis* also occurs but is not HLA-B27 associated. *Avascular necrosis*, possibly associated with corticosteroids or alcohol, is seen.

Non-articular diseases such as Sjögren- and lupus-like syndromes, systemic vasculitis of the necrotizing and hypersensitivity types and myositis also occur.

**Fungal infection**

Fungal infections of joints occur rarely. Bone abscesses may be seen. Destructive joint lesions can also occur with blastomycosis. A benign arthritis accompanied by erythema nodosum occasionally occurs in coccidioidomycosis and histoplasmosis. Culture of purulent synovial fluid and skin tests for fungi may help the diagnosis.

**Bone infections**

**Acute and chronic osteomyelitis**

Osteomyelitis can be due either to metastatic haematogenous spread (e.g. from a boil) or to local infection. Malnutrition, debilitating disease and decreased immunity may play a part in the pathogenesis. *Staphylococcus* is the organism responsible for 90% of cases of acute osteomyelitis. Other organisms include *Haemophilus influenzae* and *Salmonella*; infection with the latter may occur as a complication of sickle cell anaemia. The classic presentation is with fever and localized bone pain with overlying tenderness and erythema.

**Diagnosis**

- Imaging:
  - Plain X-ray is not sensitive in early infection but osteopenia may be present.
  - MRI is highly sensitive, showing marrow oedema in 3 days.
  - Bone scans are also helpful.
- **Blood cultures** are often positive with staphylococcal infection.
- **Bone biopsy and culture** identifies the organism and sensitivities.

**Treatment**

Treatment of osteomyelitis is with immobilization and antibiotic therapy with intravenous teicoplanin or intravenous fluocoxacin 1–2 g every 6 hours and oral fusidic acid. Switch to oral antibiotics after 2 weeks and continue for a further 4 weeks. Surgical drainage and removal of dead bone (sequestrum) may be necessary but recurrence is common. Delayed treatment leads to chronic osteomyelitis. In chronic osteomyelitis sinus formation is usual. Subacute osteomyelitis is associated with a chronic abscess within the bone (Brodie’s abscess). Symptoms may be limited to local pain.

**Tuberculous osteomyelitis**

This is usually due to haematogenous spread from a reactivated primary focus in the lungs or gastrointestinal tract. The disease starts in intra-articular bone. The spine is commonly involved (Pott’s disease), with damage to the bodies of two neighbouring vertebrae leading to vertebral collapse and acute angulation of the spine (gibbus). Later an abscess forms (‘cold abscess’). Pus can track along tissue planes and discharge at a point far from the affected vertebrae.
Symptoms consist of local pain and later swelling if pus has collected. Systemic symptoms of malaise, fever and night sweats occur.

Treatment is as for pulmonary tuberculosis but extended to 9 months (see p. 811), together with initial immobilization.

### AUTOIMMUNE RHEUMATIC DISEASES

#### Autoimmunity and autoantibodies

Autoimmune diseases are conditions in which the immune system attacks tissues of the body. The antigens can be present in multiple organs so the clinical manifestations are systemic and diverse. In some diseases, such as Graves’ disease, Hashimoto’s thyroiditis, and insulin-dependent diabetes mellitus only a single organ is affected. The term ‘autoimmune rheumatic disease’ (ARD) is preferable to the older term ‘connective tissue disease’ because the clinical effects of ARD are not limited to connective tissues. Each individual ARD has a characteristic pattern of symptoms and signs, which are used to make the diagnosis. In some ARD there are also characteristic autoantibodies (i.e. antibodies that recognize antigens which are normal constituents of the body, such as DNA and phospholipids). Positive blood tests for autoantibodies are useful but not essential in the diagnosis of ARD (Table 11.3, p. 497).

#### Systemic lupus erythematosus (SLE)

SLE is an inflammatory, multisystem autoimmune disorder with arthralgia and rashes as the most common clinical features, and cerebral and renal disease as the most serious problems.

#### Epidemiology

SLE occurs worldwide and is about nine times as common in women as in men, with a peak age of onset between 20 and 40 years. The prevalence varies between ethnic groups, being highest (at 1:250) in African/Caribbean women. In other populations, the prevalence varies between 1:1000 and 1:10000.

#### Aetiology

The cause is unknown but there are several predisposing factors.

- **Heredity.** There is a higher concordance rate in monozygotic twins (up to 25%) compared with dizygotic twins (3%). First-degree relatives have a 3% chance of developing the disease, but approximately 20% have autoantibodies.

- **Genetics.** Recent research, including three whole genome analyses, has led to the identification of approximately 20 genes linked to the development of SLE. These include some HLA genes as well as genes involved in T and B lymphocyte function. Homozygous deficiencies of the complement genes C1q, C2 or C4 are very rare but convey a high risk of developing SLE.

- **Sex hormone status.** Premenopausal women are most frequently affected.

- **Drugs** such as hydralazine, isoniazid, procainamide and penicillamine can induce a form of SLE which is usually mild in that kidneys and the CNS are not affected.

- **Ultraviolet light** can trigger flares of SLE, especially in the skin.

- **Exposure to Epstein-Barr virus** has been suggested as a trigger for SLE.

#### Pathogenesis

When cells die by apoptosis, the cellular remnants appear on the cell surface as small blebs which carry self-antigens. These antigens include nuclear constituents (e.g. DNA and histones), which are normally hidden from the immune system. In people with SLE, removal of these blebs by phagocytes is inefficient so that they are transferred to lymphoid tissues where they can be taken up by antigen-presenting cells. The self-antigens from these blebs can then be presented to T cells which in turn stimulate B cells to produce autoantibodies directed against these antigens (p. 69). It has been shown that in some patients the autoantibodies are present in stored blood samples that were taken years before the patient developed clinical features of SLE. The combination of availability of self-antigens and failure of the immune system to inactivate B cells and T cells which recognize these self-antigens (i.e. a breakdown of tolerance, see Ch. 3, p. 69) leads to the following immunological consequences.

- Development of autoantibodies that either form circulating complexes or deposit by binding directly to tissues

- This leads to activation of complement and influx of neutrophils causing inflammation in those tissues

- Abnormal cytokine production: increased blood levels of IL-10 and alpha-interferon are particularly closely linked to high activity of inflammation in SLE.

#### Pathology

SLE of the skin and kidneys is characterized by deposition of complement and IgG antibodies and influx of neutrophils and lymphocytes. Biopsies of other tissues are carried out less frequently but can show vasculitis affecting capillaries, arterioles and venules. The synovium of joints can be oedematous and may contain immune complexes. Haematoxylin bodies (rounded blue homogeneous haematoxylin-stained deposits) are seen in inflammatory infiltrates and are thought to result from the interaction of antinuclear antibodies and cell nuclei.

The pathology of lesions in other organs is described in the appropriate chapters.

#### Clinical features

The manifestations of SLE vary greatly between patients. Most patients suffer fatigue, arthralgia and/or skin problems. Involvement of major organs is less common but more serious (Fig. 11.28).

#### General features

Fever is common in exacerbations. Patients complain of marked malaise and tiredness and these symptoms do not correlate with disease activity or severity of organ-based complications.

#### The joints and muscles

Joint involvement is the most common clinical feature (>90%). Patients often present with symptoms resembling RA with symmetrical small joint arthralgia. Joints are painful but characteristically appear clinically normal, although sometimes there is slight soft tissue swelling surrounding the joint. Deformity because of joint capsule and tendon contraction is rare, as are bony erosions. Rarely, major joint
definitive explanation is required to determine the cause of symptoms. In some cases, these symptoms may persist and lead to further complications, such as joint pain or muscle weakness. However, a thorough evaluation and appropriate management can help manage these symptoms and prevent further progression.

**The skin**

The skin (see p. 1219) is affected in 85% of cases. Erythema, in a ‘butterfly’ distribution on the cheeks and across the bridge of the nose (see Fig. 24.26), is characteristic. Vasculitic lesions on the finger tips and around the nail folds, purpura and urticaria occur. In 40–50% of cases there is photosensitivity (especially in patients positive for anti-Ro antibodies). Prolonged exposure to sunlight can lead to exacerbations of the disease. Livedo reticularis, palmar and plantar rashes, pigmentation and alopecia are seen. Scarring alopecia can lead to irreversible bald patches which are especially upsetting for women, who form the majority of people with SLE. Raynaud’s phenomenon (see p. 788) is common and may precede the development of other clinical problems by years.

Discoid lupus is a benign variant of lupus in which only the skin is involved. The rash is characteristic and appears on the face as well-defined erythematous plaques that progress to scarring and pigmentation (see p. 1198). Subacute cutaneous lupus erythematosus, a rare variant, is described on page 1198.

**The lungs**

Up to 50% of patients will have lung involvement sometime during the course of the disease (see p. 848). Recurrent pleurisy and pleural effusions (exudates) are the most common manifestations and are often bilateral. Pneumonitis and atelectasis are seen; eventually a restrictive lung defect develops with loss of lung volumes and raised hemidiaphragms. This ‘shrinking lung syndrome’ is poorly understood but may have a neuromuscular basis. Rarely, pulmonary fibrosis occurs, more commonly in overlap syndromes. Intrapulmonary haemorrhage associated with vasculitis is a rare but potentially life-threatening complication.

**The heart and cardiovascular system**

The heart is involved in 25% of cases. Pericarditis, with small pericardial effusions detected by echocardiography, is common. A mild myocarditis also occurs, giving rise to arrhythmias. Aortic valve lesions and a cardiomyopathy can rarely be present. A non-infective endocarditis involving the mitral valve (Libman–Sacks syndrome) is very rare. Raynaud’s, vasculitis, arterial and venous thromboses can occur, especially in association with the antiphospholipid syndrome (see below). There is an increased frequency of ischaemic heart disease and stroke in people with SLE. This is partly due to altered levels of common risk factors such as hypertension and lipid levels but the presence of chronic inflammation over many years may also play a role. It is not known whether intensive treatment of cardiovascular risk factors in SLE will alter the risk of developing coronary disease or stroke. The benefit of statin therapy in the absence of significant hypercholesterolaemia remains to be proved.

**The kidneys**

A classification of types of nephritis is on page 574. Autopsy studies suggest that histological changes are very frequent, but clinical renal involvement occurs in only approximately 30% of cases. All patients should have regular screening of urine for blood and protein. An asymptomatic patient with proteinuria may be in the early stages of lupus nephritis, and treatment may prevent progression to renal impairment. Proteinuria should be quantified and haematuria should prompt examination for urinary casts or fragmented red cells that suggest glomerulonephritis. Renal vein thrombosis can occur in nephrotic syndrome or associated with antiphospholipid antibodies.

**The nervous system**

Involvement of the nervous system occurs in up to 60% of cases and symptoms often fluctuate. There may be a mild depression but occasionally more severe psychiatric disturbances occur. Epilepsy, migraine, cerebellar ataxia, aseptic meningitis, cranial nerve lesions, cerebrovascular disease or a polynuropathy may be seen. The pathogenic mechanism for cerebral lupus is complex. Lesions may be due to vasculitis or immune-complex deposition, thrombosis or non-inflammatory microvasculopathy. The commonest finding on MRI scan is of increased white matter signal abnormality. In people with cerebral lupus, infection should be excluded or treated in parallel with administration of corticosteroids and immunosuppression.

**The eyes**

Retinal vasculitis can cause infarcts (cytoid bodies) which appear as hard exudates, and haemorrhages. There may be episcleritis, conjunctivitis or optic neuritis, but blindness is uncommon. Secondary Sjögren’s syndrome is seen in about 15% of cases.

**The gastrointestinal system**

Mouth ulcers are common and may be a presenting feature. These may be painless or become secondarily infected...
and painful. Mesenteric vasculitis can produce inflammatory lesions involving the small bowel (infarction or perforation). Liver involvement and pancreatitis are uncommon.

Investigations

- **Blood:**
  - A full blood count may show a leucopenia, lymphopenia and/or thrombocytopenia. Anaemia of chronic disease or autoimmune haemolytic anaemia also occurs. The ESR is raised in proportion to the disease activity. In contrast, the CRP is usually normal but may be high when the patient has lupus pleuritis, arthritis or a co-existent infection.
  - Urea and creatinine only rise when renal disease is advanced. Low serum albumin or high urine albumin/creatinine ratio are earlier indicators of lupus nephritis.
  - **Autoantibodies:** many different autoantibodies may be present in SLE but the most significant are ANA, anti-dsDNA, anti-Ro, anti-Sm and anti-La (see Box 11.16). Antiphospholipid antibodies are present in 25–40% of cases but not all of these patients develop antiphospholipid syndrome (see below).
  - Serum complement C3 and C4 levels are often reduced during active disease. The combination of high ESR, high anti-dsDNA and low C3 may herald a flare of disease. All these markers tend to return towards normal as the flare improves but in some patients anti-dsDNA levels remain high even during clinical remission.

- **Histology.** Characteristic histological and immunofluorescent abnormalities (deposition of IgG and complement) are seen in biopsies from the kidney and skin.

SS-A, SS-B, Sjögren’s syndrome -A and -B; Ro, -La, first two letters of name of patients; Sm, Smith; patient’s name; RNP, ribonucleoprotein; SSC, systemic sclerosis.

- **Diagnostic imaging.** CT scans of the brain sometimes show infarcts or haemorrhage with evidence of cerebral atrophy. MR can detect lesions in white matter which are not seen on CT. However, it can be very difficult to distinguish true vasculitis from small thrombi.

Management

**General measures**

The disease and its management should be discussed with the patient, particularly the effect upon the patient’s lifestyle, e.g. appearance and debility due to fatigue. Patients are advised to avoid excessive exposure to sunlight and it is also necessary to reduce cardiovascular risk factors (p. 727).

**Symptomatic treatment**

Many patients do not need treatment with corticosteroid tablets or immunosuppressive agents. Arthralgia, arthritis, fever and serositis all respond well to standard doses of NSAIDs (p. 511). Topical corticosteroids are effective and widely used in cutaneous lupus. Antimalarial drugs (chloroquine or hydroxychloroquine) help mild skin disease, fatigue and arthralgias that cannot be controlled with NSAIDs but patients require regular eye checks because of rare retinal toxicity (1 in 2000).

**Corticosteroids and immunosuppressive drugs**

Single intramuscular injections of long-acting corticosteroids or short courses of oral corticosteroids are useful in treating severe flares of arthritis, pleuritis or pericarditis. In some cases, these symptoms can only be kept under control using long-term oral corticosteroids.

Renal (p. 578) or cerebral disease and severe haemolytic anaemia or thrombocytopenia must be treated with high-dose oral corticosteroids and the first two of these require immunosuppressive drugs in addition. Cyclophosphamide was most commonly used to achieve remission in these severe forms of lupus but is being replaced by mycophenolate mofetil, which has fewer side-effects. Azathioprine is also used to maintain remission. Newer agents, which specifically target cells or cytokines in the immune system, are coming into use, especially in refractory cases. These include rituximab (anti-CD20) and belimumab, which are both monoclonal antibodies acting against B lymphocytes.

**Course and prognosis**

An episodic course is characteristic, with exacerbations and complete remissions that may last for long periods. However, SLE can also be a chronic persistent condition. The mortality rate in SLE has fallen dramatically over the last 50 years; the 10-year survival rate is about 90%, but this is lower if major organ-based complications are present. Deaths early in the course of disease are mainly due to renal or cerebral disease or infection. Later coronary artery disease and stroke become more prevalent. Chronic progressive destruction of joints as seen in RA and OA occurs rarely, but a few patients develop deformities such as ulnar deviation. People with SLE have an increased long-term risk of developing some cancers, especially lymphoma.

**Pregnancy and SLE**

Fertility is usually normal except in severe disease and there is no major contraindication to pregnancy. Recurrent miscarriages can occur, especially in women with anti-phospholipid antibodies. Exacerbations can occur during pregnancy with frequent exacerbations of the disease post-partum. The patient’s medications should be reviewed. Mycophenolate should be stopped whereas azathioprine,
hydroxychloroquine and low-dose oral corticosteroids are safe. Hypertension must be controlled. People with anti-Ro or anti-La antibodies have a 2% risk of giving birth to babies with neonatal lupus syndrome (rash, hepatitis and fetal heart block).

Antiphospholipid syndrome

Patients who have thrombosis (arterial or venous) and/or recurrent miscarriages and who also have persistently positive blood tests for antiphospholipid antibodies (aPL) have the antiphospholipid syndrome (APS). aPL can be detected by several different tests:

- The antiphospholipid test, which detects antibodies (IgG or IgM) that bind the negatively charged phospholipid, cardiolipin
- The lupus anticoagulant test, which detects changes in the ability of blood to clot in a test tube. Despite the name, this is not a test for lupus. It is a test for APS. The anticoagulant effect caused by aPL in the test tube causes an opposite procoagulant effect inside the body, because the balance of factors stimulating thrombosis is different there.
- The anti-β2-glycoprotein I test, which detects antibodies that bind β2-glycoprotein I, a molecule that interacts closely with phospholipids.

A persistently positive test (i.e. positive on at least two occasions, ≥12 weeks apart) in one or more of these assays is needed to diagnose APS. However, some people who test positive for aPL will never get APS, i.e. not all aPLs are harmful. APS can present in patients who already have another ARD, especially SLE. APS can also occur on its own (primary APS).

Pathogenesis

Negatively charged phospholipids and β2-glycoprotein I are present on the outer surface of apoptotic blebs and so aPLs are believed to arise by a similar mechanism to the lupus autoantibodies described above. Pathogenic aPLs bind to the N-terminal domain of β2-glycoprotein I and this interaction is facilitated when the protein is bound to phospholipid on the surface of cells such as endothelial cells, platelets, monocytes and trophoblasts. This alters the functioning of those cells leading to thrombosis and/or miscarriage.

Clinical features

Since APS is defined by the presence of thrombosis and/or pregnancy loss it is not surprising that these are the most common features. Ischaemic strokes occur in about 20% of patients and deep vein thrombosis in about 40%. Unlike most causes of thrombophilia, APS can cause either arterial or venous thrombosis (though rarely both in the same patient). Of women who have had two or more spontaneous miscarriages, 27% have APS.

However, large studies show that people with APS can also have many other features including:

- Thrombocytopenia
- Chorea, migraine and epilepsy
- Valvular heart disease
- Cutaneous manifestations (e.g. livedo reticularis)
- Positive Coombs test
- Renal impairment due to ischaemia in the small renal vessels.

Occasionally, APS is catastrophic. Catastrophic APS is a rare variant (about 1% of cases) in which multiple infarcts in different organs of the body cause failure of multiple organs simultaneously. There is a high mortality from catastrophic APS.

Treatment

In people with APS who have had one or more thrombosis, the recommended treatment to prevent further thrombosis is long-term anticoagulation with warfarin. The optimal target INR is unclear and many patients are managed with lower target INR. Pregnant women with APS are given oral aspirin and subcutaneous heparin from early in gestation. This reduces the chance of a miscarriage but pre-eclampsia and poor fetal growth remain common. There are no definite guidelines for managing people with aPL who have never had thrombosis. Aspirin or clopidogrel are sometimes given prophylactically, especially in those with high IgG aPL. Warfarin is given much more rarely in these circumstances.

Systemic sclerosis (scleroderma)

Systemic sclerosis (SSc) (see p. 1218), is a multisystem disease. This distinguishes it from localized scleroderma syndromes, such as morphea, that do not involve internal organ disease and are rarely associated with vasospasm (Raynaud’s phenomenon). SSc has the highest case-specific mortality of any of the autoimmune rheumatic diseases. SSc occurs worldwide but there may be racial or ethnic differences in clinical features. For example, renal involvement is less frequent in Japanese cases.

The incidence of SSc is 10/million population per year with a 3:1 female to male ratio. The peak incidence is between 30 and 50 years of age. It is rare in children.

Environmental risk factors for scleroderma-like disorders include: exposure to vinyl chloride, silica dust, adulterated rapeseed oil and trichloroethylene. Drugs such as bleomycin also produce a similar picture. Although unusual, familial cases are reported and twin cohorts suggest higher concordance in monozygotic pairs, consistent with genetic determinants of aetiology.

Pathology and pathogenesis

Vascular features

An early lesion is widespread vascular damage involving small arteries, arterioles and capillaries. There is initial endothelial cell damage with release of cytokines including endothelin-1, which causes vasoconstriction. There is continued intimal damage with increasing vascular permeability, leading to cellular activation, activation of adhesion molecules (E-selectin, VCAM, ICAM-1), with migration of cells into the extracellular matrix. Migrating lymphocytes are IL-2-producing cells, expressing surface antigens such as CD3, CD4 and CD5. All these factors cause release of other mediators (e.g. interleukin-1, -4, -6 and -8, transforming growth factor-β and platelet-derived growth factor) with activation of fibroblasts.

The damage to small blood vessels also produces widespread oblitative arterial lesions and subsequent chronic ischaemia.

Fibrotic features

Fibroblasts synthesize increased quantities of collagen types I and III, as well as fibronectin and glycosaminoglycans, producing fibrosis in the lower dermis of the skin as well as the internal organs. It is possible that antibodies to platelet-derived growth factor receptor, which have been found in
Clinical features (Fig. 11.29)

Raynaud’s phenomenon
Raynaud’s phenomenon is seen in almost 100% of cases and can precede the onset of the full-blown disease by many years.

Limited cutaneous scleroderma (LcSSc): 70% of cases
This usually starts with Raynaud’s phenomenon many years (up to 15) before any skin changes. The skin involvement is limited to the hands, face, feet and forearms. The skin is tight over the fingers and often produces flexion deformities of the fingers. Involvement of the skin of the face produces a characteristic ‘beak’-like nose and a small mouth (microstomia). Painful digital ulcers and telangiectasia with dilated nail-fold capillary loops are seen. Digital ischaemia may lead to gangrene. Gastrointestinal tract involvement is common. Pulmonary hypertension (PHT) develops in 21% of people with LcSSc and pulmonary interstitial disease also occurs.

Diffuse cutaneous scleroderma (DcSSc): 30% of cases
Initially oedematous in onset, skin sclerosis rapidly follows. Raynaud’s phenomenon usually starts just before or concomitant with the oedema. Diffuse swelling and stiffness of the fingers is rapidly followed by more extensive skin thickening, which can involve most of the body in the severest cases. Later the skin becomes atrophic. Early involvement of other organs occurs with general symptoms of lethargy, anorexia and weight loss.

- Heartburn, reflux or dysphagia due to oesophageal involvement is almost invariable and anal incontinence occurs in many patients. Malabsorption from bacterial overgrowth due to dilatation and atony of the small bowel is not infrequent, and more rarely dilatation and atony of the colon occurs. Pseudo-obstruction is a known complication.
- Renal involvement is acute or chronic. Acute hypertensive renal crisis used to be the most common cause of death in systemic sclerosis. ACE inhibitors and better care along with dialysis and renal transplantation have changed this.
- Lung disease, both fibrosis (in 41% of cases) and pulmonary hypertension (17% of cases), contributes significantly to mortality in SSc. PHT can be isolated or secondary to fibrosis, and high plasma levels of endothelin-1 are seen.
- Myocardial fibrosis leads to arrhythmias and conduction defects. Pericarditis is found occasionally. Sometimes, these systemic features occur without skin involvement (SSc sine scleroderma).

Investigations
- Full blood count. A normochromic, normocytic anaemia occurs and a microangiopathic haemolytic anaemia is seen in some people with renal disease.
- Urea and electrolytes. Urea and creatinine rise in acute kidney injury.
- Autoantibodies (Box 11.16):
  a. In LcSSc: speckled, nucleolar or anti-centromere antibodies (ACAs) occur in 70% of cases.
  b. In DcSSc: there are anti-topoisomerase-1 antibodies (called anti-Scl-70) in 30% of cases, and anti-RNA polymerase (I, II and III) antibodies in 20–25%. Anti-Scl-70 is highly specific for DcSSC. Anti-RNA polymerase positivity is associated with pulmonary fibrosis.
  c. Rheumatoid factor is positive in 30%.
  d. ANA is positive in 95%.
- Urine microscopy and, if there is proteinuria, urine albumin/creatinine ratio should be measured.
- Imaging:
  a. CXR: to exclude other pathology, for changes in cardiac size and established lung disease
  b. Hands: deposits of calcium around fingers (in severe cases, erosion and absorption of the tufts of the distal phalanges, termed ‘acroosteolysis’)
  c. Barium swallow generally confirms impaired oesophageal motility. Scintigraphy, manometry, impedance, and upper GI endoscopy are also valuable
  d. High-resolution CT: to demonstrate fibrotic lung involvement.
- Other investigations of gastrointestinal tract (e.g. see Fig. 6.5), lung, renal and cardiac as appropriate.

Management
Treatment should be organ-based in order to try to control the disease. Currently, there is no cure. In contrast to many other ARDs, corticosteroids and immunosuppressants are rarely used in SSc, with the exception of SSC-related pulmonary fibrosis.
- Education, counselling and family support are essential.
Polymyositis (PM) and dermatomyositis (DM)

Polymyositis is a rare disorder of unknown cause, in which the clinical picture is dominated by inflammation of striated muscle, resulting in proximal muscle weakness. When the skin is involved it is called ‘dermatomyositis’. The incidence is about 2–10/million population per annum and it occurs in all races and at all ages. The aetiology is unknown, although viruses (e.g. Coxsackie, rubella, influenza) have been implicated and persons with HLA-B8/DR3 appear to be genetically predisposed.

Clinical features

Adult polymyositis

Women are affected three times more commonly than men. The onset can be insidious, over months, or acute. General malaise, weight loss and fever can develop during the acute phase, but the cardinal symptom is proximal muscle weakness. The shoulder and pelvic girdle muscles become wasted but are not usually tender. Face and distal limb muscles are not usually affected. Movements such as squatting and climbing stairs become difficult. As the disease progresses, involvement of pharyngeal, laryngeal and respiratory muscles can lead to dysphonia and respiratory failure. These severe complications are rare if the disease is treated early.

Adult dermatomyositis

This is also more common in women. Apart from muscle weakness these patients often suffer from myalgia, polyarthralgia and Raynaud’s phenomenon but DM is primarily distinguished from PM by the characteristic rash. This typically affects the eyelids, where heliotrope (purple) discoloration is accompanied by periorbital oedema, and the fingers where one sees purple-red raised vasculitic patches. These patches occur over the knuckles (Gottron’s papules) in 70% of patients, and this appearance is highly specific for DM. Ulcerative vasculitis and calcinosis of the subcutaneous tissue occurs in 25% of cases. In the long term, muscle fibrosis and contractures of joints occur.

Other organ involvement

(antisynthetase syndrome)

Some 20–30% of people with PM or DM have antibodies to tRNA synthetase enzymes. These people are more likely to develop pulmonary interstitial fibrosis, Raynaud’s phenomenon, arthritis and hardening and fissuring of skin over the pulp surface of the fingers (mechanic’s hands). This variant of PM/DM is sometimes called antisynthetase syndrome and often has a poor outcome. Respiratory muscles are affected in PM/DM and this compounds the effects of interstitial fibrosis. Dysphagia is seen in about 50% of patients owing to oesophageal muscle involvement.

Association with other ARD

There is an association with other ARD (e.g. SLE, RA and SSc) with their associated clinical features such as deformity, malar rash and skin sclerosis.

Association with malignancies

The relative risk of cancer is 2.4 for male and 3.4 for female patients, and a wide variety of cancers have been reported. The onset and clinical picture does not differ from that of typical DM/PM. The associated cancer may not become apparent for 2–3 years, and recurrent, refractory or ANA-negative DM should prompt a search for occult malignancy. Malignancy (e.g. lung, ovary, breast, stomach) can also predate the onset of myositis, particularly in males with DM.

Childhood dermatomyositis

This most commonly affects children between the ages of 4 and 10 years. The typical rash of DM is usually accompanied by muscle weakness. Muscle atrophy, subcutaneous calcification and contractures may be widespread and severe. Ulcerative skin vasculitis is common and recurrent abdominal pain due to vasculitis is also a feature.

Investigations

- Serum creatine kinase (CK), aminotransferases, lactate dehydrogenase (LDH) and aldolase are usually raised.
and are useful guides to muscle damage but may not reflect activity.

- **ESR and CRP** may be raised.
- **Serum autoantibody studies.** Antinuclear antibody testing is usually positive in people with DM. Rheumatoid factor is present in up to 50% and many myositis-specific antibodies (MSAs) have been recognized and correlate with certain subsets. Antisynthetase antibodies have been described above.
- **Electromyography (EMG)** shows a typical triad of changes with myositis: spontaneous fibrillation potentials at rest; polyphasic or short-duration potentials on voluntary contraction; and salvos of repetitive potentials on mechanical stimulation of the nerve.
- **MRI** can be used to detect abnormally inflamed muscle.
- **Needle muscle biopsy** shows fibre necrosis and regeneration in association with an inflammatory cell infiltrate with lymphocytes around the blood vessels and between muscle fibres. Open biopsy allows more thorough assessment.
- **Screening for malignancy** is usually limited to relatively noninvasive investigations such as CXR, mammography, pelvic/abdominal ultrasound, urine microscopy and a search for circulating tumour markers.
- **PET scan** for malignancy.

**Treatment**

Bed rest may be helpful but must be combined with an exercise programme. Prednisolone is the mainstay of treatment; 0.5–1.0 mg/kg body weight as initial therapy continued until at least 1 month after myositis has become clinically and enzymatically inactive. Tapering of steroids must be slow. Early intervention with steroid-sparing agents such as methotrexate, azathioprine, ciclosporin, cyclophosphamide and mycophenolate mofetil is common, especially where there is clinical relapse or rise in CRP as the dose of steroids is reduced. Intravenous immunoglobulin therapy (IVIG) is helpful in some recalcitrant cases. Treatment of childhood DM tends to be more intensive with earlier use of immunosuppressive agents. Use of biological agents such as rituximab has been described but they are not commonly used.

---

**INCLUSION BODY MYOSITIS**

Inclusion body myositis is an idiopathic inflammatory myopathy occurring usually in men over 50 years. Weakness of the pharyngeal muscles causes difficulty in swallowing in over 50%. It is a slowly progressive weakness of mainly distal muscles. In contrast to polymyositis, the creatine kinase is only slightly elevated; the EMG shows both myopathic and neuropathic changes. On MRI, the changes are often more distal but can be similar to polymyositis. A muscle biopsy shows inflammation and basophilic rimmed vacuoles with diagnostic filamentous inclusions and vacuoles on electron microscopy. A trial of corticosteroids is worthwhile but generally the response is poor.

**Sjögren’s syndrome**

The syndrome of dry eyes (keratoconjunctivitis sicca) in the absence of rheumatoid arthritis or any of the autoimmune diseases is known as ‘primary Sjögren’s syndrome’. There is an association with HLA-B8/DR3. Dryness of the mouth, skin or vagina may also be a problem. Salivary and parotid gland enlargement is seen. In the majority of cases dryness and fatigue are the only symptoms, and Sjögren’s syndrome is irritating and inconvenient rather than dangerous. However, in a minority there may be systemic symptoms such as:

- Arthralgia and occasional non-progressive polyarthritis, like that seen in SLE (but much less common)
- Raynaud’s phenomenon
- Dysphagia and abnormal oesophageal motility as seen in systemic sclerosis (but less common)
- Other organ-specific autoimmune disease, including thyroid disease, myasthenia gravis, primary biliary cirrhosis, autoimmune hepatitis and pancreatitis
- Renal tubular defects (uncommon) causing nephrogenic diabetes insipidus and renal tubular acidosis
- Pulmonary diffusion defects and fibrosis
- Polynephropathy, fits and depression
- Vasculitis
- Increased incidence of non-Hodgkin’s B cell lymphoma.

**Pathology and investigations**

Biopsies of the salivary gland or of the lip show a focal infiltration of lymphocytes and plasma cells.

- **Schirmer tear test.** A standard strip of filter paper is placed on the inside of the lower eyelid; wetting of <10 mm in 5 min indicates defective tear production.
- **Rose Bengal staining** of the eyes shows punctate or filamentary keratitis.
- **Laboratory abnormalities.** These include raised immunoglobulin levels, circulating immune complexes and autoantibodies. Rheumatoid factor is usually positive. Antinuclear antibodies are found in 80% of cases and anti mitochondrial antibodies in 10%. Anti-Ro (SSA) antibodies are found in 60–90%, compared with 10% of cases of RA and secondary Sjögren’s syndrome. This antibody is of particular interest because it can cross the placenta and cause congenital heart block.

**Management**

Symptomatic treatment is with artificial tears and saliva-replacement solutions. Hydroxychloroquine may help fatigue and arthralgia. Corticosteroids are rarely needed but are used to treat persistent salivary gland swelling or neuropathy.

**‘Overlap’ syndromes and undifferentiated autoimmune rheumatic disease**

An overlap syndrome is one where the patient shows the characteristic clinical features of more than one ARD. Treatment of each ARD is usually the same as if they occurred separately.

**Undifferentiated ARD** is a term used for patients who have evidence of autoimmunity (e.g. positive autoantibody test) and some clinical features of such diseases (commonly Raynaud’s phenomenon and/or arthralgia) but not enough to make a clear diagnosis of any individual ARD. These patients sometimes develop a clearer ARD over time, but some always remain undifferentiated and tend to have relatively mild disease without major organ problems.
SYSTEMIC INFLAMMATORY VASCULITIS

Vasculitis is a histological term describing inflammation of the vessel wall. Vasculitis can be seen in many diseases (Tables 11.19, 11.20). The group of diseases described in this section (systemic inflammatory vasculitides) is characterized by widespread vasculitis leading to systemic symptoms and signs, generally requiring treatment with corticosteroids and/or immunosuppressive drugs. Two main features are helpful in classifying these vasculitides; the size of the blood vessels involved and the presence or absence of anti-neutrophil cytoplasmic antibodies (ANCA) in the blood (Fig. 11.30 and Table 11.19).

- **Large vessel vasculitis** refers to the aorta and its major tributaries.

**Figure 11.30** Clinical features of systemic inflammatory vasculitides. These illnesses all frequently present with joint pain as well as systemic symptoms such as fatigue, malaise and weight loss. The commonest organ-specific manifestations are shown. Giant cell arteritis is usually seen in people over 50, whereas Takayasu’s disease is seen in people under 50. Kawasaki’s disease is usually seen in children under 5.
clinical history is usually diagnostic and the patient is always over 50 years old.

Approximately one-third of patients develop systemic features of tiredness, fever, weight loss, depression and occasionally nocturnal sweats especially if PMR is not diagnosed and treated early. A differential diagnosis is shown in Box 11.17.

Investigation of PMR

- A raised ESR and/or CRP is a hallmark of this condition. It is rare to see PMR without an acute-phase response. If it is absent, the diagnosis should be questioned and the tests repeated a few weeks later before treatment is started.
- Serum alkaline phosphatase and γ-glutamyl-transpeptidase may be raised as markers of the acute inflammation.
- Anaemia (mild normochromic, normocytic) is often present.
- Temporal artery biopsy shows giant cell arteritis in 10–30% of cases, but is rarely performed unless GCA is also suspected.

Giant cell arteritis (GCA)

GCA is inflammatory granulomatous arteritis of large cerebral arteries which occurs in association with PMR. The patient may have current PMR, a history of recent PMR, or be on treatment for PMR. It is extremely rare under 50 years of age. Presenting symptoms of GCA include severe headaches, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, tender.

Investigation of GCA

- Normochromic, normocytic anaemia
- ESR is usually raised (in the region of 50–120 mm/h) and the CRP very high
- Liver biochemistry. Abnormalities occur, as in PMR. The albumin may be low
- A temporal artery biopsy from the affected side is the definitive diagnostic test. This should be taken before, or within 7 days of starting, high doses of corticosteroids. The lesions are patchy and the whole length of the biopsy (≤1 cm long) must be examined; even so, negative biopsies occur.

The histological features of GCA are:
- Cellular infiltrates of CD4+ T lymphocytes, macrophages and giant cells in the vessel wall. Note that giant cells are not visible in all cases
- Granulomatous inflammation of the intima and media
- Breaking up of the internal elastic lamina
- Giant cells, lymphocytes and plasma cells in the internal elastic lamina.

Treatment of PMR or GCA

Corticosteroids produce a dramatic reduction of symptoms of PMR within 24–48 hours of starting treatment, provided the dose is adequate. If this improvement does not occur, the diagnosis should be questioned and an alternative cause sought, such as RA, vasculitis, infection or malignancy. This treatment should reduce the risk of patients who have PMR developing GCA. NSAIDs are less effective and should not be used.

In GCA, corticosteroids are obligatory because they significantly reduce the risk of irreversible visual loss and other focal ischaemic lesions, but much higher doses are needed than in PMR. If GCA is suspected, it may not be possible to arrange a temporal artery biopsy rapidly. In these circumstances, treatment should not be delayed, especially if there have already been episodes of visual loss or stroke.

Starting daily doses of prednisolone are:
- PMR: 10–15 mg prednisolone as a single dose in the morning
- GCA: 60–100 mg prednisolone, usually in divided doses.

The dose should then be reduced gradually in weekly or monthly steps. While the dose is above 20 mg, the step reductions are 5 mg, reducing the evening doses first. Between 20 mg and 10 mg the reduction can be in 2.5 mg steps, but below 10 mg the rate should be slower and the steps each of 1 mg. Most patients will eventually be able to stop corticosteroids after 12–18 months but up to 25% may need low doses long-term. Steroid-sparing immunosuppressive agents are used in refractory cases where it is hard to reduce the corticosteroid dose without causing a flare of disease or a rise in ESR or CRP.

Calcium and vitamin D supplements and sometimes bisphosphonates are necessary to prevent osteoporosis while high-dose steroids are being used (p. 556).

Takayasu’s arteritis

This is a granulomatous inflammation of the aorta and its major branches and is discussed on page 789.

Medium-sized vessel vasculitis

Polyarteritis nodosa (PAN)

Classical PAN is a rare condition which usually occurs in middle-aged men. It is accompanied by severe systemic manifestations, and its occasional association with hepatitis B antigenemia suggests a vasculitis secondary to the deposition of immune complexes. Pathologically, there is fibrinoid necrosis of vessel walls with microaneurysm formation, thrombosis and infarction.

Clinical features

These include fever, malaise, weight loss and myalgia. These initial symptoms are followed by dramatic acute features that are due to organ infarction.
- Neurological: mononeuritis multiplex is due to arteritis of the vasa nervorum.
- Abdominal: pain due to arterial involvement of the abdominal viscer, mimicking acute cholecystitis, pancreatitis or appendicitis. Gastrointestinal haemorrhage occurs because of mucosal ulceration.

Further reading

Rheumatology and bone disease

- **Renal**: presents with haematuria and proteinuria. Hypertension and acute/chronic kidney disease occur.
- **Cardiac**: coronary arteritis causes myocardial infarction and heart failure. Pericarditis also occurs.
- **Skin**: subcutaneous haemorrhage and gangrene occur. A persistent livedo reticularis is seen in chronic cases. Cutaneous and subcutaneous palpable nodules occur, but are uncommon.
- **Lung**: involvement is rare.

### Investigations and treatment

- **Blood count**: Anaemia, leucocytosis and a raised ESR occur.
- **Biopsy**: material from an affected organ shows features listed above.
- **Angiography**: Demonstration of microaneurysms in hepatic, intestinal or renal vessels if necessary.
- **Other investigations** as appropriate (e.g. ECG and abdominal ultrasound), depending on the clinical problem. ANCA is positive only rarely in classic PAN.
- **Treatment** is with corticosteroids, usually in combination with immunosuppressive drugs such as azathioprine.

### Kawasaki’s disease

This is an acute systemic vasculitis involving medium-sized vessels, affecting mainly children under 5 years of age. It is very frequent in Japan, and an infective trigger is suspected. It occurs worldwide and is also seen in adults.

#### Clinical features and treatment

The clinical features are:

- Fever lasting 5 days or more
- Bilateral conjunctival congestion 2–4 days after onset
- Dryness and redness of the lips and oral cavity 3 days after onset
- Acute cervical lymphadenopathy accompanying the fever
- Polymorphic rash involving any part of the body
- Redness and oedema of the palms and soles 2–5 days after onset.

- The persistent fever plus at least four of the other five features should be present to make the diagnosis, or fewer than four if coronary aneurysms can be seen on two-dimensional echocardiography, MRI or angiography.

Cardiovascular changes in the acute stage include pancarditis and coronary arteritis leading to aneurysms or dilatation. Other features include diarrhoea, albuminuria, aseptic meningitis and arthralgia and, in most, there is a leucocytosis, thrombocytosis and a raised CRP. Anti-endothelial cell autoantibodies are often detectable.

**Treatment** is with a single dose of high-dose intravenous immunoglobulin (2 g/kg), which prevents the coronary artery disease, followed after the acute phase by aspirin 200–300 mg daily. There is no evidence that steroid treatment improves the outcome.

### Small vessel vasculitis

This can be separated into those that are positive or negative for anti-neutrophil cytoplasmic antibody (ANCA) (see p. 498).

- **ANCA-positive small vessel vasculitis**
  - Wegener’s granulomatosis (see p. 847)
  - Churg–Strauss granulomatosis (see p. 847)
  - Microscopic polyangiitis (see p. 847)

- **ANCA-negative small vessel vasculitis**
  - Henoch–Schönlein purpura (see p. 627)
  - Cryoglobulinaemic vasculitis (see p. 581)
  - Cutaneous leucocytoclastic vasculitis (p. 1228).

### Cutaneous leucocytoclastic vasculitis

This is a chronic purpuric lesion which histologically involves the dermal post-capillary venules. This lesion affects only the skin and should be differentiated from similar lesions produced in systemic vasculitis. The purpura may be accompanied by arthralgia and glomerulonephritis. Hepatitis C infection is common and may be an aetiological agent. The condition can also be caused by drugs such as sulphonamides and penicillin.

### Treatment of small cell vasculitis

The treatment depends on the organs involved. Vasculitis confined to the skin may not require systemic treatment whereas involvement of major organs (e.g. lungs or kidneys in Wegener’s granulomatosis) requires high-dose corticosteroids, immunosuppression and sometimes plasma exchange. Two recent clinical trials have shown that depletion of B cells with rituximab is as effective as cyclophosphamide in treating ANCA-associated vasculitis and it is likely that this will become a common form of treatment in the near future.

### Behçet’s disease

Behçet’s disease is an inflammatory disorder of unknown cause. There is a striking geographical distribution, it being most common in Turkey, Iran and Japan. The prevalence per 100000 is 10–15 in Japan and 80–300 in Turkey. There is a link to the HLA-B51 allele, with a relative risk of 5–10; this association is not seen in patients in the USA and Europe.

#### Clinical features

The cardinal clinical feature is recurrent oral ulceration. The international criteria for diagnosis require oral ulceration and any two of the following: genital ulcers, defined eye lesions, defined skin lesions, or a positive skin pathergy test (see below). Oral ulcers can be aphthous or herpetiform. The eye lesions include an anterior or posterior uveitis or retinal vascular lesions. Cutaneous lesions consist of erythema nodosum, pseudofolliculitis and papulopustular lesions.

Other manifestations include a self-limiting peripheral mono- or oligoarthritis affecting knees, ankles, wrists and elbows; gastrointestinal symptoms of diarrhoea, abdominal pain and anorexia; pulmonary and renal lesions; thrombophlebitis (especially in the legs); vasculitis; a brainstem syndrome, organic confusional states and a meningoencephalitis. All the common manifestations are self-limiting except for the ocular attacks. Repeated attacks of uveitis can cause blindness.

The pathergy reaction is highly specific to Behçet’s disease. Skin injury, by a needle prick for example, leads to papule or pustule formation within 24–48 hours. Blood tests usually show raised ESR and CRP but not autoantibodies.

### Treatment

Corticosteroids, immunosuppressive agents and ciclosporin are used for chronic uveitis and the rare neurological complications. Colchicine helps erythema nodosum and joint pain. Thalidomide may be useful in some cases although side-effects of drowsiness and peripheral neuropathy are common. It should not be used in pregnant women because of phocomelia (limb abnormalities). Anti-TNF agents can be
used to control severe uveitis and serious manifestations such as neurological and gastrointestinal Behçet’s disease.

**ARTHRITIS IN CHILDREN**

Joint and limb pains are common in children but arthritis is fortunately rare. Babies and young children may present with immobility of a joint or a limp, but the diagnosis can be extremely difficult. Figure 11.31 summarizes the differential diagnosis.

For chronic conditions, the child and family often need a great deal of support from physiotherapists, occupational therapists, psychologists, teachers, social workers and orthopaedic surgeons. These are best obtained in specialist paediatric centres.

**Juvenile idiopathic arthritis (JIA)**

**Systemic onset JIA**

*Still’s disease* (which accounts for 10% of cases of JIA) affects boys and girls equally up to 5 years of age; then girls are more commonly affected. Adult-onset Still’s disease is extremely rare.

Clinical features include a high (>39°C) fever with an evanescent pink maculopapular rash and arthralgia, arthritis, myalgia and generalized lymphadenopathy. Hepatosplenomegaly, pericarditis and pleurisy occur. The differential diagnoses include malignancy, in particular leukaemia and neuroblastoma, and infection. Laboratory tests show a high ESR and CRP, neutrophilia and thrombocytosis. Autoantibodies are negative. Macrophage activation syndrome (an excessive proliferation of T cells and macrophages) is a rare but potentially fatal complication. It can follow infection (often viral) or a change in medication.

**Oligoarthritis (persistent)**

This is the most common form of JIA (50–60%) but is still a relatively uncommon condition. It affects, by definition, four or fewer joints, especially knees, ankles and wrists, often in an asymmetrical pattern. It affects mainly girls, with a peak age of 3 years. The prognosis is generally good with most going into remission. Uveitis (often with a positive ANA) occurs and requires regular screening by slit-lamp examination. Blindness can occur if it is untreated. Prognosis is generally good, with remission occurring eventually in most patients.

**Oligoarthritis (extended)**

In approximately 25% of patients, oligoarthritis extends to affect many more joints after around 6 months. This form of arthritis can be very destructive.

**Polyarthritis JIA**

The *rheumatoid factor-positive* form (usually also ACPA positive) occurs in older girls, usually over 8 years. It is a systemic disease; the arthritis commonly involves the small joints of the hands, wrists, ankles and feet initially, and eventually larger joints. It can be a very destructive arthritis and needs aggressive treatment.

The *rheumatoid factor-negative* form is commoner. It usually affects girls under 12 years but can occur at any age. The arthritis is often asymmetrical, with a distribution similar to that seen in the RF-positive form. It may also affect the cervical spine, temporomandibular joints and elbows. Patients may be ANA positive, with a risk of chronic uveitis. All children must have regular ophthalmologic examination.

**Enthesitis-related arthritis**

This affects teenage and younger boys mainly, producing an asymmetrical arthritis of lower-limb joints and enthesitis. It is associated with HLA-B27 and a risk of iritis. It is the childhood equivalent of adult ankylosing spondylitis but spinal involvement is rare in childhood. Approximately one in three develops spinal disease in adulthood.

**Psoriatic arthritis**

This occurs in children and is similar in pattern to the adult form. The arthritis can be very destructive. Psoriasis may develop long after the arthritis but is found commonly in a first-degree relative.

**Treatment of JIA**

Early recognition and aggressive treatment prevents joint damage and allows normal growth and development. There is no cure but clinical remission is an achievable goal. JIA should always be referred to a specialist paediatric rheumatology unit with facilities to assess and design treatment plans which aim to prevent long-term disability. These units also need facilities for rehabilitation, education and surgical intervention. NSAIDs reduce pain and stiffness but disease-modifying agents such as methotrexate are used to control moderate and severe disease. Corticosteroids are often required in systemic disease; intravenous pulsed methylprednisolone is used, followed by methotrexate (10–15 mg/m²) weekly to control disease and prevent growth suppression.

**Cytokine modulators** (see Table 11.16) are used if methotrexate fails, and are highly effective in all types except systemic-onset JIA where the results are variable. Etanercept and adalimumab are the commonest drugs used but anakinra, tocilizumab and abatacept are being used in systemic-onset JIA. Anakinra (p. 526), an IL-1β receptor antagonist, helps in methotrexate-resistant systemic onset disease. Sulfasalazine is used only in enthesitis-related JIA. Aspirin may be a cause of Reye’s syndrome and should not be used under the age of 12 years.

**Prognosis**

Before cytokine modulators, up to 50% of children developed long-term disability; 25% continued to have active arthritis into adult years. Death was due to infection
or systemic disease with pericarditis or amyloidosis. The prognosis has much improved but long-term studies, particularly on safety, are awaited.

Other types

Hénoch–Schönlein purpura (see also p. 583)

This is the commonest systemic vasculitis seen in children. Skin biopsy findings are pathognomonic, with IgA immune complexes deposit in the small vessels and leucocytotoxic vasculitis in host capillary venules. It often occurs after upper respiratory tract infections. Other manifestations include lower limb purpura, a transient non-migratory polyarthritis, and abdominal pain. Some 50% of these patients will have haematuria and proteinuria, due to a glomerulonephritis; treatment of this is discussed on page 583. The prognosis is excellent, although 1% develop chronic renal damage.

Rheumatic fever

Rheumatic fever still occurs occasionally in developed countries but is more common in developing countries. It is described on page 127.

The arthritis affects large joints and migrates between joints, each being affected for a few days at a time. This is unlike systemic onset JIA, where arthritis is usually much more persistent in each affected joint. The fever is persistent but rarely as high as in systemic onset JIA, and the temperature often remains above normal. A child may not volunteer a history of sore throat and the carditis may be silent. Isolated arthritis is the presenting symptom in 14–42%. The disease is easily missed if not included in the differential diagnosis of acute childhood arthritis.

Treatment is described on page 128.

Hypermobility syndrome

Around 5–10% of children are hypermobile. A proportion of them will develop various musculoskeletal complaints in early childhood, such as late walking, flat feet or nocturnal leg pains, probably due to hypermobile ankles and knees suffering recurrent sprains and strains after exercise. Joint effusions, subluxation, dislocation and ligamentous injuries may occur throughout childhood. Low back pain may develop in affected adolescents. There is a risk of the early development of osteoarthritis in adulthood. More severe hypermobility is also seen in Ehlers–Danlos and Marfan’s syndromes (see pp. 743) and in the joint hypermobility syndrome.

Treatment is with exercise directed at improving the strength of muscles that cross affected joints, as well as overall fitness and endurance. It may be necessary to reduce or change sporting and other activities. Cognitive behavioural therapy helps in teenagers.

Miscellaneous conditions

Idiopathic musculoskeletal pain can become chronic in children. Management requires exclusion of the causes shown in Figure 11.31, but without performing unnecessary laboratory investigations. Nocturnal musculoskeletal pains are episodic and may be associated with hypermobility. They are called ‘growing pains’. They often last 15–30 minutes and awaken the child from sleep, and may require physiotherapy and analgesics, together with advice and support to the parents.

Low back pain in children may reflect psychosocial problems at home or school as much as any obvious musculoskeletal pathology.

Osteochondritis can affect the ossification centre of the ends of bones. A typical condition is Osgood–Schlatter disease, which is characterized by localized pain and swelling over the tibial tubercle or at the patellar tendon insertion. It is usually seen in athletic teenagers and responds to local treatment and changes of sporting activities. Sever’s disease is an osteochondritis of the insertion of the Achilles tendon into the calcaneum.

Perthes’ disease is an idiopathic, possibly avascular, necrosis of the proximal femoral epiphysis, of unknown aetiology. It presents as a painless limp, usually in boys aged 3–12 years, and is occasionally bilateral. If severe it may require surgical correction.

Transient synovitis of the hip (irritable hip) causes painful limitation of movement, usually of one hip, after an upper respiratory infection in young children (usually boys). Symptoms usually resolve within a few weeks (2–3% develop Perthes’ disease) but other more serious causes of hip pain should be excluded. Treatment is with rest and analgesia until the pain resolves.

Rheumatological problems seen in other diseases

Gastrointestinal and liver disease

- Enteropathic synovitis.
- Autoimmune hepatitis (see p. 326) may be accompanied by an arthralgia similar to that seen in systemic lupus erythematosus. Joint pain occurs in a bilateral, symmetrical distribution, with the small joints of the hands being predominantly affected. Joints usually look normal but sometimes there is a slight soft tissue swelling. These patients often have positive tests for antinuclear antibodies.
- Primary biliary cirrhosis patients occasionally have a symmetrical arthropathy.
- Hereditary haemochromatosis is associated with arthritis in 50% of cases; this is often the first sign of the disease and chondrocalcinosis is common.
- Whipple’s disease (see p. 268) is accompanied by fever and arthralgia.

Malignant disease

It is not uncommon for malignant diseases to present with musculoskeletal symptoms. Bone pain may be due to multiple myeloma, lymphoma, a primary tumour of bone or secondary deposits. The pain is typically unremitting, worse at night and there are other clinical clues such as weight loss or ill-health. Secondary gout occurs in conditions such as chronic myeloid leukaemia.

Neoplastic disease of bone

Malignant tumours of bone are shown in Table 11.21. The most common tumours are metastases from the bronchus, breast and prostate. Metastases from kidney and thyroid are less common. Primary bone tumours are rare and usually seen only in children and young adults.

Symptoms are usually related to the anatomical position of the tumour, with local bone pain. Systemic symptoms (e.g. malaise and pyrexia) and aches and pains occur and are occasionally related to hypercalcaemia (see p. 544). The diagnosis of metastases can often be made from the history and examination, particularly if the primary tumour has...
Paraneoplastic polyarthritis
This is seen with carcinoma of the breast in women and of the lung in men, and also with renal cell carcinoma. The neoplasm may be occult at onset and the diagnosis is then difficult to make.

Skin disease
Psoriatic arthritis
This is discussed on page 528.

Erythema nodosum (see p. 1216)
This is accompanied by arthritis in over 50% of cases. The knees and ankles are particularly affected, being swollen, red and tender. The arthritis subsides, along with the skin lesions, within a few months. Treatment is with NSAIDs or occasionally steroids.

Neurological disease

Neuropathic joints (Charcot’s joints) are joints damaged by trauma as a result of the loss of the protective pain sensation. They were first described by Charcot in relation to tabes dorsalis. They are also seen in syringomyelia, diabetes mellitus and leprosy. The site of the neuropathic joint depends upon the localization of the pain loss:

- In tabes dorsalis, the knees and ankles are most often affected.
- In diabetes mellitus, the joints of the tarsus are involved.
- In syringomyelia, the shoulder is involved.

Neuropathic joints are not painful, although there may be painful episodes associated with crystal deposition. Presentation is usually with swelling and instability. Eventually severe deformities develop.

The characteristic finding is a swollen joint with abnormal but painless movement. This is associated with neurological findings that depend upon the underlying disease (e.g. dissociated sensory loss in syringomyelia or polyneuropathy in diabetes). X-ray changes are characteristic, with gross joint disorganization and bony distortion. Treatment is symptomatic. Surgery may be required in advanced cases.

Blood disease
Arthritis due to haemarthrosis is a common presenting feature of people with haemophilia (see p. 411). Attacks begin in early childhood in most cases and are recurrent. The knee is the most commonly affected joint but the elbows and ankles are sometimes involved. The arthritis can lead to bone destruction and disorganization of joints. Apart from replacement of factor VIII, affected joints require initial immobilization followed by physiotherapy to restore movement and measures to prevent and correct deformities.

Sickle cell crises (p. 408) are often accompanied by joint pain that particularly affects the hands and feet in a bilateral, symmetrical distribution. Affected joints usually look normal but are occasionally swollen. This condition may also be complicated by avascular necrosis (see p. 556) and by osteomyelitis.

Arthritis can also occur in acute leukaemia; it may be the presenting feature in childhood. The knee is particularly affected and is very painful, warm and swollen. Treatment is directed at the underlying leukaemia. Arthritis may also occur in chronic leukaemia, with leukaemic deposits in and around the joints.

already been diagnosed. Symptoms from bony metastases may, however, be the first presenting feature.

Investigations
- **Skeletal isotope scan** show bony metastases as ‘hot’ areas before radiological changes occur.
- **X-rays** may show metastases as osteolytic areas with bony destruction. Osteosclerotic metastases are characteristic of prostatic carcinoma.
- **MRI** is used extensively, particularly for vertebral lesions.
- **CT and CT-PET** are useful.
- **Serum alkaline phosphatase** (from bone) is usually raised.
- **Hypercalcaemia** is seen in 10–20% of patients who have metastatic malignancies or is due to ectopic parathormone or parathyroid hormone-related protein secretion.
- **Prostate-specific antigen** (PSA) and serum acid phosphatase are raised in the presence of prostatic metastases.

Treatment
Treatment is usually with analgesics and anti-inflammatory drugs. Local radiotherapy to bone metastases relieves pain and reduces the risk of pathological fracture. Some tumours respond to chemotherapy; others are hormone-dependent and respond to hormonal therapy. Bisphosphonates (p. 555) can help symptomatically. Occasionally, pathological fractures require internal fixation.

Hypertrophic pulmonary osteoarthropathy
Hypertrophic osteoarthropathy is most often associated with carcinoma of the bronchus. It is a paraneoplastic, non-metastatic complication and may be the presenting feature of the disease. It occurs only rarely with other conditions that also cause clubbing. It is seen most often in middle-aged men, who present with pain and swelling of the wrists and ankles. Other joints are involved occasionally. The mechanism is unclear. One suggestion is the release of vascular endothelial growth factor (VEGF) into the circulation. Primary HPO is a hereditary condition involving a mutation in the HPGD gene that degrades prostaglanding E2 (PGE2). The mutation therefore allows over-production of PGE2, which may cause clubbing.

The diagnosis is made on the presence of clubbing of the fingers, which is usually gross, and periosteal new bone formation along the shafts of the distal ends of the radius, ulna, tibia and fibula on X-ray. A chest X-ray usually shows the malignancy.

Treatment should be directed at the underlying carcinoma; if this can be removed, the arthropathy disappears. NSAIDs relieve the symptoms.
Individuals with thalassaemia major (see p. 374) are living longer and are presenting with back pain due to premature disc degeneration, secondary spondylosis and crush fractures due to osteoporosis. There is marked discal calcification.

**Endocrine and metabolic disorders**

**Hypothyroid** patients may complain of pain and stiffness of proximal muscles, resembling polymyalgia rheumatica. They may also have carpal tunnel syndrome. Less often, there is an arthritis accompanied by joint effusions, particularly in the knees, wrist and small joints of the hands and feet. These problems respond rapidly to thyroxine.

**Hyperparathyroidism** may be complicated by chondrocalcinosis and acute pseudogout.

In *acromegaly*, arthralgia occurs in about 50% of patients. It particularly affects the small joints of the hands and knees. There may be carpal tunnel syndrome.

In *Cushing’s disease*, back pain is common.

Joint disorders related to *diabetes mellitus* are described on page 1026.

**Familial hypercholesterolaemia** is associated with oligo- or polyarthritis usually with tendon xanthomata. Arthritis also occurs in combined hyperlipidaemia.

**Familial Mediterranean fever (FMF)**

FMF is inherited as an autosomal recessive condition and occurs in certain ethnic groups, particularly Arabs, Turks, Armenians and Sephardic Jews. The gene, called *MEFV*, has been localized to chromosome 16. It encodes for pyrin (or marenosin), a suppressor of the activation of caspase 1, which stimulates the biosynthesis of interleukin-1β, which drives inflammation. Failure of suppression leads to FMF attacks.

These are characterized by recurrent attacks of fever, arthritis and serositis. Abdominal or chest pain due to peritonitis or pleurisy occurs. The arthritis is usually monoarticular and attacks last up to 1 week. The CRP is markedly raised during the attacks. The condition may be mistaken for paipnodic rheumatism (p. 519), but such attacks are not usually accompanied by fever.

The diagnosis can be made by PCR, if available, but usually it is based on the clinical picture and exclusion of other conditions.

**Treatment.** Regular colchicine 1000–1500 μg daily can usually prevent the attacks. In resistant patients, thalidomide (p. 445) and anakinra can be tried. In general, the disorder is benign but in 25% of cases, renal amyloidosis develops.

**Sarcoidosis**

Sarcoidosis (see p. 847) is a multisystem granulomatous disease and is associated with erythema nodosum, which occurs in 20% of cases at or soon after the onset of the disease. The most useful diagnostic test is a chest X-ray, which shows hilar lymphadenopathy in 80% of cases. The serum ACE may be raised.

Other patterns of arthritis occur later in the disease. These include a transient rheumatoid-like polyarthritis and an acute monoarthritis that can be mistaken for gout. Bone cysts can also develop.

**Treatment** is with NSAIDs, but if these fail to control the symptoms, corticosteroids are usually very effective.

**SAPHO (Synovitis, Acne, Palmoplantar pustulosis, Hyperostosis, Osteitis)**

This rare syndrome appears to be a reaction to chronic *Propionibacterium acnes* infection. It produces chronic multifocal osteitis with anterior chest wall pain and peripheral synovitis. There is inflammatory cytokine release and global neutrophil activation. Etanercept (p. 524) may help.

**Osteochondromatosis**

In this condition, foci of cartilage form within the synovial membrane. These foci become calcified and then ossified (osteochondromas). They may give rise to loose bodies within the joint. The condition occurs in a single joint of a young adult and X-rays are usually diagnostic.

**Treatment** involves removal of loose bodies and synovectomy.

**Pigmented villonodular synovitis**

This is characterized by exuberant synovial proliferation that occurs either in joints or in tendon sheaths. The main manifestation in joints is recurrent haemarthrosis. It may produce progressive local bone destruction. A malignant form is seen occasionally.

**Treatment** is synovectomy or radiotherapy. In tendon sheaths, the condition gives rise to a nodular mass that requires excision.

**Relapsing polychondritis**

Relapsing polychondritis is a rare inflammatory condition of cartilage. It occurs equally in males and females, usually the elderly. Tenderness, inflammation and eventual destruction of cartilage occur, mainly in the ear, nose, larynx or trachea. A seronegative polyarthritis occurs, as well as episcleritis and evidence of a vasculitis (e.g. glomerulonephritis). The diagnosis is clinical with laboratory evidence of acute inflammation.

**Treatment** involves corticosteroids and immunosuppressive agents.

**Mechanical** – structure and muscle attachment for movement

**Metabolic** – providing the body’s primary store of calcium and phosphate

**Protective** – enclosing the marrow and other vital organs.
cell signalling, which in turn activates bone formation with or without prior resorption.

**Osteoblasts**
Derived from local mesenchymal stem cells, these cells synthesize matrix (osteoid) and regulate its mineralization. After bone formation, the majority of osteoblasts are removed by apoptosis, others remaining at the bone/marrow interface as lining cells or within the bone as osteocytes. Osteoblasts critically regulate bone resorption through the balance in expression of the stimulatory RANKL (the ligand for receptor activator of nuclear factor kappaB) and its antagonist, osteoprotererin (OPG). Osteoblasts are rich in alkaline phosphatase and express receptors forPTH, oestrogen, glucocorticoids, vitamin D, inflammatory cytokines and the transforming growth factor-β family, all of which may therefore influence bone remodelling.

**Osteoclasts**
These are cells with the unique capacity to resorb bone and are derived from haematopoietic precursors of the macrophage lineage. In response to RANKL and macrophage colony stimulating factor (M-CSF), they attach to bone, creating a ruffled border which forms a number of extracellular lysosomal compartments. Hydrogen ions are actively secreted into these spaces and the acid environment removes the mineral phase before specialized cysteine proteases (e.g. cathepsin K) resorb the collagen matrix.

**Bone growth and remodelling**
Longitudinal growth occurs at the epiphyseal growth plate, a cartilage structure between the epiphysis and metaphysis (Fig. 11.32). Cartilage production is tightly regulated, with subsequent mineralization and growth finally arrested at between 18 and 21 years when the epiphysis and metaphysis fuse.

In adults, bone is regularly remodelled to ensure repair of microdamage and turnover of calcium and phosphate for homeostasis. Signals regulating initiation of remodelling include changes in osteocytes (apoptosis or altered signalling of sclerostin, prostaglandins and other molecules), resulting in altered balance of RANKL and OPG expression by adjacent osteoblasts. Regulation of bone formation involves reciprocal effects of Wnt versus dickkopf (Dkk) and sclerostin on the LRPs/6/7-catenin pathway.

Remodelling is carried out by the basic multicellular unit (BMU) (Fig. 11.33). Retraction of bone lining cells precedes binding of multinucleate osteoclasts to the bone surface, resulting in bone resorption. Unknown factors limit the amount of bone resorbed, after which osteoblasts fill in the resorption cavity. Bone remodelling is said to be coupled as formation normally follows resorption. New bone formation without resorption may, however, occur in the adult skeleton in response to anabolic therapy such as parathyroid hormone peptides. Additional influences include systemic hormones of which oestrogen (in both sexes) is particularly involved, promoting survival of osteocytes and inhibiting osteoclastogenesis.

![Diagram of a longitudinal section of a growing long bone.](image)

**Matrix components**
Type I collagen is the main protein, forming parallel lamellae of differing density (which impairs spreading of cracks). In cortical bone, concentric lamellae form around a central blood supply (Haversian system) which communicates via transverse (Volkmann’s) canals. Non-collagen proteins include osteopontin, osteocalcin and fibronectin. Bone mineral largely consists of calcium and phosphate in the form of hydroxyapatite.

**Bone cells**

**Osteocytes**
These are small cells, derived from osteoblasts, embedded in bone and interconnected with each other and with bone lining cells through cytoplasmic processes. They respond to mechanical strain by undergoing apoptosis or through altered calcium homeostasis and its regulation

Calcium homeostasis is regulated by the effects of parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D (1,25(OH)₂D₃) on gut, kidney and bone. Calcium-sensing...
receptors are present in the parathyroid glands, kidney, brain and other organs.

**Calcium absorption and distribution**

Daily calcium consumption (Fig. 11.34), primarily from dairy foods, should ideally be around 20–25 mmol (800–1000 mg). The combined effect of calcium and vitamin D deficiency contributes to bone fragility in some older persons. Intestinal absorption of calcium is reduced by vitamin D deficiency, and in malabsorption states.

**Vitamin D metabolism**

The primary source of vitamin D (Fig. 11.35) in humans is photoactivation in the skin of 7-dehydrocholesterol to cholecalciferol, which is then converted first in the liver to 25-hydroxyvitamin D (25(OH)D3) and subsequently in the kidney (by the enzyme 1α hydroxylase) to 1,25(OH)2D3. Regulation of the latter step is by PTH, phosphate and feedback inhibition by 1,25(OH)2D3.

**Parathyroid hormone (PTH)**

PTH, an 84 amino-acid hormone, is secreted from the chief cells of the parathyroid gland, which bear calcium-sensing and vitamin D receptors. PTH increases renal phosphate excretion and increases plasma calcium by:

- increasing osteoclastic activity (a rapid response)
- increasing intestinal absorption of calcium (a slower response)
- increasing 1α-hydroxylation of vitamin D (the rate-limiting step)
- increasing renal tubular reabsorption of calcium.

Hypomagnesaemia can suppress the normal PTH response to hypocalcaemia.

**Calcitonin**

Calcitonin is produced by thyroid C cells. Although calcitonin inhibits osteoclastic bone resorption and increases the renal excretion of calcium and phosphate, neither excess calcitonin (in medullary carcinoma of the thyroid) nor its deficiency following thyroidectomy has significant skeletal effects in humans.

**INVESTIGATION OF BONE AND CALCIUM DISORDERS** (Table 11.22)

**Total plasma calcium (2.2–2.6 mmol/L)**

About 40% is ionized and physiologically active: the remainder is complexed or protein bound. As ionized calcium is difficult to measure, normal practice is to measure total...
Investigation of bone and calcium disorders

calcium, correcting the value to allow for protein binding according to the following formula: add or subtract 0.02 mmol/L for each gram per litre of a simultaneous albumin level below or above 40 g/L. For critical measurements, samples should be taken in the fasting state and without a tourniquet (the latter may increase local plasma calcium concentration).

**Plasma phosphate (0.8–1.4 mmol/L)**
Phosphate is essential to most biological systems. High levels are found in renal failure and hypoparathyroidism, while low levels are associated with primary hyperparathyroidism, hypophosphataemic rickets and osteomalacia and other disorders associated with reduced renal tubular phosphate reabsorption.

**Plasma PTH (reference range 10–65 ng/mL, need to check with your local laboratory)**
The PTH assay measures the intact hormone. In hypercalcaemia due to causes other than hyperparathyroidism, serum PTH levels are suppressed. Lithium toxicity may be associated with raised PTH levels, and in familial hypocalciuric hypercalcaemia (FHH) serum PTH may be normal or marginally elevated.

**Serum 25-hydroxyvitamin D (deficiency <25 nmol/L (10 ng/mL) insufficiency <75 nmol/L (30 ng/mL))**
Vitamin D status is best assessed using serum 25-(OH)D3, as 1,25(OH)2D3 has a short half-life and does not accurately reflect true vitamin D status. Levels are only measured if disorders of vitamin D metabolism are suspected. Whilst rickets and osteomalacia occur with vitamin D deficiency, vitamin D insufficiency may increase the risk of a wide range of conditions, including ischaemic heart disease and a number of cancers.

**24-hour urinary calcium (normal range 2.5 up to 6.25 (female) and 7.5 (male) mmol/24 h)**
This is increased where renal tubular reabsorption of calcium is decreased, and in hypercalcaemia. One exception is familial hypocalciuric hypercalcaemia where the genetic defect leads to inappropriately reduced calcium excretion. Measurement of 24-hour urinary calcium excretion should be performed in the assessment of hypercalcaemic patients.

**Biochemical markers of bone formation and resorption**
While these are available in many laboratories, their use is limited by large biovariability and measurement variance.

![Figure 11.34](image-url) **Calcium exchange in the normal human.** The amounts are shown in mmol per day.

Serial measurements at the same time of day in individual patients are useful in assessing response to treatment of metabolic bone diseases. In addition, measurements of bone turnover markers may have a role in the assessment of fracture risk.

- **Bone-specific alkaline phosphatase.** Circulating alkaline phosphatase is derived from bone, liver and placenta. The bone-specific isoenzyme can be measured as a marker of formation, although there is some overlap with the liver isoenzyme. Elevated serum levels occur during bone growth, fracture repair, and in high bone turnover states.

- **Type 1 collagen propeptides** are by-products of collagen synthesis. Serum levels of both the carboxyterminal (P1CP) and aminoterminal (P1NP) propeptides reflect bone formation.

- **Serum osteocalcin** is another bone formation marker.

- **Serum or urine levels of N-terminal (NTX) and C-terminal (CTX) cross-linked telopeptides** reflect bone resorption. They may change rapidly in response to anti-resorptive drugs or in disease states.

### Diagnostic imaging

- **Plain radiographs** identify fractures, tumours and infections. Other specific features may be seen (see following sections).

- **Radionuclide imaging.** Technetium-99m-labelled methylene bisphosphonate uptake in bone reflects bone turnover and blood flow. Increased uptake is therefore seen in fractures, tumour and metastatic deposits, infection and Paget’s disease of bone.

- **Magnetic resonance imaging** is the most sensitive and specific test for the diagnosis of osteomyelitis. It is also useful in the detection of stress fractures, which may not be demonstrated on plain radiographs. A technique to suppress the high signal associated with bone marrow (such as STIR sequences, see p. 488) allows highly sensitive recognition of ‘bone marrow oedema’, a nonspecific feature of a number of bone disorders including avascular necrosis. High-resolution MRI provides information about bone microarchitecture, but this is not yet applied in the clinical setting.

- **Bone biopsy** (Fig. 11.36). A core of bone is removed, including both cortices of the iliac crest, using a trephine. The non-decalcified specimen is examined for static and dynamic (bone turnover) indices. An oral tetracycline is given to the patient prior to the biopsy, for 2 days on two occasions 10 days apart, allowing assessment of the rate of bone turnover and mineralization. Biopsy is most commonly used in assessment of suspected renal bone disease and osteomalacia.

- **Bone densitometry measurements** (p. 553).

### OSTEOPOROSIS

#### Definition and incidence

Osteoporosis is defined as ‘a disease characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and an increase in fracture risk’.

The World Health Organization (WHO) defines osteoporosis as a bone density of 2.5 standard deviations (SDs) below the young healthy adult mean value (T-score ≤−2.5) or lower. Values between −1 and −2.5 SDs below the young adult mean are termed ‘osteopenia’. The rationale for this definition is the inverse relationship between bone mineral density and fracture risk in postmenopausal women and also older men. However, this definition should not be applied to younger women, men or children.
Fractures due to osteoporosis are a major cause of morbidity and mortality in elderly populations, with osteoporotic fractures of the spine causing acute pain or deformity and postural back pain. One in two women and one in five men aged 50 years will have an osteoporotic fracture during their remaining lifetime. Caucasian and Asian races are particularly at risk. As the risk of fracture increases exponentially with age, changing population demographics will increase the burden of disease.

Pathogenesis
Osteoporosis results from increased bone breakdown by osteoclasts and decreased bone formation by osteoblasts leading to loss of bone mass.

Bone mass decreases with age (Fig. 11.37) but will depend on the ‘peak’ mass attained in adult life and on the rate of loss in later life. Genetic factors are the single most significant influence on peak bone mass, but multiple genes are involved, including collagen type 1A1 (p. 494), vitamin D receptor and oestrogen receptor genes. Nutritional factors, sex hormone status and physical activity also affect peak mass.

Risk factors
Oestrogen deficiency is a major factor in the pathogenesis of accelerated bone loss. In the elderly, vitamin D insufficiency and consequent hyperparathyroidism are pathogenic factors.

Additional risk factors are associated with increased bone loss, or with increased bone fragility but are independent of effects on the bone mineral density (Table 11.23). For example, hyperparathyroidism, hyperthyroidism and malabsorption each increase the risk of the person having a low bone mass and are BMD dependent. However, other risk factors such as previous fracture, increasing age, glucocorticoid therapy, smoking and falls increase the risk of fracture, on top of the risk associated with their particular low bone mass. The effect of many of these risk factors is particularly notable in terms of hip fracture risk.

Treatment also can depend on the type of risk factors, for if they are recognized as ‘skeletal’, they respond to bone-directed treatment and if as ‘non-skeletal’, they require other intervention (e.g. reduction of falls risk).

Not all causes of osteoporosis affect bone remodelling and architecture in the same way. For example, oestrogen deficiency results in increased numbers of remodelling units, and increased resorption depth exceeding osteoblast synthetic capacity, with a loss of resistance to fracture that is not fully reflected in the bone density measurement. Glucocorticoids induce a high turnover state initially, with increased fracture risk evident within three months of starting therapy. More prolonged use leads to a reduced turnover state but with a net loss due to reduced synthesis (through increased inhibition of the wnt-LRP5/6 axis).

Clinical features
Fracture is the only cause of symptoms in osteoporosis. Sudden onset of severe pain in the spine, often radiating around to the front, suggests vertebral crush fracture. However, only about one in three vertebral fractures is symptomatic. Pain from mechanical derangement, increasing kyphosis, height loss and abdominal protuberance follow crushed vertebrae. Colles’ fractures typically follow a fall on an outstretched arm. Fractures of the proximal femur usually occur in older individuals falling on their side or back. Other causes of low-trauma fractures must not be overlooked, including metastatic disease and myeloma.

Investigations
Plain radiographs usually show a fracture and may reveal previously asymptomatic vertebral deformities. Such clinically silent fractures may also be detected during the DXA scan with an additional analysis (called lateral vertebral assessment, Fig. 11.38) carried out with a much lower radiation dose than conventional imaging.

Bone density
- Dual energy X-ray absorptiometry (DXA) measures areal bone density (mineral per surface area rather than a true volumetric density), usually of the lumbar spine and proximal femur. It is precise, accurate, uses low
performed and are particularly necessary in men, in whom secondary causes are more common (Table 11.23).

Selection of individuals for treatment: risk assessment
The purpose of treatment is to reduce the risk of fractures (Box 11.18). Thus, assessment of absolute fracture risk should be made in every case. Although bone mineral density measurements in the spine and proximal femur provide useful information about fracture risk, they have a relatively low sensitivity and the majority of fragility fractures occur in women with a T-score $\geq -2.5$. Prediction of fracture risk can be improved by the addition of risk factors that are at least partially independent of bone mineral density (Table 11.23).

BMD monitoring is required in:
- selected high-risk cases
- low-risk cases not treated

Associated disease and risk factors
Investigations to exclude other diseases or identify contributory factors associated with osteoporosis should be

**Box 11.18 Management of osteoporosis: summary**

Treatment is guided by risk of fracture, not BMD alone.
- If intermediate risk from clinical factors, request DXA scan (see: www.shef.ac.uk/FRAX or other risk calculator until familiar with assessments).
- Do not underestimate the risk from steroids or previous fracture.
- Many guidelines (e.g. NICE) recommend bisphosphonate as first-line drugs in most cases.
- Other options include:
  - strontium ranelate or denosumab:
    - in young (to defer bisphosphonate use)
    - new fracture on a bisphosphonate or a fall in BMD or bisphosphonate use for 5–10 years
  - teriparatide if multiple vertebral fractures or high risk
  - i.v. zoledronate after hip fracture

The intervention threshold can then be determined by the cost-effectiveness of treatment and by clinical judgement.
Figure 11.40 A graph illustrating the combined effects of age (x-axis) and reduced bone mass (expressed as T-scores on the z-axis) on the 10-year probability of fracture (y-axis) in a population of women. Reduced bone mass osteopenia, T-scores between –1 and –2.5. Osteoporotic bone (T-scores < –2.5) is shown in pale green. Note that the risk of fracture may be greater in an older woman with osteopenia than in a young woman with osteoporosis. (Data from Kanis JA. Diagnosis of osteoporosis and assessment of fracture risk. Lancet 359:1929–1936.)

### Prevention and treatment

- **Symptomatic management.** New vertebral fractures may require bed rest for 1–2 weeks with strong analgesia, muscle relaxants (e.g. diazepam 2 mg three times daily) and gradual physiotherapy to restore confident mobilization (p. 505). Intravenous pamidronate helps severe pain. Non-vertebral fractures should be treated by conventional orthopaedic means.

- **Calcium and vitamin D.** Daily intakes of 800–1000 mg of calcium and 400–800 IU of vitamin D are recommended, throughout life. Vitamin D and calcium supplements should also be given to patients receiving bone protective medication. Calcium given with vitamin D has been shown to reduce non-vertebral fractures, including hip fractures, in elderly women living in residential care (but not in those living in the community).

- **Lifestyle measures.** Weight-bearing exercise for 30 minutes three times a week may increase BMD, while gentle exercise in the elderly may reduce the risk of falls and improve the protective responses to falling. Smoking is associated with lower BMD and increased fracture risk. Excess alcohol use (>3 units/day) should be avoided.

- **Reduction of falls.** Physiotherapy and assessment of home safety are helpful. Hip protectors do reduce fractures in the elderly in residential care when worn correctly, but compliance is poor.

### Pharmacological intervention (Fig. 11.36)

Most interventions used act by inhibiting bone resorption (anti-resorptives) although parathyroid hormone peptides stimulate bone formation. The mechanism of action of strontium ranelate remains incompletely defined.

The evidence base for anti-fracture efficacy of interventions varies. Adequately powered randomized controlled trials, with fracture as the primary endpoint, exist for alendronate, risedronate, ibandronate, zoledronate, raloxifene, hormone replacement therapy, strontium ranelate, denosumab, teriparatide (recombinant human PTH peptide 1–34), human recombinant parathyroid hormone 1–84 and combined calcium/vitamin D (the latter in frail older individuals only).

Some interventions have been shown to reduce fracture at vertebral and non-vertebral sites, including the hip, whereas others have not been demonstrated to be effective at all sites (Table 11.25). Since a fracture at one site increases the risk of subsequent fracture at any site, treatments with efficacy at all major fracture sites (particularly spine and hip) are preferable. Hence, the bisphosphonates and strontium ranelate are generally regarded as first-line options in the majority of postmenopausal women with osteoporosis.

- **Bisphosphonates.** Synthetic analogues of bone pyrophosphate, adhere to hydroxyapatite and inhibit osteoclasts. Alendronate and risendronate are given most commonly as once weekly doses (70 mg and 35 mg, respectively) and zoledronate is given as a once yearly infusion of 5 mg. Ibandronate is available as a once monthly oral therapy (150 mg per month) or as a three-monthly intravenous injection (3 mg per 3 months). However, anti-fracture efficacy at non-vertebral sites has only been shown in high-risk subgroups with this latter choice.
  - Oral bisphosphonates should be taken in the fasting state with a large drink of water, while the patient

Paget’s disease

Osteitis deformans or Paget’s disease is a focal disorder of bone remodelling. The initial event of excessive resorption is followed by a compensatory increase in new bone formation, increased local bone blood flow and fibrous tissue in adjacent bone marrow. Ultimately, formation exceeds resorption but the new bone is structurally abnormal.

Epidemiological studies are difficult because most affected individuals are asymptomatic. Paget’s disease is most often seen in Europe and particularly in northern England. It affects men and women (2:3) over the age of 40 years. The incidence approximately doubles per decade thereafter, with up to 10% of individuals radiologically affected by the age of 90. A positive family history is noted in about 14%.

Aetiology and pathogenesis

A number of genes have been implicated in Paget’s disease, including nuclear factor kappa B (NF-κB), sequestosome p62 (which results in activation of NF-κB), osteoprotegerin and 6C12 (an anti-apoptotic gene). Intracellular inclusions in the osteoclasts in pagetic lesions are believed to be paramyxovirus nucleocapsid (e.g. canine distemper virus, measles or respiratory syncytial virus). However, similar microfilaments are seen in other bone disorders, and theories of a viral aetiology in Paget’s remain contentious. Altered expression of c-fos (an oncogene) is one suggested mechanism linking viral infection with the pathogenic changes in osteoclasts, which are more numerous and contain an increased number of nuclei (up to 100). Increased osteoclastic bone resorption is followed by formation of woven bone, which is weaker than normal bone, which leads to deformity and increased fracture risk. Unaffected bone remains normal throughout the disease course (i.e. Paget’s disease does not spread, but can become symptomatic at previously silent sites).

Clinical features

Most (60–80%) people with radiologically identified Paget’s disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, or a plain X-ray performed for other indications. The disease of an asymptomatic elevation of serum alkaline phosphatase, disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, disease are symptomatic.

Symptoms include the following:

- Bone pain, most often in the spine or the pelvis
- Joint pain when an involved bone is close to a joint, leading to cartilage damage and osteoarthritis
- Deformities, in particular bowed tibia and skull changes
- Neurological complications: nerve compression (deafness from VIIIth cranial nerve involvement; also cranial nerves II, V, VII may be involved); spinal stenosis; hydrocephalus due to blockage of the aqueduct of Sylvius
- High-output cardiac failure and myocardial hypertrophy due to increased bone blood flow
- Pathological fractures

- Osteogenic sarcoma in pagetic bone (fewer than 1% of cases, but a 30-fold increased risk compared with non-pagetic patients).

Investigations

- X-ray features (Fig. 11.41b) vary from predominantly lytic lesions (ostoporosis circumscripta in the skull is characteristic), through a mixed phase, to a mainly sclerotic phase of bone expansion, thickening of trabeculae and loss of distinction between cortex and trabeculae (de-differentiation).
- Isotope bone scans show the extent of skeletal involvement, but are unable to distinguish between Paget’s disease and sclerotic metastatic carcinoma (especially breast and prostate).
- Increased serum alkaline phosphatase with normal serum calcium and phosphate reflects increased bone turnover. Levels may be normal with limited or monostotic Paget’s. Levels are reduced with treatment and increase during relapse. Mild hypercalcaemia follows immobilization only when there is extensive disease.
- Urinary hydroxyproline excretion is increased and may also be used as a marker of disease activity.

Treatment

Bisphosphonates are the mainstay of treatment. New bone formed after treatment is lamellar, not woven (reflecting normalization of bone turnover rather than a direct effect on osteoblasts). Treatment is interrupted and repeat courses are guided by symptoms and by recurrence in elevation of alkaline phosphatase or urinary hydroxyproline. In addition to treating symptomatic patients, treatment of asymptomatic lesions is appropriate if there is a significant risk of potential complications, e.g. fracture in weight-bearing long bones or the spine, nerve entrapment or deafness with skull involvement, and before orthopaedic procedures in involved bone (to reduce vascularity).

Intravenous bisphosphonates

Zoledronate is the most commonly used agent for Paget’s disease, administered as a single infusion over 15 min. Pamidronate is an alternative but takes longer to infuse, is less potent and some patients develop drug resistance for unknown reasons. Both drugs can be associated with a first-dose reaction characterized by ‘flu-like’ symptoms, including transient pyrexia over 24–48 hours, which can be ameliorated with paracetamol.

Oral bisphosphonates

Oral bisphosphonates are typically used at doses higher than those for osteoporosis. They are less effective than zolendronate but at least as effective as pamidronate. Alendronate is given at a dose of 40 mg daily for 6 months, repeated after a further 6 months if necessary. Risedronate is given at a dose of 30 mg daily for 2 months, repeated after a further 2 months if necessary.

Surgery

Joint replacement or osteotomy is sometimes necessary to correct deformity or pain due to associated degenerative joint disease (osteoarthritis). Intra-articular injection of lidocaine can be useful to differentiate joint or bone disease. Neurosurgery may be required where there is spinal disease. Osteosarcoma usually requires amputation, though...

wide excision and limb-salvage can be successful at distal sites.

RICKETS AND OSTEOMALACIA

Osteomalacia is defective mineralization of newly formed bone matrix or osteoid. Rickets is defective mineralization at the epiphyseal growth plate and is found in association with osteomalacia in children.

Aetiology

Many factors can result in defective mineralization of the osteoid. For normal mineralization, adequate levels of vitamin D, calcium and phosphate, adequate activity of alkaline phosphatase, a normal pH at the osteoid surface and normal osteoid composition are all necessary (Table 11.26).

The most common cause of osteomalacia is hypophosphataemia due to hyperparathyroidism secondary to vitamin D deficiency. The most common cause of vitamin D deficiency worldwide is dietary deficiency. Bread, milk and cereals in First World countries are now fortified with vitamin D. This has led to a greatly decreased incidence of osteomalacia and rickets.

Vitamin D is produced in the skin through the action of sunlight on 7-dehydrocholesterol (Fig. 11.35). Lack of sun exposure can lead to vitamin D deficiency, especially in individuals living in temperate regions who keep large parts of the skin covered throughout the year.

Vitamin D is a fat soluble vitamin so gastrointestinal disease can result in malabsorption of the vitamin. Gastrectomy, cystic fibrosis, coeliac disease, Crohn’s disease and primary biliary cirrhosis are all well-recognized causes. Due to the intimate involvement of the kidney in phosphate balance a number of causes of osteomalacia are mediated by the kidney. Primary renal phosphate wasting occurs in tumour-induced osteomalacia, multiple myeloma and the Fanconi’s syndrome. Proximal (type 2) renal tubular acidosis can cause osteomalacia both due to renal phosphate wasting

FURTHER READING

FURTHER READING
and due to abnormal osteoid pH secondary to metabolic acidosis.

**Clinical features**

Osteomalacia may be asymptomatic and identified incidentally on routine investigations. When symptomatic it characteristically causes muscle weakness and widespread bone pain. Muscle weakness is due to a multifactorial proximal myopathy, with low vitamin D, hypophosphataemia and high PTH levels all contributing. It results in a characteristic waddling gait with difficulty climbing stairs and getting out of a chair. Generalized bone pain and tenderness is thought to be caused by hydration of the demineralized matrix; the resultant swelling pushes against the periosteum. The pain is typically a dull ache that is worse on weight-bearing and walking. It can be reproduced by pressure on the sternum or tibia. Insufficiency fractures can occur.

At birth, neonatal rickets may present as craniotabes (thin deformed skull). In the first few years of life, there may be widened epiphyses at the wrists and beading at the costochondral junctions, producing the ‘rickety rosary’, or a groove in the rib cage (Harrison’s sulcus). In older children, lower chondral junctions, producing the ‘rickety rosary’, or a groove in the tibia. Insufficiency fractures can occur.

Walking. It can be reproduced by pressure on the sternum or tibia. **Investigations**

- **Serum alkaline phosphatase** is elevated in 90% of cases.
- **Low serum calcium, low phosphate** and **elevated PTH** are each present in approximately half of the cases.
- **Serum 25-(OH)D**$_2$ is low, usually less than 25 nmol/L ($10 \text{ ng/mL}$).
- **Serum FGF-23** is elevated in many people with tumour-induced osteomalacia.
- **Plain radiographs** demonstrate decreased bone mineralization. The characteristic finding in osteomalacia is Looser’s pseudofractures. These are narrow radiolucent lines with sclerotic borders running perpendicular to the cortex. They can be found at any site but are most commonly seen in the femur and pelvis.
- **Tetracycline-labelled bone biopsy** is the gold standard diagnostic test. This is not practical in most clinical settings and is mainly used in research studies.

**Table 11.26 Causes of rickets/osteomalacia**

**SKELETAL DYSPLASIAS**

These include a large group of heterogeneous disorders of bone and connective tissue.

**Collagen defects**

Collagen is responsible for many of the structural, tensile and load-bearing properties in the various tissues where it is found. (The structure of collagen is discussed on page 494.) Thirty or more dispersed genes encode for more than 19 different types of collagen (Table 11.27).

**Joint hypermobility syndrome**

Joint laxity, which often starts in childhood (p. 546), can later produce widespread soft tissue lesions which are often caused initially by trauma. Mechanical back pain is common (p. 503). An arthralgia lasting over 3 months in 4 or more joints also occurs. The Beighton score (Box 11.19) is used in epidemiological studies to assess hypermobility.

Management is multidisciplinary, ensuring that the patient understands the nature of the problem so that injury can be prevented.

**Ehlers–Danlos syndrome**

This is a heterogeneous group of disorders of collagen. Ten different types have been recognized with varying degrees of skin fragility, skin hyperextensibility and joint hypermobility.

**Types I, II and III** are inherited in an autosomal dominant fashion; the biochemical basis is unknown. No abnormalities in COL1A1, COL1A2 and COL2A1 genes have been found.

**Type IV** (vascular type) is also autosomal dominant and involves arteries, the bowel and uterus, as well as the skin. Mutations in COL3A1 gene produce abnormalities in structure, synthesis or secretion of type III collagen.

**Type VI** is a recessively inherited disorder and results from a mutation in the gene that encodes lysyl hydroxylase.

**Type VII** is an autosomal dominant disorder in which there is a defect in the conversion of procollagen to collagen; COL1A1 and COL1A2 mutations delete the N-proteinase cleavage sites.
Osteogenesis imperfecta (fragilitas ossium, brittle bone syndrome)

This is a heterogeneous group of mainly autosomal dominant inherited disorders with mutations in COL1A1, COL1A2 genes. There are four main types of osteogenesis imperfecta, and clinical subtypes are also described (V, VI and VII). The major clinical feature is bone fragility but other collagen-containing tissues are also involved, such as tendons, the skin and the eyes.

**Type I**: has mild bony deformities, blue sclerae, defective dentine, early-onset deafness, hypermobility of joints, and heart valve disorders

**Type II**: death in the perinatal period

**Type III**: severe bone deformity, blue sclerae

**Type IV**: fewer fractures, normal sclerae, normal lifespan.

Treatment with bisphosphonates (particularly intravenous pamidronate) has improved bone cortical thickness and skeletal development. Prognosis is variable, depending on the severity of the disease. Stem cell therapy is being used.

### Miscellaneous defects

#### Osteopetrosis (marble bone disease)

This condition may be inherited in either an autosomal dominant or a typically severe, autosomal recessive pattern. Another recessive form associated with renal tubular acidosis is due to carbonic anhydrate II deficiency.

The severe form is due to a mutation in the gene encoding a chloride channel necessary for osteoclast activity. Bone density is increased throughout the skeleton but bones tend to fracture easily. Encroachment on the marrow space leads to a leucoerythroblastic anaemia. There is mental retardation and early death. In the mild form there may be only X-ray changes, but fractures and infection can occur. The acid phosphate level is raised. Stem cell transplantation has been successful.

#### Marfan's syndrome

This is described on page 743.

#### Fibroblast growth factor receptor defect

Achondroplasia (‘dwarfism’) is diagnosed in the first years of life. The disease is inherited in an autosomal dominant manner and is caused by a defect in the fibroblast growth factor receptor-3 gene. The trunk is of normal length but the limbs are very short and broad due to abnormal endochondrial ossification. The vault of the skull is enlarged, the face is small and the nose bridge is flat. Intelligence is normal.

### FURTHER READING

Pearce SH, Cheetham TD. Diagnosis and management of vitamin D deficiency. BMJ 2010; 340: b5664.
FUNCTIONAL ANATOMY

The kidneys are paired organs, 11–14 cm in length in adults, 5–6 cm in width and 3–4 cm in depth. They lie retroperitoneally on either side of the vertebral column at the level of T12 to L3. The renal parenchyma comprises an outer cortex and an inner medulla. The functional unit of the kidney is the nephron, of which each contains approximately one million. Each nephron is made up of a glomerulus, proximal tubule, loop of Henle, distal tubule and collecting duct. The renal capsule and ureters are innervated via T10–12 and L1 nerve roots, and renal pain is felt over the corresponding dermatomes.

Renal arteries and arterioles
Arterial blood is supplied to the kidneys via the renal arteries, which branch off the abdominal aorta, and venous blood is conveyed to the inferior vena cava via the renal veins. Approximately 25% of humans possess dual or multiple renal arteries on one or both sides. The left renal vein is longer than the right and for this reason the left kidney, where possible, is usually chosen for live donor transplant nephrectomy.

The renal artery undergoes a series of divisions within the kidney (Fig. 12.1) forming successively, the interlobar arteries, which run radially to the corticomedullary junction, arcuate arteries, which run circumferentially along the corticomedullary junction, and interlobular arteries, which run radially through the renal cortex towards the surface of the kidney. Afferent glomerular arterioles arise from the interlobular arteries to supply the glomerular capillary bed, which drains into efferent glomerular arterioles. Efferent arterioles from the outer cortical glomeruli drain into a peritubular capillary network within the renal cortex and then into increasingly large and more proximal branches of the renal vein. By contrast, blood from the juxtamedullary glomeruli passes via the vasa recta in the medulla and then turns back towards the area of the cortex from which the vasa recta originated.

Vasa recta possess fenestrated walls, which facilitates movement of diffusible substances. The collecting ducts merge in the inner medulla to form the ducts of Bellini, which empty at the apices of the papillae into the calyces. The calyces, in common with the renal pelvis, ureter and bladder, are lined with transitional cell epithelium.

The glomerulus
The glomerulus comprises four main cell types:

- Endothelial cells which are fenestrated with 500–1000 Å pores
Kidney and urinary tract disease

- Visceral epithelial cells (podocytes) which support the delicate glomerular basement membrane by means of an extensive trabecular network (foot processes)
- Parietal epithelial cells which cover the Bowman’s capsule
- Mesangial cells (see Fig. 12.11).

Mesangial cells are believed to be related to macrophages of the reticuloendothelial system and have a phagocytic function and contractile capabilities that can control blood flow and filtration surface area along the glomerular capillaries in response to a host of mediators. They also secrete the mesangial matrix, which provides a skeletal framework for the glomerular capillaries. The glomerular capillary basement membrane lies between the endothelial and the visceral epithelial cells. The latter put out multiple long foot processes which interdigitate with those of adjacent epithelial cells. Together the endothelial cells, basement membrane and epithelial cells form the filtration barrier or sieve (see Fig. 12.12a).

Renal tubules
The renal tubules are lined by epithelial cells, which are cuboidal except in the thin limb of the loop of Henle where they are flat. Proximal tubular cells differ from other cells of the system as they have a luminal brush border. The cortical portion of the collecting ducts contains two cell types with different functions, namely principal cells and intercalated cells (see p. 561). Fibroblast-like cells in the renal cortical interstitium have been shown to produce erythropoietin in response to hypoxia (p. 567).

The juxtaglomerular apparatus
The juxtaglomerular apparatus comprises the macula densa, the extraglomerular mesangium and the terminal portion of the afferent glomerular arteriole (which contains renin-producing granular cells) together with the proximal portion of the efferent arteriole. The macula densa is a plaque of cells containing large, tightly packed cell nuclei (hence the name macula densa; see Fig. 12.2) within the thick ascending limb of the loop of Henle. This anatomical arrangement is such as to allow changes in the renal tubule to influence behaviour of the adjacent glomerulus (tubuloglomerular feedback).

RENAL FUNCTION

Physiology
A conventional diagrammatic representation of the nephron is shown in Figure 12.2a and a physiological version in Figure 12.2b.

An essential feature of renal function is that a large volume of blood – 25% of cardiac output or approximately 1300 mL/min – passes through the two million glomeruli.

A hydrostatic pressure gradient of approximately 10 mmHg (a capillary pressure of 45 mmHg minus 10 mmHg of pressure within Bowman’s space and 25 mmHg of plasma oncotic pressure) provides the driving force for ultrafiltration of virtually protein-free and fat-free fluid across the glomerular capillary wall into Bowman’s space and so into the renal tubule (Fig. 12.3).

The ultrafiltration rate (glomerular filtration rate; GFR) varies with age and sex but is approximately 120–130 mL/min per 1.73 m² surface area in adults. This means that, each day, ultrafiltration of 170–180 L of water and unbound small-molecular-weight constituents of blood occurs. If these large
Volumes of ultrafiltrate were excreted unchanged as urine, it would be necessary to ingest huge amounts of water and electrolytes to stay in balance. This is avoided by the selective reabsorption of water, essential electrolytes and other blood constituents, such as glucose and amino acids, from the filtrate in transit along the nephron. Thus, 60–80% of filtered water and sodium are reabsorbed in the proximal tubule along with virtually all the potassium, bicarbonate, glucose and amino acids (Fig. 12.2b). Additional water and sodium chloride are reabsorbed more distally, and fine tuning of salt and water balance is achieved in the distal tubules and collecting ducts under the influence of aldosterone and antidiuretic hormone (ADH). The final urine volume is thus 1–2 L daily. Calcium, phosphate and magnesium are also selectively reabsorbed in proportion to the need to maintain a normal electrolyte composition of body fluids.

The urinary excretion of some compounds is more complicated. For example, potassium is freely filtered at the glomerulus, almost completely reabsorbed in the proximal tubule, and secreted in the distal tubule and collecting ducts.

**Figure 12.2** (a) Principal parts of the nephron. The point where the distal tubule is in close proximity to its own glomerulus is called the juxtaglomerular apparatus. This contains the macula densa. (b) The countercurrent system. (i) Vasa recta: these vessels descend from the cortex into the medulla and then turn back towards the cortex. (ii) Cortical nephron: these have short descending limbs extending into the outer medulla. (iii) Juxtamedullary nephron: the descending limb dips deeply into the hypertonic inner medulla. Numbers indicate approximate osmolalities.
A clinical consequence of this is that the ability to eliminate unwanted potassium is less dependent on GFR than is the elimination of urea or creatinine. Other compounds filtered and reabsorbed or secreted to a variable extent include urate, many organic acids and many drugs or their metabolic breakdown products. The more tubular secretion of a compound that occurs, the less dependent elimination is on the GFR; penicillin and cefradine are examples of drugs secreted by the tubules.

Urine concentration and the countercurrent system

Urine is concentrated by a complex interaction between the loops of Henle, the medullary interstitium, medullary blood vessels (vasa recta) and the collecting ducts (see p. 640). The proposed mechanism of urine concentration is termed ‘the countercurrent mechanism’. The countercurrent hypothesis states that: ‘a small difference in osmotic concentration at any point between fluid flowing in opposite directions in two parallel tubes connected in a hairpin manner is multiplied many times along the length of the tubes’. Tubular fluid moves from the renal cortex towards the papillary tip of the medulla via the proximal straight tubule and the thin descending limb of the loop of Henle, which is permeable to water and impermeable to sodium. The tubule then loops back towards the cortex so that the direction of the fluid movement is reversed in the ascending limb, which is impermeable to water but permeable to sodium. This results in a large osmolar concentration difference between the corticomedullary junction and the hairpin loop at the tip of the papilla, and hence countercurrent multiplication. There is an analogy with heat exchangers.

Since the urine that emerges from the proximal tubule is iso-osmotic, the first nephron segment actually involved in urinary concentration is the descending limb of Henle’s loop. There are two types of descending limbs (Fig. 12.2b).

- **The short loops** originate in superficial and midcortical glomeruli, and turn in the outer medulla. Approximately 85% of nephrons have these.

- **The long loops**, which originate in the deep cortical and juxtamedullary glomeruli, comprise 15% of nephrons which penetrate the outer medulla up to the tip of the papilla.

Both the ascending limb in the outer and inner medulla and the first part of the distal tubule are impermeable to water and urea. Through the Na⁺/K⁺/2Cl⁻ cotransporter, the thick ascending limb actively transports sodium chloride, increasing the interstitial tonicity, resulting in tubular dilution with no net movement of water and urea on account of low permeability. The hypotonic fluid under ADH action undergoes osmotic equilibration with the interstitium in the late distal and the cortical and outer medullary collecting duct, resulting in water removal. Urea concentration in the tubular fluid rises on account of low urea permeability. At the inner medullary collecting duct, which is highly permeable to urea and water, especially in response to ADH, the urea enters the interstitium down its concentration gradient, preserving interstitial hypertonicity and generating high urea concentration in the interstitium.

The hypertonic interstitium pulls water from the descending limb of the loop of Henle, which is relatively impermeable to NaCl and urea. This makes the tubular fluid hypertonic with high NaCl concentration as it arrives at the bend of the loop of Henle. Urea plays a key role in the generation of medullary interstitial hypertonicity. The urea that is reabsorbed into the inner medullary stripe from the terminal inner medullary collecting duct is carried out of this region by ascending vasa recta, which deposit urea into the adjacent descending limb of both short and long loops of Henle, thus recycling the urea to the inner medullary collecting tubule. This process is facilitated by the close anatomical relationship that the hairpin loop of Henle and the vasa recta share.

### Glomerular filtration rate (GFR)

In health, the GFR remains remarkably constant owing to intrarenal regulatory mechanisms. In disease (e.g. a reduction in intrarenal blood flow, damage to or loss of glomeruli or obstruction to the free flow of ultrafiltrate along the tubule), the GFR will fall. The ability to eliminate waste material and to regulate the volume and composition of body fluid will decline. This will be manifest as a rise in the plasma urea or creatinine and as a reduction in measured GFR.

The concentration of urea or creatinine in plasma represents the dynamic equilibrium between production and elimination. In healthy subjects there is an enormous reserve of renal excretory function, and serum urea and creatinine do not rise above the normal range until there is a reduction of 50–60% in the GFR. Thereafter, the level of urea depends both on the GFR and its production rate (Table 12.1). The latter is heavily influenced by protein intake and tissue catabolism. The level of creatinine is much less dependent on diet but is more related to age, sex and muscle mass. Once it is elevated, serum creatinine is a better guide to GFR than urea and, in general, measurement of serum creatinine is a good way to monitor further deterioration in the GFR.

It must be re-emphasized that a normal serum urea or creatinine is not synonymous with a normal GFR.

### Measurement of the glomerular filtration rate

Measurement of the GFR is necessary to define the exact level of renal function. It is essential when the serum (plasma) urea or creatinine is within the normal range. The most widely used measurement is the creatinine clearance (Fig. 12.4). The creatinine clearance is dependent on the fact that daily production of creatinine (principally from muscle cells) is remarkably constant and little affected by protein intake. Serum creatinine and urinary output thus vary very little throughout the day.

Creatinine excretion is, however, by both glomerular filtration and tubular secretion, although at normal serum levels the latter is relatively small.

GFR, glomerular filtration rate.
With progressive renal failure, creatinine clearance may overestimate GFR but, in clinical practice, this is seldom significant.

Given these observations, creatinine clearance, is nevertheless a reasonably accurate measure of GFR = normal or near normal renal function. Urine is collected over 24 h for measurement of urinary creatinine. A single plasma level of creatinine is measured some time during the 24-hour period.

Creatinine clearance = \( U \times V \)

where \( U \) = urine concentration of creatinine; \( V \) = rate of urine flow in mL/min; \( P \) = plasma concentration of creatinine. Normal ranges are 90–140 mL/min in men, 80–125 mL/min in women.

**Calculated GFR.** Measurement of true GFR is cumbersome, time-consuming and may be inaccurate if 24-hour urine collections are incomplete. Therefore, several formulae have been developed that allow a prediction of creatinine clearance or GFR from serum creatinine and demographics. The Cockcroft–Gault equation for creatinine clearance is shown in Box 12.1.

A prediction equation has been developed based on the data derived from the Modification of Diet in Renal Disease (MDRD) study in people with chronic kidney disease (CKD) (Box 12.1). This equation is based on age, sex, creatinine and ethnicity. A modification of MDRD equation is used by most ethnic groups. Examples include cystinuria and Fanconi’s syndrome (see p. 1040 and Ch. 13). Tubular function

The major function of the tubule is the selective reabsorption or excretion of water and various cations and anions to keep the volume and electrolyte composition of body fluid normal (see Ch. 13). The active reabsorption from the glomerular filtrate of compounds such as glucose and amino acids also takes place. Within the normal range of blood concentrations these substances are completely reabsorbed by the proximal tubule. However, if blood levels are elevated above the normal range, the amount filtered (filtered load = GFR × plasma concentration) may exceed the maximal absorptive capacity of the tubule and the compound “spills over” into the urine. Examples of this occur with hyperglycaemia in diabetes mellitus or elevated plasma phenylalanine in phenylketonuria.

Conversely, inherited or acquired defects in tubular function may lead to incomplete absorption of a normal filtered load, with loss of the compound in the urine (a lowered ‘renal threshold’). This is seen in renal glycosuria, in which there is a genetically determined defect in tubular reabsorption of glucose. It is diagnosed by demonstrating glycosuria in the presence of normal blood glucose levels. Inherited or acquired defects in the tubular reabsorption of amino acids, phosphate, sodium, potassium and calcium also occur, either singly or in combination. Examples include cystinuria and Fanconi’s syndrome (see p. 1040 and Ch. 13). Tubular defects in the reabsorption of water result in nephrogenic
diabetes insipidus (p. 992). Under normal circumstances, antidiuretic hormone induces an increase in the permeability of water in the collecting ducts by attachment to receptors with subsequent activation of adenylyl cyclase. This then activates a protein kinase, which induces preformed cytoplasmic vesicles containing water channels (termed ‘aquaporins’) to move to and insert into the tubular luminal membrane. This allows water entry into tubular cells down a favourable osmotic gradient. Water then crosses the basolateral membrane and enters the bloodstream. When the effect of ADH wears off, water channels return to the cell cytoplasm (see Fig. 13.5).

**Acid-base balance**

Tubular function is also critical to the control of acid-base balance. Thus, filtered bicarbonate is largely reabsorbed and hydrogen ions are excreted mainly buffered by phosphate (see p. 698).

**Investigation of tubular function in clinical practice**

Various tubular mechanisms could theoretically be investigated, but, in clinical practice, tests of tubular function are required less often than glomerular function.

Twenty-four-hour sodium output may be helpful in determining whether a patient is complying with a low-salt diet and in the management of salt-losing nephropathy. Tests of proximal tubular function may be required in the diagnosis of Fanconi’s syndrome or isolated proximal tubular defects (e.g. urate clearance). Bicarbonate, glucose, phosphate and amino acid are all reabsorbed in the proximal tubule. Their presence in the urine is abnormal, and though formal methods of measuring maximal reabsorption are available, they are seldom necessary.

Retinol-binding protein and β₂-microglobulin are normally reabsorbed by the proximal tubule, and their urinary excretion is nonspecifically increased by diseases of the proximal tubule.

Two tests of distal tubular function are commonly applied in clinical practice:

- **Measurement of urinary concentrating capacity** in response to water deprivation, and
- **Measurement of urinary acidification**.

These tests are dealt with on page 993 and page 665.

**Protein and polypeptide metabolism**

The kidney is a major site for the catabolism of many small-molecular-weight proteins and polypeptides, including many hormones such as insulin, parathyroid hormone (PTH) and calcitonin, by endocytosis carried out by the megalin-cubilin complex in the brush border of proximal tubular cells. In chronic kidney disease the metabolic clearance of these substances is reduced and their half-life is prolonged. This accounts, for example, for the reduced insulin requirements of patients with diabetes as their renal function declines.

**Drug and toxicant elimination**

A substantial fraction of prescription drugs are handled and eliminated by the kidney. Many of these medications (e.g. penicillins, cephalosporins, diuretics, NSAIDs, antivirals and methotrexate) circulate in the plasma as small organic anions. These organic anions, which are often bound to albumin, are actively eliminated by the proximal tubule of the nephron by an organic anion transporter (OAT) system. The OAT system translocates drugs as well as endogenous substances and toxins.

**Endocrine function**

**Renin-angiotensin system**

**Juxtaglomerular apparatus**

The juxtaglomerular apparatus is made up of specialized arterial smooth muscle cells that are sited on the afferent glomerular arteriole as it enters the glomerulus. These cells synthesize prorenin, which is cleaved into the active proteolytic enzyme renin. Active renin is then stored in and released from secretory granules. Prorenin is also released in the circulation and comprises 50–90% of circulating renin, but its physiological role remains unclear as it cannot be converted into active renin in the systemic circulation. In the blood, renin converts angiotensigen, an α₂ globulin of hepatic origin, to angiotensin I. Angiotensin release is controlled by:

- Pressure changes in the afferent arteriole
- Sympathetic tone
- Chloride and osmotic concentration in the distal tubule via the macula densa (Fig. 12.2a)
- Local prostaglandin and nitric oxide release.

The renin-angiotensin-aldosterone system is illustrated in Figure 12.5.
Angiotensin I is inactive but is further cleaved by angiotensin-converting enzyme (ACE; present in lung and vascular endothelium) into the active peptide, angiotensin II, which has two major actions (mediated by two types of receptor, AT1 and AT2). The AT1 subtype which is found in the heart, blood vessels, kidney, adrenal cortex, lung and brain mediates the vasoconstrictor effect. AT2 is probably involved in vascular growth. Angiotensin II:

- causes rapid, powerful vasoconstriction
- stimulates the adrenal zona glomerulosa to increase aldosterone production (over hours or days), leading to sodium and water retention.

Both of these actions will tend to reverse the hypovolaemia or hypotension that is usually responsible for the stimulation of renin release. Angiotensin II promotes renal NaCl and water absorption by direct stimulation of Na+ reabsorption in the early proximal tubule and by increased adrenal aldosterone secretion which enhances Na+ transport in the collecting duct.

In addition to influencing systemic haemodynamics, angiotensin II also regulates GFR. Although it constricts both afferent and efferent arterioles, vasoconstriction of efferent arterioles is three times greater than that of afferent, resulting in increase of glomerular capillary pressure and maintenance of GFR. In addition, angiotensin II constricts mesangial cells, reducing the filtration surface area, and sensitizes the afferent arteriole to the constricting signal of tubuloglomerular feedback (see p. 562). The net result is that angiotensin II has opposing effects on the regulation of GFR: (a) an increase in glomerular pressure and consequent rise in GFR; (b) reduction in renal blood flow and mesangial cell contraction, reducing filtration (see Fig. 12.48). In renal artery stenosis with resultant low perfusion pressure, angiotensin II maintains GFR. However, in cardiac failure and hypertension, GFR may be reduced by angiotensin II.

The renin-angiotensin system can be blocked at several points with renin inhibitors, angiotensin-converting enzyme inhibitors (ACEI) and angiotensin II receptor antagonists (A-II-RA). These are useful agents in treatment of hypertension and heart failure (see p. 782 and p. 719) but have differences in action: ACEIs also block kinin production while A-II-RA are specific for the AT-II receptors.

Erythropoietin
Erythropoietin (see also p. 374) is the major stimulus for erythropoiesis. It is a glycoprotein produced principally by fibroblast-like cells in the renal interstitium.

- Under hypoxic conditions both the α and β subunits of hypoxia inducible factor 2 (HIF-2) are expressed forming a heterodimer, causing erythropoietin gene transcription via the combined effects of hepatic nuclear factor 4 (HNF-4) and coactivator p300. Erythropoietin, once formed, binds to its receptors on erythroid precursor cells.

- Under normal oxygen conditions, only the HIF-2-β subunit is constitutively expressed. The α subunit undergoes proline hydroxylation in the presence of iron and oxygen by prolyl hydroxylases.

- The hydroxylated HIF-2-α subunit binds to von Hippel-Lindau protein and a ubiquitin ligase E3 complex is activated. This leads to ubiquitination (p. 31) and subsequent degradation of HIF-2-α via proteosomes so that no erythropoietin is transcribed. In normoxic conditions HIF-2-α also undergoes asparaginyl hydroxylation which prevents HIF complex from recruiting coactivators. These hydroxylation steps have absolute requirement for molecular oxygen which forms the basis of oxygen sensing.

Loss of renal substance, with decreased erythropoietin production, results in a normochromic, normocytic anaemia. Conversely, erythropoietin secretion may be increased, with resultant polycythaemia, in people with polycystic renal disease, benign renal cysts or renal cell carcinoma. Recombinant human erythropoietin has been biosynthesized and is available for clinical use, particularly in people with chronic kidney disease (CKD) (see p. 623).

Vitamin D metabolism
Naturally occurring vitamin D (see also p. 622) (cholecalciferol) requires hydroxylation in the liver at position 25 and again by a 1α-hydroxylase enzyme (mitochondrial cytochrome P450) mainly in the distal convoluted tubule, the cortical and inner medullary part of the collecting ducts and the papillary epithelia of the kidney to produce the metabolically active 1,25-dihydroxycholecalciferol (1,25-(OH)2D3).

The 1α-hydroxylase activity is increased by high plasma levels of parathyroid hormone (PTH), low phosphate and low 1,25-(OH)2D3. 1,25-dihydroxycholecalciferol and 25-hydroxycholecalciferol are degraded in part by being hydroxylated at position 24 by 24-hydroxylase. The activity of this enzyme is reduced by PTH and increased by 1,25-(OH)2D3 (which therefore promotes its own inactivation).

Reduced 1α-hydroxylase activity in diseased kidneys results in relative deficiency of 1,25-(OH)2D3. As a result, gastrointestinal calcium and to a lesser extent phosphate absorption is reduced and bone mineralization impaired. Receptors for 1,25-(OH)2D3 exist in the parathyroid glands, and reduced occupancy of the receptors by the vitamin alters the set-point for release of PTH in response to a given decrement in plasma calcium concentration. Gut calcium malabsorption, which induces hypocalcaemia, and relative lack of 1,25-(OH)2D3 contribute therefore to the hyperparathyroidism seen regularly in patients with CKD, even of modest degree.

Autocrine function
Endothelins
The endothelins ET-1, ET-2 and ET-3 are a family of similar potent vasoactive peptides that also influence cell proliferation and epithelial solute transport. They do not circulate but act locally. ETs are produced by most types of cells in the kidney. The vascular actions are mediated by two receptors, with ETA (specific for ET-1) mediating vasoconstriction and ETB (responsive to all ETs) causing vasodilatation. Endothelins inhibit sodium and water absorption by suppressing Na+/K+-ATPase and Na+/H+ antiporter activity in the proximal tubule and antagonizing the action of ADH and aldosterone in the collecting duct. Tubular transport actions are mediated by ETB. Endothelins, through vasoconstriction by ETA and salt and water retention via ETB receptors, cause hypertension. Endothelins, mainly through ETA receptors, can also alter cell proliferation and matrix accumulation by increasing tissue inhibitor of metalloproteinase (TIMP), cytokines, fibronectin and collagen. These peptides also stimulate the proliferation of a variety of renal cell types.

Prostaglandins
Prostaglandins are unsaturated, oxygenated fatty acids, derived from the enzymatic metabolism of arachidonic acid, mainly by constitutively expressed cyclo-oxygenase-1 (COX-1) or inducible COX-2 (see Fig. 15.30). COX-1 is highly
expressed in the collecting duct, while COX-2 expression is restricted to the macula densa. Both COX isoforms convert arachidonic acid to the same product, the bioactive but unstable prostanooid precursor, prostaglandin \( \text{H}_2 \) (PGH\(_2\)). PGH\(_2\) is converted to:

- PGEl (formed by PDE\(_2\) synthase in the collecting duct, responsible for natriuretic and diuretic effects)
- PGD\(_2\) (undetermined significance, produced in proximal tubule)
- prostacyclin (PGI\(_2\)) (mainly synthesized in the interstitial and vascular compartment)
- thromboxane \( \text{A}_2 \) (vasoconstrictor, mainly synthesized in glomerulus).

They all act through G-coupled transmembrane receptors, maintaining renal blood flow and glomerular filtration rate in the face of reductions induced by vasoconstrictor stimuli such as angiotensin II, catecholamines and \( \alpha \)-adrenergic stimulation. In the presence of renal underperfusion, inhibition of prostaglandin synthesis by non-steroidal anti-inflammatory drugs results in a further reduction in GFR, which is sometimes sufficiently severe as to cause acute kidney injury. Renal prostaglandins also have a natriuretic renal tubular effect and antagonize the action of antidiuretic hormone. Renal prostaglandins do not regulate salt and water excretion in normal subjects, but in some circumstances, such as CKD, prostaglandin-induced vasodilatation is involved in maintaining renal blood flow. Patients with CKD are thus vulnerable to further deterioration in renal function on exposure to non-steroidal anti-inflammatory drugs, as are elderly people, in many of whom renal function is compromised by renal vascular disease and/or the effects of ageing upon the kidney. Moreover, in conditions such as volume depletion, which are associated with high renin release (facilitated by prostaglandins), inhibition of prostaglandin synthesis may lead to hyperkalaemia due to hyporeninaemic hyperaldosteronism (since angiotensin II is the main stimulus for aldosterone).

### Natriuretic peptides

Natriuretic peptides play a significant role in cardiovascular and fluid homeostasis, but there is no evidence of primary defects in their secretion causing disease.

#### Atrial natriuretic factors/peptides (ANP)

Atrial natriuretic peptides (ANP), a family of varying length forms, are secreted from atrial granules in response to atrial stretch. They produce marked effects on the kidney, increasing sodium and water excretion and glomerular filtration rate. ANP is also a direct vasodilator, lowering BP; it reduces renin release and aldosterone secretion and consequently inhibits angiotensin II synthesis.

#### Brain natriuretic peptide (BNP)

Brain natriuretic peptide (BNP) is found in the ventricle as well as the brain and has sequence homology with ANP. Normally its circulating level is 25% less than for ANP but may exceed it in congestive cardiac failure (p. 716).

### Nitric oxide and the kidney

Nitric oxide (see Fig. 16.18), a molecular gas, is formed by the action of three isoforms of nitric oxide synthase (NOS; p. 879). The most recognized cellular target of nitric oxide is soluble guanylate cyclase. The stimulation of this enzyme enhances the synthesis of cyclic GMP from GTP. All three isoforms are expressed in the kidney with eNOS in the vascular compartment, nNOS mainly in the macula densa and inner medullary collecting duct, and iNOS in several tubule segments. Nitric oxide mediates the following physiological actions in the kidney:

- Regulation of renal haemodynamics
- Natriuresis by inhibiting Na\(^+/-\)K\(^+\)-ATPase and Na\(^+/-\)H\(^+\) antiporter and antagonizing ADH
- Modulation of tubuloglomerular feedback so that the composition of tubular fluid delivered to the macula densa changes the filtration rate of the associated glomerulus.

### INVESTIGATIONS

#### Examination of the urine

**Appearance**

This is of little value in the differential diagnosis of renal disease except in the diagnosis of haematuria. Overt ‘bloody’ urine is usually unmistakable but should be checked using dipsticks (Stix testing).

**Volume**

In health, the volume of urine passed is primarily determined by diet and fluid intake. In temperate climates it lies within the range 800–2500 mL per 24 h. The minimum amount passed to stay in fluid balance is determined by the amount of solute – mainly urea and electrolytes – being excreted and the maximum concentrating power of the kidneys would be approximately 650 mL.

In diseases such as CKD or diabetes insipidus, impairment of concentrating ability requires increased volumes of urine to be passed, given the same daily solute output. An increased solute output, such as in glycosuria or increased protein catabolism following surgery, also requires increased urine volumes.

**Specific gravity and osmolality**

Urine specific gravity is a measure of the weight of dissolved particles in urine, whereas urine osmolality reflects the number of such particles. Usually the relationship between the two is close. Measurement of urine specific gravity or osmolality is required only in the differential diagnosis of oliguric renal failure or the investigation of polyuria or inappropriate ADH secretion. Specific gravity is usually fixed at 1.010 in CKD or acute tubular necrosis as compared to pre-renal acute kidney injury and inappropriate ADH secretion. Specific gravity is very high – close to 1.025.

#### Urinary pH

Measurement of urinary pH is unnecessary except in the investigation and treatment of renal tubular acidosis (see p. 664).

#### Chemical (Stix) testing

Routine Stix testing of urine for blood, protein and sugar is obligatory in all patients suspected of having renal disease.

**Blood**

Haematuria may be overt, with bloody urine, or microscopic and found only on chemical testing. A positive Stix test must always be followed by microscopy of fresh urine (with the exception of menstruating women) to confirm the presence of red cells or red-cell casts and so exclude the relatively rare conditions of haemoglobinuria or myoglobinuria. Bleeding may come from any site within the urinary tract (Fig. 12.6):
normal individuals excrete less than 20 μg of albumin per minute (30 mg in 24 hours). Dipsticks, however, detect albumin only in a concentration above 200 μg (300 mg per 24 hours if urine volume is normal). An albumin excretion between these two levels – called microalbuminuria – is an early indicator of diabetic glomerular disease and systemic endothelial dysfunction and is a useful prognostic marker for future cardiovascular events.

Timed 24-hour urinary excretion rates provide the most precise measure of microalbuminuria. However, in clinical practice it is more convenient, practical and relatively accurate to test for microalbuminuria using either random or early morning urine samples in which albumin concentration is related to urinary creatinine concentration. Generally an albumin:creatinine ratio (ACR) of 2.5:20 corresponds to albuminuria of 30–300 mg daily respectively. Kits are available to test for microalbuminuria. The urinary total protein:creatinine ratio (PCR) is also used for monitoring patients with CKD of various etiologies in their clinical practice. It is relatively cheap and identifies patients whose proteinuria is of tubular rather than glomerular origin. ACR or PCR levels independently predict all-cause and cardiovascular mortality in the general population in addition to better risk stratifications of patients with CKD for future renal outcomes.

Glucose
Renal glycosuria is uncommon, so that a positive test for glucose always requires exclusion of diabetes mellitus.

Bacteriuria
Dipstick tests for bacteriuria are based on the detection of nitrite produced from the reduction of urinary nitrate by bacteria and also for the detection of leucocyte esterase, an enzyme specific for neutrophils. Although each test on its own has limitations, a positive reaction with both tests has a high predictive value for urinary tract infection (p. 593).

Microscopy
Urine microscopy should be carried out in all patients suspected of having renal disease, on a ‘clean’ sample of mid-stream urine. The presence of numerous skin squames suggests a contaminated, poorly collected sample that cannot be properly interpreted.

If a clean sample of urine cannot be obtained, suprapubic aspiration is required in suspected urinary tract infections, particularly in children.

- **White blood cells.** The presence of ≥10 WBCs/mm³ in fresh unspun mid-stream urine samples is abnormal and indicates an inflammatory reaction within the urinary tract such as urinary tract infection (UTI), stones, tubulointerstitial nephritis, papillary necrosis, tuberculosis and interstitial cystitis.

- **Red cells.** The presence of one or more red cells per cubic millimetre in unspun urine samples results in a positive Stix test for blood and is abnormal.

- **Casts** are cylindrical bodies, moulded in the shape of the distal tubular lumen, and may be hyaline, granular or cellular. Coarse granular casts occur with pathological proteinuria in glomerular and tubular disease. Red-cell casts – even if only single – always indicate renal disease. White cell casts may be seen in acute pyelonephritis. They may be confused with the tubular cell casts that occur in patients with acute tubular necrosis.

- **Bacteria.** see page 593. Always culture urine prior to starting antibiotic therapy for sensitivities. Stix testing for blood or protein is of no value in the diagnosis of a UTI as both can be absent in the urine of many people with bacteriuria.

Blood and quantitative tests
The use of serum urea, creatinine and GFR as measures of renal function is discussed on page 564. Other quantitative tests of disturbed renal function are described under the relevant disorders, as are diagnostic tests, e.g. ANCA, immunofluorescence and complement.

Imaging techniques
Plain X-ray
A plain radiograph of the abdomen is valuable to identify renal calcification or radiodense calculi in the kidney, renal pelvis, line of the ureters or bladder (Fig. 12.7).
Kidney and urinary tract disease

Ultrasonography

Ultrasonography of the kidneys and bladder has the advantage over X-ray techniques of avoiding ionizing radiation and intravascular contrast medium. In renal diagnosis it is the imaging method of choice for:

- Renal measurement and for renal biopsy or other interventional procedures
- Checking for pelvicalyceal dilatation as an indication of renal obstruction when chronic renal obstruction is suspected. (In suspected acute ureteric obstruction, unenhanced spiral CT is the method of choice.)
- Characterizing renal masses as cystic or solid
- Diagnosing polycystic kidney disease
- Detecting intrarenal and/or perinephric fluid (e.g. pus, blood)
- Demonstrating renal arterial perfusion or detecting renal vein thrombosis using Doppler. Doppler ultrasonography (duplex) has the advantage of being non-invasive and is based on the principle that, when incident sound waves are reflected from a moving structure, their frequency is shifted by an amount proportional to the velocity of the reflector (e.g. an RBC); this shift can be quantified and displayed as a spectral Doppler scan or colour overlay (colour Doppler). However, duplex imaging is limited by central obesity, bowel gas and certain body habitus characteristics. Moreover, it is technically demanding, highly operator dependent, and is not universally available. It is at best a screening initial investigation and always requires confirmation by more reliable imaging techniques (CTA/MRA see below) if renal stenosis is suspected
- Measurement of bladder wall thickness in a distended bladder and to check for bladder tumours and stones. A scan obtained after voiding allows bladder emptying to be assessed.

The disadvantages of using ultrasonography to assess the urinary tract are:

- It may miss small renal calculi and does not detect the majority of ureteric calculi
- It is operator-dependent.

In people with suspected benign prostatic hypertrophy, examination of the bladder before and after voiding, with measurement of the prostate, and examination of the kidneys to check for pelvicalyceal dilatation suffice. If prostate cancer is suspected, more detailed ultrasound examination of the prostate with a transrectal transducer, usually with transrectal prostate biopsy, is necessary.

Computed tomography (CT)

Computed tomography is used as a first-line investigation in cases of suspected ureteric colic. Multislice detector CT has both improved image resolution and allows reconstruction of the imaging data in a variety of planes. CT is also used to:

- Characterize renal masses which are indeterminate at ultrasonography
- Stage renal tumours
- Detect ‘lucent’ calculi (low-density calculi which are lucent on plain films, e.g. uric acid stones, are well seen on CT)
- Evaluate the retroperitoneum for tumours, retroperitoneal fibrosis (periaortitis) and other causes of ureteric obstruction
- Assess severe renal trauma
- Visualize the renal arteries and veins by CT angiography
- Stage bladder and prostate tumours (MRI is increasingly used instead to stage prostate cancer).

Disadvantages include radiation and contrast nephrotoxicity. The use of unenhanced CT in suspected ureteric colic permits diagnosis of causes of pain other than calculi more readily than does urography.

Magnetic resonance imaging (MRI)

MRI is used:

- To characterize renal masses as an alternative to CT
- To stage renal, prostate and bladder cancer
- To demonstrate the renal arteries by magnetic resonance angiography with gadolinium as contrast medium. In experienced hands its sensitivity and specificity approaches renal angiography.

Magnetic resonance urography is preferred over intravenous urography (IVU) in patients with chronic urolithiasis or intrinsic or extrinsic ureteric tumour, and in paediatric uro-radiology. Gadolinium is used as contrast medium and is less nephrotoxic than iodine-containing agents used in IVU. However, the Federal Drug Administration (FDA) advises not using gadolinium in patients with renal insufficiency because of development of nephrogenic systemic fibrosis (pp. 1220 and 598).

Excretion urography

Excretion urography (also known as IVU or intravenous pyelography, IVP) has largely been replaced by ultrasonography and CT scanning.

Antegrade pyelography

Antegrade pyelography (Fig. 12.8) involves percutaneous puncture of a pelvicalyceal system with a needle and the injection of contrast medium to outline the pelvicalyceal system and ureter to the level of obstruction. It is used when...
Complications include cholesterol embolizations (p. 599) and contrast-induced kidney damage (contrast nephropathy).

**Renal scintigraphy**

Renal scintigraphy using a gamma camera is divided into:

- dynamic studies in which the function of the kidney is examined serially over a period of time, most often using a radiopharmaceutical excreted by glomerular filtration
- static studies involving imaging of tracer that is taken up and retained by the renal tubule.

**Dynamic scintigraphy**

The radiopharmaceutical technetium-labelled diethylenetriaminepenta-acetic acid, \([^{99m}\text{Tc}]\text{DTPA}\), is excreted by glomerular filtration. Dimercaptosuccinic acid labelled with technetium (\([^{99m}\text{Tc}]\text{DMSA}\)) is filtered by the glomerulus and then bound to proximal tubular cells. Mercaptoacetyltriglycine (MAG3) labelled with technetium (\([^{99m}\text{Tc}]\)) is excreted by renal tubular secretion. Following venous injection of a bolus of tracer, emissions from the kidney can be recorded by gamma camera. This information allows examination of blood perfusion of the kidney, uptake of tracer as a result of glomerular filtration, transit of tracer through the kidney, and the outflow of tracer-containing urine from the collecting system.

**Renal blood flow.** Dynamic studies can be used to investigate people in whom renal artery stenosis is suspected as a cause for hypertension and patients with severe oliguria (post-traumatic, post-aortic surgery, or after a kidney transplant) to establish whether, and to what extent, there is renal perfusion. In patients with unilateral renal artery stenosis there is, typically, a slowed and reduced uptake of tracer with delay in reaching a peak. Studies carried out before and after administration of an ACE inhibitor may demonstrate a fall in uptake that is suggestive of functional arterial stenosis. Both false-positive and false-negative results occur, particularly in patients with CKD, and renal arteriography remains the ‘gold standard’ in the diagnosis of renal artery stenosis. In patients with total renal artery occlusion, no kidney uptake of tracers is observed.

**Investigation of obstruction.** Renal scintigraphy provides functional evidence of obstruction. After injection usually of \([^{99m}\text{Tc}]\text{MAG3}\) a rise in resistance to flow in the pelvis or ureter prolongs the parenchymal transit of tracer and there is usually a delay in emptying the pelvis. On whole-kidney renograms, the time-activity curve fails to fall after an initial peak, or continues to rise (Fig. 12.10).

When the possibility of obstruction is suspected, a dynamic renal scintigram is performed with diuresis. Furosemide (0.5 mg/kg, adult dose 40 mg) is given intravenously about 18–20 min into the study. Time-activity curves show an immediate fall after furosemide in the absence of obstruction.
Kidney and urinary tract disease

**GLOMERULAR DISEASES**

A glomerulus consists of a collection of capillaries which come from the afferent arteriole and are confined within the urinary space (Bowman’s capsule); this is continuous with the proximal tubule. The capillaries are partially attached to mesangium, a continuation of the arteriolar wall consisting of mesangial cells and the matrix. The free wall of glomerular capillaries (across which filtration takes place) consists of basement membrane covered by visceral epithelial cells with individual foot processes and lined by endothelial cells (Fig. 12.11). The normal thickness of the basement membrane is about 250–300 nm. The spaces between foot processes, with diameters of 20–60 nm, are called filtration pores, by which filtered fluid reaches the urinary space. The endothelial cells on the luminal aspect of the basement membrane are fenestrated (diameter 70–100 nm). The basement membrane is arranged in three zones: lamina rara externa, lamina rara densa and lamina rara interna, and is composed of type IV collagen and negatively charged proteoglycans (heparan sulphate).

but the retention of activity in the pelvis persists in the presence of obstruction. A decision as to whether conservative surgery or nephrectomy should be carried out in unilateral obstruction is facilitated by renographic assessment of the contribution of each kidney.

At the end of dynamic studies, bladder emptying may be investigated and any postmicturition residual urine measured.

**Glomerular filtration rate.** This is discussed on page 564.

**Static scintigraphy**

This is usually performed using $^{99m}$TcDMSA (dimercaptosuccinic acid), which is taken up by tubular cells. Uptake is proportional to renal function.

**Relative renal function.** Function is normally evenly divided between the kidneys, with a range of 45–55%. Static studies are particularly useful in unilateral renal disease, where the relative uptake of the two kidneys can be calculated.

**Kidney visualization.** Normal kidneys show a uniform uptake with a smooth renal outline. Scars can be identified as photon-deficient ‘bites’. Static scintigraphy is of considerable value in identifying ectopic kidneys or ‘pseudotumours’ of the kidneys (i.e. normally functioning renal tissue abnormally placed within the kidney).

**Localization of infection.** The use of citrate labelled with gallium-67 or isotopically labelled leukocytes that are taken up by inflammatory tissue may be of value in defining localized infection, such as renal abscesses or infection within a renal cyst.

**Transcutaneous renal biopsy**

(Practical Box 12.1)

Renal biopsy is carried out under ultrasound control in specialized centres and requires interpretation by an experienced pathologist. Renal biopsy is helpful in the investigation of the nephritic and nephrotic syndromes, acute and CKD, haematuria after urological investigations and renal graft dysfunction. Native renal biopsy material must be examined by conventional histochemical staining, by electron microscopy, and by immunoperoxidase or immunofluorescence. Techniques like in situ hybridization and polymerase chain reaction analysis are also widely used in renal biopsy specimens.

The complications of transcutaneous renal biopsy are shown in Table 12.2.

**GLOMERULAR DISEASES**

A glomerulus consists of a collection of capillaries which come from the afferent arteriole and are confined within the urinary space (Bowman’s capsule); this is continuous with the proximal tubule. The capillaries are partially attached to mesangium, a continuation of the arteriolar wall consisting of mesangial cells and the matrix. The free wall of glomerular capillaries (across which filtration takes place) consists of basement membrane covered by visceral epithelial cells with individual foot processes and lined by endothelial cells (Fig. 12.11). The normal thickness of the basement membrane is about 250–300 nm. The spaces between foot processes, with diameters of 20–60 nm, are called filtration pores, by which filtered fluid reaches the urinary space. The endothelial cells on the luminal aspect of the basement membrane are fenestrated (diameter 70–100 nm). The basement membrane is arranged in three zones: lamina rara externa, lamina rara densa and lamina rara interna, and is composed of type IV collagen and negatively charged proteoglycans (heparan sulphate).
Filtration barrier (slit diaphragm) (Fig. 12.12)
The glomerular filtration barrier consists of the fenestrated endothelium, the glomerular basement membrane and the terminally differentiated visceral epithelial cells known as podocytes. Podocytes dictate the size-selective nature of the filtration barrier. They attach to the glomerular basement membrane by foot processes via adhesion molecules, e.g. αvβ3, and dystroglycans. Adjacent podocytes are joined laterally via their foot process by slit diaphragms which bridge across the filtration slits. The various proteins comprising the slit diaphragm include nephrin, CD2AP (CD2-associated protein), canonical TRPC6 (transient receptor potential channel 6), podocin, P-cadherin, α- and β-catenin, ZO-1 (zonula occludens-1). These co-localize within the subcellular domain to function as a molecular sieve. These proteins, in addition to providing structural support to the cytoskeletal proteins like filamentous actin, also have signalling functions in order to maintain the normal function of podocytes. Abnormalities in any of these proteins result in the breakdown of the filtration barrier with consequent torrential leak of macromolecules.

Podocyte changes
The podocyte structure (see above) is maintained by actin which supports the cytoskeleton (Fig. 12.12). A rearrangement of the fluid actin cytoskeleton leads to foot process effacement (flattening) with a leak of albumin while its reversal (and stabilization) decreases proteinuria.

The cytoskeleton can be altered by abnormalities of the above cytoskeletal proteins, e.g. alpha-actinin-4, which causes hereditary focal segmental glomerular sclerosis, injury to the slit diaphragm proteins, changes in the glomerular basement membrane or by direct injury to the podocytes by, e.g. viral infection, drugs, toxins or the local activation of the renin–angiotensin system.

Types of glomerular disease
Glomerular disease includes:
- **glomerulonephritis**, i.e. inflammation of the glomeruli and
- **glomerulopathies**, where there is no evidence of inflammation.

There is an overlap between these terms.

GLOMERULOPATHIES
Glomerulopathies are the third most common cause of end-stage kidney disease (ESKD) (after diabetes and hypertension) in Europe and the USA, accounting for some 10–15% of such patients. Glomerulopathy (GN) is a general term for a group of disorders in which:
- there is primarily an immunologically mediated injury to glomeruli, although renal interstitial damage is a regular accompaniment
- the kidneys are involved symmetrically
- secondary mechanisms of glomerular injury come into play following an initial immune insult such as fibrin deposition, platelet aggregation, neutrophil infiltration and free radical-induced damage
- renal lesions may be part of a generalized disease (e.g. systemic lupus erythematosus, SLE).

![Diagram showing a normal (left) and proteinuric (right) glomerulus.](Figure 12.11)
Pathogenesis
GN is considered to be an immunologically mediated disorder with involvement of cellular immunity (T lymphocytes, macrophages/dendritic cells), humoral immunity (antibodies, immune complexes, complement) and other inflammatory mediators (including cytokines, chemokines and the coagulation cascade). The immune response can be directed against known target antigens, particularly when GN complicates infections, neoplasia or drugs. More frequently the underlying antigenic target is unknown. Primary GN may occur in genetically susceptible individuals following an environmental insult. The genetic susceptibility is usually determined by major histocompatibility complex (HLA) genes (e.g. HLA-A1, B8, DR2, DR3). The environmental factors may be drugs (e.g. hydralazine), chemicals (e.g. gold, silica, hydrocarbons) or infectious agents. The known predisposing factors are discussed in more detail below. The physical evidence of immune reactions is indicated by the presence of circulating autoantibodies and/or abnormalities in serum complement and glomerular deposition of antibodies, immune complexes, complement and fibrin.

Pathological terms in glomerular disease
The most commonly used terms are:

- **Focal**: some, but not all, glomeruli show the lesion
- **Diffuse** (global): most of the glomeruli (>75%) contain the lesion
- **Segmental**: only a part of the glomerulus is affected (most focal lesions are also segmental, e.g. focal segmental glomerulosclerosis)
- **Proliferative**: an increase in cell numbers due to hyperplasia of one or more of the resident glomerular cells with or without inflammation
- **Membrane alterations**: capillary wall thickening due to deposition of immune deposits or alterations in basement membrane
- **Crescent formation**: epithelial cell proliferation with mononuclear cell infiltration in Bowman’s space.

Classification of glomerulopathies
There is no complete correlation between the histopathological types of GN and the clinical features of disease. Glomerular diseases have been classified in numerous ways. Here they are organized and discussed as they relate to four major glomerular syndromes:

- **Nephrotic syndrome** – massive proteinuria (>3.5 g/day), hypoalbuminaemia, oedema, lipiduria and hyperlipidaemia.
- **Acute glomerulonephritis (acute nephritic syndrome)** – abrupt onset of glomerular haematuria (RBC casts or dysmorphic RBC), non-nephrotic range proteinuria, oedema, hypertension and transient renal impairment.
- **Rapidly progressive glomerulonephritis** – features of acute nephritis, focal necrosis with or without crescents and rapidly progressive renal failure over weeks.
- **Asymptomatic haematuria, proteinuria** or both.

Certain types of GN, particularly those that are a part of a systemic disease, can present as more than one syndrome, e.g. lupus nephritis, cryoglobulinaemia, and Henoch–Schönlein purpura. They are usually associated with the nephrotic syndrome and will be discussed below. Investigation of glomerular diseases is shown in Table 12.3.

### Nephrotic syndrome

**Pathophysiology**

**Hypoalbuminaemia.** Urinary protein loss of the order 3.5 g daily or more in an adult is required to cause hypoalbuminaemia. The normal dietary protein intake in the UK is around 70 g daily and the normal liver can synthesize albumin at a rate of 10–12 g daily. How then does a urinary protein loss of the order of 3.5 g daily result in hypoalbuminaemia? This can be partly explained by increased catabolism of reabsorbed albumin in the proximal tubules during the nephrotic syndrome even though actual albumin synthesis rate is increased. However, in addition, dietary intake of protein increases albuminuria, so that the plasma albumin concentration tends to decrease during consumption of a high-protein diet. If the increase in urinary albumin excretion that follows dietary augmentation is prevented by administration of ACE inhibitors (ACEI), a high-protein diet causes an increase in plasma albumin concentration in the nephrotic syndrome. Therefore, to maximize serum albumin concentration in nephrotic patients, a reduction in urinary albumin excretion with an ACEI is always necessary.

**Proteinuria.** The mechanism of the proteinuria is complex. It occurs partly because structural damage to the glomerular basement membrane leads to an increase in the size and number of pores, allowing passage of more and larger molecules. Electrical charge is also involved in glomerular permeability. Fixed negatively charged components are present in the glomerular capillary wall, which repel negatively charged protein molecules. Reduction of this fixed charge occurs in glomerular disease and appears to be a key factor in the genesis of heavy proteinuria.

**Hyperlipidaemia.** The characteristic disorder is an increase in the low-density lipoprotein (LDL), very-low-density lipoprotein (VLDL), and/or intermediate-density lipoprotein (IDL) fractions, but no change or decrease in HDL. This results in an increase in the LDL/HDL cholesterol ratio. Hyperlipidaemia is the consequence of increased synthesis of lipoproteins.
(such as apolipoprotein B, C-III lipoprotein (a)), as a direct consequence of a low plasma albumin. There is also a reduced clearance of the principal triglycerides bearing lipoprotein (chylomicrons and VLDL) in direct response to albuminuria.

**Oedema in hypoalbuminaemia.** See Chapter 13 (p. 643).

**Management**

**General measures**

- **Initial treatment** should be with dietary sodium restriction and a thiazide diuretic (e.g. bendroflumethiazide 5 mg daily). Unresponsive patients require furosemide 40–120 mg daily with the addition of amiloride (5 mg daily), with the serum potassium concentration monitored regularly. Nephrotic patients may malabsorb diuretics (as well as other drugs) owing to gut mucosal oedema, and parenteral administration is then required initially. Patients are sometimes hypovolaemic, and moderate oedema may have to be accepted in order to avoid postural hypotension.

- **Normal protein intake** is advisable. A high-protein diet (80–90 g protein daily) increases proteinuria and can be harmful in the long term.

- **Albumin infusion** produces only a transient effect. It is only given to patients who are diuretic-resistant and those with oedema and uraemia in the absence of severe glomerular damage, e.g. in minimal-change nephropathy. Albumin infusion is combined with diuretic therapy and diuresis often continues with diuretic treatment alone.

- **Hypercoagulable states** predispose to venous thrombosis. The hypercoagulable state is due to loss of clotting factors (e.g. antithrombin) in the urine and an increase in hepatic production of fibrinogen. Prolonged bed rest should therefore be avoided as thromboembolism is very common in the nephrotic syndrome. In the absence of any contraindication, long-term prophylactic anticoagulation is desirable. If renal vein thrombosis occurs, permanent anticoagulation is required.

- **Sepsis** is a major cause of death in nephrotic patients. The increased susceptibility to infection is partly due to loss of immunoglobulin in the urine. Pneumococcal infections are particularly common and pneumococcal vaccine should be given. Early detection and aggressive treatment of infections, rather than long-term antibiotic prophylaxis, is the best approach.

- **Lipid abnormalities** are responsible for an increase in the risk of cardiovascular disease in patients with proteinuria. Treatment of hypercholesterolaemia starts with an HMG-CoA reductase inhibitor.

- **ACE inhibitors and/or angiotensin II receptor antagonists (AIIRA)** are used for their antiproteinuric properties in all types of GN. These groups of drugs reduce proteinuria by lowering glomerular capillary filtration pressure; the blood pressure and renal function should be monitored regularly.

**Specific measures**

The aim is to reverse the abnormal urinary protein leak. These measures are discussed in detail below. Table 12.4 shows the glomerular lesions commonly associated with the nephrotic syndrome. These are divided into diseases with or without RBC casts (active or bland urine sediments). Each of these entities occurs as a primary renal lesion or as a secondary component of a systemic disease.

**Figure 12.13 Normal glomerulus on light microscopy in minimal change disease.**

**Nephrotic syndrome with ‘bland’ urine sediments**

**Minimal-change glomerular lesion**

(minimal-change nephropathy, minimal-change disease, MCD)

In this condition the glomeruli appear normal on light microscopy (Fig. 12.13). The only abnormality seen on electron microscopy is fusion of the foot processes of epithelial cells (podocytes) (Fig. 12.12b; p. 573). This is a nonspecific finding and is seen in many conditions associated with proteinuria, e.g. focal segmental glomerulosclerosis (FSGS). Neither immune complexes nor anti-GBM antibody can be demonstrated by immunofluorescence.

However, an explanation for the proteinuria is that immature differentiating CD34 stem cells rather than mature T lymphocytes are responsible for the pathogenesis of minimal change nephropathy. Other factors that may have an effect on the podocytes include IL-13, the production of vascular endothelial growth factor (VEGF), or the upregulation of vascular angiopoietin-like-4 (ANGPTL4) secreted by the podocytes.

Many drugs have been implicated in MCD, e.g. NSAIDs, lithium, antibiotics (cephalosporins, rifampicin, ampicillin), bisphosphonates and sulphasalazine. Atopy is present in 30% of cases of MCD and allergic reactions can trigger the nephrotic syndrome. Infections, e.g. HCV, HIV and TB, are rarer causes.

**Clinical features**

Minimal-change nephropathy is most common in children, particularly males, accounting for the large majority of cases.
of nephrotic syndrome (proteinuria is usually highly selective) in childhood. Oedema is present and in children this may be facial. The condition accounts for 20–25% of cases of adult nephrotic syndrome. It is often regarded as a condition that does not lead to CKD (but see FSGS, below).

**Management**

High-dose corticosteroid therapy with prednisolone 60 mg/m<sup>2</sup> daily (up to a maximum of 80 mg/day) for a maximum of 4–6 weeks followed by 40 mg/m<sup>2</sup> every other day for a further 4–6 weeks corrects the urinary protein leak in more than 95% of children. Response rates in infants are significantly lower and response may occur only after many months (12 weeks with daily steroid therapy and 12 weeks of maintenance with alternate-day therapy). Spontaneous remission also occurs and steroid therapy should, in general, be withheld if urinary protein loss is insufficient to cause hypoalbuminaemia or oedema.

In children, two-thirds subsequently relapse and further courses of corticosteroids are required. One-third of these children regularly relapse on steroid withdrawal, so that cyclophosphamide should be added after repeat induction with steroids. A course of cyclophosphamide 1.5–2.0 mg/kg daily is given for 8–12 weeks with concomitant prednisolone 7.5–15 mg/day. This increases the likelihood of long-term remission. Steroid unresponsive patients may also respond to cyclophosphamide. No more than two courses of cyclophosphamide should be prescribed in children because of the risk of side-effects, which include azoosperma.

In both children and adults, if remission lasts for 4 years after steroid therapy, further relapse is very rare.

An alternative to cyclophosphamide is ciclosporin 3–5 mg/kg per day, which is effective but must be continued long term to prevent relapse on stopping treatment. The anti-proteinuric effect of ciclosporin is normally attributed to its immunosuppressive action but it may result from the stabilization of the actin cytoskeleton in kidney podocytes. Ciclosporin inhibits the calcineurin-mediated dephosphorylation of synaptopodin (a regulator of actin cytoskeleton) and protects it from cathepsin L-mediated degradation. These results have shed new light on the role of calcineurin signalling in proteinuric kidney diseases. Excretory function and ciclosporin blood levels (recommended trough levels 80–150 ng/mL) must be monitored regularly, as ciclosporin is potentially nephrotoxic.

In corticosteroid-dependent children, the anthelmintic agent levamisole 2.5 mg/kg to a maximum of 150 mg on alternate days is useful in maintenance of remission but its mode of action is unexplained.

**Congenital nephrotic syndrome**

Congenital nephrotic syndrome (Finnish type) is an autosomal recessively inherited disorder due to mutations in the gene coding for a transmembrane protein, nephrin, that occurs with a frequency of 1 per 8200 live births in Finland. Its loss of function results in massive proteinuria shortly after birth; these patients usually have an enlarged placenta. This disorder can be diagnosed in utero; increased α-fetoprotein in amniotic fluid is a common feature. The microscopic features of the kidney are varied. Some glomeruli are small and infantile, whereas others are enlarged, more mature and have diffuse mesangial hypercellularity. Because of the massive proteinuria, some tubules develop microcysts and are dilated. On electron microscopy, complete effacement of the foot processes of visceral epithelial cells is observed. This condition is characterized by relentless progression to ESKD.

Other inherited nephrotic syndromes involve mutations in other genes that encode podocyte proteins such as podocin, α-actinin-4 and Wilms’ tumour suppressor gene.

**Focal segmental glomerulosclerosis (FSGS)**

**Clinical features**

This disease of unknown aetiology usually presents as massive proteinuria (usually non-selective), haematuria, hypertension and renal impairment. People with nephrotic syndrome are often resistant to steroid therapy. All age groups are affected. It usually recurs in transplanted kidneys, sometimes within days of transplantation, particularly in patients with aggressive renal disease.

**Aetiology.** A circulating permeability factor causes the increased protein leak; plasma from patients increases membrane permeability in isolated glomeruli. Kidneys transplanted into murine models of FSGS develop the lesion, but kidneys from FSGS-prone mice transplanted to a normal strain are protected. Removal of this factor by plasmapheresis results in transient amelioration of proteinuria. The identity of the permeability factor remains unknown but recent findings suggest that cardiometabol-in-like cytokine-1 and/or soluble urokinase receptor are likely candidates in FSGS. In addition upregulation of CD80 in podocytes has a major role in the co-stimulatory immune response pathway. Anti-CD80 antibodies, used in renal transplantation, are likely to be used in FSGS in the future.

**Pathology**

This glomerulopathy is defined primarily by its appearance on light microscopy. Segmental glomerulosclerosis is seen, which later progresses to global sclerosis. The deep glomeruli at the corticomedullary junction are affected first. These may be missed on transcutaneous biopsy, leading to a mistaken diagnosis of a minimal-change glomerular lesion. A pathogenetic link may exist between minimal-change nephropathy (p. 575) and focal glomerulosclerosis, as a proportion of cases classified as having the former condition develop progressive CKD, which is unusual. Immunofluorescence shows deposits of C3 and IgM in affected portions of the glomerulus. The other glomeruli are usually enlarged but may be of normal size. In some patients, mesangial hypercellularity is a feature. Focal tubular atrophy and interstitial fibrosis are invariably present.

Electron microscopic findings mirror light microscopic features with capillary obliteration by hyaline deposits (mesangial matrix and basement membrane material) and lipids. The other glomeruli exhibit primarily foot process effacement, occasionally in a patchy distribution. Five histological variants of FSGS exist:

- In **classic FSGS** (Fig. 12.14a) the involved glomeruli show sclerotic segments in any location of the glomerulus.
- The **glomerular tip lesion** is characterized by segmental sclerosis, at the tubular pole of all the affected glomeruli at a very early stage (tip FSGS) (Fig. 12.14b). Capillaries contain foam cells, and overlying visceral epithelial cells are enlarged and adherent to the most proximal portion of proximal tubules. These patients have a more favourable response to steroids and run a more benign course.
- In **collapsing FSGS** (Fig. 12.14c) the visceral cells are usually enlarged and coarsely vacuolated with wrinkled and collapsed capillary walls. These features indicate a severe lesion, with a corresponding progressive clinical
course of the disease. Collapsing FSGS is commonly seen in young blacks with human immunodeficiency virus (HIV) infection or disease and is known as HIV-associated nephropathy (HIVAN) (see p. 93).

- The perihilar variant (Fig. 12.14d) consists of perihilar sclerosis and hyalinosis in more than 50% of segmentally sclerotic glomeruli. It is frequently observed with secondary FGS due to processes associated with increased glomerular capillary pressure and declining renal mass.

- The cellular variant (Fig. 12.14e) is characterized by at least one glomerulus with segmental endocapillary hypercellularity that occludes the capillary lumen. Other glomeruli may exhibit findings consistent with classic FGS.

The tip and collapsing variants have to be excluded histologically to make a diagnosis of the cellular variant. Patients with this variant can have severe proteinuria.

Similar glomerular changes are seen as a secondary phenomenon when the number of functioning nephrons is reduced for any reasons (e.g. nephrectomy, hypertension, gross obesity, ischaemia, sickle nephropathy, reflux nephropathy, chronic allograft nephropathy, IgA nephropathy and scarring following renal vasculitis), leading to the hypothesis that FSGS results from overloading (glomerular hyperfiltration) of the remaining nephrons.

Secondary forms are also caused by mutations in specific podocyte genes. Some viruses, e.g. HIV type 1, cytomegalovirus, Epstein–Barr virus and the simian virus 40, are associated with FGS. Drugs such as heroin, all interferons, anabolic steroids, lithium sirolimus, pamidronate and calcineurin inhibitors, e.g. ciclosporin, can also cause FGS.

The cause of the primary form is unknown but could be due to circulating permeability factors mentioned above.

**Treatment**

- **Prednisolone** 0.5–2 mg/kg per day is used in most patients and continued for 6 months before the patient is considered resistant to therapy, which is common.

- **Ciclosporin** at doses to maintain serum trough levels at 150–300 ng/mL may be effective in reducing or stopping ciclosporin is very common so that long-term use is required.

  - **Cyclophosphamide, chlorambucil or azathioprine** are used for second-line therapy in adults. In patients with FGS with mesangial hypercellularity and tip lesion, cyclophosphamide 1–1.5 mg/kg per day with 60 mg of prednisolone for 3–6 months followed by prednisolone and azathioprine can be used as maintenance therapy.

  About 50% of patients progress to ESKD within 10 years of diagnosis, particularly those who are resistant to therapy. The recurrence of this renal lesion following renal transplantation is very high with poor renal prognosis. Plasmapheresis or immunosuppression has been the mainstay of treatment in patients with post-transplant recurrence but with modest success.

**Membranous glomerulopathy**

**Clinical features**

This condition occurs mainly in adults, predominantly in males. People present with asymptomatic proteinuria or frank nephrotic syndrome. Microscopic haematuria, hypertension and/or renal impairment may accompany the nephrotic syndrome. As in all nephritides, hypertension and a greater degree of renal impairment are poor prognostic signs. In membranous GN almost half of the patients undergo spontaneous or therapy-related remission. However, eventually about 40% develop CKD, usually in association with persistent nephrotic range proteinuria. Younger people, females and those with asymptomatic proteinuria of modest degree at the time of presentation do best.

**Aetiopathogenesis**

An identical glomerular histological picture is seen in the primary or idiopathic form (which comprises 75% of the cases) and also when membranous GN is secondary to drugs (e.g. penicillamine, gold, NSAIDs, probenecid, mercury, captopril), autoimmune disease (e.g. SLE, thyroiditis), infectious disease (e.g. hepatitis B, hepatitis C, schistosomiasis, Plasmodium malariae), neoplasia (e.g. carcinoma of lung, colon, stomach, breast and lymphoma) and other causes (e.g. sarcoidosis, kidney transplantation, sickle cell disease). At all stages, immunofluorescence shows the presence of uniform

(e) FSGS cellular variant.
granular capillary wall deposits of IgG and complement C3. In the early stage the deposits are small and can be missed on light microscopy. Electron microscopy reveals small electron-dense deposits in the subepithelial aspects of the capillary walls. In the intermediate stage the deposits are encircled by basement membrane, which gives an appearance of spikes of basement membrane perpendicular to the basement membrane on silver staining. Late in the disease the deposits are completely surrounded by basement membrane and are undergoing resorption, which appears as uniform thickening of the capillary basement membrane on light microscopy (Fig. 12.15).

An animal model (Heymann nephritis) in which the morphological appearances closely resemble the human condition can be induced in susceptible rats by immunization with renal autoantigens such as the brush border component of proximal tubular cells, megalin (gp330). However, the target autoantigen in humans can not be megalin as it is absent from human podocytes.

A majority of patients with idiopathic membranous nephropathy have been found to have IgG4 type autoantibodies against phospholipase receptor A2 (PLA2R), a glycoprotein protein constituent of normal glomeruli. PLA2R is present in normal human podocytes and in immune deposits in patients with idiopathic membranous nephropathy, indicating that PLA2R could be a major autoantigen in this disease; it is linked to HLA-DQA1. Specific IgG4 autoantibodies to anti-aldose reductase (AR) and anti-manganese superoxide dismutase (SOD2) have also been found in the sera and glomeruli of patients with membranous nephropathy but not in other renal pathologies or normal kidney. This suggests that AR and SOD2 could be additional renal autoantigens of human membranous nephropathy under certain clinical circumstances.

**Treatment**

There is no consensus on therapies for all cases but, in general, patients with moderate to heavy proteinuria are treated:

- Oral high-dose corticosteroids and azathioprine are not associated with any significant benefits.
- The alkyating agents, cyclophosphamide and chlorambucil, are both effective in the management of membranous GN but are reserved for patients with severe or prolonged nephrosis (i.e. proteinuria >6 g/day for >6 months), renal insufficiency and hypertension. There is a high likelihood of progression to ESKD.
- Chlorambucil (0.2 mg/kg per day in months 2, 4 and 6 alternating with oral prednisolone 0.4 mg/kg per day in months 1, 3 and 5) or cyclophosphamide (1.5–2.5 mg/kg per day for 6–12 months with 1 mg/kg per day of oral prednisolone on alternate days for the first 2 months) are equally effective.
- Ciclosporin and mycophenolate with oral steroids may become the agents of choice.
- Anti-CD20 antibodies (rituximab, which ablates B lymphocytes) have been shown to improve renal function, reduce proteinuria and increase the serum albumin; no significant adverse affects have been shown in the short term.

**Amyloidosis** (see p. 1042)

Amyloidosis is an acquired or inherited disorder of protein folding, in which normally soluble proteins or fragments are deposited extracellularly as abnormal insoluble fibrils causing progressive organ dysfunction and death.

**Pathology**

On light microscopy, eosinophilic deposits are seen in the mesangium, capillary loops and arteriolar walls. Staining with Congo red renders these deposits pink and they show green birefringence under polarized light (Fig. 12.16). Immunofluorescence is unhelpful, but on electron microscopy the characteristic fibrils of amyloid can be seen. Amyloid consisting of immunoglobulin light chains (AL amyloid) can be identified by immunohistochemistry in only 40% of the cases as compared to almost 100% of patients with protein found in secondary amyloid (AA amyloid). Amyloid A (AA) amyloidosis, also referred to as secondary amyloidosis, is a rare but serious complication of chronic inflammatory diseases and chronic infections.

![Figure 12.16 Amyloid.](image)

(a) Light microscopy of eosinophilic amyloid deposits (arrow). (b) Congo red stain under polarized light showing apple green birefringence.
Diagnosis and treatment

The diagnosis can often be made clinically when features of amyloidosis are present elsewhere. On imaging, the kidneys are often large. Scintigraphy with radiolabelled serum amyloid P (SAP), a technique for quantitatively imaging amyloid deposits in vivo, is used to detect the rate of regression or progression of amyloidosis over a period of time (p. 1043). Renal biopsy is necessary in all suspected cases of renal involvement.

Treatment. Treatments that reduce production of the amyloidogenic protein can improve organ function and survival in immunoglobulin-Light-chain-related (AL) amyloidosis and hereditary transthyretin-associated (ATTR) amyloidosis (see p. 1042).

In AA amyloidosis, production of serum amyloid A can sometimes be decreased by treatment of the underlying inflammatory condition but cannot be completely suppressed. A new class of drug, eprodisate (see p. 1043), has shown modest success in patients with renal amyloidosis.

Renoprotective measures should be started (p. 622). The success of dialysis and kidney transplantation is dependent upon the extent of amyloid deposition in extrarenal sites, especially the heart.

Diabetic nephropathy

Diabetic renal disease is the leading cause of ESKD in the western world. People with type 1 and type 2 diabetes (see p. 1025) have equivalent rates of proteinuria, azotaemia, and ultimately ESKD. Both types of diabetes show strong similarities in their rate of renal functional deterioration, and onset of co-morbid complications.

Pathology

The kidneys enlarge initially and there is glomerular hyperfiltration (GFR >150 mL/min). The major early histological lesions seen are glomerular basement membrane thickening and mesangial expansion. Moreover, progressive depletion of podocytes (p. 573) from the filtration barrier due to either apoptosis or detachment and resulting podocyturia appears to be a very early ultrastructural change. Later, glomerulosclerosis develops with nodules (Kimmelstiel–Wilson lesion) and hyaline deposits in the glomerular arterioles (Fig. 12.17).

It has recently been shown that the mesangial expansion and the hyalinosis are partly due to amylin (beta islet specific amyloidogenic protein) deposits. These later changes are associated with heavy proteinuria. The lesions seen in type 1 are also seen in type 2.

The Renal Pathology Society has developed a consensus classification combining type 1 and type 2 diabetic nephropathies (Table 12.5). This discriminates lesions by various degrees of severity for use in international clinical practice.

The pathophysiology is discussed on page 1025.

Treatment

Lifestyle changes (cessation of smoking and increase in exercise), hypertension, poor metabolic regulation and hyperlidaemia should be addressed in every diabetic. Microalbuminuria is a reason to start treatment with ACE inhibitors or an angiotensin II receptor antagonist (AIIRA) in either type of diabetes, regardless of blood pressure elevation. Like other kidney diseases, however, nearly the entire course of renal injury in diabetes is clinically silent. The timing of medical intervention during this silent phase (see Box 12.6) is renoprotective, as judged by slowed loss of glomerular filtration. Despite intensified metabolic control and antihypertension treatment in patients with diabetes, a substantial number still go on to develop ESKD. In a randomized controlled trial, the addition of paricalcitol (a selective activator of the vitamin D receptor) to treatment with ACE inhibitors reduced albuminuria (a surrogate marker of progressive renal disease) in patients with type 2 diabetes. Paricalcitol worked best in patients with a high sodium intake in their diet, who respond poorly to ACE inhibitor and ARB therapy.

Nephrotic syndrome with ‘active’ urine sediments (mixed nephrotic/nephritic)

Mesangiocapillary (membranoproliferative) glomerulonephritis (MCGN)

This uncommon lesion has three subtypes with similar clinical presentations: the nephrotic syndrome, haematuria, hypertension and renal impairment. They also have similar microscopic findings although the pathogenesis may be different. Electron microscopy defines:

- **Type 1 MCGN.** There is mesangial cell proliferation, with mainly subendothelial immune deposit and apparent splitting of the capillary basement membrane, giving a ‘tram-line’ effect. It can be associated with persistently reduced plasma levels of C3 and normal levels of C4 due to activation of the complement cascade by the classical pathway. It is often idiopathic but occurs with chronic infection (abscesses, infective endocarditis, infected ventriculoperitoneal shunt) or cryoglobulinaemia secondary to hepatitis C infections (Fig. 12.18a).

- **Type 2 MCGN.** There is mesangial cell proliferation with electron-dense, linear intramembranous deposits that usually stain for C3 only (Fig. 12.18b). This type may be
idiopathic or be associated with partial lipodystrophy (loss of subcutaneous fat on face and upper trunk). MCGN affects young adults. These patients have low C3 levels as in type 1 but this is due to the activation of the alternative pathway of the complement cascade; they also have autoantibodies to C3 convertase enzyme.

**Type 3 MCGN** has features of both types 1 and 2. Complement activation appears to be via the final common pathway of the cascade.

Most patients eventually go on to develop ESKD over several years. Type 2 MCGN recurs in virtually 100% of renal transplant patients but recurrence is less common in type 1 (25%). However, recurrence does not interfere with long-term graft function.

**Management**

In idiopathic MCGN (all age groups) with normal renal function, non-nephrotic range proteinuria, no specific therapy is required. Follow-up every 4 months, with specific attention to blood pressure control, is required.

In children with the nephritic syndrome and/or impaired renal function, a trial of steroids is warranted (alternate-day prednisolone 40 mg/m² for a period of 6–12 months). If no benefit is seen, this treatment is discontinued. Regular follow-up with control of blood pressure, use of agents to reduce proteinuria and correction of lipid abnormalities is necessary.

In adults with the nephritic syndrome and/or renal impairment, aspirin (325 mg) or dipyridamole (75–100 mg) daily or a combination of the two, should be given for 6–12 months. Again, if no benefits are seen, the treatment should be stopped. Treatment to slow the rate of progression of CKD is instituted (p. 622).

**Mesangial proliferative GN (IgM nephropathy, C1q nephropathy)**

In addition to minimal-change disease, there are two other disorders that usually present with heavy proteinuria with only minor changes on light microscopy.

**IgM nephropathy** is characterized by increased mesangial cellularity in most of the glomeruli, associated with granular immune deposits (IgM and complement) in the mesangial regions. People present with episodic or persistent haematuria with the nephrotic syndrome. Unlike minimal-change disease, the prognosis is not uniformly good, as steroid response is only 50%. Between 10% and 30% develop progressive renal insufficiency with evidence of secondary FSGS (p. 576) on repeat biopsy. A trial of cyclophosphamide with prednisolone is used with persistent nephrotic syndrome, particularly with a rising plasma creatinine concentration.

**C1q nephropathy** is very similar to IgM nephropathy in presenting features and microscopic appearance with the exception of C1q deposits in the mesangium. Sometimes it is misdiagnosed as lupus nephritis, particularly in people with negative serology (so-called ‘seronegative lupus’). The distinguishing features are intense C1q staining and absence of tubuloreticular inclusions (attributable to high circulating α-interferon) on electron microscopy. Only some people are steroid dependent. Progression to CKD is, as in most glomerular diseases, most likely to occur in people with heavy proteinuria and renal insufficiency.

**Systemic lupus erythematosus (lupus glomerulonephritis)**

Overt renal disease occurs in at least one-third of SLE patients and, of these, 25% reach end-stage CKD within 10 years (see also p. 536). Histologically, almost all patients will have changes. Box 12.2 shows the progression of histological findings and the clinical picture from classes I to VI.

Serial renal biopsies show that in approximately 25% of patients, histological appearances change from one class to another during the interbiopsy interval. Immune deposits in the glomeruli and mesangium are characteristic of SLE (tubuloreticular structure in glomerular endothelial cells) and stain positive for IgG, IgM, IgA and the complement components C3, C1q and C4 on immunofluorescence.

**Pathophysiology**

SLE is now known to be an autoantigen-driven, T-cell-dependent and B-cell-mediated autoimmune disorder (p. 535).

Lupus nephritis typically has circulating autoantibodies to cellular antigens (particularly anti-dsDNA, anti-Ro) and complement activation which leads to reduced serum levels of C3, C4, and particularly C1q. C1q is the first component of the classical pathway of the complement cascade (see p. 51) and is involved in the activation of complement and clearance of self-antigens generated during apoptosis. Anti-C1q antibodies may help in distinguishing a renal from a non-renal relapse. However, not all autoantibodies are pathogenic to the kidney. These nephrologic antibodies have specific physicochemical characteristics and correlate well with the pattern of renal injury. DNA was thought to be the inciting autoantigen, but nucleosomes (structures comprising DNA and histone, generated during apoptosis) are the most likely
Box 12.2 Classification of lupus nephritis

Class I – Minimal mesangial lupus nephritis (LN), with immune deposits but normal on light microscopy. Asymptomatic.

Class II – Mesangial proliferative LN with mesangial hypercellularity and matrix expansion. Clinically, mild renal disease.

Class III – Focal LN (involving <50% of glomeruli) with subdivisions for active or chronic lesions. Subepithelial deposits seen. Clinically have haematuria and proteinuria; 10–20% of all LN.

Class IV – Diffuse LN (involving >50% of glomeruli) (Fig. 12.19) classified by the presence of segmental and global lesions as well as active and chronic lesions. Subendothelial deposits are present. Clinically, there is progression to the nephrotic syndrome, hypertension and renal insufficiency. Most common and most severe form of LN.

Class V – Membranous LN affects 10–20% of patients. Can occur in combination with III or IV. Good prognosis.

Class VI – Advanced sclerosing LN (>90% globally sclerosed glomeruli without residual activity). This represents the advanced stages of the above, as well as healing. Immunosuppressive therapy is unlikely to help as it is ‘inactive’. Progressive CKD.

Figure 12.19 Lupus nephritis type IV – a diffuse proliferative nephritis. There is proliferation of endothelial and mesangial cells.

autoantigen. Nucleosome-specific T cells, antinucleosome antibodies and nephritogenic immune complexes are generated. Positively charged histone components of the nucleosome bind to the negatively charged heparan sulphate (within the glomerular basement membrane) inciting an inflammatory reaction and resulting in mesangial cell proliferation, mesangial matrix expansion and inflammatory leukocytes. Other pathogenic mechanisms include infarction of glomerular segments, thrombotic microangiopathy, vasculitis and glomerular sclerosis.

Although humoral responses are the main effector mediators of lupus nephritis, IgE autoantibodies, basophils and type 2 helper (Th2) cells are also involved. IgE-containing immune complexes trigger circulating basophils (thought to play a role in SLE) to home in on secondary lymphoid organs and express MHC class II. In secondary lymphoid organs, these activated basophils secrete interleukin-4 and thus promote Th2 cell differentiation. Th2 cells, in cooperation with basophils, enhance B-cell differentiation and survival, and the production of autoreactive antibodies. The immune complexes in which these autoreactive antibodies are present are subsequently deposited in glomeruli and most likely cause lupus nephritis.

The extraglomerular features of lupus nephritis include tubulointerstitial nephritis (75% of patients), renal vein thrombosis and renal artery stenosis. Thrombotic manifestations are associated with autoantibodies to phospholipids (anticardiolipin or lupus anticoagulant) (p. 538).

Management

Initial treatment depends on the clinical presentation but hypertension and oedema should always be treated. A definite histopathological diagnosis is required. Type I requires no treatment. Type II usually runs a benign course but some patients are treated with steroids.

There have been a number of clinical trials with immunosuppressive agents have been trialled in types III, IV and V which are the most severe form of lupus nephritis. Outcomes of these types are affected by ethnicity, clinical characteristics, irreversible damage (on renal biopsy), initial response to treatment and the future frequency of renal flares.

Steroids and high-dose intravenous cyclophosphamide or mycophenolate mofetil (MMF) are usually used for induction. In white populations, low-dose cyclophosphamide is a good alternative to high-dose cyclophosphamide as it is similarly effective and associated with less toxicity.

Mycophenolate mofetil is as effective as high-dose intravenous cyclophosphamide in the induction phase with a similar safety profile but cyclophosphamide may be inferior to MMF in black and Hispanic people.

Most patients respond to induction therapy. Remission is maintained with MMF (superior to azathioprine) and azathioprine, which is similar in effectiveness to ciclosporin in reducing the risk of relapse.

B cell depletion with rituximab (anti-CD20) has been used in some patients with favourable results over the short term. However, controlled trials have not shown consistent results. It might be useful in severe, refractory lupus nephritis.

Prognosis

Treatment leading to the normalization of proteinuria, hypertension and renal dysfunction indicates a good prognosis. The prognosis is better in patients with types I, II and V. Glomerulosclerosis (type VI) usually predicts end-stage renal disease (p. 581).

Cryoglobulaemia renal disease

Cryoglobulins (CG) are immunoglobulins and complement components, which precipitate reversibly in the cold. Three types are recognized:

Type I: the cryoprecipitable immunoglobulin is a single monoclonal type, as is found in multiple myeloma and lymphoproliferative disorders.

Types II and III cryoglobulaemias are mixed types. In each, a polyclonal IgG antigen is bound to an antiglobulin. In type II, the antiglobulin component, which is usually of the IgM or IgA class with rheumatoid factor activity, is monoclonal, while in type III it is polyclonal. Type II CGs account for 40–60% cases, while 40–50% of all CG cases are of type III.

Glomerular disease is more common in type II than in type III cryoglobulaemia. In approximately 30% of these ‘mixed’ cryoglobulaemias, no underlying or associated disease is found (essential cryoglobulaemia). Recognized associations include viral infections (hepatitis B and C, HIV, cytomegalovirus, Epstein–Barr infection), fungal and spirochaetal infections, malaria and infective endocarditis and autoimmune rheumatic diseases (SLE, rheumatoid arthritis and Sjögren’s syndrome). Glomerular pathological changes resemble MCGN (Fig. 12.18).
Presentation is usually in the 4th or 5th decades of life, and women are more frequently affected than men. Systemic features include purpura, arthralgia, leg ulcers, Raynaud’s phenomenon, evidence of systemic vasculitis, a polyneuropathy and hepatic involvement. The glomerular disease presents typically as asymptomatic proteinuria, microscopic haematuria or both, but presentation with an acute nephritic and nephrotic syndrome (commonest presentation) or features of CKD also occurs.

A reduction in concentration of early complement components with an elevation of later components, detection of CGs, monoclonal gammapathy, rheumatoid factor, autoantibodies and antiviral antibodies or mRNA of hepatitis C, depending on the associated disorder, is seen.

Spontaneous remission occurs in about one-third of cases and approximately one-third pursue an indolent course. Corticosteroid and/or immunosuppressive therapy with cyclophosphamide may be of benefit, but evaluation of treatment is difficult owing to the rarity of the disease and the occurrence of spontaneous remissions. Intensive plasma exchange or cryofiltration has been used in selected cases. Interferon with ribavirin reduces the viraemia in hepatitis C but does not influence the cryoglobulinaemia. Uncontrolled studies of the anti-CD20 chimeric monoclonal antibody rituximab, which depletes B cells, appear promising, reporting improvement in general manifestations as well as glomerulonephritis.

Henoch–Schönlein syndrome (purpura)
This clinical syndrome comprises a characteristic skin rash, abdominal colic, joint pain and glomerulonephritis. Approximately 30–70% have clinical evidence of renal disease with haematuria and/or proteinuria. The renal disease is usually mild but the nephrotic syndrome and acute kidney injury can occur. The renal lesion is a focal segmental proliferative glomerulonephritis, sometimes with mesangial hypercellularity. In the more severe cases, epithelial crescents may be present. Immunoglobulin deposition is mainly IgA in the glomerular mesangium distribution, similar to IgA nephropathy. There is no treatment of proven benefit; steroid therapy is ineffective. Treatment is usually supportive but with crescentic GN aggressive immunosuppression has been tried with variable outcome.

Idiopathic fibrillary glomerulopathy
In this rare condition, characteristic microfibrillar structures are seen in the mesangium and glomerular capillary wall on electron microscopy that are clearly different from those seen in amyloidosis; the fibrils are larger than those in amyloidosis (20–30 vs 10 nm diameter) and do not stain with Congo red. The median age at presentation is approximately 45 years (range 10–80 years). People present with proteinuria, mostly in the nephrotic range (60%), and microscopic haematuria (70%), hypertension and CKD (50%) that may progress rapidly; 40–50% of patients develop ESKD within 2–6 years.

No treatment is known to be of benefit, although isolated instances of an apparent response to corticosteroid and immunosuppressive therapy have been reported.

Immunotactoid glomerulopathy
In this disorder, microtubules which are much larger (30–40 nm diameter) than the fibrils in fibrillary glomerulopathy are seen on electron microscopy. The majority of patients have circulating paraproteins, or monoclonal immunoglobulin deposition is seen in the glomeruli on immunofluorescence microscopy. A lymphoproliferative disease is the underlying cause in over 50% of cases. The clinical presentation and course are similar to fibrillary glomerulopathy. Complete or partial remission of the nephrotic syndrome can be achieved by various chemotherapeutic agents in over 80% of patients.

Fibronectin glomerulopathy
This is also a form of glomerulonephritis due to fibrillar deposits which, unlike amyloidosis but like fibrillary glomerulonephritis and immunotactoid glomerulopathy, is Congo red staining negative. It is inherited as an autosomal dominant disorder and is associated with the massive deposition of fibronectin, a large dimeric glycoprotein consisting of two similar subunits (approximately 250 kDa in weight). The possible genetic abnormality in this disorder is a loss of function mutation in uteroglobin.

Fibronectin glomerulopathy is extremely rare and was originally described only in Caucasians of European descent. An Asian family with this disease has since been reported. There are as yet no known cases in black or Hispanic people. It presents with varying degrees of proteinuria seen first between the ages of 20 and 40. This is followed by hypertension, microscopic haematuria, and slow progression to end-stage renal disease in most patients. Diagnosis is confirmed by renal biopsy which demonstrates enlarged glomeruli with minimal proliferation and massive Congo red negative fibrillary deposits in the capillary walls.

Treatment includes nonspecific measures such as adequate blood pressure control by blockade of the renin-angiotensin system. ESKD patients are treated with dialysis, and recurrence of disease following renal transplant has been noted.

Acute glomerulonephritis (acute nephritic syndrome) (Table 12.6)
This comprises:
- Haematuria (macroscopic or microscopic) – red-cell casts are typically seen on urine microscopy
- Proteinuria
- Hypertension
- Oedema (periorbital, leg or sacral)
- Temporarily oliguria and uraemia

The histological pattern is characterized by cellular proliferation (mesangial and endothelial) and inflammatory cell infiltration (neutrophils, macrophages).

Post-streptococcal glomerulonephritis (PSGN)
The patient, usually a child, suffers a streptococcal infection 1–3 weeks before the onset of the acute nephritic infection.

Glomerulonephritis with infective endocarditis

GN occurs rarely in patients with infective endocarditis (usually i.v. drug users). It usually manifests itself as the acute nephritic syndrome. A similar presentation is in patients with infected ventriculoperitoneal shunt (shunt nephritis). Microscopic appearances resemble post-infectious GN, but lesions are usually focal and segmental. Crescentic GN with acute kidney injury has been described, particularly with Staphylococcus aureus infection. Appropriate antibiotic therapy or surgical eradication of infection in fulminant cases (embolic infarct of the kidney) usually results in a return of normal renal function.

Glomerulonephritis associated with visceral abscesses (mainly pulmonary)

Clinical and microscopic features are indistinguishable from post-infectious GN, but usually complement levels are normal and immune deposits are absent on biopsy. Antibiotic therapy and surgical drainage of the abscess result in complete recovery of renal function in approximately 50% of patients.

Asymptomatic urinary abnormalities

A variety of renal lesions may present as either isolated proteinuria or haematuria, alone or with proteinuria. Isolated proteinuria without haematuria in asymptomatic patients is usually an incidental finding. It is usually in the sub-nephrotic range without an active urine sediment and there is normal renal function. Over 50% of these patients have postural proteinuria. The outcome of isolated proteinuria (postural or non-postural) is excellent in the majority of patients, with a gradual decline in proteinuria. Occasionally, it may be an early sign of a serious glomerular lesion such as membranous GN, IgA nephropathy, FSGS, diabetic nephropathy or amyloidosis. Moreover, mild proteinuria may accompany a febrile illness, congestive heart failure or infectious diseases with no clinical renal significance.

Haematuria with or without sub-nephrotic range proteinuria in an asymptomatic patient may lead to early discovery of potentially serious glomerular disease such as SLE, Henoch–Schönlein purpura, post-infectious GN or idiopathic hypercalciuria in children. Asymptomatic haematuria is also the primary presenting manifestation of a number of specific glomerular diseases discussed below.

IgA nephropathy (Fig. 12.21)

This disease has replaced post-streptococcal glomerulonephritis as the commonest form of glomerulonephritis worldwide. Demographic and family studies support the existence of a genetic contribution to the pathogenesis of IgA nephropathy.

Management

The acute phase should be treated with antihypertensives, diuretics, salt restriction and dialysis as necessary. If recovery is slow, corticosteroids may be helpful. The prognosis is usually good in children. A small number of adults develop hypertension and/or CKD later in life. Therefore in older patients, an annual blood pressure check and measurement of serum creatinine are required. Evidence in support of long-term penicillin prophylaxis after the development of glomerulonephritis is lacking. In non-streptococcal post-infectious glomerulonephritis, prognosis is equally good if the underlying infection is eradicated.
nephropathy, but results from genetic association studies of candidate genes are inconsistent. In a genome-wide analysis study conducted in European patients showed a strong association on chromosome 6p in the region of the MHC/DQ and HLA-B loci. These results suggest that the HLA region contains the strongest common susceptibility alleles that predispose to IgA nephropathy in the European population.

### Histology

There is a focal and segmental proliferative glomerulonephritis with mesangial deposits of polymeric IgA1. In some cases IgG, IgM and C3 are also seen in the glomerular mesangium.

A new Oxford histological classification for IgA nephropathy is shown in Table 12.7. The features have prognostic significance and it is recommended that they be taken into account for predicting outcome independent of the clinical features both at the time of presentation and during follow-up.

### Pathogenesis

The disease may be a result of an exaggerated bone marrow and tonsillar IgA1 immune response to viral or other antigens and is associated with an abnormality in O-linked galactosylation in the hinge region of the IgA1 molecule. Functional abnormalities of two IgA receptors – CD89 expressed on blood myeloid cells and the transferring receptor (CD71) on mesangial cells – are seen. IgA nephropathy is due to circulating immune complexes composed of a glycanspecific IgG and a galactose-deficient IgA1 antibody which deposit in the glomerular mesangium and induce the mesangioproliferative glomerulonephritis characteristic of IgA nephropathy. Removal of the complexes by bacterial proteases results in attenuation of IgA nephropathy. Available evidence suggests that glycanspecific autoantibodies rather than IgA1 itself may play a key role in the pathogenesis.

Up to 50% of patients exhibit elevated serum IgA (polyclonal) concentration. Superimposed crescent formation is frequent, particularly following macroscopic haematuria due to upper respiratory tract infection.

Several diseases are associated with IgA deposits, including Henoch–Schönlein purpura, chronic liver disease, malignancies (especially carcinoma of bronchus), seronegative spondyloarthritis, coeliac disease, mycosis fungoides and psoriasis.

### Clinical presentation

IgA nephropathy tends to occur in children and young males. They present with asymptomatic microscopic haematuria or recurrent macroscopic haematuria sometimes following an upper respiratory or gastrointestinal viral infection. Proteinuria occurs and 5% can be nephrotic. The prognosis is usually good, especially in those with normal blood pressure, normal renal function and absence of proteinuria at presentation. Surprisingly, recurrent macroscopic haematuria is a good prognostic sign, although this may be due to ‘lead-time bias’ (p. 436), as patients with overt haematuria come to medical attention at an earlier stage of their illness. The risk of eventual development of ESKD is about 25% in those with proteinuria of more than 1 g per day, elevated serum creatinine, hypertension, ACE gene polymorphism (DD isoform) and tubulointerstitial fibrosis on renal biopsy.

### Management

Patients with proteinuria over 1–3 g/day, mild glomerular changes only and preserved renal function should be treated with steroids. Steroids reduce proteinuria and stabilize renal function. Addition of azathioprine to steroids does not confer additional benefits. The combination of cyclophosphamide, dipyridamole and warfarin should not be used, nor should ciclosporin. In patients with progressive disease (eGFR <60 mL/min) fish oil or prednisolone with cyclophosphamide for 3 months followed by maintenance with prednisolone and azathioprine may be tried. A tonsillectomy can reduce proteinuria and haematuria in those patients with recurrent tonsillitis. All patients, with or without hypertension and proteinuria, should receive a combination of ACE inhibitor and angiotensin II receptor antagonist which enhances reduction of proteinuria and preservation of renal function. Mesangial IgA deposits are commonly found in the allografts of transplanted patients but loss of graft function as a result is uncommon.

### Alport’s syndrome

Alport’s syndrome is a rare condition characterized by an hereditary nephritis with haematuria, proteinuria (<1–2 g/day), progressive kidney disease and high-frequency nerve deafness. Approximately 15% of cases may have ocular abnormalities such as bilateral anterior lenticonus and macular and perimacular retinal flecks. In about 85% of patients with Alport’s syndrome there is X-linked inheritance of a mutation in the COL4A5 gene encoding the COL4A5 collagen chain. In female carriers, penetrance is variable and depends on the type of mutation or degree of mosaicism following hybridization of the X chromosome. Patients with autosomal recessive or dominant modes of inheritance have also been described with mutations in COL4A3 or COL4A4 genes. In families with stromal cell tumours there is an additional mutation in the COL4A6 gene.

Mutations present in Alport’s syndrome that produce post-translational defects in α3, α4 and α5 chains result in

*Mesangial hypercellularity is scored zero (0) for glomeruli with <4 mesangial cells per mesangial area; 1 for those with 4–5 cells; 2 for 6–7 cells; and 3 for ≥8 cells. Scores obtained for all glomeruli are then averaged.
incorrect assembly or folding of monomers; such defective monomers are rapidly degraded. These mutations arrest the normal developmental switch and cause the persistence of embryonic α1, α1 and α2 networks in glomerular basement membrane. These networks are more susceptible to endoproteolysis and oxidative stress than the α3, α4 and α5 network. Over time, patients with Alport’s syndrome probably become more sensitive to selective basement membrane proteolysis, which may explain why their glomerular membranes thicken unevenly, split and ultimately deteriorate.

The primary glomerular filtration barrier of the glomerular capillary consists of the basement membrane and the outer slit diaphragm formed between adjacent podocytes. Loss of slit function causes massive proteinuria (congenital nephrotic syndrome, p. 576) but deterioration of glomerular basement membrane produces only mild proteinuria. The mild proteinuria in Alport’s syndrome is the result of glomerular sclerosis, rather than primary loss of slit pores. In pedigrees with a history of CKD, disease progresses from concomitant interstitial fibrosis, macrophage and lymphocyte infiltration secondary to tubular basement disruption and transdifferentiation of epithelial mesenchymal cells to fibroblasts. This fibrogenic response destroys renal architecture. The renal histology characteristically shows split basement membrane. In some patients with Alport’s syndrome and carriers, thin basement membrane, as seen in benign familial haematuria, is the only abnormality detected on histology. For this reason, the boundary between Alport’s and benign familial haematuria has become increasingly vague.

**Management**

The disease is progressive and accounts for some 5% of cases of ESKD in childhood or adolescence. Patients with mild CKD can be treated with ACE inhibitors to attenuate proteinuria. Exciting experimental evidence suggests that mesenchymal stem cells can transdifferentiate into podocytes and repair basement abnormalities and slow the rate of progression. Anti-GBM antibody does not adhere normally to the glomerular basement membrane of affected individuals but development of crescentic glomerulonephritis in the transplanted kidney due to anti-GBM alloantibody is a well-recognized complication.

**Thin glomerular basement membrane disease**

This condition is inherited as an autosomal dominant and typically presents with persistent microscopic glomerular haematuria (RBC casts or dysmorphic RBCs). The diagnosis is made by renal biopsy, which shows thinning of the glomerular capillary basement membrane on electron microscopy. The condition was underdiagnosed and is much commoner than previously believed. The prognosis for renal failure is usually very good but some patients develop renal insufficiency over decades. The cause of renal impairment in this condition is not known but may be due to secondary FSGS or concomitant IgA nephropathy. Misdiagnosis occurs with Alport’s syndrome which shares similar histological features. No treatment is of known benefit.

**C3 glomerulonephritis/complement factor H-related protein 5 (CFHR5) nephropathy**

This newly described familial renal disease mainly affects people of Cypriot origin and is an autosomal dominant trait. It is characterized by persistent microscopic hematuria, synpharyngitic macroscopic hematuria and progressive CKD culminating in ESKD. Typically there is isolated glomerular accumulation of complement component 3 (C3) with variable degrees of glomerular inflammation. Patients have a heterozygous duplication in the CFHR5 gene; however, how this results in renal disease is not understood. Recurrence after renal transplantation suggests that CFHR5 protein derived from the new kidney cannot prevent the development of CFHR5 nephropathy.

CFHR5 nephropathy should be included in the differential diagnosis of familial haematuria and kidney disease, particularly if renal biopsy shows C3 deposition in the kidney. Even though IgA nephropathy with microscopic haematuria accompanied by macroscopic haematuria after an upper respiratory tract infection remains highly prevalent, CFHR5 nephropathy shares these features.

Standard CKD intervention is the only therapy which can be offered to these patients like in any other form of progressive kidney disease.

**Rapidly progressive glomerulonephritis (RPGN)**

RPGN is a syndrome with glomerular haematuria (RBC casts or dysmorphic RBCs), rapidly developing acute kidney failure over weeks to months and focal glomerular necrosis (Fig. 12.22) with or without glomerular crescent development on renal biopsy. The ‘crescent’ is an aggregate of macrophages and epithelial cells in Bowman’s space (Fig. 12.22). RPGN can develop with immune deposits (anti-GBM or immune complex type, e.g. SLE) or without immune deposits (pauci-immune, e.g. anti-PR3 and or anti-MPO-ANCA positive vasculitides). It can also develop as an idiopathic primary glomerular disease or can be superimposed on secondary glomerular diseases such as IgA nephropathy, membranous GN and post-infective GN. The classification used here is based on the immunofluorescence information obtained from renal histology (Table 12.8), viz linear, granular and negative immunofluorescent patterns.

**Anti-GBM glomerulonephritis** (Fig. 12.23a)

Anti-GBM glomerulonephritis, characterized by linear capillary loop staining with IgG and C3 and extensive crescent formation, accounts for 15–20% of all cases of RPGN, although overall it accounts for less than 5% of all forms of glomerulonephritis. This condition is rare, with an incidence of 1 per 2 million in the general population. About two-thirds of these patients have Goodpasture’s syndrome with associated lung haemorrhage (p. 850). The remainder have a renal restricted anti-GBM RPGN, which is seen in patients over 50 years and affects both genders equally.

Anti-GBM antibodies (detected by ELISA) are present in serum and are directed against the non-collagenous (NCI) component of α3 (IV) collagen of basement membrane. This target antigen must be present as a component of the native
α3, α4, α5 (IV) network of selected basement membrane in order for pulmonary and renal disease to develop. Consequently, there are no known cases of anti-GBM glomerulonephritis in patients with Alport’s syndrome (p. 584). However, the α3, α4, α5 (IV) network is also a target for anti-GBM alloantibodies in Alport’s syndrome (see this chapter) post-transplantation glomerulonephritis, which occurs in 3–5% of patients with Alport’s syndrome and results in allograft loss. Alport’s post-transplantation nephritis is mediated by the deposition of alloantibodies to the α3NC1 and α5NC1 domains in response to the ‘foreign’ α3, α4, α5 (IV) collagen network that is absent in the patient’s own kidneys with Alport’s syndrome but present in the renal allograft. Alloantibodies in Alport’s syndrome patients bind to epitopes in intact cross-linked α345NC1 hexamers. In contrast, autoantibodies in Goodpasture’s syndrome bind to epitopes in α3NC1 hexamers only if dissociated first to unmask hidden epitopes.

Anti-GBM RPGN is restricted by the major histocompatibility complex; HLA-DRB1*1501 and HLA-DRB1*1502 alleles increase susceptibility, whereas HLA-DR7 and HLA-DR1 are protective. The thymus expresses α3 (IV) NC1 peptides that can eliminate autoreactive CD4+ helper T cells, but a few such cells escape deletion and are kept in check by circulating regulatory cells (Treg). Breakdown of this peripheral tolerance (the mechanism of which is unknown) results in autoreactive CD4+ cells producing anti-GBM antibodies. These antibodies are very specific as shown by the fact that antibodies against α1, α1 and α2 NC1 domains do not cause RPGN. Since the α3 (IV) NC1 epitope is hidden within the α3, α4 and α5 (IV) promoter, it is presumed that an environmental factor, such as exposure to hydrocarbons or tobacco smoke, is required in order to reveal cryptic epitopes to the immune system.

The mechanism of renal injury is complex. When anti-GBM antibody binds basement membrane it activates complement and proteases and results in disruption of the filtration barrier and Bowman’s capsule, causing proteinuria and the formation of crescents. Crescent formation is facilitated by interleukin-12 and γ-interferon which are produced by resident and infiltrating inflammatory cells.

**Management**

This is based on counteracting the factors involved in the pathogenesis and employs:

- **Plasma exchange** to remove circulating antibodies
- **Steroids** to suppress inflammation from antibody already deposited in the tissue
- **Cyclophosphamide** to suppress further antibody synthesis.

The prognosis is directly related to the extent of glomerular damage (measured by percentage of crescents, serum creatinine and need for dialysis) at the initiation of treatment. When oliguria occurs or serum creatinine rises above 600–700 μmol/L, renal failure is usually irreversible. Once the active disease is treated, this condition, unlike other autoimmune diseases, does not follow a remitting/relapsing course. Furthermore, if left untreated, autoantibodies diminish spontaneously within 3 years and autoreactive T cells cannot be detected in the convalescent patients. This is suggestive of re-establishment of peripheral tolerance which coincides with re-emergence of regulatory CD25+ cells in the peripheral blood: these play a key role in inhibiting the autoimmune response. The emergence and persistence of these regulatory cells may underlie the ‘single hit’ nature of this condition.

**ANCA-positive vasculitides** (see also p. 544)

Inflammation and necrosis of the blood vessel wall occurs in many primary vasculitic disorders. Wegener’s granulomatosis, microscopic polyangiitis and Churg–Strauss syndrome are described as small vessel vasculitides and are commonly associated with antineutrophil cytoplasm antibodies (ANCA).

**Figure 12.23**  
**Immunofluorescence.** (a) Showing antiglomerular basement membrane antibody (anti-GBM) deposition in a linear pattern typical of Goodpasture’s syndrome. (b) Showing immune complex deposition in a diffuse granular pattern.
These diseases share common pathology with focal necrotizing lesions, which affect many different vessels and organs; in the lungs, a capillaritis may cause lung haemorrhage; within the glomerulus of the kidney, crescentic GN and/or focal necrotizing lesions (FNGN) may cause acute kidney injury (Fig. 12.22); in the dermis, a purpuric rash or vasculitic ulceration. Wegener’s and Churg–Strauss syndrome may have additional granulomatous lesions.

Renal histology is regarded as a ‘gold standard’ for the diagnosis and prognostication of ANCA-associated GN. A consensus group proposed a new classification around four general categories of lesions:

- **Focal** (≥50% normal glomeruli that are not affected by the disease process)
- **Crescentic** (≥50% of glomeruli with cellular crescents)
- **Mixed** (a heterogeneous glomerular phenotype wherein no glomerular feature predominates)
- **Sclerotic** (≥50% of glomeruli with global sclerosis).

This system has been shown to have a prognostic value for 1- and 5-year renal outcomes. It is believed that it will aid in the prognostication of patients at the time of diagnosis and facilitate uniform reporting between centers. This classification at some point might also provide a means to guide therapy.

**Pathogenesis**

There are two forms of ANCA (p. 544), viz PR3-ANCA (cANCA) and MPO-ANCA (pANCA). If ELISA and indirect immunofluorescence techniques are combined, diagnostic specificity is 99%. Testing for antineutrophil cytoplasmic autoantibodies should be accompanied by appropriate tests of autoantibodies directed against DNA and the glomerular basement membrane antigen. The simultaneous occurrence of ANCA and anti-GMB antibody is well documented; such patients tend to follow the natural history of Goodpasture’s syndrome. Variations in the ANCA titres have been used in the assessment of disease activity.

- **PR3-ANCA positivity** is found in the large majority (>90%) of patients with active Wegener’s granulomatosis and in up to 50% of patients with microscopic polyangiitis.
- **Anti-MPO positivity** is present in the majority of patients with idiopathic crescentic glomerulonephritis and in a variable number of cases of microscopic polyangiitis. There is some evidence to suggest that ANCA are pathogenic and not just markers of disease; for example, development of drug-induced ANCA is associated with vasculitic lesions in humans. Churg–Strauss syndrome may have either anti-MPO- or anti-PR3-ANCA.

- **Positivity for both types of ANCA** antibodies occurs in up to 10% of patients who have a variable clinical course but a worse renal outcome.

- **Drugs** (e.g. propylthiouracil, hydralazine, minocycline, penicillamine) may induce vasculitides associated with ANCA. Most patients reported with drug-induced ANCA-associated vasculitis have MPO-ANCA, often in very high titres. In addition to MPO-ANCA, most also have antibodies to elastase or to lactoferrin. A relatively small number have PR3-ANCA. Many cases of drug-induced ANCA-associated vasculitis present with constitutional symptoms, arthralgias/arthritis, and cutaneous vasculitis. However, the full range of clinical features associated with ANCA, including crescentic GN and lung haemorrhage, can also occur.

Both ANCA autoantigens are present in immature neutrophil granules. In contrast to the normally silenced state of these two genes in mature neutrophils of healthy subjects, PR3 and MPO are aberrantly expressed in mature neutrophils of patients with ANCA vasculitis due to unsilencing of both antigens because of an epigenetic modifications.

- **Autoimmunity.** It is unclear how and why autoimmunity causes the formation of ANCA antibodies. Patients with anti-PR3 also have autoantibodies to a peptide translated from the antisense DNA strand of PR-3 (complementary PR-3; cPR-3) or to a mimic of this peptide. This suggests that autoimmunity can be initiated through an immune response against a peptide that is antisense or complementary to the autoantigen, which then induces anti-idiotypic antibodies (autoantibodies) that cross-react with the autoantigen.

- **A recent study has shown** that infection by fimbriated bacteria (Gram-negative pathogens such as *Escherichia coli*, *Klebsiella pneumoniae* and *Proteus mirabilis*) can trigger, due to molecular mimicry, a cross-reactive autoimmune to lysosomal membrane protein 2 (LAMP-2), a glycosylated membrane protein which is co-localized with PR3 and MPO in the intracellular vesicles of neutrophils.

There may be multiple factors that contribute to the initiation of an ANCA autoimmune response and the induction of injury by ANCA, such as genetic predisposition (α1-antitrypsin deficiency; Pi-Z allele) and environmental factors (e.g. silica exposure, viral infection, *Staph. aureus* infection) can result in high local or systemic pro-inflammatory cytokines such as tumour necrosis factor (TNF).

**Treatment**

The sooner treatment is instituted the more chance there is of recovery of renal function.

- **Corticosteroids** and **cyclophosphamide** are of benefit: high-dose oral prednisolone (maximum 80 mg/day reducing over time to 15 mg/day by 3 months) and cyclophosphamide (2 mg/kg per day, adjusted for age, renal function and prevailing WBC count). Intravenous pulse, rather than daily oral, cyclophosphamide is associated with an equivalent response with better side-effect profile but is associated with higher relapse rate. The best indicators of prognosis are pulmonary haemorrhage and severity of renal failure at presentation.

- **Patients who present with fulminant disease** need intensification of immunosuppression with adjuvant plasma exchanges (7 × 3–4 L over 14 days) or intravenous pulse methyl prednisolone (1 g/day for 3 consecutive
days). Plasma exchange appeared to have better outcome than pulse methyl prednisolone in one study.

- Once remission has been achieved, azathioprine should be substituted for cyclophosphamide. In cases of intolerance to azathioprine or cyclophosphamide, mycophenolate or methotrexate has been tried with some success.

- Colonization of the upper respiratory tract with Staph. aureus increases the risk of relapse, and treatment with sulfamethoxazole/trimethoprim reduces the relapse rate.

- Relapse after complete cessation of immunosuppressive therapy has been observed relatively frequently, and therefore long-term, albeit relatively low-dose, immunosuppression is necessary.

- Intravenous immunoglobulin (anti-thymocyte globulin, ATG, directed against activated T lymphocytes causes lymphopenia), lymphocyte-depleting anti-CD52 (campath-IH) antibodies, and anti-TNF therapy have shown promise in the treatment of severe and drug-resistant cases as induction therapy. However, an anti-TNF agent, etanercept, has been ineffective as a sole agent for maintenance.

- Two studies have shown that rituximab is equally effective compared to cyclophosphamide for inducing remission in ANCA-associated vasculitides in the short term (6–12 months) with similar adverse event rates. Rituximab may be a therapeutic option in those patients who cannot tolerate cyclophosphamide, and patients whose disease is poorly controlled who relapse while on cyclophosphamide.

- Up to 25% of patients with PR3-ANCA harbour antibodies against human plasminogen and/or tissue plasminogen activator. Their presence has been correlated with venous thromboembolic events and fibrinoid necrotic glomerular lesions, suggesting functional interference with fibrinolysis. However, a formal role for anticoagulation in patients with ANCA-associated GN remains uncertain.

### Other glomerular disorders

#### HIV-associated nephropathy (HIVAN)

A number of renal lesions have been described in association with HIV infection (see p. 177). These include glomerulonephritis of various histological types and the haemolytic uraemic syndrome. The most common (80–90%) histological abnormality is a focal glomerulosclerosis (FGS).

#### HIV-associated FGS

A characteristic ‘collapsed’ appearance of glomeruli is often seen on light microscopy similar to that seen in other causes of focal segmental glomerulosclerosis (see Fig. 12.14c). In HIVAN many visceral epithelial cells (podocytes) are enlarged, hyperplastic, coarsely vacuolated, contain protein absorption droplets and overlie capillaries with varying degrees of wrinkling and collapse of the walls. It is associated with loss of podocyte-specific markers such as Wilms’ tumour factor and synaptopodin due to HIV-1 infection of podocytes of patients with HIVAN. HIVAN has striking predilection; over 90% of patients are black. Clinically HIVAN presents with proteinuria in the nephrotic range, oedema and a ‘bland’ urine. Hypertension is unusual. If untreated, patients go on to CKD which can be rapid in progression.

IgA may be an integral feature of HIV-1 infection, as is IgA nephropathy. In this setting, HIV antigen may be a part of the glomerular immune complexes and circulating immune complexes.

Highly active antiretroviral therapy (HAART) may result in stabilization of renal function and prevention of progression to ESKD (efficacy 23%) and HIV-associated mortality in patients with ESKD. A cyclin-dependent kinase inhibitor, roscovitine, has been successfully used in the treatment of experimental HIVAN.

#### Fabry’s disease

This is the result of deficiency of the enzyme α-galactosidase with accumulation of sphingolipids in many cells. In the kidney, accumulation of sphingolipids especially affects podocytes, which on light microscopy appear enlarged and vacuolated. Ultrastructurally, these inclusion bodies appear as zebra or myeloid bodies representing sphingolipids. Similar appearances have been described in patients taking chloroquine, hydroxychloroquine and amantadine because these can cause hyperlipidosis. These structures can also be found in endothelial, mesangial, and arterial and arteriolar smooth muscle cells. The most common renal manifestation is proteinuria and progressive CKD.

**Treatment** (see p. 1034).

#### Sickle nephropathy

Sickle disease or trait is complicated relatively commonly by papillary sclerosis or necrosis, nephrogenic diabetes insipidus and incomplete renal tubular acidosis. Glomerular lesions are rare and can sometimes be traced to hepatitis B or C infection acquired through repeated blood transfusions. Occasionally, proteinuria or nephrotic syndrome with progressive renal insufficiency is seen without prior infection. The rare glomerular lesion is that of membranous GN or membranoproliferative GN with IgG deposits. No form of effective therapy is known.

#### Glomerulopathy associated with pre-eclampsia

The glomerular lesion of pre-eclampsia is characterized by marked endothelial swelling and obliteration of capillary lumina. Fibrinogen-fibrin deposits may be found in the mesangium. The renal lesion may not be reversible and 30% of patients have changes for >8 months. Patients who have had pre-eclampsia are more likely to develop hypertension in subsequent pregnancies. Severe proteinuria may occur during the course of pre-eclampsia and from time to time, produce features of nephrotic syndrome. Ordinarily, proteinuria disappears after delivery.

In severe cases, associated with cortical necrosis, there may be microangiopathic haemolytic anaemia. Vascular endothelial growth factor (VEGF) and placental growth factor (PLGF) play a key role in the development of the placenta.

Relative deficiency of either factor can theoretically cause implantation abnormalities normally seen in pre-eclampsia. A soluble fms-like tyrosine kinase (sFlt1) receptor also called VEGF-receptor, which is an antagonist of PLGF and specifically of VEGF, is upregulated in the placenta of patients with pre-eclampsia. High circulating levels of these receptors antagonize angiopoietic factors and cause endothelial dysfunction. Excessive free radical generation in the placenta of pre-eclamptic patients is due to upregulation of NADPH oxidase.
oxidase activity caused by generation of an angiotensin II receptor agonist antibody in some patients.

Paraneoplastic glomerulonephritis
A rare complication of malignancy, paraneoplastic glomerulonephritis is usually misdiagnosed as idiopathic glomerulonephritis. Such misdiagnosis can subject patients to potentially harmful, ineffective therapy.

The pathology of paraneoplastic glomerulonephritis varies depending on types of malignancy.

- **Thymoma or Hodgkin’s lymphoma**: polarization of the immune response toward a T-helper-2 profile and possibly excessive production of interleukin-13 may lead to the development of minimal change disease or focal associated membranoproliferative glomerulonephritis and membranous nephropathy
- **B cell lymphoma and leukaemia** are related to the presence of monoclonal immunoglobulin, cryoglobulin, and possibly C virus infection
- **Polycythaemia vera, essential thrombocythaemia or primary myelofibrosis**: severe thrombocytosis may induce focal segmental glomerulosclerosis, possibly due to elevated levels of platelet derived growth factor
- **Myelodysplastic syndromes**: autoimmunity causes a variety of glomerulonephritides
- **Epithelial carcinoma**: the presence of glomerular inflammatory cells, and subepithelial immune IgG1- and IgG2-containing complexes are usually present and may aid in the diagnosis of paraneoplastic membranous nephropathy.

**KIDNEY INVOLVEMENT IN OTHER DISEASES**

Polyarteritis nodosa (PAN)
Classical PAN is a multisystem disorder (see also p. 543). Aneurysmal dilatation of medium-sized arteries may be seen on renal arteriography. The condition is more common in men and in the elderly and, typically, the patient is ANCA negative. Hypertension, polyneuropathy and features indicating ischaemic infarction of various organs including the kidney are presenting features. It may be associated with drug use and hepatitis B infection. This form of polyangiitis is associated with slowly progressive CKD, often accompanied by severe hypertension. Rapidly progressive kidney failure is rare. Treatment with immunosuppression is less effective than it is for microscopic polyangiitis.

Systemic sclerosis (scleroderma)
Systemic sclerosis (scleroderma) is a chronic, multisystem disease characterized by fibrosis and vasculopathy of the skin and visceral organs. Of the patients, 10% develop scleroderma renal crisis, which is characterized by accelerated hypertension, rapidly progressive kidney failure and proteinuria.

Histopathological changes occur in the arcuate and interlobular arteries. Characteristically in the acute stage there are fibrin thrombi and areas of fibrinoid necrosis; these are followed by ‘onion skin’ hypertrophy of the arteries in the chronic stage. The treatment of choice is ACE inhibitors, which have led to remarkable improvement of outcomes in scleroderma renal crisis. Death is now rare, and <50% of patients progress to ESKD.

![Figure 12.25 Typical haemolytic ureaemic syndrome (HUS) renal lesion – light microscopy. Arrow shows microthrombi.](image)

**Haemolytic ureaemic syndrome (HUS)**
HUS is characterized by intravascular haemolysis with red-cell fragmentation (microangiopathic haemolysis), thrombocytopenia and acute kidney injury due to thrombosis in small arteries and arterioles (Fig. 12.25). These features are also seen in disseminated intravascular coagulation, but coagulation tests are typically normal in HUS.

**Diarrhoea-associated HUS (D-HUS)**
This often follows a febrile illness, particularly gastroenteritis and usually associated with *Escherichia coli*, notably strain O157. This strain of *E. coli* produces verocytotoxin (shiga toxin), which has an A unit and five B units. The A unit is pathogenic by inhibiting protein synthesis and initiating endothelial damage. The role of B units is to facilitate the entry of the A unit into the endothelial cells by binding to a receptor (Gb3) on the endothelial cell. The toxins are transported to endothelial cells from the gut on neutrophils. Most patients with D–HUS recover renal function, but supportive care including maintenance of fluid and electrolyte balance, antihypertensive medication, nutritional support and dialysis is commonly required. Plasmapheresis is not beneficial but is usually tried as a last resort. About 5% die during the acute episode, 5% develop ESKD and 30% exhibit evidence of long-term damage with persistent proteinuria. Antibiotic and antimotility agents for the diarrhoea increase the risk of HUS and its complications.

Recently, an outbreak caused by shiga toxin-producing *Escherichia coli* O104:H4 (new strain) was reported in Germany and other European countries. In this outbreak, HUS cases were unusually high and associated with significant morbidity and mortality (see p. 121). Severe neurological complications were seen; immunoadsorption was successful in many cases.

Recurrent episodes of HUS have been described in the same individual, and familial forms of the disease (with both recessive and dominant inheritance) exist.

**Non-diarrhoeal-induced form of HUS (D–HUS)**
Also called atypical HUS (aHUS), this probably is a complement-driven illness due to a deficiency of complement factor H (CFH) or complement factor I (CFI). Factor H is a soluble protein produced by the liver, which regulates the activity of the alternative complement activation pathway; in particular, it protects host cell surfaces from complement-mediated damage. In some families with D–HUS, a mutation has been traced to another complement regulatory protein, CD46 (previously known as membrane cofactor protein, MCP). This protein is highly expressed in the kidney and...
normally prevents glomerular C3 activation. A loss of function mutation in CD46 results in unopposed complement activation and development of HUS. Functional deficiency of these factors can be acquired due to autoantibody formation either as an isolated phenomenon or as part of a rheumatic autoimmune disease such as SLE. A loss of function mutation in thrombomodulin (a membrane-bound anticoagulant glycoprotein) has been identified as an alternative complement pathway. Rarely gain of function mutations can affect genes encoding the alternative pathway C3 convertase components, CFB and C3. CFB mutations, which lead to chronic alternative-pathway activation, occur in only 1–2% of patients with D–HUS. About 4–10% of patients have heterozygous mutations in C3, usually with low C3 levels. Most mutations reduce C3b binding to CFH and CD46, which severely impairs degradation of mutant C3b.

Treatment
Treatment is often very difficult because of severe hypertension and the possibility of frequent recurrences. The course of the disease is often indolent and progressive. Plasmaperesis or plasma infusion is still the only therapy used in the majority of patients. C5 activation is one of the critical steps in the activation of complement cascade. Eculizumab, a monoclonal humanized anti-C5 antibody, has shown success in patients with D–HUS either dependent or refractory to plasmaperesis therapy. Liver transplantation is potentially the only curative treatment in patients harbouring CFH and CFI mutations.

Sporadic cases of D–HUS
These can be associated with pregnancy, SLE, scleroderma, malignant hypertension, metastatic cancer, HIV infection and various drugs including oral contraceptives, ciclosporin, tacrolimus, chemotherapeutic agents (e.g. cisplatin, mitomycin C, bleomycin) and heparin. Treatment is supportive with removal of the offending agent or specific treatment of the underlying cause. There is no evidence in favour of plasma infusion or plasmaperesis in these sporadic cases but it is tried, usually as a last resort.

Pneumococcus-associated HUS
This rare complication of Streptococcus pneumoniae infection was previously associated with a high morbidity and mortality. This organism produces an enzyme (possibly neuraminidase) which can expose an antigen (Thomsen antigen) present on RBCs, platelets and glomeruli. Antibodies to the Thomsen antigen result in an antigen-antibody reaction and can lead to HUS and anaemia. The improved outcome is due to increasing awareness of this complication, judicious use of blood products (washed blood products) and avoiding plasma infusion or plasmaperesis.

Thrombotic thrombocytopenic purpura (TTP)
TTP (see p. 420) is characterized by microangiopathic haemolysis, renal failure and evidence of neurological disturbance. Young adults are most commonly affected.

Antiphospholipid syndrome (APS)
In antiphospholipid syndrome (APS, see p. 538), the binding of antiphospholipid antibodies (aPL) to beta 2 glycoprotein I (β2GPI) induces endothelial cell–leukocyte adhesion and thrombus formation by the inhibition of eNOS. The inhibition of eNOS is caused by antibody recognition and dimerization of β2GPI and impairment of eNOS phosphorylation.

The central feature of APS is recurrent thrombosis (both venous and arterial) and fetal loss in the presence of antiphospholipid antibodies. Such antibodies may be primary or secondary to infections (HIV, hepatitis C) or autoimmune disease (SLE). Some 50% have renal involvement with proteinuria. Thrombotic microangiopathy is a rare but well-recognized presentation. In some cases, a lupus nephritis-like (usually membranous GN) lesion is seen. The only proven treatment for APS is warfarin with an INR of 3–4. Use of steroids or plasmapheresis is reserved for patients with APS and life-threatening renal involvement with thrombotic microangiopathy. Treatment is variably successful (30–70%).

Multiple myeloma
Acute kidney injury (AKI) is relatively common in myeloma, occurring in 20–30% of affected individuals at the time of diagnosis, and is mainly due to the nephrotoxic effects of the abnormal immunoglobulins. It is often irreversible. The following types of renal lesions are associated with myeloma.

- **Light chain cast nephropathy** – intratubular deposition of light chains, particularly kappa chains facilitated by Tamm–Horsfall glycoprotein, which characteristically appear on renal histology as fractured casts with giant cell reaction (Fig. 12.26).
- **AL amyloidosis** – deposition of amyloid fibrils of light chains (Congo red positive).
- **Light chain deposition disease** – nodular glomerulosclerosis with granular deposits of usually lambda light chains (Congo red negative).
- **Plasma cell infiltration** – often incidental finding at autopsy.
- **Fanconi’s syndrome** – tubular toxicity due to light chains.
- **Hypercalcemic nephropathy** – bone resorption causing hypercalcaemia.
- **Hyperuricaemic nephropathy** – tumour lysis causing tubular crystallization of uric acid.
- **Radiocontrast nephropathy** – interaction between light chains and radiocontrast.

Treatment of underlying myeloma is indicated (p. 471). If a patient with cast nephropathy and severe AKI remains dialysis-dependent, the prognosis is poor. Commencement of effective bortezomib-based chemotherapy, which decreases light chain production, and a high cut-off haemodialysis has shown some promise in relapsed myeloma.

*More common in hospital practice.
*More common in young women (20–30%).

**URINARY TRACT INFECTION**

Urinary tract infection (UTI) is common in women, in whom it usually occurs in an anatomically normal urinary tract. Conversely, it is uncommon in men and children, and the urinary tract is often abnormal and requires investigation. The incidence of UTI is 50,000 per million persons per year and accounts for 1–2% of patients in primary care. Recurrent infection causes considerable morbidity; if complicated, it can cause severe renal disease including ESKD. It is also a common source of life-threatening Gram-negative septicemia.

**Aetiology and pathogenesis**

Infection is most often due to bacteria from the patient’s own bowel flora (Table 12.9). Transfer to the urinary tract is most often via the ascending transurethral route but may be via the bloodstream, the lymphatics or by direct extension (e.g. from a vesicocolic fistula).

Symptomatic infection is related to the virulence of the organisms, which compete with the innate host defence system. However, inflammation and injury are determined by the host response and not by the bacterium.

**Virulence.** Ability to adhere to epithelial cells determines the degree of virulence of the organism. For *E. coli*, these adhesive factors include flagellae (for motility), aerobactin (for iron acquisition in the iron-poor environment of the urinary tract), haemolysin (for pore forming) and above all, the presence of adhesins on the bacterial fimbriae and on the cell surface.

There are two types of *E. coli*: those with *type 1 fimbriae* (with adhesin known as FimH) associated with cystitis; and those with *type P fimbriae* (with adhesin known as PapG) commonly responsible for pyelonephritis. Bacterial adhesins are necessary for attachment of bacteria to the mucous membranes of the perineum and urothelium. There are several molecular forms of adhesins. The most studied is the PapG adhesin, which is located on the tip of *P* fimbriae. This lectin (one of the P blood group antigens) structure recognizes binding sites consisting of oligosaccharide sequences present on the mucosal surface.

**Innate host defence.** The following host defence mechanisms are necessary to prevent UTI:

- **Neutrophils** – adhesins activate receptors, e.g. Toll receptor 4, on the mucosal surface, resulting in IL-8 production and expression of its receptor CXCR1 on neutrophil surfaces. Activation of neutrophils is essential for bacterial killing. Defective IL-8 production or reduced expression of CXCR1 results in impaired function of neutrophils predisposing an individual to severe UTI.
- **Urinary osmolality and pH** – urinary osmolality >800 mOsm/kg and low or high pH reduce bacterial survival.
- **Complement** – complement activation with IgA production by uroepithelium (acquired immunity) also plays a major role in defence against UTI.
- **Commensal organisms** – such as lactobacilli, corynebacteria, streptococci and bacteroides are part of the normal host defence. Eradication of these commensal organisms by spermicidal jelly or disruption by certain antibiotics results in overgrowth of *E. coli*.
- **Urinary flow** – urine flow and normal micturition wash out bacteria. Urine stasis promotes UTI.
- **Uroepithelium** – mannosylated proteins such as Tamm–Horsfall proteins (THP), which are present in the mucus and glycosalix covering uroepithelium, have antibacterial properties. These proteins interfere with bacterial binding to uroepithelium. Disruption of this uroepithelium by trauma (e.g. sexual intercourse or catheterization) predisposes to UTI. Cranberry juice and blueberry juice contain a large-molecular-weight factor (proanthrocyanidins) that prevents binding of *E. coli* to the uroepithelium (see p. 591).
- **Blood group antigens** – women who are non-secretors of ABH blood group antigens are three to four times more likely to have recurrent UTIs.

**Natural history**

UTI is commonly an isolated, rather than a repeated, event (Fig. 12.27).

**Complicated versus uncomplicated infection** (Fig. 12.28)

It is necessary to distinguish between UTI occurring in patients with functionally normal urinary tracts and in those with abnormal tracts.

**Functionally normal urinary tracts (with normal renal imaging).** Here, persistent or recurrent infection seldom results in serious kidney damage (uncomplicated UTI).

**Abnormal urinary tracts.** Tracts with stones, or associated diseases such as diabetes mellitus which themselves cause kidney damage, may be made worse with infection (complicated UTI). UTI, particularly with *Proteus*, may predispose to stone formation. The combination of infection and obstruction results in severe, sometimes rapid, kidney damage (obstructive pyonephrosis) and is a major cause of Gram-negative septicemia.

**Acute pyelonephritis**

The combination of fever, loin pain with tenderness and significant bacteriuria usually implies infection of the kidney (acute pyelonephritis). Small renal cortical abscesses and streaks of pus in the renal medulla are often present. Histologically, there is focal infiltration by polymorphonuclear leucocytes and many polymorphs in tubular lumina.
Kidney and urinary tract disease

Diagnosis is based on CT scan of the kidneys, which shows irregular renal outlines, clubbed calyces and a variable reduction in renal size. The condition may be unilateral or bilateral and affect all or part of the kidney.

Reflux usually ceases around puberty with growth of the bladder base. Damage already done persists and progressive renal fibrosis and further loss of function occur in severe cases even though there is no further infection.

Reflux nephropathy cannot occur in the absence of reflux and therefore does not begin in adult life. Consequently, adult females with bacteriuria and a normal urogram can be reassured that kidney damage will not develop.

Chronic reflux nephropathy acquired in infancy predisposes to hypertension in later life and, if severe, is a relatively common cause of ESKD in childhood or adult life. Meticulous early detection and control of infection, with or without ureteral reimplantation to create a competent valve, can prevent further scarring and allow normal growth of the kidneys. No proof exists, however, that reimplantation surgery confers long-term benefit.

Reinfection versus relapsing infection

When UTI is recurrent, it is necessary to distinguish between relapse and reinfection.

Relapse is diagnosed by recurrence of bacteriuria with the same organism within 7 days of completion of antibacterial treatment and implies failure to eradicate infection (Fig. 12.31) usually in conditions such as stones, scarred kidneys, polycystic disease or bacterial prostatitis.

Reinfection is when bacteriuria is absent after treatment for at least 14 days, usually longer, followed by recurrence of infection with the same or different organisms. This is not due to failure to eradicate infection, but is the result of reinvansion of a susceptible tract with new organisms. Approximately 80% of recurrent infections are due to reinfection.

Symptoms and signs of UTI

The most typical symptoms of UTI are:

- Frequency of micturition by day and night
- Painful voiding (dysuria)
- Suprapubic pain and tenderness
- Haematuria
- Smelly urine.

These symptoms relate to bladder and urethral inflammation, commonly called ‘cystitis’, and suggest lower urinary tract disease.
treatment failure in urinary tract infection. Dipsticks that detect significant pyuria depend on red colour in the reagent square. False-negative results are negative organisms reduce nitrates to nitrites and produce a city of 82% (sensitivity of 75% and specificity of 100%). Positive urine culture – same or different

Abacteriuric frequency or dysuria ('urethral syndrome')

Causes of truly abacteriuric frequency/dysuria include post-coital bladder trauma, vaginitis, atrophic vaginitis or urethritis in the elderly, and interstitial cystitis (Hunner’s ulcer). In symptomatic young women with ‘sterile pyuria’, Chlamydia infection and tuberculosis must be excluded.

Interstitial cystitis is an uncommon but distressing complaint, most often affecting women over the age of 40 years. It presents with frequency, dysuria and often severe suprapubic pain. Urine cultures are sterile. Cystoscopy shows typical inflammatory changes with ulceration of the bladder base. It is commonly thought to be an autoimmune disorder. Various treatments are advocated with variable success. These include oral prednisolone therapy, bladder instillation of sodium cromoglycate or dimethyl sulphoxide and bladder stretching under anaesthesia.

Predominant frequency and passage of small volumes of urine ('irritable bladder') is possibly consequent on previous UTI or conditioned by psychosexual factors. Such patients must be distinguished from those with frequency due to polyuria. Repeated courses of antibiotics in patients with genuine abacteriuric frequency or dysuria are quite inappropriate and detract from identifying the true nature of the problem.

Special investigations

Uncomplicated UTI usually does not require radiological evaluation unless it is recurrent or affecting males and children or there are unusually severe symptoms. Patients with predisposing conditions such as diabetes mellitus or immunocompromised states benefit from early imaging.

- **Ultrasound** is used in the assessment of patients with suspected pyelonephritis that requires drainage. This allows the detection of calculi, obstruction and also incomplete emptying.
- **CT** is a more sensitive modality for diagnosis and follow-up of complicated renal tract infection. Contrast-enhanced CT allows different phases of excretion to be studied and can define the extent of disease and identify significant complications or obstruction.
- **MRI** is particularly useful in those with iodinated contrast allergies, offering an ionizing radiation-free alternative in the diagnosis of both medical and surgical diseases of the kidney.
- **Nuclear medicine** has a limited role in the evaluation of UTI in adults. Its main role is in the assessment of renal function and detection of scars by DMSA scan, often prior to surgery.

Treatment

**Single isolated attack**

Pre-treatment urine culture is desirable.

- **Antibiotics** for 3–5 days with amoxicillin (250 mg three times daily), nitrofurantoin (50 mg three times daily), trimethoprim (200 mg twice daily) or an oral cephalosporin. The treatment regimen is modified in light of the result of urine culture and sensitivity testing, and/or the clinical response.

- For **resistant organisms** the alternative drugs are co-amoxiclav or ciprofloxacin.

- **Single-shot treatment** with 3 g of amoxicillin or 1.92 g of co-trimoxazole is used for patients with bladder symptoms of less than 36 hours’ duration who have no previous history of UTI.

- **A high (2 L daily) fluid intake** should be encouraged during treatment and for some subsequent weeks. Urine culture should be repeated 5 days after treatment.

- **If the patient is acutely ill with high fever, loin pain and tenderness** (acute pyelonephritis), antibiotics
are given intravenously, e.g. aztreonam, cefuroxime, ciprofloxacin or gentamicin (2–5 mg/kg daily in divided doses), switching to a further 7 days’ treatment with oral therapy as symptoms improve. Intravenous fluids may be required to achieve a good urine output.

- **In patients presenting for the first time with high fever, loin pain and tenderness**, urgent renal ultrasound examination is required to exclude an obstructed pyonephrosis. If this is present it should be drained by percutaneous nephrostomy (p. 570).

**Recurrent infection**

Pre-treatment and post-treatment urine cultures are necessary to confirm the diagnosis and identify whether recurrent infection is due to relapse or reinfection.

**Relapse.** A search should be made for a cause (e.g. stones or scarred kidneys), and this should be eradicated. Intense or prolonged treatment – intravenous or intramuscular aminglosycose for 7 days or oral antibiotics for 4–6 weeks – is required. If this fails, long-term antibiotics are required.

**Reinfection** implies that the patient has a predisposition to periurethral colonization or poor bladder defence mechanisms. Contraceptive practice should be reviewed and the use of a diaphragm and spermicidal jelly discouraged. Atrophic vaginitis should be identified in postmenopausal women, who should be treated (see below). All patients must undertake prophylactic measures:

- A 2 L daily fluid intake
- Voiding at 2–3-hour intervals with double micturition if reflux is present
- Voiding before bedtime and after intercourse
- Avoidance of spermicidal jellies and bubble baths and other chemicals in bath water
- Avoidance of constipation, which may impair bladder emptying.

Evidence of impaired bladder emptying on excretion urography/ultrasound requires urological assessment. If UTI continues to recur, treatment for 6–12 months with low-dose prophylaxis (trimethoprim 100 mg, co-trimoxazole 480 mg, cefalexin 125 mg at night or macrocrystalline nitrofurantoin) is required; it should be taken last thing at night when urine flow is low. Intravaginal oestrogen therapy has been shown to produce a reduction in the number of episodes of UTI in postmenopausal women. Cranberry juice is said to reduce the risk of symptoms and reinfection by 12–20% but studies are limited.

**Urinary infections in the presence of an indwelling catheter**

Colonization of the bladder by a urinary pathogen is common after a urinary catheter has been present for more than a few days, partly due to organisms forming biofilms. So long as the bladder catheter is in situ, antibiotic treatment is likely to be ineffective and will encourage the development of resistant organisms. Treatment with antibiotics is indicated only if the patient has symptoms or evidence of infection, and should be accompanied by replacement of the catheter. When changing catheters, a single injection of gentamicin is recommended.

Infection by *Candida* is a frequent complication of prolonged bladder catheterization. Treatment should be reserved for patients with evidence of invasive infection or those who are immunosuppressed, and should consist of removal or replacement of the catheter. In severe infections continuous bladder irrigation with amphotericin 50 μg/mL is used.

**Bacteriuria in pregnancy**

The urine of all pregnant women must be cultured, as 2–6% have asymptomatic bacteriuria. While asymptomatic bacteriuria in the non-pregnant female seldom leads to acute pyelonephritis and often does not require treatment, acute pyelonephritis frequently occurs in pregnancy under these circumstances. Failure to treat may thus result in severe symptomatic pyelonephritis later in pregnancy, with the possibility of premature labour. Asymptomatic bacteriuria, in the presence of previous renal disease, may predispose to pre-eclamptic toxemia, anaemia of pregnancy, and small or premature babies. Theretof bacteriuria must always be treated and be shown to be eradicated. Reinfection may require prophylactic therapy. Tetracycline, trimethoprim, sulphonamides and 4-quinolones must be avoided in pregnancy. Amoxicillin and ampicillin, nitrofurantoin and oral cephalosporins may safely be used in pregnancy.

**Bacterial prostatitis**

Bacterial prostatitis is a relapsing infection which is difficult to treat. It presents as perineal pain, recurrent epididymo-orchitis and prostatic tenderness, with pus in expressed prostatic secretion. Treatment is for 4–6 weeks with drugs that penetrate into the prostate, such as trimethoprime or ciprofloxacin. Long-term low-dose treatment may be required. Prostatodynia (prostatic pain in the absence of active infection) may be a very persistent sequel to bacterial prostatitis. Amiriptyline and carbamazepine may alleviate the symptoms.

**Renal carbuncle**

Renal carbuncle is an abscess in the renal cortex caused by a blood-borne *Staphylococcus*, usually from a boil or carbuncle of the skin. It presents with a high swinging fever, loin pain and tenderness, and fullness in the loin. The urine shows no abnormality, as the abscess does not communicate with the renal pelvis, more often extending into the perirenal tissue. Staphylococcal septicaemia is common. Diagnosis is by ultrasound or CT scanning. Treatment involves antibacterial therapy with fluoalexacin and surgical drainage.

**Tuberculosis of the urinary tract**

Tuberculous infection is on the increase worldwide, partly due to the reservoir of infection in susceptible HIV-infected individuals and the emergence of drug-resistant strains. Tuberculosis of the urinary tract presents with frequency, dysuria or haematuria. In the UK, it is mainly seen in the Asian immigrant population. Cortical lesions result from haematogenous spread in the primary phase of infection. Most heal, but in some, infection persists and spreads to the papillae, with the formation of cavitating lesions and the discharge of mycobacteria into the urine. Infection of the ureters and bladder commonly follows, with the potential for the development of ureteral stricture and a contracted bladder. Rarely cold abscesses may form in the loin. In males the disease may present with testicular or epididymal discomfort and thickening.

**Diagnosis** depends on constant awareness, especially in patients with sterile pyuria. Imaging may show cavitating lesions in the renal papillary areas, commonly with calcification. There may also be evidence of ureteral obstruction with hydronephrosis. Diagnosis of active infection depends on culture of mycobacteria from early-morning urine samples. Imaging may be normal in diffuse interstitial renal tuberculosis.
when diagnosis is made by renal biopsy demonstrating caseating granuloma with multinucleate giant cells and acid-fast bacilli on Ziehl–Neelsen staining (Fig. 12.32). Some patients present with small unobstructed kidneys, when the diagnosis is easy to miss. **Treatment.** The treatment is as for pulmonary tuberculosis (see p. 842). Renal ultrasonography and/or CT scanning should be carried out 2–3 months after initiation of treatment as ureteric strictures may first develop in the healing phase.

**Xanthogranulomatous pyelonephritis**

This is an uncommon chronic interstitial infection of the kidney, most often due to Proteus, in which there is fever, weight loss, loin pain and a palpable enlarged kidney. It is usually unilateral and associated with staghorn calculi and urinary tract infection. CT scanning shows up intrarenal abscesses as lucent areas within the kidney. Nephrectomy is the treatment of choice; antibacterial treatment rarely, if ever, eradicates the infection.

**TUBULOINTERSTITIAL NEPHRITIS (TIN)**

Diseases of the kidney primarily affect the glomeruli, vascu- lature, or the remainder of the renal parenchyma that consists of the tubules and interstitium. Although the tubules and the interstitium are distinct functional entities, they are intimately related. Injury involving one of them invariably results in damage to the other.

**Acute tubulointerstitial nephritis (TIN)**

In approximately 70% of the cases, acute TIN is due to a hypersensitivity reaction to drugs (Table 12.11), most commonly drugs of the penicillin family and non-steroidal anti-inflammatory drugs (NSAIDs).

**Drug induced acute TIN.** Patients present with fever, arthralgia, skin rashes and acute oliguric or non-oliguric kidney injury. Many have eosinophilia and eosinophiluria. Renal histology shows an intense interstitial cellular infiltrate, often including eosinophils, with variable tubular necrosis (Fig. 12.33). Rarely, NSAIDs can cause a glomerular minimal-change lesion in addition to TIN and present as the nephrotic syndrome. Treatment involves withdrawal of offending drugs. High-dose steroid therapy (prednisolone 60 mg daily) is commonly given but its efficacy has not been proven. Patients may require dialysis for management of the acute kidney injury. Most patients make a good recovery in kidney function, but some may be left with significant interstitial fibrosis and CKD.

**Infection causing acute TIN.** Acute pyelonephritis leads to inflammation of the tubules, producing a neutrophilic cellular infiltrate. TIN can complicate systemic infections with viruses (Hantavirus, Epstein–Barr virus, HIV, measles, adenovirus), bacteria (Legionella, Leptospira, streptococci, Mycoplasma, Brucella, Chlamydia) and others (Leishmania, Toxoplasma). Hantavirus causes haemorrhagic fever with TIN and can be fatal. Epstein–Barr virus DNA has been found in renal biopsy tissue of cases of idiopathic TIN. In immuno-compromised patients such as post-renal transplantation, CMV, polyoma, and HSV can cause acute TIN in the renal graft. Treatment involves eradication of infection by appropriate antibiotics or antiviral agents and in renal transplantation modifying immunosuppressive regimen.

**Acute TIN as part of multisystem inflammatory diseases.** Several non-infectious inflammatory disorders such as Sjögren’s syndrome, SLE and Wegener’s granulomatosis can cause acute or chronic TIN rather than glomerulonephritis. Sjögren’s syndrome may additionally present as renal tubular acidosis. Sarcoidosis presents as granulomatous TIN in up to 20% of patients. Associated hypercalcaemia causes acute kidney injury. These heterogeneous conditions with TIN generally respond to steroids.

**TINU syndrome.** In this syndrome, uveitis generally coincides with acute TIN. It is common in childhood, but has been reported in adulthood. Among adults it is more common in females, but its cause remains unknown. Available evidence suggests that it is associated with autoantibodies directed against modified C-reactive protein. Patients present with weight loss, anaemia and raised ESR. A prolonged course of

steroids leads to improvement in both renal function and uveitis.

**Chronic tubulointerstitial nephritis**

The major causes of chronic tubulointerstitial nephritis are given in Table 12.12. It is characterized by generalized inflammatory cellular infiltration of the interstitium with tubular atrophy and generalized interstitial oedema or fibrosis. In many cases no cause is found. Chronic TIN changes evolve into progressive primary glomerular or vascular disease of the kidney, where its severity is a better predictor of long-term renal survival than the primary site of insult.

The patient usually presents with either polyuria and nocturia, or is found to have proteinuria or uraemia. Proteinuria is usually slight (<1 g daily). Papillary necrosis with ischaemic damage to the papillae occurs in a number of tubulointerstitial nephritides, for example in analgesic abuse, diabetes mellitus, sickle cell disease or trait. The papillae can separate and be passed in the urine. Microscopic or overt haematuria or sterile pyuria also occurs, and occasionally a sloughed papilla may cause ureteric colic or produce acute ureteric obstruction. The radiological appearances must be distinguished from those of reflux nephropathy (Fig. 12.34) or obstructive uropathy which is usually accompanied by tubular dilatation and atrophy and intense interstitial fibrosis with patchy inflammatory cellular infiltrate in the scarred areas.

Tubular damage to the medullary area of the kidney leads to defects in urine concentration and sodium conservation with polyuria and salt wasting. Fibrosis progressing into the cortex leads to loss of excretory function and uraemia.

**Analgesic nephropathy**

The chronic consumption of large amounts of analgesics (especially those containing phenacetin) and NSAIDs leads to chronic tubulointerstitial nephritis and papillary necrosis. Analgesic nephropathy is twice as common in women as in men and presents typically in middle age. Patients are often depressed or neurotic. Presentation may be with anaemia, CKD, UTIs, haematuria or urinary tract obstruction (owing to sloughing of a renal papilla). Salt and water-wasting renal disease may occur. Chronic analgesic abuse also predisposes to the development of uroepithelial tumours. Diagnosis is usually made on clinical grounds combined with the non-pathognomonic appearance on imaging (such as ultrasonography or CT scan), which demonstrates smallish irregularly outlined kidneys.

The consumption of the above analgesics should be discouraged. If necessary, dihydrocodeine or paracetamol is a reasonable alternative. This may result in the arrest of the disease and even in improvement in function. UTI, hypertension (if present) and saline depletion will require appropriate management. The development of flank pain or an unexpectedly rapid deterioration in renal function should prompt ultrasonography to screen for urinary tract obstruction due to a sloughed papilla.

### Chinese herb nephropathy

Chinese herbal medicines have been increasingly used in the West, e.g. for slimming, and have caused a nephropathy. The renal histology is similar to Balkan nephropathy but the clinical course is very aggressive. The causal agent has been identified as aristolochic acid produced as a result of fungal contamination of the herbal medicine. It is characterized by relentless progression to ESKD. There is a high incidence of uroepithelial tumours.

### Balkan nephropathy (BN)

This is a chronic TIN endemic in areas along the tributaries of the River Danube. Inhabitants of the low-lying plains, which are subjected to frequent flooding and where the water supply comes from shallow wells, are affected, whereas the disease does not occur in hillside villages where surface water provides the water supply. Its cause was essentially unknown. However, new research suggests that chronic dietary poisoning by aristolochic acid (AA) is responsible for BN and its associated urothelial cancer. AA-DNA adduct is found in tissue biopsies both from BN and associated urothelial cancers. This research suggests that AA is the environmental agent responsible for BN and its associated transitional-cell cancer. The disease is insidious in onset, with mild proteinuria progressing to ESKD in 3 months to 10 years. There is no treatment.
Hypertension and the kidney

Hypertension and the kidney

Hypertension can be the cause or the result of renal disease. It is often difficult to differentiate between the two on clinical grounds. Routine tests (as described on p. 780) should be performed on all hypertensive patients, but renal imaging is usually unnecessary.

The mechanisms responsible for the normal regulation of arterial blood pressure and the development of essential primary hypertension are unclear (p. 777). One basic concept is that the long-term regulation of arterial pressure is closely linked to the ability of the kidneys to excrete sufficient salt to maintain normal sodium balance, extracellular fluid volume, and normal blood volume at normotensive arterial pressures. Cross-transplantation experiments suggest that hypertension travels with the kidney, in that hypertension will develop in a normotensive recipient of a kidney genetically programmed for hypertension. Similarly, patients with ESKD due to hypertension become normotensive after receiving a renal allograft from normotensive donors, provided the new kidney works.

One of many renal factors involved in the genesis of hypertension is the total number of nephrons in the kidney. Patients with hypertension and normal renal function have a significantly reduced number of nephrons in each kidney alongside enlargement of the remaining glomeruli due to glomerular hyperfiltration. Moreover, certain races (black, Hispanics) with predilection for hypertension have increased glomerular volume, a surrogate marker for a reduced number of nephrons.

Whether the reduced number of nephrons is caused by genetic or environmental factors is unclear. Changes in the intrauterine environment may lead to retarded renal growth before birth and low birth weight and hypertension during adult life. In humans, an association has been found between low birth weight and reduced renal volume, possibly indicating reduced numbers of nephrons.

Essential hypertension

Pathophysiology

In benign essential hypertension, arteriosclerosis of major renal arteries and changes in the intrarenal vasculature (nephrosclerosis) occur as follows:

- In small vessels and arterioles, intimal thickening with reduplication of the internal elastic lamina occurs and the vessel wall becomes hyalinized.
- In large vessels, concentric reduplication of the internal elastic lamina and endothelial proliferation produce an ‘onion skin’ appearance.
- Reduction in size of both kidneys occurs; this may be asymmetrical if one major renal artery is more affected than the other.
- The proportion of sclerotic glomeruli is increased compared with age-matched controls.

Deterioration in excretory function accompanies these changes, but severe CKD is unusual in whites (1 in 10 000). In black Africans, by contrast, hypertension much more often results in the development of CKD with a fourfold higher incidence of ESKD in blacks compared to whites. This racial difference in incidence of hypertensive renal disease may be due to overestimation of diagnosis on clinical grounds, poor compliance with medication, higher incidence of hypertension, which is usually a salt-sensitive type, reduced number

Hyperuricaemic nephropathy

Acute hyperuricaemic nephropathy (see p. 503) is a well-recognized cause of acute kidney injury in patients with marked hyperuricaemia that is usually due to lymphoproliferative or myeloproliferative disorders. It may occur prior to treatment but most often follows commencement of treatment, when there is rapid lysis of malignant cells, release of large amounts of nucleoprotein and increased uric acid production. Renal failure is due to intrarenal and extrarenal obstruction caused by deposition of uric acid crystals in the collecting ducts, pelvis and ureters. The condition is manifest as oliguria or anuria with increasing uraemia. There may be flank pain or colic. Plasma urate levels are above 0.75 mmol/L and may be as high as 4.5 mmol/L. Diagnosis is based on the hyperuricaemia and the clinical setting. Ultrasound may demonstrate extrarenal obstruction due to stones, but a negative scan does not exclude this where there is coexistent intrarenal obstruction.

Allopurinol 100–200 mg three times daily for 5 days is given prior to and throughout treatment with radiotherapy or cytotoxic drugs. A high rate of urine flow must be maintained by oral or parenteral fluid and the urine kept alkaline by the administration of sodium bicarbonate 600 mg four times daily and acetazolamide 250 mg three times daily, since uric acid is more soluble in an alkaline than in an acid medium. Febuxostat, a non-purine-analogue inhibitor of xanthine oxidase, can be used if allopurinol cannot be tolerated and eGFR is >30 mL/min. Rasburicase, a recombinant urate oxidase (p. 449), and pegloticase, a pegylated uricase in development, are occasionally used. In severely oliguric or anuric patients, dialysis is required to lower the plasma urate.

There is no convincing direct evidence for chronic hyperuricaemia nephropathy. However, a few observational studies have recently suggested that elevated levels of uric acid independently increase the risk for new-onset CKD, and that lowering plasma urate reduction with allopurinol has a beneficial effect in slowing the rate of progression of CKD.

Other forms of chronic tubulointerstitial nephritis

These are rare (Table 12.12). Diagnosis of all forms depends on a history of drug ingestion or industrial exposure to nephrotoxins. In patients with unexplained renal impairment with normal-sized kidneys, renal biopsy must always be undertaken to exclude a treatable tubulointerstitial nephritis such as granulomatous TIN due to sarcoidosis (Fig. 12.35), which may be the first presentation of sarcoidosis (see p. 846). Renal sarcoidosis generally responds rapidly to steroids.

Figure 12.35 Granulomatous tubulointerstitial nephritis. The granuloma consists of both giant cells (arrow) and epithelioid cells. These findings are characteristic of renal sarcoid but can be seen with any cause (drug or infection) of interstitial nephritis.
of nephrons and possibly resulting from higher frequency of susceptibility alleles for ESKD in the West African than the European gene pool.

A recent genome-wide study found statistically stronger associations between two independent sequence variants in the apolipoprotein L1 gene (APOL1) and non-diabetic nephropathy in African Americans, in hypertension-attributed ESKD. These kidney disease risk variants most likely arose due to positive selection for evolutionary advantage these variants in APOL1 conferred against trypanosomal infection and protection from African sleeping sickness. These observations provide some evidence, similar to findings with sickle cell anaemia, that natural selection might protect from one disease but allow another one to develop.

In accelerated or malignant-phase hypertension:

- Arteriolar fibrinoid necrosis occurs, probably as a result of plasma entering the media of the vessel through splits in the intima. It is prominent in afferent glomerular arterioles.
- Fibrin deposition within small vessels is often associated with thrombocytopenia and red-cell fragmentation seen in the peripheral blood film (microangiopathic haemolytic anaemia).

Microscopic haematuria, proteinuria, usually of modest degree (1–3 g daily), and progressive uraemia occur. If untreated, fewer than 10% of patients survive 2 years.

Management

The management of benign essential and malignant hypertension is described on page 781.

If treatment is begun before CKD has developed, the prognosis for renal function is good. Stabilization or improvement in renal function with healing of intrarenal arteriolar lesions and resolution of microangiopathic haemolysis occur with effective treatment of malignant phase hypertension. In blacks with hypertensive nephrosclerosis and CKD, a blood pressure target of <140/85 mmHg should be achieved.

Renal hypertension

Hypertension commonly complicates bilateral renal disease such as chronic glomerulonephritis, bilateral reflux nephropathy, polycystic disease and analgesic nephropathy. Two main mechanisms are responsible:

- Activation of the renin-angiotensin-aldosterone system
- Retention of salt and water owing to impairment in excretory function, leading to an increase in blood volume and hence blood pressure.

The second of these assumes greater significance as renal function deteriorates.

Hypertension occurs earlier, is more common and tends to be more severe in patients with renal cortical disorders, such as glomerulonephritis, than in those with disorders affecting primarily the renal interstitium, such as reflux or analgesic nephropathy.

Management is described on page 781. Meticulous control of the blood pressure is necessary to prevent further deterioration of renal function secondary to vascular changes produced by the hypertension itself. There is good evidence that ACE-inhibitor drug treatment confers an additional renoprotective effect for a given degree of blood pressure control than other hypotensive drugs. In a study of African Americans with hypertension, intensive blood pressure control (130/78) was not superior to standard control (141/86) in the prevention of ESKD. However, in the same study patients with proteinuria (protein creatinine ratio >0.22) benefited more from intensive blood pressure control.

Renovascular disease

Mechanism of hypertension

Renal ischaemia results in a reduction in the pressure in afferent glomerular arterioles. This leads to an increase in the production and release of renin from the juxtaglomerular apparatus (see p. 567) with a consequent increase in angiotensin II, a very potent vasoconstrictor. Angiotensin II also causes hypertension by upregulating NADPH oxidase enzyme with excessive superoxide generation. Superoxide chelates nitric oxide (a potent vasodilator) resulting in reduced vasodilator activity and also hypertension.

Physiological changes in renal artery stenosis

In renal artery stenosis, renal perfusion pressure is reduced and neprhon transit time is prolonged on the side of the stenosis; salt and water reabsorption is therefore increased. As a result, urine from the ischaemic kidney is more concentrated and has a lower sodium concentration than urine from the contralateral kidney. Creatinine clearance is decreased on the ischaemic side.

Pathology

Narrowing of the renal arteries (renal artery stenosis) is caused by two of the pathological entities: fibromuscular disease or atherosclerotic renovascular disease (ARVD).

Fibromuscular disease of the renal arteries

Fibromuscular disease (FMD) accounts for 20–40% of renal vascular disease and encompasses four distinct types: (1) medial fibroplasia (65–85%); (2) perimedial fibroplasia (10–15%); (3) intimal fibroplasia (5–10%); and (4) medial hyperplasia (5%). Medial fibroplasia usually follows a benign course and never follows a progressive course after the age of 40 years. The other two types of fibroplasia follow a progressive course and may lead to total occlusion.

Medial hyperplasia is a distinct but rare entity, which accounts for only 1% of renovascular disease. It commonly affects young females, who exhibit elevated blood pressures but with well-preserved renal function.

MR angiography (gadolinium enhanced) reveals a characteristic string of beads appearance in fibroplasia.

Angioplasty (occasionally stent insertion) or surgery is usually performed in affected individuals. Cure rates were only 36% and 54% after angioplasty and surgery, respectively, in a recent study of over 2000 patients (defining cure as blood pressure <140/90 mm Hg without treatment), and the blood pressure outcome was strongly age related. Furthermore, the incidence of complications was substantial: combined risks of periprocedural complications were 12% after angioplasty and 17% after surgery, with fewer major complications after angioplasty (6%) than after surgery (15%). Given the efficacy of current medical antihypertensive therapy, intervention in these patients is usually not warranted.

Atherosclerotic renovascular disease (ARVD)

This is a common cause of hypertension and CKD due to ischaemic nephropathy. Its incidence increases with age, rising from 5% under 60 years to 16% in those over 60 years old. In most patients, the atherosclerotic lesion is ostial (within 1 cm of the origin of the renal artery) and usually associated with symptomatic atherosclerotic vascular disease elsewhere. Patients with peripheral vascular disease
(39%), coronary artery disease (10–29%), congestive cardiac failure (34%) and aortic aneurysm (38%) are at high risk of developing significant renal artery stenosis.

Many patients are asymptomatic and are discovered incidentally during investigation for other conditions. Aortography experience from the USA shows 11% of asymptomatic patients have significant unilateral stenosis and 4% have bilateral disease. The renal consequences of ARVD are functional, such as hypertension (present in 50%), sodium retention (ankle and flash pulmonary oedema), proteinuria (usually sub-nephrotic range) and decreased GFR. The morphological features of the affected kidneys include vascular sclerosis, tubular atrophy, interstitial fibrosis with inflammatory cellular infiltrate, atubular glomeruli, cholesterol emboli and secondary focal segmental glomerulosclerosis (FSGS) changes. Baseline renal function is related to the extent of renal parenchymal injury rather than to the degree of stenosis, as is the response (improvement in hypertension and renal function) to revascularization.

Renovascular disease should be looked for in the following: patients with hypertension and/or CKD; patients with abdominal audible bruits, as well as bruits over carotid arteries suggestive of generalized arterial disease; Doppler ultrasound showing >1.5 cm renal asymmetry; recurrent flash pulmonary oedema without cardiopulmonary disease; sonography showing arteriosclerotic plaques; patients with hypertension and/ or CKD; patients with renal function deterioration. Renovascular disease can progress to occlusion, particularly in patients with stenosis >75% as shown by serial angiography, necessitating revascularization in ARVD.

The options in renal artery stenosis include transluminal angioplasty to dilate the stenotic region, insertion of stents across the stenosis (sometimes the only endoscopic option when the stenosis occurs close to the origin of the renal artery from the aorta, rendering angioplasty technically difficult or impossible), reconstructive vascular surgery and nephrectomy.

Indications for revascularization. Vessels with stenosis >75% and recurrent flash pulmonary oedema, drug-resistant severe hypertension, ARVD affecting solitary functioning kidney, patients with cardiac failure needing ACE inhibitors, unexplained progressive CKD and dialysis-dependent renal failure. Generally, endovascular procedures are considered better than medical therapy alone and, with good selection of patients, hypertension is cured or improved by intervention in more than 50%. Occasional dramatic improvements in renal function ensue but results are generally disappointing. Deterioration of the renal function occurs in 20–30% of the patients after renal angioplasty stenting. Atheroembolism seems to play a role and is probably the main cause of this renal function deterioration.

Medication. All patients with ARVD should be treated with a combination of aspirin, statins and optimal control of blood pressure as prophylaxis against progression of atherosclerosis.

Prognosis. Mortality is high because of other associated co-morbidities, and ARVD patients have generalized endothelial dysfunction. ARVD patients with ESKD have higher rates than those with good renal function. Five-year survival is only 18% in patients with ESKD due to ARVD.

Screening for renovascular disease

Radionuclide studies (see p. 571). These can demonstrate decreased renal perfusion on the affected side. In unilateral renal artery stenosis, a disproportionate fall in uptake of isotope on the affected side following administration of captopril or aspirin is suggestive of the presence of significant renal artery stenosis. A completely normal result renders the diagnosis unlikely.

Doppler ultrasound. This method is very sensitive but highly operator-dependent and time-consuming. Measurement of renal-artery velocity by Doppler ultrasound provides a functional assessment of the severity of stenosis; higher velocity usually means higher pressure differential across the stenosis. It also generates useful data about intrarenal vascular resistance, which can be valuable in predicting the success of revascularization procedures. A resistive index of >0.8 is a predictor of poor response following intervention.

Magnetic resonance angiography. MRA can be used to visualize the renal arteries and there is a good – though not perfect – correlation between MRA findings and those of renal arteriography.

CT scanning. This permits non-invasive imaging of the renal arteries. It is much less expensive than MRA but does expose the patient to ionizing radiation and to contrast injection and is less reliable than MRA.

Renal arteriography (see this chapter) is used to confirm the diagnosis of renal arterial disease.

Other vascular disorders of the kidney

Renal artery occlusion

This occurs from thrombosis in situ, usually in a severely damaged atherosclerotic vessel, or more commonly from embolization, e.g. in atrial fibrillation. Both lead to renal infarction, resulting in a wide spectrum of clinical manifestations depending on the size of the artery involved. Occlusion of a small branch artery may produce no effect, but occlusion of larger vessels results in dull flank pain and varying degrees of CKD.

Intra-arterial thrombolytic therapy has been tried with mixed results.

Cholesterol embolization or atheroembolic renal disease (AERD)

Showerings of cholesterol-rich atheromatous material from ulcerated plaques reach the kidney from the aorta and/or renal arteries, particularly after catheterization of the abdominal aorta or attempts at renal artery angioplasty. Anticoagulants and thrombolytic agents also precipitate cholesterol embolization. Renal failure from cholesterol emboli may be acute or slowly progressive. Clinical features include fever, eosinophilia, back and abdominal pain, and evidence of embolization elsewhere, e.g. to the retina or digits. The diagnosis can be confirmed by renal biopsy (Fig. 12.36). It is more common in males, the elderly (>70 years) and patients with cardiovascular disease. Over 80% have abnormal renal function at baseline. AERD occurs spontaneously in 25% of the cases. The 2-year mortality is 30% and a similar percentage of patients develop CKD. Baseline co-morbidities, i.e.
Reduced renal function, presence of diabetes, history of heart failure, acute/subacute presentation, and gastrointestinal tract involvement, are significant predictors of event occurrence. The risk of dialysis and death is 50% lower among those receiving statins.

**Renal vein thrombosis**

This is usually of insidious onset, occurring in patients with the nephrotic syndrome, with a renal cell carcinoma, and in thrombophilia (p. 424) with an increased risk of venous thrombosis. Anticoagulation is indicated.

### Renal and vesical calculi

Renal stones are very common worldwide, with a lifetime risk of about 10%. Prevalence of stone disease is much higher in the Middle East. Most stones occur in the upper urinary tract.

Most stones are composed of calcium oxalate and phosphate; these are more common in men (Table 12.13). Mixed infective stones, which account for about 15% of all calculi, are twice as common in women as in men. The overall male to female ratio of stone disease is 2:1.

Stone disease is frequently a recurrent problem. More than 50% of patients with a history of nephrolithiasis will develop a recurrence within 10 years. The risk of recurrence increases if a metabolic or other abnormality predisposing to stone formation is present and is not modified by treatment. Nephrolithiasis is not a benign condition as several observational studies have demonstrated its association with increased risk of ESKD, bone diseases, hypertension and myocardial infarction.

### Renal calculi and nephrocalcinosis

#### Aetiology

Inhibitors of crystal formation are present in normal urine preventing the formation of stones, as the concentrations of stone-forming substances in many cases exceed their maximum solubility in water. Many stone-formers have no detectable metabolic defect, although microscopy of warm, freshly passed urine reveals both more and larger calcium oxalate crystals than are found in normal subjects. Factors predisposing to stone formation in these so-called ‘idiopathic stone-formers’ are:

- Chemical composition of urine that favours stone crystallization
- Production of a concentrated urine as a consequence of dehydration associated with life in a hot climate or work in a hot environment
- Impairment of inhibitors that prevent crystallization in normal urine. Postulated inhibitors include inorganic magnesium, pyrophosphate and citrate. Organic inhibitors include glycosaminoglycans and nephrocalcin (an acidic protein of tubular origin). Tamm–Horsfall protein may have a dual role in both inhibiting and promoting stone formation.

Recognized causes of stone formation are listed in Table 12.14.

#### Hypercalciuria

If the GFR is normal, hypercalciuria almost invariably leads to hypercalciuria. The common causes of hypercalciemia leading to stone formation are:

- Primary hyperparathyroidism
- Vitamin D ingestion
- Sarcoidosis.

Of these, primary hyperparathyroidism (see p. 994) is the most common cause of stones.

#### Hypercalcaemia

This is by far the most common metabolic abnormality detected in calcium stone-formers. Approximately 8% of men excrete in excess of 7.5 mmol of calcium in 24 hours. Calcium stone formation is more common in this group, but as the majority of even these individuals do not form stones the definition of ‘pathological’ hypercalciuria is arbitrary. A reasonable definition is 24-hour calcium excretion of >7.5 mmol in male stone-formers and >6.25 mmol in female stone-formers.

The kidney is the major site for plasma calcium regulation. Approximately 90% of the ionized calcium filtered by the kidney is reabsorbed. Renal tubular reabsorption is controlled largely by parathyroid hormone (PTH).

Approximately 65% of the filtered calcium is absorbed in the proximal convoluted tubule, 20% by the thick ascending
Renal calculi and nephrocalcinosis

Can occur as a primary defect in idiopathic gout, and as a secondary consequence of increased cell turnover, e.g. in myeloproliferative disorders. Increased uric acid excretion occurs in these conditions, and stones will develop in some patients. Some uric acid stone-formers have hyperuricosuria (>4 mmol/24 hours on a low-purine diet), without hyperuricaemia.

Dehydration alone may also cause uric acid stones to form. Patients with leaestomies are at particular risk both from dehydration and from the fact that loss of bicarbonate from gastrointestinal secretions results in the production of an acid urine (uric acid is more soluble in an alkaline than in an acid medium).

Some patients with calcium stones also have hyperuricaemia and/or hyperuricosuria; it is believed the calcium salts precipitate upon an initial nidus of uric acid in such patients.

Urinary tract infection

Mixed infective stones are composed of magnesium ammonium phosphate together with variable amounts of calcium. Such struvite stones are often large, forming a cast of the collecting system (staghorn calculus). These stones are usually due to UTI with organisms such as Proteus mirabilis that hydrolyse urea, with formation of the strong base ammonium hydroxide. The availability of ammonium ions and the alkalinity of the urine favour stone formation. An increased production of mucoprotein from infection also creates an organic matrix on which stone formation can occur.

Cystinuria

Cystinuria results in the formation of cystine stones. About 1–2% of all stones are composed of cystine.

Primary renal diseases

- **Polycystic renal disease** (see p. 632) shows a high prevalence of stone disease.
- **Medullary sponge kidney** is also associated with stones. There is dilatation of the collecting ducts with associated stasis and calcification (Fig. 12.37). Approximately 20% of these patients have hypercalciuria and a similar proportion have a renal tubular acidification defect.
- **Renal tubular acidosces**, both inherited and acquired, are associated with nephrocalcinosis and stone formation, owing, in part, to the production of a persistently alkaline urine and reduced urinary citrate excretion.

**Hypercalciuria**

Causes of hypercalciuria are:

- Hypercalcaemia
- An excessive dietary intake of calcium
- Excessive resorption of calcium from the skeleton, such as occurs with prolonged immobilization or weightlessness
- Idiopathic hypercalciuria.

Idiopathic hypercalciuria is a common risk factor for the formation of stones, and uncontrolled hypercalciuria is a cause of recurrences. The majority of patients with idiopathic hypercalciuria have increased absorption of calcium from the gut. Moreover, studies have shown that animal protein and salt also have a considerable influence on calcium excretion.

**Hyperoxaluria**

There are two inborn errors of glyoxalate metabolism that cause increased endogenous oxalate biosynthesis and are inherited in an autosomal recessive manner:

- **Type 1**: alanine-glyoxylate aminotransferase deficiency
- **Type 2**: glyoxylate reductase hydroxypyruvate reductase deficiency.

In both types, calcium oxalate stone formation occurs.

The prognosis is poor owing to widespread calcium oxalate crystal deposition in the kidneys. CKD typically develops in the late teens or early twenties. Successful liver transplantation has been shown to cure the metabolic defect.

Much more common causes of mild hyperoxaluria are:

- Excess ingestion of foodstuffs high in oxalate, such as spinach, rhubarb and tea
- Dietary calcium restriction, with compensatory increased absorption of oxalate
- Gastrointestinal disease (e.g. Crohn’s), usually with an intestinal resection, associated with increased absorption of oxalate from the colon.

Dehydration secondary to fluid loss from the gut also plays a part in stone formation.

**Hyperuricaemia and hyperuricosuria**

Uric acid stones account for 3–5% of all stones in the UK, but in Israel the proportion is as high as 40%. Uric acid is the endpoint of purine metabolism. Hyperuricaemia (see p. 530) can occur as a primary defect in idiopathic gout, and as a secondary consequence of increased cell turnover, e.g. in myeloproliferative disorders. Increased uric acid excretion occurs in these conditions, and stones will develop in some patients. Some uric acid stone-formers have hyperuricosuria (>4 mmol/24 hours on a low-purine diet), without hyperuricaemia.

Dehydration alone may also cause uric acid stones to form. Patients with leaestomies are at particular risk both from dehydration and from the fact that loss of bicarbonate from gastrointestinal secretions results in the production of an acid urine (uric acid is more soluble in an alkaline than in an acid medium).

Some patients with calcium stones also have hyperuricaemia and/or hyperuricosuria; it is believed the calcium salts precipitate upon an initial nidus of uric acid in such patients.

**Hypercalciuria**

Causes of hypercalciuria are:

- Hypercalcaemia
- An excessive dietary intake of calcium
- Excessive resorption of calcium from the skeleton, such as occurs with prolonged immobilization or weightlessness
- Idiopathic hypercalciuria.

Idiopathic hypercalciuria is a common risk factor for the formation of stones, and uncontrolled hypercalciuria is a cause of recurrences. The majority of patients with idiopathic hypercalciuria have increased absorption of calcium from the gut. Moreover, studies have shown that animal protein and salt also have a considerable influence on calcium excretion.

**Hyperoxaluria**

There are two inborn errors of glyoxalate metabolism that cause increased endogenous oxalate biosynthesis and are inherited in an autosomal recessive manner:

- **Type 1**: alanine-glyoxylate aminotransferase deficiency
- **Type 2**: glyoxylate reductase hydroxypyruvate reductase deficiency.

In both types, calcium oxalate stone formation occurs.

The prognosis is poor owing to widespread calcium oxalate crystal deposition in the kidneys. CKD typically develops in the late teens or early twenties. Successful liver transplantation has been shown to cure the metabolic defect.

Much more common causes of mild hyperoxaluria are:

- Excess ingestion of foodstuffs high in oxalate, such as spinach, rhubarb and tea
- Dietary calcium restriction, with compensatory increased absorption of oxalate
- Gastrointestinal disease (e.g. Crohn’s), usually with an intestinal resection, associated with increased absorption of oxalate from the colon.

Dehydration secondary to fluid loss from the gut also plays a part in stone formation.

**Hyperuricaemia and hyperuricosuria**

Uric acid stones account for 3–5% of all stones in the UK, but in Israel the proportion is as high as 40%. Uric acid is the endpoint of purine metabolism. Hyperuricaemia (see p. 530) can occur as a primary defect in idiopathic gout, and as a secondary consequence of increased cell turnover, e.g. in myeloproliferative disorders. Increased uric acid excretion occurs in these conditions, and stones will develop in some patients. Some uric acid stone-formers have hyperuricosuria (>4 mmol/24 hours on a low-purine diet), without hyperuricaemia.

Dehydration alone may also cause uric acid stones to form. Patients with leaestomies are at particular risk both from dehydration and from the fact that loss of bicarbonate from gastrointestinal secretions results in the production of an acid urine (uric acid is more soluble in an alkaline than in an acid medium).

Some patients with calcium stones also have hyperuricaemia and/or hyperuricosuria; it is believed the calcium salts precipitate upon an initial nidus of uric acid in such patients.

**Urinary tract infection**

Mixed infective stones are composed of magnesium ammonium phosphate together with variable amounts of calcium. Such struvite stones are often large, forming a cast of the collecting system (staghorn calculus). These stones are usually due to UTI with organisms such as Proteus mirabilis that hydrolyse urea, with formation of the strong base ammonium hydroxide. The availability of ammonium ions and the alkalinity of the urine favour stone formation. An increased production of mucoprotein from infection also creates an organic matrix on which stone formation can occur.

**Cystinuria** (see also p. 1040)

Cystinuria results in the formation of cystine stones. About 1–2% of all stones are composed of cystine.

**Primary renal diseases**

- **Polycystic renal disease** (see p. 632) shows a high prevalence of stone disease.
- **Medullary sponge kidney** is also associated with stones. There is dilatation of the collecting ducts with associated stasis and calcification (Fig. 12.37). Approximately 20% of these patients have hypercalciuria and a similar proportion have a renal tubular acidification defect.
- **Renal tubular acidosces**, both inherited and acquired, are associated with nephrocalcinosis and stone formation, owing, in part, to the production of a persistently alkaline urine and reduced urinary citrate excretion.

**Figure 12.37 Medullary sponge kidney.** (a) Plain film showing ‘spotty’ calcification in the renal areas (arrow). (b) After injection of contrast, the calcification is shown to be small calculi in the papillary zones.
Kidney and urinary tract disease

A history of possible aetiological factors should be obtained, including:
- Occupation and residence in hot countries likely to be associated with dehydration
- A history of vitamin D consumption
- Gouty arthritis.

Calcified papillae may mimic ordinary calculi, so that causes of papillary necrosis such as analgesic abuse should be considered.

Physical examination should include a search for corneal or conjunctival calcification, gouty tophi and arthritis and features of sarcoidosis.

Investigations
- A mid-stream specimen of urine for culture
- Serum urea, electrolyte, creatinine (eGFR) and calcium levels.
- Plain abdominal X-ray
- CT-KUB is the best diagnostic test available. Ureteric stones can be missed by ultrasound.

CT-KUB (CT of kidney, ureter and bladder) is carried out during the episode of pain; a normal CT excludes the diagnosis of pain due to calculous disease. The CT-KUB appearances in a patient with acute left ureteric obstruction are shown in Figure 12.38.

Drugs
Some drugs promote calcium stone formation (e.g. loop diuretics, antacids, glucocorticoids, theophylline, vitamins D and C, acetazolamide); some promote uric acid stones (e.g. thiazides, salicylates,); and some precipitate into stones (e.g. indinavir, triamterene, sulphadiazine).

Aetiology of bladder stones
Bladder stones are endemic in some developing countries but the incidence is declining. The cause of this is unknown but dietary factors probably play a role. Bladder stones may be the result of:
- bladder outflow obstruction (e.g. urethral stricture, neuropathic bladder, prostatic obstruction)
- the presence of a foreign body (e.g. catheters, non-absorbable sutures).

Significant bacteriuria is usually found in patients with bladder stones. Some stones found in the bladder have been passed down from the upper urinary tract.

Pathology
Stones may be single or multiple and vary enormously in size from minute, sand-like particles to staghorn calculi or large stone concretions in the bladder. They may be located within the renal parenchyma or within the collecting system. Pressure necrosis from a large calculus can cause direct damage to the renal parenchyma, and stones regularly cause obstruction, leading to hydroureter. They may ulcerate through the wall of the collecting system, including the ureter. A combination of obstruction and infection accelerates damage to the kidney.

Clinical features
Most people with urinary tract calculi are asymptomatic. Pain is the most common symptom and may be sharp or dull, constant, intermittent or colicky (Table 12.15).

When urinary tract obstruction is present, measures that increase urine volume, such as copious fluid intake or diuretics, including alcohol, make the pain worse. Physical exertion may cause mobile calculi to move, precipitating pain and, occasionally, haematuria. Ureteric colic occurs when a stone enters the ureter and either obstructs it or causes spasm during its passage down the ureter. This is one of the most severe pains known. Radiation from the flank to the iliac fossa and testis in the distribution of the first lumbar nerve root is common. Pallor, sweating and vomiting often occur and the patient is restless, trying to obtain relief from the pain. Haematuria often occurs. Untreated, the pain of ureteric colic typically subsides after a few hours.

When urinary tract obstruction and infection are present, the features of acute pyelonephritis or of a Gram-negative septicemia may dominate the clinical picture.

Vesical calculi associated with bladder bacteriuria present with frequency, dysuria and haematuria; severe introital or perineal pain may occur if trigonitis is present. A calculus at the bladder neck or an obstruction in the urethra may cause bladder outflow obstruction, resulting in anuria and painful bladder distension.

Figure 12.38 CT-KUB in ureteric stone obstruction.
(a) Left ureteric calculus. (b) A dilated renal pelvis (arrow) proximal to the ureteric stone in (a).
Renal calculi and nephrocalcinosis

Management

Adequate analgesia should be given. An NSAID, e.g. diclofenac 75 mg by i.v. infusion, compares favourably with pethidine and does not cause nausea. Stones less than 0.5 cm diameter usually pass spontaneously. Alpha blockers (e.g. tamsulosin) facilitate spontaneous expulsion of distal ureteral stones of <6 mm size and should be tried first as alpha receptors are predominantly present in distal ureter and detrusor and this strategy is very cheap and has a high safety profile.

Stones >1 cm diameter usually require urological or radiological intervention. Extracorporeal shock wave lithotripsy (ESWL) will fragment most stones, which then pass spontaneously. Ureteroscopy with a YAG laser can be used for larger stones. Percutaneous nephrolithotomy is also used. Open surgery is rarely needed.

Investigating the cause of stone formation

In an elderly patient who has had a single episode with one stone, only limited investigation is required. Younger patients and those with recurrent stone formation require detailed investigation.

- Renal imaging is necessary to define the presence of a primary renal disease predisposing to stone formation.
- Significant bacteriuria may indicate mixed infective stone formation, but relapsing bacteriuria may be a consequence of stone formation rather than the original cause.
- Chemical analysis of any stone passed is of great value and all that is required in the diagnosis of cystinuria or uric acid stone formation.
- Serum calcium concentration should be estimated and corrected for serum albumin concentration (see p. 634). Hypercalcaemia, if present, should be investigated further (see p. 995).
- Serum urate concentration is often, but not invariably, elevated in uric acid stone-formers.
- A screening test for cystinuria should be carried out by adding sodium nitroprusside to a random unacidified urine sample; a purple colour indicates that cystinuria may be present. Urine chromatography is required to define the diagnosis precisely.

- Urinary calcium, oxalate and uric acid output should be measured in two consecutive carefully collected 24-hour urine samples. After withdrawing aliquots for estimation of uric acid, it is necessary to add acid to the urine in order to prevent crystallization of calcium salts upon the walls of the collection vessel, which would give falsely low results for urinary calcium and oxalate.
- Plasma bicarbonate is low in renal tubular acidosis.

The finding of a urine pH that does not fall below 5.5 in the face of metabolic acidosis is diagnostic of this condition (see p. 664).

Prophylaxis

The age of the patient and the severity of the problem affect both the need for and the type of prophylaxis.

Idiopathic stone-formers

Where no metabolic abnormality is present, the mainstay of prevention is maintenance of a high intake of fluid throughout the day and night. The aim should be to ensure a daily urine volume of 2–2.5 L, which requires a fluid intake in excess of this, substantially so in the case of those who live in hot countries or work in a hot environment.

Idiopathic hypercalciuria

Severe dietary calcium restriction is inappropriate (see p. 627) and patients should be encouraged to consume a normal-calcium (30 mmol/day) diet. Dietary calcium restriction results in hyperabsorption of oxalate, and so foods containing large amounts of oxalate should also be limited. A high fluid intake should be advised as for idiopathic stone-formers. Patients who live in a hard-water area may benefit from drinking softened water.

If hypercalciuria persists and stone formation continues, a thiazide is used (e.g. bendroflumethiazide 2.5 or 5 mg each morning). Thiazides reduce urinary calcium excretion by an indirect effect due to mild volume contraction resulting in increased calcium absorption in the proximal renal tubule. They may precipitate diabetes mellitus or gout and worsen hypercholesterolaemia. Reduction of animal proteins to 50 g/day and sodium intake to 50 mmol/day is also advisable.

Mixed infective stones

Recurrent stones should be prevented by maintenance of a high fluid intake and meticulous control of bacteriuria. This will require long-term follow-up and often the use of long-term low-dose prophylactic antibacterial agents.

Uric acid stones

Dietary measures are probably of little value and are difficult to implement. Effective prevention can be achieved by the long-term use of allopurinol to maintain the serum urate and urinary uric acid excretion in the normal range. A high fluid intake should also be maintained. Uric acid is more soluble at alkaline pH, and long-term sodium bicarbonate supplementation to maintain an alkaline urine is an alternative approach in those few patients unable to take allopurinol (see p. 995). However, alkalization of the urine facilitates precipitation of calcium oxalate and phosphate.

Cystine stones

These can be prevented and indeed will dissolve slowly with a high fluid intake. Five litres of water is drunk each 24 hours, and the patient must wake twice during the night to ingest.

Figure 12.39 CT scan, showing a uric acid stone, which appears as a bright lesion in the left kidney (arrow).
500 mL or more of water. Many patients cannot tolerate this regimen. Alkalization to a pH of 7 requires high doses of potassium citrate or bicarbonate. An alternative option is the long-term use of the chelating agent penicillamine; this causes cystine to be converted to the more soluble penicillamine-cysteine complex. Side-effects include drug rashes, blood dyscrasias and immune complex-mediated glomerulonephritis. However, it is especially effective in promoting dissolution of cystine stones already present. Other cystine-binding drugs include tiopronin which may lower precipitation more readily in an alkaline medium and the calcium-chelating action of urinary citrate is preferred.

Mild hyperoxaluria with calcium oxalate stones

Hyperoxaluria can result from rare monogenic conditions. Type 1 can be managed with oral high-dose pyridoxine, but type 2 is unlikely to respond to it. Unfortunately, there is currently no proven pharmacotherapy to effectively treat the more common form of ‘idiopathic’ hyperoxaluria present in up to 40% of stone formers. Probiotic Oxalobacter formigenes has shown some promise.

Current advice for idiopathic hyperoxaluria patients includes high fluid intake and dietary oxalate restriction. Dietary advice as in hypercalciuria is also advisable.

Nephrocalcinosis

The term ‘nephrocalcinosis’ means diffuse renal parenchymal calcification that is detectable radiologically (Fig. 12.40). The condition is typically painless. Hypertension and CKD commonly occur. The main causes of nephrocalcinosis are listed in Table 12.16.

Dystrophic calcification occurs following renal cortical necrosis. In hypercalcaemia and hyperoxaluria, deposition of calcium oxalate results from the high concentration of calcium and oxalate within the kidney.

In renal tubular acidosis (see p. 664) failure of urinary acidification and a reduction in urinary citrate excretion both favour calcium phosphate and oxalate precipitation, since precipitation occurs more readily in an alkaline medium and the calcium-chelating action of urinary citrate is reduced.

Treatment and prevention of nephrocalcinosis consists of treatment of the cause.

**URINARY TRACT OBSTRUCTION**

The urinary tract can be obstructed at any point between the kidney and the urethral meatus. This results in dilatation of the tract above the obstruction. Dilatation of the renal pelvis is known as hydrenephrosis.

Aetiology

Obstructing lesions may lie within the lumen, or in the wall of the urinary tract, or outside the wall, causing obstruction by external pressure. The major causes of obstruction are shown in Table 12.17. Overall, the frequency is the same in men and women. However, in the elderly, urinary tract obstruction is more common in men owing to the frequency of bladder outflow obstruction from prostatic disease.

Pathophysiology

Obstruction with continuing urine formation results in:
- Progressive rise in intraluminal pressure
- Dilatation proximal to the site of obstruction
- Compression and thinning of the renal parenchyma, eventually reducing it to a thin rim and resulting in a decrease in the size of the kidney.

Acute obstruction is followed by transient renal arterial vasodilatation succeeded by vasoconstriction, probably

---

**FURTHER READING**

mediated mainly by angiotensin II and thromboxane A₂. Ischaemic interstitial damage mediated by free oxygen radicals and inflammatory cytokines compounds the damage induced by compression of the renal substance.

Clinical features

**Symptoms of upper tract obstruction**

Loin pain occurs which can be dull or sharp, constant or intermittent. It is often provoked by measures that increase urine volume and hence distension of the collecting system, such as a high fluid intake or diuretics, including alcohol. Complete anuria is strongly suggestive of complete bilateral obstruction or complete obstruction of a single kidney.

Conversely, polyuria may occur in partial obstruction owing to impairment of renal tubular concentrating capacity. Intermittent anuria and polyuria indicates intermittent complete obstruction.

Infection complicating the obstruction may give rise to malaise, fever and septicaemia.

**Symptoms of bladder outflow obstruction**

Symptoms may be minimal. Hesitancy, narrowing and diminished force of the urinary stream, terminal dribbling and a sense of incomplete bladder emptying are typical features (see p. 635).

Infection commonly occurs, causing increased frequency, urgency, urge incontinence, dysuria and the passage of cloudy smelly urine. It may precipitate acute retention.

**Signs**

Loin tenderness may be present. An enlarged hydronephrotic kidney is often palpable. In acute or chronic retention the enlarged bladder can be felt or percussed. Examination of the genitalia, rectum and vagina is essential, since prostatic enlargement is seldom used. The nephrogram is delayed on the obstructed side, owing to a reduction in the GFR. With time, the nephrogram on the affected side becomes denser than normal, owing to the prolonged nephron transit time, and the site of obstruction with proximal dilatation is seen (Fig. 12.41).

Excretion urography is seldom used. The nephrogram is delayed on the obstructed side, owing to a reduction in the GFR. With time, the nephrogram on the affected side becomes denser than normal, owing to the prolonged nephron transit time, and the site of obstruction with proximal dilatation is seen (Fig. 12.41).

Radionuclide studies (see p. 571). These have no place in the initial investigation of acute obstruction. Their main role is in possible longstanding obstruction to differentiate true obstructive nephropathy from retention of tracer in a baggy, low-pressure, unobstructed pelvicalyceal system.

Investigations

- **Routine blood and biochemical investigations** show a raised serum urea or creatinine (eGFR), hyperkalaemia, anaemia of chronic disease or blood in the urine.
- **Plain abdominal X-ray** may detect radiolucent stones/calcification but can miss stones lying over the bone.
- **CT scanning** has a high sensitivity and can visualize uric acid (radiolucent) stones as small as 1 mm, as well as details of the obstruction.
- **Ultrasonography** (see p. 570) can rule out upper urinary tract dilatation. Ultrasound cannot distinguish a baggy, low-pressure unobstructed system from a tense, high-pressure obstructed one, so that false-positive scans are seen. Stones in the ureter can be missed.
- **Excretion urography** is seldom used. The nephrogram is delayed on the obstructed side, owing to a reduction in the GFR. With time, the nephrogram on the affected side becomes denser than normal, owing to the prolonged nephron transit time, and the site of obstruction with proximal dilatation is seen (Fig. 12.41).
- **Radionuclide studies** (see p. 571). These have no place in the initial investigation of acute obstruction. Their main role is in possible longstanding obstruction to differentiate true obstructive nephropathy from retention of tracer in a baggy, low-pressure, unobstructed pelvicalyceal system.

**Treatment**

The aim is to relieve symptoms and preserve renal function by:

- Relieving the obstruction
- Treating the underlying cause
- Preventing and treating infection.

Temporary external drainage of urine by nephrostomy may be valuable, as this allows time for further investigation when the site and nature of the obstructing lesion are...
depends on the cause of the disease. IgG4-related disease.

**Surgical management** depends on the cause of the obstruction (see below) and local expertise. Dialysis may be required in the ill patient prior to surgery.

Diuresis usually follows relief of obstruction at any site in the urinary tract. Massive diuresis may occur following relief of bilateral obstruction owing to previous sodium and water overload and the osmotic effect of retained solutes combined with a defective renal tubular reabsorptive capacity (as in the diuretic phase of recovering acute tubular necrosis). This diuresis is associated with increased blood volume and high levels of atrial natriuretic peptide (ANP). Defective renal tubular reabsorptive capacity cannot be the sole mechanism of severe diuresis since this phenomenon is not observed following relief of unilateral obstruction. The diuresis is usually self-limiting, but a minority of patients will develop severe sodium, water and potassium depletion requiring appropriate intravenous replacement. In milder cases, oral salt and potassium supplements together with a high water intake are sufficient.

**Specific causes of obstruction**

**Calculi**

These are discussed on page 600.

**Pelviureteric junction obstruction** (Fig. 12.42)

This results from a functional disturbance in peristalsis of the collecting system in the absence of mechanical obstruction. Surgical attempts at correction of the obstruction by open or percutaneous pyeloplasty are indicated in patients with recurrent loin pain and those in whom serial scans or measurements of GFR indicate progressive kidney damage. Nephrectomy to remove the risk of developing pyonephrosis and sepsicaemia is indicated if longstanding obstruction has destroyed kidney function.

**Obstructive megaureter**

This childhood condition may become evident only in adult life. It results from the presence of a region of defective peristalsis at the lower end of the ureter adjacent to the ureterovesical junction. The condition is more common in males. It presents with UTI, flank pain or haematuria. The diagnosis is made on imaging with ultrasound, CT or, if necessary, ascending ureterography.

Excision of the abnormal portion of ureter with reimplantation into the bladder is always indicated in children and in adults when the condition is associated with evidence of progressive deterioration in renal function, bacteriuria that cannot be controlled by medical means, or recurrent stone formation.

**Retroperitoneal fibrosis (RPF; chronic periaortitis)**

The incidence and prevalence are 0.1 per 100 000 and 1.38 per 100 000, respectively. It is three times more common in men than in women.

The ureters become embedded in dense retroperitoneal fibrous tissue with resultant unilateral or bilateral obstruction. Obstruction is usually due to loss of peristalsis rather than occlusion. The condition may extend from the level of the second lumbar vertebra to the pelvic brim. In up to 15% of patients, the fibrotic process can extend outside the retroperitoneum, consistent with it being a systemic condition. Mediastinal fibrosis, Riedel fibrosing thyroiditis, sclerosing cholangitis, fibrotic orbital pseudotumour, fibrotic arthropathy, pleural, pericardial and lung fibrosis have been reported with increasing frequency.

**Aetiology** is either an autoallergic response to leakage of material, probably ceroid, from atheromatous plaques producing an inflammatory reaction, or a systemic autoimmune disease. There is an association with HLA-DRB1*03, an allele linked to various autoimmune diseases. RPF is possibly initiated as a vasa vasorum vasculitis in the aortic wall which is often seen in chronic periaortitis. This inflammatory process can cause medial wall thinning and promote atherosclerosis, and also extends into the surrounding retroperitoneum with a fibro-inflammatory reaction typical of chronic periaortitis. The autoimmune reaction to plaque antigens could be an epiphenomenon of this immune-mediated process. Activating antibodies against fibroblasts (detectable in one-third of patients) have also been implicated in the pathogenesis, as has the presence of IgG4-bearing plasma cells; the latter is a common finding in autoimmune chronic pancreatitis, a disorder sometimes associated with idiopathic retroperitoneal fibrosis. In addition, several infiltrating B cells show clonal or oligoclonal immunoglobulin heavy chain rearrangement. These findings raise the possibility of RPF being a primary B-cell disorder.

**Pathology.** The hallmark of idiopathic RPF is background sclerosis with myofibroblasts associated with a diffuse and perivascular infiltrate mainly consisting of T and B lymphocytes and IgG4 isotype bearing plasma cells. Small vessel vasculitis may be found in approximately 50% of the patients.

**Causes** are many but 66% are idiopathic. **Secondary causes include drugs** (methysergide, lysergic acid, ergot derived dopamine receptor agonists (cabergoline, bromocriptine, pergolide), ergotamine, methylidopa, hydralazine, beta-blockers, malignant diseases (carcinomas of the colon, prostate, breast, stomach, carcinoid, Hodgkin’s and non-Hodgkin’s lymphomas, sarcomas), infections (tuberculosis, syphilis, histoplasmosis, actinomycosis and fungal infections), and surgery/radiotherapy (lymph node resection,
colectomy, hysterectomy, aortic aneurysm repair). Recognized associations include untreated abdominal aortic aneurysm, smoking and asbestosis.

**Clinical.** Malaise, low back pain, weight loss, testicular pain, claudication and haematuria occur.

**Laboratory tests** show normochromic anaemia, uраеmia and a raised erythrocyte sedimentation rate (ESR) and CRP.

**Imaging** with ultrasound will show a poorly circumscribed periaortic mass. The test of choice is a contrast-enhanced CT, which will show the mass, lymph nodes and tumour (Fig. 12.43). MRI will show similar findings but does not require contrast. Positron emission tomography (PET) is helpful (see below).

**Treatment.** Obstruction is relieved surgically by ureterolysis. A biopsy is performed to exclude an underlying lymphoma or carcinoma. Corticosteroids are of benefit, and in bilateral obstruction in frail patients it may be best to free only one ureter and to rely upon steroid therapy to induce regression of fibrous tissue on the contralateral side, since bilateral ureterolysis is a major operation. An alternative approach is placement of a ureteric stent or stents and corticosteroid therapy, but regular (usually 6-monthly) changes of the stent or stents are required if the periaortic mass does not regress.

**Management.** Response to treatment and disease activity are assessed by serial measurements of ESR and eGFR supplemented by isotopic and imaging techniques including CT scanning. Fluorodeoxyglucose-PET (FDG-PET), a functional imaging modality, assesses the metabolic activity of the retroperitoneal mass. FDG-PET also allows whole-body imaging and can detect occult malignant or infectious foci, particularly in secondary retroperitoneal fibrosis. In idiopathic RPF, FDG-PET can be used to monitor the residual inflammatory component following medical therapy. Relapse after withdrawal of steroid therapy may occur and treatment may need to be continued for years. Mycophenolate or tamoxifen is also effective. Long-term follow-up is mandatory.

**Benign prostatic hypertrophy**

Benign prostatic hypertrophy is a common cause of urinary tract obstruction. It is described on page 635.

**Prognosis of urinary tract obstruction**

The prognosis depends upon the cause and the stage at which obstruction is relieved. In obstruction, four factors influence the rate at which kidney damage occurs, its extent and the degree and rapidity of recovery of renal function after relief of obstruction. These are:

- Whether obstruction is partial or complete
- The duration of obstruction
- Whether or not infection occurs
- The site of obstruction.

Complete obstruction for several weeks will lead to irreversible or only partially reversible kidney damage. If the duration of complete obstruction is several months, total irreversible destruction of the affected kidney will result. Partial obstruction carries a better prognosis, depending upon its severity. Bacterial infection coincident with obstruction rapidly increases kidney damage. Obstruction at or below the bladder neck may induce hypertrophy and trabeculation of the bladder without a rise in pressure within the upper urinary tract, in which case the kidneys are protected from the effects of back-pressure.

**DRUGS AND THE KIDNEY**

**Drug-induced impairment of renal function**

**Pre-renal**

Impaired perfusion of the kidneys can result from drugs that cause:

- Hypovolaemia, e.g.
  - Potent loop diuretics such as furosemide, especially in elderly patients
  - Renal salt and water loss, such as from hypercalcaemia induced by vitamin D therapy (since hypercalcaemia adversely affects renal tubular salt and water conservation)
- Decrease in cardiac output, which impairs renal perfusion (e.g. beta-blockers)
- Decreased renal blood flow (e.g. ACE inhibitors particularly in the presence of renovascular disease).

**Renal**

Several mechanisms of drug-induced renal damage exist and may co-exist.

- **Acute tubular necrosis produced by direct nephrotoxicity.** Examples include prolonged or excessive treatment with aminoglycosides (e.g. gentamicin, streptomycin), amphotericin B, heavy metals or carbon tetrachloride. The combination of aminoglycosides with furosemide is particularly nephrotoxic.
- **Acute tubulointerstitial nephritis** (see p. 595) with interstitial oedema and inflammatory cell infiltration. This cell-mediated hypersensitivity nephritis occurs with many drugs, including penicillins, sulphonamides and NSAIDs (which have many other effects on the kidney; Box 12.3).
- **Chronic tubulointerstitial nephritis** due to drugs, see page 596.
- **Membranous glomerulonephritis,** e.g. penicillamine, gold, anti-TNF (p. 577).

**Post-renal**

Retroperitoneal fibrosis with urinary tract obstruction can result from the use of drugs (p. 606).

---

Box 12.4 Safe prescribing in kidney disease

Safe prescribing in CKD demands knowledge of the clinical pharmacology of the drug and its metabolites in normal individuals and in uraemia. The clinician should ask the following questions when prescribing, and discuss with the patient:

1. **Is treatment mandatory?** Unless it is, it should be withheld.
2. **Can the drug reach its site of action?** For example, there is little point in prescribing the urinary antiseptic, nitrofurantoin, in severe CKD since bacteriostatic concentrations will not be attained in the urine.
3. **Is the drug’s metabolism altered in uraemia?**
4. **Will accumulation of the drug or metabolites occur?** Even if accumulation is a potential problem owing to the drug or its metabolites being excreted by the kidneys, it is not necessarily an indication to change the drug given. The size of the loading dose will depend upon the size of the patient and is unrelated to renal function. Avoidance of toxic levels of drug in blood and tissues subsequently requires the administration of normal doses of the drug at longer time intervals than usual or smaller doses at the usual time intervals.
5. **Is the drug toxic to the kidney?**
6. **Are the effective concentrations of the drug in biological tissues similar to the toxic concentrations?** Should blood levels of the drug be measured?
7. **Will the drug worsen the uraemic state?** by means other than nephrotoxicity, e.g. steroids, tetracyclines?
8. **Is the drug a sodium or potassium salt?** These are potentially hazardous in uraemia.

Not surprisingly, adverse drug reactions are more than twice as common in CKD as in normal individuals. Elderly patients, in whom unsuspected CKD is common, are particularly at risk. Attention to the above and titration of the dose of drugs employed should reduce the problem.

The dose may be titrated by:
- Observation of its clinical effect, e.g. hypotensive agents
- Early detection of toxic effects
- Measurement of drug levels in the blood, e.g. gentamicin levels.

Use of drugs in patients with impaired renal function (Box 12.4)

Many aspects of drug handling are altered in patients with CKD.

Absorption

This may be unpredictable in uraemia, as nausea and vomiting are frequently present.

Metabolism

Oxidative metabolism of drugs by the liver is altered in uraemia, although this is rarely of clinical significance.

The rate of drug metabolism by the kidney is reduced as a result of two factors:

- **Reduced drug catabolism.** Insulin, for example, is in part catabolized by the normal kidney. In renal disease, insulin catabolism is reduced. The insulin requirements of diabetics decline as renal function deteriorates, for this reason.
- **Reduced conversion of a precursor to a more active metabolite.** Such as the conversion of 25-hydroxycholecalciferol to the more active 1,25-(OH)2D3. The 1α-hydroxylase enzyme responsible for this conversion is located in the kidney. In renal disease, production of the enzyme declines and deficiency of 1,25-(OH)2D3 results.

Protein binding

Reduced protein binding of a drug potentiates its activity and increases the potential for toxic side-effects. Measurement of the total plasma concentration of such a drug can give misleading results. For example, the serum concentration of phenytoin required to produce an antiepileptic effect is much higher in normal individuals than in those with CKD, since in the latter proportionately more drug is present in the free form.

Some patients with renal disease are hypoproteinaemic and reduced drug-binding to protein results. This is not the sole mechanism of reduced drug-binding in such patients. For example, hydrogen ions, which are retained in CKD, bind to receptors for acidic drugs such as sulphonamides, penicillin and salicylates, thus enhancing their potential for causing toxicity.

Volume of distribution

Salt and water overload or depletion may occur in patients with renal disease. This affects the concentration of drug obtained from a given dose.

End-organ sensitivity

The renal response to drug treatment may be reduced in renal disease. For example, mild thiazide diuretics have little diuretic effect in patients with severe CKD.

Renal elimination

The major problem in the use of drugs in CKD concerns the reduced elimination of many drugs normally excreted by the kidneys.

Water-soluble drugs such as gentamicin that are poorly absorbed from the gut, typically given by injection and not metabolized by the liver, give rise to far more problems than lipid-soluble drugs such as propranolol, which are well absorbed and principally metabolized by the liver. Metabolites of lipid-soluble drugs, however, may themselves be water-soluble and potentially toxic.

Drugs causing uraemia by effects upon protein anabolism and catabolism

Tetracyclines, with the exception of doxycycline, have a catabolic effect and as a result the concentration of nitrogenous waste products is increased. They may also cause impairment of GFR by a direct effect. Corticosteroids have a catabolic effect and so also increase the production of nitrogenous wastes. A patient with moderate impairment of renal function may therefore become severely uraemic if given tetracyclines or corticosteroid therapy.
Drugs and toxic agents causing specific renal tubular syndromes include mercury, lead, cadmium and vitamin D.

Problem patients
Particular problems are presented by patients in whom renal function is altering rapidly, such as those with recovering acute tubular necrosis. In addition, drugs may be removed by dialysis and haemofiltration, which will affect the dosage required.

**ACUTE KIDNEY INJURY (AKI)**

**Definition**
Acute kidney injury has variably been defined as an abrupt deterioration in parenchymal renal function, which is usually, but not invariably, reversible over a period of days or weeks. In clinical practice, such deterioration in renal function is sufficiently severe to result in uraemia. Oliguria is usually, but not invariably, a feature. Acute kidney injury may cause sudden, life-threatening biochemical disturbances and is a medical emergency. The distinction between acute and CKD or even acute-on-chronic kidney disease, cannot be readily apparent in a patient presenting with uraemia. In view of these difficulties, the Acute Dialysis Quality Initiative group proposed the RIFLE (Risk, Injury, Failure, Loss, End-stage renal disease; Box 12.5) criteria utilizing either increases in serum creatinine or decreases in urine output. It characterizes three levels of renal dysfunction (R, I, F) and two outcome measures (L, E). These criteria indicate an increasing degree of renal damage and have a predictive value for mortality.

The Acute Kidney Injury Network (AKIN) has proposed a modification of the RIFLE criteria. It now includes less severe AKI, a time constraint of 48 hours, and gives a correction for volume status before classification. ‘R’ in RIFLE is stage 1 (a serum creatinine of ≥26.4 μmol/L, i.e. a 1.5-fold increase within 48 hours); stage 2 is ‘I’, i.e. a 2–3-fold increase in serum creatinine; and ‘F’ is stage 3, i.e. an increase in serum creatinine of >300% (equal to ≥354 μmol/L). Urine output data are the same.

**Epidemiology**
The observed incidence of AKI is highly dependent upon the populations studied and the definition of AKI employed, e.g.:

- Community-acquired AKI on admission to hospital: approximately 1% in the UK (superimposed on CKD in half of these patients)
- Severe AKI (creatinine >500 μmol/L): about 130–140/ million population per year
- Less severe AKI (creatinine levels of up to 177 μmol/L or a 50% rise from baseline): about 200/million/year.

The incidence of hospital-acquired AKI has increased. The outcome of AKI also varies greatly. Uncomplicated AKI can usually be managed outside the intensive care unit (ITU) setting and carries a good prognosis, with mortality rates <5–10%. In contrast, AKI complicating non-renal organ system failure (in the ITU setting) is associated with mortality rates of 50–70%, which have not changed for several decades. Sepsis-related AKI has a significantly worse prognosis than AKI in the absence of sepsis.

**Classification**
Renal failure results in reduced excretion of nitrogenous waste products, of which urea is the most commonly measured. A raised serum urea concentration (uraemia) is classified as:
- pre-renal
- renal or
- post-renal.

More than one category may be present in an individual patient. Other causes of altered serum urea and creatinine concentration are shown in Table 12.18.

**Pre-renal uraemia**
In pre-renal uraemia, there is impaired perfusion of the kidneys with blood. This results either from hypovolaemia, hypotension, impaired cardiac pump efficiency or vascular disease limiting renal blood flow, or combinations of these factors. Usually the kidney is able to maintain glomerular filtration close to normal despite wide variations in renal perfusion pressure and volume status – so-called ‘autoregulation’. Further depression of renal perfusion leads to a drop in glomerular filtration and development of pre-renal uraemia. Drugs which impair renal autoregulation, such as ACE inhibitors and NSAIDs, increase the tendency to develop pre-renal uraemia.

All causes of pre-renal uraemia may lead to established parenchymal kidney damage and the development of AKI. By definition, excretory function in pre-renal uraemia improves once normal renal perfusion has been restored.

**FURTHER READING**
A number of criteria have been proposed to differentiate between pre-renal and intrinsic renal causes of uraemia (Table 12.19).

- **Urine specific gravity and urine osmolality** are easily obtained measures of concentrating ability but are unreliable in the presence of glycosuria or other osmotically active substances in the urine.
- **Urine sodium** is low if there is avid tubular reabsorption, but may be increased by diuretics or dopamine.
- **Fractional excretion of sodium** (\( \text{FE} \text{Na} \)) (Table 12.19), the ratio of sodium clearance to creatinine clearance, increases the reliability of this index but may remain low in some ‘intrinsic’ renal diseases, including contrast nephropathy and myoglobinuria.

Laboratory tests, however, are no substitute for clinical assessment. A history of blood or fluid loss, sepsis potentially leading to vasodilatation, or of cardiac disease may be helpful. Hypotension (especially postural), a weak rapid pulse and a low jugular venous pressure will suggest that the uraemia is pre-renal. In doubtful cases, measurement of central venous pressure is often invaluable, particularly with fluid challenge (see p. 873).

### Management

If the pre-renal uraemia is a result of hypovolaemia and hypotension, prompt replacement with appropriate fluid is essential to correct the problem and prevent development of ischaemic renal injury and acute kidney disease (p. 885).

Since pre-renal and renal uraemia may co-exist, and fluid challenge in the latter situation may lead to volume overload with pulmonary oedema, careful clinical monitoring is vital. Blood pressure should be checked regularly and signs of elevated jugular venous pressure and of pulmonary oedema sought frequently. Central venous pressure monitoring is usually advisable (see p. 872). If the problem relates to cardiac pump insufficiency or occlusion of the renal vasculature, appropriate measures – albeit often unsuccessful – need to be taken.

### Post-renal uraemia

Here, uraemia results from obstruction of the urinary tract at any point from the calyces to the external urethral orifice. The causes and presentation of urinary tract obstruction are dealt with on page 604. Screening for urinary tract obstruction is by renal ultrasonography. Urinary tract obstruction may present in an acute fashion (if obstruction of a single functioning kidney by, e.g. a calculus occurs) but typically is of insidious onset.

### Acute uraemia due to renal parenchymal disease

#### Causes

This is most commonly due to acute renal tubular necrosis (Table 12.20). Other causes include disease affecting the intrarenal arteries and arterioles as well as glomerular capillaries, such as a vasculitis (Chapter 11), accelerated hypertension, cholesterol embolism, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura (TTP), Pre-eclampsia and crescentic glomerulonephritis. Acute tubulo-interstitial nephritis (p. 595) may also cause AKI. This also occurs when renal tubules are acutely obstructed by crystals, for example following sulphamamide therapy in a dehydrated patient (sulphonamide crystalluria) or after rapid lysis of certain malignant tumours following chemotherapy (acute hyperuricaemic nephropathy). Acute bilateral suppurative pyelonephritis or pyelonephritis of a single kidney can cause acute uraemia.

### Acute tubular necrosis

#### Causes

Acute tubular necrosis (ATN) is common, particularly in hospital practice. It results most often from renal ischaemia but can also be caused by direct renal toxins including drugs such as the aminoglycosides, lithium and platinum derivatives (Table 12.20).

Kidneys are particularly vulnerable to ischaemic injury when cholestatic jaundice is present, and more than one ischaemic factor appears to be present in some situations. For example, disseminated intravascular coagulation complicating Gram-negative septicaemia and complications of pregnancy such as placental rupture, pre-eclampsia and eclampsia may result in occlusion or partial occlusion of intrarenal vessels, exacerbating the ischaemic insult resulting from hypotension associated with the underlying condition.

Myoglobinuria and haemoglobinuria consequent upon muscle injury (rhabdomyolysis) complicating trauma, pressure necrosis or heroin use predispose to ATN, perhaps in part owing to occlusion of renal tubules by myoglobin and haemoglobin casts. In liver failure, AKI appears to result from rapidly reversible vasomotor abnormalities within the kidney. A kidney removed from a patient with hepatic cirrhosis and liver failure dying with oliguric renal failure may function normally immediately after transplantation into a normal environment.
individual. Efferent glomerular arteriolar dilatation resulting from ACE-inhibitor drug therapy, with consequent lowering of glomerular filtration pressure, may cause acute deterioration in excretory function if renal arterial disease is also present (see Fig. 12.48). The effect is compounded by concomitant use of non-steroidal anti-inflammatory agents which reduce prostaglandin production, opposing this effect.

Pathogenesis
Factors postulated to be involved in the development of ATN include:

- **Intrarenal microvascular vasoconstriction:**
  - Vasoconstriction is increased in response to endothelin, adenosine, thromboxane A₂, leukotrienes and sympathetic nerve activity. However, endothelin antagonists failed to show any beneficial effect in the clinical setting.
  - Vasodilatation is impaired due to reduced sensitivity in response to:
    - Nitric oxide, prostaglandins (PGE₂), acetylcholine and bradykinin
    - Increased endothelial and vascular smooth muscle cell structural damage
  - Increased leucocyte-endothelial adhesion, vascular congestion and obstruction, leucocyte activation and inflammation. After success in the prevention of AKI in animal models, anti-ICAM (intercellular adhesion molecule) in the clinical setting failed to live up to its initial promise.

- **Tubular cell injury.** Ischaemic injury results in rapid depletion of intracellular ATP stores resulting in cell death either by necrosis or apoptosis, due to the following:
  - Entry of calcium into cells with an increase in cytosolic cell calcium concentration
  - Induction by hypoxia of inducible nitric oxide synthases with increased production of nitric oxide causing cell death
  - Increased production of intracellular proteases such as calpain, which cause proteolysis of cytoskeletal proteins and cell wall collapse
  - Activation of phospholipase A₂ with increased production of free fatty acids, particularly arachidonic acid, due to its action on the lipid layer of cell membranes
  - Cell injury resulting from reperfusion with blood after initial ischaemia causing excessive free radical generation
  - Tubular obstruction by desquamated viable or necrotic cells and casts
  - Loss of cell polarity, i.e. integrins located on the basolateral side of the cell are translocated to the apical surface, which when combined with other desquamated cells forms casts, with tubular obstruction and back leak of tubular fluid.

- **Tubular cellular recovery.** Tubular cells have the capacity to regenerate rapidly and to reform the disrupted tubular basement membrane, which explains the reversibility of ATN. Multiple growth factors, including insulin-like growth factor 1, epidermal growth factor and hepatocyte growth factor, and their receptors are upregulated during the regenerative process after injury.

In established ATN, renal blood flow is much reduced, particularly blood flow to the renal cortex. Ischaemic tubular damage contributes to a reduction in glomerular filtration by a number of interrelated mechanisms:

- **Glomerular contraction** reducing the surface area available for filtration, due to reflex afferent arteriolar spasm mediated by increased solute delivery to the macula densa. Increased solute delivery is due to impaired sodium absorption in the proximal tubular cells because of loss of cell polarity with mislocalization of the Na⁺/K⁺-ATPase and impaired tight junction integrity, resulting in decreased apical-to-basal transcellular sodium absorption.

- **‘Back leak’ of filtrate** in the proximal tubule owing to loss of function of the tubular cells.

- **Obstruction of the tubule** by debris shed from ischaemic tubular cells; these appear on renal biopsy as flat rather than the normal tall appearance (Fig. 12.44).

Course
The clinical course of AKI associated with ATN is variable depending on the severity and duration of the renal insult. Oliguria is common in the early stages: non-oliguric AKI is usually a result of a less severe renal insult. Recovery of renal function typically occurs after 7–21 days, although recovery is delayed by continuing sepsis. In the recovery phase, GFR may remain low while urine output increases, sometimes to many litres a day owing to defective tubular reabsorption of filtrate. The clinical course is variable and ATN may last for up to 6 weeks, even after a relatively short-lived initial insult. Eventually renal function usually returns to almost normal or to normal, although exceptions exist (e.g. in renal cortical necrosis, see below).

No treatment is, as yet, known which will reduce the duration of acute renal tubular necrosis once it has occurred. The use of intravenous mannitol, furosemide or ‘renal-dose’ dopamine is not supported by controlled trial evidence, and none of these treatments is without risk.

Clinical and biochemical features
These are the features of the causal condition together with features of rapidly progressive uraemia. The rate at which serum urea and creatinine concentrations increase is dependent upon the rate of tissue breakdown in the individual patient. This is increased in the presence of trauma, sepsis and following surgery. **Hyperkalaemia** is common, particularly following trauma to muscle and in haemolytic states. **Metabolic acidosis** is usual unless hydrogen ion loss by vomiting or aspiration of gastric contents is a feature. **Hyponatraemia** may
be present owing to water overload if patients have continued
to drink in the face of oliguria, or if overenthusiastic fluid
replacement with 5% glucose has been carried out. Pulmo-

nary oedema owing to salt and water retention is not uncom-

mon, particularly after inappropriate attempts to initiate a
diuresis by infusion of 0.9% saline without adequate monitor-

ing of the patient’s volume status. Hypocalcaemia due to
reduced renal production of 1,25-dihydroxycholecalciferol
and hyperphosphataemia due to phosphate retention are

common.

Symptoms of uraemia such as anorexia, nausea, vomiting
and pruritus develop, followed by intellectual clouding, drow-
siness, fits, coma and haemorrhagic episodes. Epistaxes and
gastrointestinal haemorrhage are relatively common. Severe
infection may have initiated the AKI or have complicated it
owing to the impaired immune defences of the uraemic

patient or ill-considered management, such as the insertion
and retention of an unnecessary bladder catheter with com-

plicating urinary tract infection and bacteraemia.

Investigation of the uraemic emergency
Investigations are aimed at defining whether the patient has
acute or chronic uraemia, whether uraemia results from pre-

renal, renal or post-renal factors, and establishing the cause.

Acute or chronic uraemia?
The distinction between acute and chronic uraemia depends
in part on the history, duration of symptoms and previous
urinalysis or measurements of renal function.

A rapid rate of change of serum urea and creatinine with
time suggests an acute process. A normochromic, normo-
cytic anaemia suggests chronic disease, but anaemia may

complicate many of the diseases that cause AKI, owing to
a combination of haemolysis, haemorrhage and deficient
eythropoietin production.

Ultrasound assessment of renal echogenicity and size is
helpful. Small kidneys of increased echogenicity are diagno-

stic of a chronic process, although the reverse is not true; the
kidney may remain normal in size in diabetes and amyloido-

sis, for instance.

Evidence of renal osteodystrophy (e.g. digital subperi-
osteal erosions due to hyperparathyroid bone disease) is
indicative of CKD.

Pre-renal, renal or post-renal uraemia?
Bladder outflow obstruction is ruled out by insertion of a
urethral catheter or flushing of an existing catheter, which
should then be removed unless a large volume of urine is
obtained. Absence of upper tract dilatation on renal ultra-

sonography will, with very rare exceptions, rule out urinary
tract obstruction.

The distinction between pre-renal and renal uraemia may
be difficult (see p. 610). Assessment of the patient’s volume
status is essential and central venous pressure measurement
is extremely helpful. If volume status is low, appropriate cor-

rective measures are indicated. If no diuresis ensues, AKI is
present.

Other investigations
- Urinalysis, urine microscopy, particularly for red cells
  and red-cell casts (indicative of glomerulonephritis)
  and urine culture. Urine should be tested for free
  haemoglobin and myoglobin, where appropriate.
- In AKI it takes 48–72 hours before creatinine rises in the
  plasma; by that time cell injury is well established and
  irreversible. Urinary and plasma biomarkers (e.g. kidney
  injury molecule 1, neutrophil gelatinase associated
  lipocalin) rise within few hours of AKI and may allow
  earlier treatment.
- Blood tests include measurement of serum urea,
  electrolytes, creatinine, calcium, phosphate, albumin,
  alkaline phosphatase and urate concentrations, as well
  as full blood count and examination of the peripheral
  blood film where necessary. Coagulation studies, blood
cultures and measurements of nephrotoxic drug blood
levels should be carried out.

Management
The aim of management of acute renal tubular necrosis is
to keep the patient alive until spontaneous recovery of renal
function occurs. Ideally patients should be managed by a
nephrologist or intensivist with access to facilities for blood
purification and fluid removal (see below). Early specialist
referral is advisable. Poor initial management and late referral
result in the arrival in the specialist centre of a patient who
is severely uraemic, acidic and hyperkalaemic.

General measures
Good nursing and physiotherapy are vital. Regular oral toilet,
chest physiotherapy and consistent documentation of fluid
intake and output, and where possible measurement of daily
bodyweight to assess fluid balance changes, all have a role.
The patient should be confined to bed only if essential.

Emergency measures
Hyperkalaemia
This is a life-threatening complication owing to the risk
of cardiac dysrhythmias, particularly ventricular fibrillation.
Treatment is outlined in Emergency Box 13.1.

Correction of acidosis with intravenous sodium bicarbo-
nate will also reduce serum potassium concentration, but
administration of sodium is inappropriate if the patient is salt
and water overloaded. Rapid correction of acidosis in a
hypocalcaemic patient may also trigger tetany, since hydro-
gen ions displace calcium from albumin-binding sites, thus
increasing the physiologically active calcium concentration in
blood. Ion exchange resins are used to prevent subsequent
hyperkalaemia. In many patients, hyperkalaemia will be con-
trolled only by dialysis or haemofiltration.

Pulmonary oedema
Unless a diuresis can be induced with intravenous furose-
mode, dialysis or haemofiltration will be required.

Sepsis
Infections, when detected, should be treated promptly,
bearing in mind the need to avoid nephrotoxic drugs and to
use drugs with appropriate monitoring and drug levels (e.g.
gentamicin, vancomycin). Prophylactic antibiotics or barrier
nursing is not recommended in all cases.

Use of drugs
Great care must be exercised in the use of drugs (see p. 607).

Fluid and electrolyte balance
Twice-daily clinical assessment is needed. In general, once
the patient is euvoalaemic, daily fluid intake should equal urine
output plus losses from fistulae and from vomiting, plus
an allowance of 500 mL daily for insensible loss. Febrile
patients will require an additional allowance. Sodium and
potassium intake should be minimized. If abnormal losses of
Fluid occur, e.g. in diarrhoea, additional fluid and electrolytes will be required. The development of signs of salt and water overload (peripheral oedema, basal crackles, elevation of jugular venous pressure) or of hypovolaemia should prompt reappraisal of fluid intake. Large changes in daily weight reflecting change in fluid balance status should also prompt a reappraisal of volume stasis.

**Diet**

With rare exceptions, sodium and potassium restriction are appropriate. The place of dietary protein restriction is controversial. If it is hoped to avoid dialysis or haemofiltration, protein intake is sometimes restricted to approximately 40 g daily. This poses the risk of a negative nitrogen balance despite attempts to reduce endogenous protein catabolism by maintenance of a high energy intake in the form of carbohydrate and fat. Patients treated by blood purification techniques are more appropriately managed by providing 70 g protein daily or more. Hypercatabolic patients will require an even higher nitrogen intake to prevent negative nitrogen balance.

Routes of intake are, in preferred order, enteral by mouth, enteral by nasogastric tube, and parenteral. The last of these is, however, only necessary if vomiting or bowel dysfunction render the enteral route inappropriate.

Vitamin supplements are usually supplied. Vitamin D analogue therapy and pharmacological doses of erythropoietin are not employed routinely.

**Dialysis and haemofiltration**

The main indications for blood purification and/or excess fluid removal by these techniques are:

- Symptoms of uraemia
- Complications of uraemia, such as pericarditis
- Severe biochemical derangement in the absence of symptoms (especially if a rising trend is observed in an oliguric patient and in hypercatabolic patients)
- Hyperkalaemia not controlled by conservative measures
- Pulmonary oedema
- Severe acidosis
- For removal of drugs causing the AKI, e.g. gentamicin, lithium, severe aspirin overdose.

The main options are intermittent haemodialysis (HD) combined with ultrafiltration if necessary, intermittent haemofiltration, continuous arteriovenous or venovenous haemofiltration, haemodiafiltration and peritoneal dialysis. For reasons that are incompletely understood, adverse cardiovascular effects are much less during haemofiltration than during haemodialysis. Continuous treatments are superior to intermittent ones in this respect.

**Continuous renal replacement treatments (CRRT)**

Blood flow is achieved either by using the patient’s own blood pressure to generate arterial blood flow through a filter or by the use of a blood pump to draw blood from the lumen of a dual-lumen catheter placed in the jugular, subclavian or femoral vein.

**Continuous arteriovenous or venovenous haemofiltration (CAVH, CVVH)** refers to the continuous removal of ultrafiltrate from the patient, usually at rates of up to 1000 mL/h, combined with simultaneous infusion of replacement solution. For instance, in a fluid-overloaded patient one might remove filtrate at 1000 mL/h and replace at a rate of 900 mL/h, achieving a net fluid removal of 100 mL/h.

**Continuous haemodiafiltration (CAVHDF, CVVHDF)** is a combination of haemofiltration and haemodialysis, involving both the net removal of ultrafiltrate from the blood and its replacement with a replacement solution, together with the countercurrent passage of dialysate (which may be identical to the replacement solution). Both the ultrafiltrate and the spent dialysate appear as ‘waste’.

**Comparisons of dialysis modalities**

Peritoneal dialysis (PD) is used infrequently in the management of AKI. Drawbacks to the use of PD in AKI are:

- Low efficiency in fluid and solute removal compared to CRRT or intermittent HD
- AKI complicating intra-abdominal pathology is unsuitable for PD
- Increasing intraabdominal pressure can compromise lung function
- Use of dialysis fluids with a high glucose content may produce hyperglycaemia and other metabolic derangements. Data suggest that PD is significantly less effective than CRRT in the management of AKI and should be reserved for situations where other modalities of therapy are not available.

There are thus insufficient data to favour either HD or CRRT as a superior mode of therapy in AKI. However, there is consensus that in haemodynamically unstable patients, CRRT is better tolerated.

**Membrane biocompatibility**

The concept of membrane ‘biocompatibility’ relates to the activation of cellular (neutrophils, platelets) and humoral (complement system and coagulation cascade) components upon contact between blood and dialysis membranes. As a general rule, unsubstituted cellulose membranes (cuprophane) are the least biocompatible, with biocompatibility improving with substitution of free hydroxyl groups by tertiary amino groups (hemophan), acetate (cellulose acetate, diacetate, triacetate) or the use of synthetic polymers (e.g. polysulphone, polyamide, polyacrylonitrile and polymethylmethacrylate).

Synthetic membranes appear to confer a significant survival advantage over unsubstituted cellulose (cuprophane)-based membranes but no benefit on recovery of renal function.

**Acute kidney injury in the intensive care unit (ICU)** (see Chapter 16)

Increasing numbers of patients with AKI are managed in the setting of an intensive care unit. Many such patients have multigorgan failure, sepsis or both, with associated cardiovascular instability.

**Fluids**

The appropriate replacement fluid for plasma losses is 0.9% saline (e.g. burns, pancreatitis); 4% albumin or 0.9% saline is used for fluid resuscitation in ICU patients. There are no significant differences between them with respect to death rates, organ failure, the need for RRT or the duration of hospitalization. Serum K⁺ and acid-base status should be monitored in all subjects. K⁺ supplementation of replacement fluids should not be given unless there is hypokalemia.

**Fluid overload**

Diuretics may be useful in volume overload in AKI. Oliguric patients with AKI fare better than oliguric patients. However, conversion of oliguria to non-oliguria has not been shown to decrease mortality. Diuretics have not been
shown to prevent AKI or improve outcomes in AKI. In fact, in AKI patients in the ICU, diuretic use is associated with a significant increase in the risk of death or non-recovery of renal function.

**Nutrition**
- Enteral feeding is the preferred means of nutritional supplementation.
- Protein and non-protein calories should be provided to meet calculated energy expenditures and at a protein intake not exceeding 1.5 g/kg per day.
- Total parenteral nutrition should be administered only to patients who are severely malnourished or patients expected to be unable to eat for >14 days.

**Dialysis**
Timing of initiation of dialysis is essentially an unresolved issue. However, there appears to be some evidence that early initiation of RRT (BUN levels of <76 mg/dL) may be associated with better outcomes. Continuous methods of blood purification and control of fluid balance, such as veno-venous haemofiltration, are preferable to intermittent haemodialysis or peritoneal dialysis in such patients. Advantages include:
- Much less disturbance of cardiovascular stability
- The ability to generate as much ‘space’ for fluid administration as is required, which can be adjusted flexibly to the needs of the patient (many patients require large volumes of fluid to be administered for nutritional and other reasons)
- The removal of potentially harmful substances such as inflammatory cytokines via the more porous membrane employed in haemofiltration.

Two large trials have failed to show a survival benefit of augmented doses of renal replacement therapy in critically ill patients. These essentially negative studies underscore the urgent need for strategies in the early detection and prevention of AKI.

**Other interventions**
Acute respiratory distress syndrome (ARDS) is not uncommon in patients with multiorgan failure, including acute kidney injury, requiring intensive therapy. In such patients the wish to remove as much fluid from the patient as possible to reduce pulmonary congestion must be balanced against the need of organs, including the kidneys, for an adequate blood flow, if recovery is to occur. Anaemia is relatively common in patients admitted to ITU and is managed by blood transfusions. In a study, erythropoietin (EPO) given weekly did not reduce the blood transfusion requirements but unexpectedly increased survival in trauma patients. This also showed that EPO has non-erythropoietic pleiotrophic effects by which it reduces the risk of acute ischaemia and reperfusion injury in multiple organs.

**Management of the recovery phase**
Usually, after 1–3 weeks, renal function improves, as evidenced by an increase in urine volume and improvement in serum biochemistry. Dialysis or haemofiltration, if they have been required, can be discontinued. A careful watch on clinical state, salt and water balance, and serum chemistry is required at this stage, particularly if a major diuretic phase develops owing to recovery of glomerular filtration at a time when renal tubular reabsorptive capacity for sodium, potassium and water remains impaired. Intravenous fluid replacement is sometimes required together with supplements of sodium chloride and potassium. Typically, the diuretic phase lasts for only a few days.

**Acute cortical necrosis**
Renal hypoperfusion results in diversion of blood flow from the cortex to the medulla, with a drop in GFR. Medullary ischaemic damage is largely reversible owing to the capacity of the tubular cells for regeneration. In contrast, glomerular ischaemic injury does not heal with regeneration but with scarring—glomerulosclerosis. Prolonged cortical ischaemia may lead to irreversible loss of renal function termed ‘cortical necrosis’. This may be patchy or complete. Any cause of acute tubular necrosis, if sufficiently severe or prolonged, may lead to cortical necrosis. This outcome is particularly common if acute kidney injury has been accompanied by derangements of the vascular endothelial system or coagulation system, such as occurs in the haemolytic uraemic syndrome and with complications of pregnancy.

**Contrast nephropathy**
In patients with impaired renal function, iodinated radiological contrast media may be nephrotoxic, possibly by causing renal vasoconstriction and by a direct toxic effect upon renal tubules. The effect is dose-dependent and therefore more commonly seen in procedures that require large amounts of contrast media, such as angiography with or without angioplasty. In many patients, the effect is mild, transient, fully reversible and was thought of as benign and of no clinical significance. However, even transient elevation of creatinine following contrast administration particularly as part of coronary angiography is associated with long-term consequences such as increased risk of cardiac events, end-stage renal disease and mortality. The risk and severity of contrast nephropathy is amplified by the presence of hypovolaemia and severity of CKD, especially if due to diabetic nephropathy. Diabetes per se is not a risk factor. However, metformin can precipitate acidosis and should be stopped and not restarted until renal function returns to the baseline level.

**Prevention** involves minimization, as far as possible, of the dose of contrast employed and use of an iso-osmolar or low-osmolality contrast medium. Superiority of iso-osmolar agents has been questioned by randomized trials in patients with severe CKD (eGFR <30 mL/min) undergoing coronary angiogram, where no differences were seen between the two types of contrast agent. Pre-hydration with intravenous saline is of proven benefit. A popular regimen involves infusion of 1 L of 0.9% saline during the 12 h before and 12 h after contrast exposure. Administration of 1 L of sodium bicarbonate 1.4% peri-procedure and up to 8–12 h post-procedure has been shown to be more effective than saline in some studies. Care must be taken to avoid volume overload in susceptible patients.

Acetylcysteine (potent antioxidant) given 48 hours prior to radiological intervention may be of borderline benefit in preventing worsening of pre-existing CKD following intravenous contrast, but the beneficial effects on morbidity and mortality are not detected. Routine use of dopamine, theophylline (an adenosine antagonist) and prophylactic haemodialysis (removing contrast agent from circulation) is of no benefit. In patients with advanced CKD who are undergoing coronary angiography, periprocedural haemofiltration given in an ITU setting appears to be effective in preventing the deterioration of renal function due to contrast agent-induced nephropathy and is associated with improved in-hospital and long-term outcomes.
When deterioration in renal function occurs after intravenous injection of contrast (e.g. after coronary angiography) it may be difficult to differentiate the effects of contrast-induced damage from those of atheromatous embolization (see p. 599). The latter carries a worse prognosis.

Note: Gadolinium used in contrast MRI causes problems in CKD (see p. 598).

### Acute phosphate nephropathy (APN)

Administration of oral sodium phosphate solution as bowel preparation for gastrointestinal investigations has recently been recognized as a cause of AKI. Risk factors for the development of APN include CKD, dehydration, older age, hypertension treated with ACE inhibitors and or ARBs and or loop diuretics, female gender and NSAIDs. Oral phosphate solution is contraindicated in patients with CKD, congestive heart failure, gastrointestinal obstruction, and pre-existing electrolyte disorders like hypercalcemia. The diagnosis of acute phosphate nephropathy is made by:

- AKI
- Recent exposure to oral phosphate
- Renal biopsy findings of acute and chronic tubular injury with abundant calcium phosphate deposits (usually involving more than 40 tubular lumina in a single biopsy).
- No evidence of hypercalcemia
- No other significant pattern of kidney injury on renal biopsy.

Treatment is usually supportive and dialysis if necessary with good renal recovery.

### Hepatorenal syndrome (HRS)

The renal failure observed in HRS results from profound renal vasoconstriction with histologically normal kidneys (p. 337). Although many of the features of HRS resemble pre-renal AKI, the defining feature is a lack of improvement in renal function with volume expansion. Renal recovery is usually observed after restoration of hepatic function after successful liver transplantation.

### CHRONIC KIDNEY DISEASE (CKD)

The term ‘CKD’ has replaced terms such as chronic renal failure or insufficiency. CKD implies longstanding (more than 3 months), and usually progressive, impairment in renal function. In many instances, no effective means are available to reverse the primary disease process. Exceptions include correction of urinary tract obstruction, immunosuppressive therapy for systemic vasculitis and Goodpasture’s syndrome, treatment of accelerated hypertension, and correction of critical narrowing of renal arteries causing CKD. The rate of deterioration in renal function can, however, be slowed (see p. 622). A list of causes of CKD is given in Table 12.21.

Wide geographical variations in the incidence of disorders causing CKD exist. The most common cause of glomerulonephritis in sub-Saharan Africa is malaria. Schistosomiasis is a common cause of CKD due to urinary tract obstruction in parts of the Middle East, including southern Iraq. The incidence of ESKD varies between racial groups. ESKD is three to four times as common in black Africans in the UK and USA as it is in whites, and hypertensive nephropathy is a much more frequent cause of ESKD in this group. The prevalence of diabetes mellitus and hence of diabetic nephropathy is much higher in some Asian groups than in whites. The age of relevance; CKD due to atherosclerotic renal vascular disease is much more common in the elderly than in the young. Over 70% of all cases with CKD are due to diabetes mellitus, hypertension and atherosclerosis.

Patients with CKD should be referred to a nephrologist with access to facilities for renal replacement therapy at an early stage since late referral has been shown to be associated with increased mortality and morbidity when such patients commence renal replacement therapy. Old age is no bar to referral in the reasonably fit elderly patient.

For CKD referral and treatment pathways, the Kidney Disease Outcomes Quality Initiative (K/DOQI) of the National Kidney Foundation established a classification of CKD in the USA in 2002, and endorsed by the Kidney Disease: Improving Global Outcomes (KDIGO) in 2004. According to KDIGO and KDOQI, the definition and classification should reflect patient prognosis and outcomes. KDIGO initiated a collaborative meta-analysis to examine the relationship of eGFR and proteinuria to mortality and kidney outcomes. It has been agreed by experts that:

- The current definition for CKD will be retained: GFR <60 mL/min per 1.73 m² or a urinary albumin-to-creatinine ratio >65 mg/mmol or protein creatinine ratio of 100 mg/mmol (Table 12.22)
- The classification has been modified by adding albuminuria stage, subdivision of stage 3 into A and B, and emphasizing clinical diagnosis.

High prevalences of CKD have now been found in population-based surveys particularly in elderly patients (Table 12.23) using the MDRD method (p. 565) to estimate GFR. Adoption of albuminuria or proteinuria along with eGFR in the new proposed classification will, according to some estimates, reduce the prevalence of CKD stages 3 and 4 from 10–15% of total population to more realistic numbers of less than 5% and would in the process avoid unnecessary referrals.

Clinical approach to the patient with CKD or any other form of renal disease

History

Particular attention should be paid to:

- **Duration of symptoms**
- **Drug ingestion**, including non-steroidal anti-inflammatory agents, analgesic and other medications, and unorthodox treatments such as herbal remedies
- **Previous medical and surgical history**, e.g. previous chemotherapy, multisystem diseases such as SLE, malaria
- **Previous occasions** on which urinalysis or measurement of urea and creatinine might have been performed, e.g. pre-employment or insurance medical examinations, new patient checks
- **Family history** of renal disease

Symptoms

The early stages of CKD are often completely asymptomatic, despite the accumulation of numerous metabolites. Serum urea and creatinine concentrations are measured in CKD, since methods for their determination are available and a rough correlation exists between urea and creatinine concentrations and symptoms. These substances are, however, in themselves not particularly toxic. The nature of the metabolites that are involved in the genesis of symptoms is unclear. Such metabolites must be products of protein catabolism (since dietary protein restriction may reverse symptoms associated with CKD) and many of them must be of relatively small molecular size (since haemodialysis employing membranes which allow through only relatively small molecules improves symptoms). Little else is known with certainty.

Symptoms are common when the serum urea concentration exceeds 40 mmol/L, but many patients develop uraemic symptoms at lower levels of serum urea. Symptoms include:

- Malaise, loss of energy
- Loss of appetite
- Insomnia
- Nocturia and polyuria due to impaired concentrating ability
- Itching
- Nausea, vomiting and diarrhoea
- Paraesthesiae due to polyneuropathy
- ‘Restless legs’ syndrome (overwhelming need to frequently alter position of lower limbs)
- Bone pain due to metabolic bone disease
- Paraesthesiae and tetany due to hypocalcaemia
- Symptoms due to salt and water retention – peripheral or pulmonary oedema
- Symptoms due to anaemia
- Amenorrhoea in women; erectile dysfunction in men.

In more advanced uraemia CKD stage 5, these symptoms become more severe and CNS symptoms are common:

- Mental slowing, clouding of consciousness and seizures
- Myoclonic twitching.

Severe depression of glomerular filtration can result in oliguria. This can occur with either acute kidney injury or in the terminal stages of CKD. However, even if the GFR is profoundly depressed, failure of tubular reabsorption may lead to very high urine volumes; the urine output is therefore not a useful guide to renal function.

Examination

There are few physical signs of uraemia per se. Findings include: short stature (in patients who have had CKD in childhood); pallor (due to anaemia); increased photosensitive pigmentation (which may make the patient look misleadingly healthy); brown discoloration of the nails; scratch marks due to uraemic pruritus; signs of fluid overload (p. 642); pericardial friction rub; flow murmurs (mitral regurgitation due to mitral annular calcification; aortic and pulmonary regurgitant murmurs due to volume overload); and glove and stocking peripheral sensory loss (rare).

The kidneys themselves are usually palpable unless grossly enlarged as a result of polycystic disease, obstruction or tumour. Rectal and vaginal examination may disclose evidence of an underlying cause of CKD, particularly urinary obstruction, and should always be performed.
In addition to these findings, there may be physical signs
of any underlying disease which may have caused the CKD,
for instance:

- Cutaneous vasculitic lesions in systemic vasculitides
- Retinopathy in diabetes and hypertensive retinopathy in
  hypertension
- Evidence of peripheral vascular disease and associated
  renal artery stenosis
- Evidence of spina bifida or other causes of neurogenic
  bladder.

An assessment of the central venous pressure, skin turgor,
blood pressure both lying and standing and peripheral circu-
lation should also be made. The major symptoms and signs
of CKD are shown in Figure 12.45.

**Investigations**
The following investigations are common for all renal patients.
This includes patients with glomerular or non-glomerular
disease, renal involvement in systemic diseases, AKI and
CKD, as renal symptoms and signs are nonspecific.

**Urinalysis**
- **Haematuria** may indicate glomerulonephritis, but other
  sources must be excluded. Haematuria should not be
  assumed to be due to the presence of an indwelling
  catheter.
- **Proteinuria**, if heavy, is strongly suggestive of glomerular
disease. Urinary infection may also cause proteinuria.
  **Glycosuria** with normal blood glucose is common in CKD.
- **Urine culture**, including early-morning urine samples
  for TB.

**Urine microscopy** (see p. 569)
- **White cells** in the urine usually indicate active bacterial
  urinary infection, but this is an uncommon cause of
  CKD: sterile pyuria suggests papillary necrosis or renal
  tuberculosis.
- **Eosinophilia** is strongly suggestive of allergic
  tubulointerstitial nephritis or cholesterol embolization.
- **casts. Granular casts** are formed from abnormal cells
  within the tubular lumen, and indicate active renal
disease. **Red-cell casts** are highly suggestive of
  glomerulonephritis.
- **Red cells in the urine** may be from anywhere between
  the glomerulus and the urethral meatus (Fig. 12.6).

**Urine biochemistry**
- **Measurements of urinary electrolytes** are unhelpful in
  CKD. The use of urinary sodium concentration in the
  distinction between pre-renal and intrinsic renal disease
  is discussed on page 576.
- **Urine osmolality** is a measure of concentrating ability.
  A low urine osmolality is normal in the presence of a
  high fluid intake but indicates renal disease when the
  kidney should be concentrating urine, such as in
  hypovolaemia or hypotension.
- **Urine electrophoresis and immunofixation** is
  necessary for the detection of light chains, which can be
  present without a detectable serum paraprotein.

**Serum biochemistry**
- **Urea and creatinine**.
- **Calculation of eGFR**.
- **Electrophoresis and immunofixation for myeloma**.
- **Elevations of creatine kinase and a disproportionate
elevation in serum creatinine and potassium compared
  with urea suggest rhabdomyolysis**.

**Haematology**
- **Eosinophilia** suggests vasculitis, allergic
  tubulointerstitial nephritis, or cholesterol embolism.
- **Markedly raised viscosity** or ESR suggests myeloma or
  vasculitis.
- **Fragmented red cells and/or thrombocytopenia**
suggest intravascular haemolysis due to accelerated
  hypertension, haemolytic uraemic syndrome or
  thrombotic thrombocytopenic purpura.
- **Tests for sickle cell disease** should be performed
  when relevant.

**Immunology**
- **Complement components** may be low in active
  renal disease due to SLE, mesangiocapillary
  glomerulonephritis, post-streptococcal
glomerulonephritis, and cryoglobulinaemia.
- **Autoantibody screening** is useful in detection of SLE
  (p. 537); scleroderma (p. 539); Wegener’s
  granulomatosis and microscopic polyangiitis (p. 854);
  and Goodpasture’s syndrome (p. 812).
- **Cryoglobulins** in unexplained glomerular disease,
  particularly mesangiocapillary glomerulonephritis.
- **Antibodies to streptococcal antigens** (antistreptolysin
  O titre (ASOT), anti-DNAse B) if post-streptococcal
  glomerulonephritis is possible.
- **Antibodies to hepatitis B and C** may point to
  polyarteritis or membranous nephropathy (hepatitis B) or
to cryoglobulinaemic renal disease (hepatitis C).
- **Antibodies to HIV** raise the possibility of HIV-associated
  renal disease.
Radiological investigation

- **Ultrasound.** Every patient should undergo ultrasonography (for renal size and to exclude hydroureter nephrosis), and plain abdominal radiography and CT (without contrast) to exclude low-density renal stones or nephrocalcinosis, which may be missed on ultrasound.
- **CT** is also useful for the diagnosis of retroperitoneal fibrosis and some other causes of urinary obstruction, and may also demonstrate cortical scarring.
- **MRI.** Magnetic resonance angiography in renovascular disease. For gadolinium used as contrast in CKD, see this chapter.

Renal biopsy (see p. 572)

This should be performed in every person with unexplained CKD and normal-sized kidneys, unless there are strong contraindications. If rapidly progressive glomerulonephritis is possible, this investigation must be performed within 24 h of presentation if at all possible.

**Complications of chronic kidney disease**

**Anaemia**

Several factors have been implicated:

- **Erythropoietin deficiency** (the most significant)
- **Bone marrow toxins** retained in CKD
- **Bone marrow fibrosis** secondary to hyperparathyroidism
- **Haematinic deficiency** – iron, vitamin B₁₂, folate
- **Increased red-cell destruction**
- **Abnormal red-cell membranes** causing increased osmotic fragility
- **Increased blood loss** – occult gastrointestinal bleeding, blood sampling, blood loss during haemodialysis or because of platelet dysfunction
- **ACE inhibitors** (may cause anaemia in CKD, probably by interfering with the control of endogenous erythropoietin release).

Red-cell survival is reduced in CKD. Increased red-cell destruction may occur during haemodialysis owing to mechanical, oxidant and thermal damage.

**Bone disease: renal osteodystrophy**

The term ‘renal osteodystrophy’, more appropriately described as bone mineral disorder, embraces the various forms of bone disease that may develop alone or in combination in CKD – hyperparathyroid bone disease, osteomalacia, osteoporosis, osteosclerosis and adynamic bone disease (Fig. 12.46). Most patients with CKD are found, histologically, to have mixed bone disease. Covert renal osteodystrophy is present in many patients with moderate CKD and in almost all of those with ESKD.

**Pathogenesis of bone disease**

Phosphate retention owing to reduced excretion by the kidneys occurs in the very early stages of CKD. This results in the release of fibroblast growth factor 23 (FGF 23) and other phosphaturic agents by osteoblasts as a compensatory mechanism. FGF 23 causes phosphaturia to bring the plasma phosphate level to within the normal range. FGF 23 also downregulates 1α-hydroxylase in an attempt to reduce intestinal absorption of phosphate. However, consistently elevated levels of FGF 23 after a while cannot control phosphate levels and its effects are overwhelmed by development of secondary hyperparathyroidism. Elevated FGF 23 levels are the strongest independent predictor of mortality in patients with CKD. This underscores the necessity of controlling phosphate levels during very early stages of CKD.

- Decreased renal production of the 1α-hydroxylase enzyme results in reduced conversion of 25-(OH)₂D₃ to the more metabolically active 1,25-(OH)₂D₃.
- Reduced activation of vitamin D receptors (VDR) in the parathyroid glands leads to increased release of parathyroid hormone (secondary hyperparathyroidism).
- The calcium sensing receptors (CaR), expressed in the parathyroid glands, react rapidly to acute changes in extracellular calcium concentrations and a low calcium also leads to increased release of PTH.
- 1,25-Dihydroxycholecalciferol deficiency also results in gut calcium malabsorption.
- Phosphate retention owing to reduced excretion by the kidneys, also indirectly by lowering ionized calcium (and probably directly via a putative but unrecognized phosphate receptor), results in an increase in PTH synthesis and release.
- PTH promotes reabsorption of calcium from bone and increased proximal renal tubular reabsorption of calcium, and this opposes the tendency to develop hypocalcaemia induced by 1,25-(OH)₂D₃ deficiency and phosphate retention. This ‘secondary’ hyperparathyroidism leads to increased osteoclastic activity, cyst formation and bone marrow fibrosis (osteitis fibrosa cystica).
Radiologically, digital subperiosteal erosions and ‘pepper-pot skull’ are seen. Longstanding secondary hyperparathyroidism ultimately leads to hyperparathyroidism of the glands with autonomous or tertiary hyperparathyroidism in which hypercalcaemia is present. Serum alkaline phosphatase concentration is raised in both secondary and tertiary hyperparathyroidism. Longstanding parathyroid hormone excess is also thought to cause increased bone density (osteosclerosis) seen particularly in the spine where alternating bands of sclerotic and porotic bone give rise to a characteristic ‘rugger jersey’ appearance on X-ray.

1,25-(OH)2D3 deficiency and hypocalcaemia result in impaired mineralization of osteoid (osteomalacia). Such impaired mineralization also occurs when osteoblasts are inhibited by, e.g. aluminium given as gut phosphorus binders, or accumulated in bone as a result of exposure to aluminium in source water used to make up dialysate for haemodialysis. In this situation, serum alkaline phosphatase concentration tends to be low or normal.

The condition of ‘adynamic bone disease’ in which both bone formation and resorption are depressed (in the absence of aluminium bone disease or overtreatment with vitamin D) is also seen. The pathogenesis of this condition is unclear and it is not known whether it leads to an increased risk of fractures or other complications. There may be hypercalcaemia; the serum alkaline phosphatase is normal, the PTH is low. X-rays and dual X-ray absorptiometry (DXA) scan show osteopenia. No treatment is of proven benefit.

Osteoporosis is commonly found in CKD, often after transplantation and the use of corticosteroids. Monitoring is with yearly DXA scan.

Management is discussed on page 555.

Skin disease

Pruritus (itching) is common in severe CKD and is mainly due to retention of nitrogenous waste products of protein catabolism as it improves following dialysis. Other causes of pruritus include hypercalcaemia, hyperphosphataemia, elevated calcium×phosphate product, hyperparathyroidism (even if calcium and phosphate levels are normal) and iron deficiency.

In dialysis patients, inadequate dialysis is usually the cause of pruritus. Nevertheless, a significant number of dialysis patients who are well dialysed and in whom other causes of pruritus can be excluded suffer persistent itching. The cause is unknown and no effective treatment exists.

Many patients with CKD suffer from dry skin for which simple aqueous creams are helpful. Eczematous lesions, particularly in relation to the region of an arteriovenous fistula, are relatively common. CKD may also cause porphyria cutanea tarda (PCT), a blistering photosensitive skin rash. This results from a decrease in hepatic uroporphyrinogen decarboxylase combined with a decreased clearance of porphyrins in the urine or by dialysis. Pseudoporphyria, a condition similar to PCT but without enzyme deficiency, is also seen in CKD with increased frequency.

Nephrogenic systemic fibrosis (NSF)

NSF is a systemic fibrosing disorder with predominant skin involvement. It is seen only in patients with moderate to severe CKD (eGFR <30 mL/min), particularly patients on dialysis. Gadolinium-containing contrast agents, which are excreted exclusively by the kidney, have been implicated in the causation of over 95% cases of NSF (see p. 1220).

The diagnosis is based upon a biopsy of an involved site, showing proliferation of dermal fibrocytes with excessive collagen deposition. Special testing may show gadolinium.

NSF usually follows a chronic and unremittent course, with 30% having no improvement, 20% having modest improvement and 30% dying. No single therapy or combination of therapies has shown consistent benefit in NSF except for improvement in renal function. Improvement in the NSF may follow renal transplantation. Prevention is by avoiding the use of gadolinium-based contrast agents in patients with severe CKD (eGFR <30 mL/min) or those on dialysis therapy.

Gastrointestinal complications

These include decreased gastric emptying and increased risk of reflux oesophagitis, peptic ulceration, acute pancreatitis and constipation, particularly in patients on continuous ambulatory peritoneal dialysis (CAPD).

Elevations of serum amylase of up to three times normal may be found in CKD without any evidence of pancreatic disease, owing to retention of high-molecular-weight forms of amylase normally excreted in the urine.

Metabolic abnormalities

Gout. Urate retention is a common feature of CKD. Treatment of clinical gout is complicated by the nephrotoxic potential of NSAIDs. Colchicine is useful for the acute attack, and allopurinol should be introduced under colchicine cover to prevent further attacks. The dose of allopurinol should be reduced in CKD, e.g. 100 mg on alternate days.

Insulin. Insulin is catabolized by and to some extent excreted via the kidneys. For this reason, insulin requirements in diabetic patients decrease as CKD progresses. By contrast, end-organ resistance to insulin is a feature of advanced CKD resulting in modestly impaired glucose tolerance. Insulin resistance may contribute to hypertension and lipid abnormalities.

Lipid metabolism abnormalities. These are common in CKD, and include:

- Impaired clearance of triglyceride-rich particles
- Hypercholesterolaemia (particularly in advanced CKD).

The situation is further complicated in ESKD, when regular heparinization (in haemodialysis), excessive glucose absorption (in CAPD) and immunosuppressive drugs (in transplantation) may all contribute to lipid abnormalities. Correction of lipid abnormalities by, e.g. HMG-CoA reductase inhibitor therapy (statins), is used in patients with CKD, although without formal proof of survival benefit.

Endocrine abnormalities

These include:

- Hyperprolactinaemia, which may present with galactorrhoea in men as well as women
- Increased luteinizing hormone (LH) levels in both sexes, and abnormal pulsatility of LH release
- Decreased serum testosterone levels (only seldom below the normal level). Erectile dysfunction and decreased spermatogenesis are common
- Absence of normal cyclical changes in female sex hormones, resulting in oligomenorrhea or amenorrhea
- Complex abnormalities of growth hormone secretion and action, resulting in impaired growth in uraemic children (pharmacological treatment with recombinant growth hormone and insulin-like growth factor is used)
- Abnormal thyroid hormone levels, partly because of altered protein binding. Measurement of thyroid-stimulating hormone (TSH) is the best way to assess
thyroid function. True hypothyroidism occurs with increased frequency in CKD. Posterior pituitary gland function is normal in CKD.

**Muscle dysfunction**

Uraemia appears to interfere with muscle energy metabolism, but the mechanism is uncertain. Decreased physical fitness (cardiovascular deconditioning) also contributes.

**Nervous system**

*Central nervous system*

**Severe uraemia** causes an unusual combination of depressed cerebral function and decreased seizure threshold. However, convulsions in a uraemic patient are much more commonly due to other causes such as accelerated hypertension, thrombotic thrombocytopenic purpura or drug accumulation. Asterixis, tremor and myoclonus are also features of severe uraemia.

Rapid correction of severe uraemia by haemodialysis leads to *dialysis disequilibrium* owing to osmotic cerebral swelling. This can be avoided by correcting uraemia gradually by short, repeated haemodialysis treatments or by the use of peritoneal dialysis.

*‘Dialysis dementia’* is a syndrome of progressive intellectual deterioration, speech disturbance, myoclonus and fits, which is due to aluminium intoxication; it may be accompanied by aluminium bone disease and by microcytic anaemia. Low-grade aluminium exposure may also cause more subtle, subclinical deterioration in intellectual function. Prevention involves removal of aluminium from source water used to manufacture dialysis fluid, and restriction or avoidance of aluminium-containing gut phosphorus binders. Treatment is with the chelating agent desferrioxamine.

*Psychiatric problems* are common. Patients can have anxiety, depression, phobias and psychoses.

*Autonomic nervous system*

Increased circulating catecholamine levels associated with downregulation of $\alpha$-receptors, impaired baroreceptor sensitivity and impaired effrent vagal function are common in CKD.

Overactivity of the sympathetic nervous system in CKD is believed to play a part in the genesis of hypertension in this condition. All of these abnormalities improve to some extent after institution of regular dialysis and resolve after successful renal transplantation.

*Peripheral nervous system*

- *Median nerve compression* in the carpal tunnel is common, usually due to $\beta_2$-microglobulin-related amyloidosis. This can be avoided by haemofiltration and haemodiafiltration.

- *‘Restless legs’ syndrome* (p. 620) is common in uraemia. The syndrome is difficult to treat. Iron deficiency should be treated if present. Attention should be paid to adequacy of dialysis. Symptoms may improve with the correction of anaemia by erythropoietin. Clonazepam is sometimes useful. Renal transplantation cures the problem.

- *A polyneuropathy* occurs in patients who are inadequately dialysed.

**Calciphylaxis**

Also known as calcific uraemic arteriolopathy, this is a rare but serious life-threatening complication in CKD patients. It is increasingly recognized as a contributing factor to death in dialysis patients. Aetiological factors include reduced serum levels of a calcification inhibitory protein (fetuin-A) and abnormalities in smooth muscle cell biology in uraemia. It presents as painful non-healing eschars with panniculitis and dermal necrosis. The characteristic feature on histology is vascular calcification and superimposed small vessel thrombosis (Fig. 12.47).

Hyperparathyroidism and elevated concentrations of serum phosphate, morbid obesity and warfarin use remain consistent clinical features of most cases reported. Control of hyperparathyroidism is with either surgical intervention or with a calcimimetic agent.

Promising treatment options include hyperbaric oxygen therapy and sodium thiosulphate infusion. Benefits from bisphosphonates and tissue plasminogen activator have also been reported.

**Cardiovascular disease**

Life expectancy remains severely reduced compared with the normal population owing to a greatly increased (16-fold) incidence of cardiovascular disease, particularly myocardial infarction, cardiac failure, sudden cardiac death and stroke.

**Risk factors**

Hypertension is a frequent complication of CKD. Diabetes mellitus is the commonest cause of CKD. Dyslipidaemia is universal in uraemic patients. Furthermore, smoking is as common as in the general population and male gender is over-represented in patients with CKD. Ventricular hypertrophy is common, as is systolic and diastolic dysfunction. Diastolic dysfunction is largely attributable to left ventricular hypertrophy and contributes to hypotension during fluid removal on haemodialysis. Systolic dysfunction may be due to:

- Myocardial fibrosis
- Abnormal myocyte function owing to uraemia
- Calcium overload and hyperparathyroidism
- Carnitine and selenium deficiency.

Left ventricular hypertrophy is a risk factor for early death in CKD, as in the general population. Systolic dysfunction is also a marker for early death.

*Coronary artery calcification.* Traditional risk factors (e.g. smoking, diabetes) can only partly explain the risk in patients with chronic nephropathies.

Coronary artery calcification is more common in patients with ESKD than in normal individuals and it is highly likely that this contributes significantly to cardiovascular mortality. Vascular calcification is frequent in all sizes of vessel in CKD.

In addition to the classical risk factors for atherosclerosis:

- A raised *(calcium x phosphate)* product causes medial calcification.
- **Hyperparathyroidism** may also contribute independently to the pathogenesis by increasing intracellular calcium.
- **Vascular calcification** in uraemia is now thought to be an active process whereby vascular smooth muscle cells acquire osteoblast-like characteristics, possibly in response to elevated phosphate or (calcium × phosphate) product.
- **Inflammation** is a potent mediator of vascular calcification by inhibition of fetuin (a glycoprotein synthesized by liver, which is a potent inhibitor of vascular calcification).

The impact of vascular calcification is the *reduction of vascular compliance*, which manifests by increased pulse pressure and pulse wave velocity, and increased afterload contributes further to left ventricular hypertrophy. In addition to myocardial abnormalities, vascular calcification with its associated biomechanical vessel wall alterations is a strong predictor of all-cause and cardiovascular morbidity and mortality in patients with CKD. Diffuse calcification of the myocardium is also common; the causes are similar.

**Other cardiovascular risk factors.** These include hyperhomocysteinaemia, *Chlamydia pneumoniae* infection, oxidative stress and elevated endogenous inhibitor of nitric oxide synthase and asymmetric dimethyl arginine (ADMA) levels. High ADMA levels in uraemia are in part caused by oxidative stress and can possibly explain the 52% increase in the risk of death and 34% increase in the risk of the cardiovascular events in uraemic patients. The use of antioxidants, vitamin E or acetylcysteine has been associated with a significant reduction in all-cause and cardiovascular mortality. However, recent trials to reduce levels of homocysteine with folic acid, B₆ and B₁₂ supplementation have been unsuccessful.

The conclusion from a recent study of heart and renal protection (SHARP) in over 9500 CKD patients was that around one-quarter of all heart attacks, strokes, and revascularizations could be avoided in CKD by using a combination of ezetimibe and simvastatin to lower blood cholesterol. This combination however did not confer any survival advantage over the treatment of hypercalcaemia and hyperparathyroidism.

**Pericarditis**

This is common and occurs in two clinical settings:

- Uraemic pericarditis is a feature of severe, pre-terminal uraemia or of underdialysis. Haemorrhagic pericardial effusion and atrial arrhythmias are often associated. There is a danger of pericardial tamponade, and anticoagulants should be used with caution. Pericarditis usually resolves with intensive dialysis.
- Dialysis pericarditis occurs as a result of an intercurrent illness or surgery in a patient receiving apparently adequate dialysis.

**Malignancy**

The incidence of malignancy is raised in patients with CKD and with dialysis. Malignant change can occur in multicystic kidney disease. Lymphomas, primary liver cancer and thyroid cancers also occur.

**Management**

Successful renal transplantation improves some, but not all, of the complications of CKD, therefore attempts should be made to prevent these complications by careful monitoring with ECG, echocardiography, angiography (if necessary) and nuclear imaging. CT (spiral CT) and/or MRI are useful in the assessment of arterial calcification. Treatment is with the control of risk factors (p. 608) as well as the treatment of hypercalcaemia and hyperparathyroidism (p. 624).

**Progression of chronic kidney disease**

CKD tends to progress inexorably to ESKD, although the rate of progression may depend upon the underlying nephropathy. Patients with chronic glomerular diseases tend to deteriorate more quickly than those with chronic tubulointerstitial nephropathies. Hypertension and heavy proteinuria are bad prognostic indicators. A nonspecific renal scarring process common to renal disorders of different aetiologies may be responsible for progression.

Possible causes of glomerular scarring and proteinuria include:

- A rise in intraglomerular capillary pressure
- Adaptive glomerular hypertrophy due to reduced arteriolar resistance and increased glomerular blood flow when there is reduced nephrin mass.

This glomerular hyperfiltration, in response to nephron loss, was postulated as a common pathway for the progression of CKD.

Since the afferent arteriolar tone decreases more than efferent arteriolar tone, intraglomerular pressure and the amount of filtrate formed by a single nephron rises. Angiotensin II produced locally modulates intraglomerular capillary pressure and GFR, predominantly causing vasoconstriction of postglomerular arterioles, thereby increasing the glomerular hydraulic pressure and filtration fraction (Fig. 12.48).

---

**Figure 12.48 Glomerular dynamics:** effect of the renin-angiotensin system. A.I, angiotensin I; A.II, angiotensin II.
addition, by its effect on mesangial cells and podocytes, it increases the pore sizes and impairs the size-selective function of basement membrane for macromolecules.

Angiotensin II also modulates cell growth directly and indirectly by upregulating TGF-β, a potent fibrogenic cytokine, increases collagen synthesis and also causes epithelial cell transdifferentiation to myofibroblasts which contribute to excessive matrix formation. Furthermore, angiotensin II by upregulating plasminogen activator inhibitor-1 (PAI-1) inhibits matrix proteolysis by plasmin, resulting in accumulation of excessive matrix and scarring both in the glomeruli and interstitium.

Renal interstitial scarring is also a factor. The cause of this progressive interstitial damage and fibrosis is multifactorial. In addition to non-haemodynamic effects of angiotensin II, proteinuria per se (by exposing tubular cells to albumin and its bound fatty acids and cytokines) promotes secretion of pro-inflammatory mediators, which promote interstitial inflammatory cell infiltrate and further augment fibrosis and progression of CKD. The prognosis for renal function in chronic glomerular disorders is judged more accurately by progression of CKD. The prognosis for renal function in inflammatory cell infiltrate and further augment fibrosis and of pro-inflammatory mediators, which promote interstitial

Box 12.6 Renoprotection

Goals of treatment
- BP <120/80
- Proteinuria <0.3 g/24 h

Treatment
Patients with chronic kidney disease and proteinuria
>1 g/24 h:
- ACE inhibitor increasing to maximum dose
- Add angiotensin receptor antagonist if goals are not achieved
- Add diuretic to prevent hyperkalaemia and help to control BP
- Add calcium-channel blocker (verapamil or diltiazem) if goals not achieved

Additional measures
- Statins to lower cholesterol to <4.5 mmol/L
- Stop smoking (three-fold higher rate of deterioration in CKD)
- Treat diabetes (HbA1c <7%, 53 mmol/mol)
- Normal protein diet (0.8–1 g/kg bodyweight)

*In type 2 diabetes start with angiotensin receptor antagonist.

Acidosis
Correction of acidosis helps to correct hyperkalaemia in CKD, and may also decrease muscle catabolism. Sodium bicarbonate supplements are often effective (4.8 g (57 mmol) of Na+ and HCO3⁻ daily), and the possibility of oedema and hypertension owing to the so-called ‘extracellular fluid expansion’ was not borne out by a trial. Interestingly, correction of metabolic acidosis by sodium bicarbonate at a mean dose of 1.8 g/day was also associated with marked reduction in the rate of progression of CKD and development of ESKD in patients with stage 4 and 5 CKD. Calcium carbonate, also used as a calcium supplement and phosphate binder, has a beneficial effect on acidosis.

Calcium and phosphate control and suppression of PTH
Hypocalcaemia and hyperphosphataemia should be treated aggressively, preferably with regular (e.g. 3-monthly) measurements of serum PTH to assess how effectively hyperparathyroidism is being suppressed. Suppression of PTH levels to below two or three times the upper limit of ‘normal’ carries a high risk of development of a dynamic bone disease.

Dietary restriction of phosphate is seldom effective alone, because so many foods contain it. Oral calcium carbonate or acetate reduces absorption of dietary phosphate but is contraindicated where there is hypercalcaemia or hypercalciuria. Aluminium-containing gut phosphate binders are very effective but absorption of aluminium poses the risk of aluminium bone disease and development of cognitive impairment. They are now rarely used in the developed countries but are still used in the developing countries because they are extremely cheap.

Management of chronic kidney disease
The underlying cause of CKD should be treated aggressively wherever possible.

Renoprotection
The multidrug approach to chronic nephropathies has been formalized in an international protocol (Box 12.6).

Correction of complications
Hyperkalaemia
Hyperkalaemia often responds to dietary restriction of potassium intake. Drugs which cause potassium retention (see p. 655) should be stopped. Occasionally, it may be necessary to prescribe ion-exchange resins to remove potassium in the gastrointestinal tract. Emergency treatment of severe hyperkalaemia is described on page 655.

Acidosis
Correction of acidosis helps to correct hyperkalaemia in CKD, and may also decrease muscle catabolism. Sodium bicarbonate supplements are often effective (4.8 g (57 mmol) of Na⁺ and HCO₃⁻ daily), and the possibility of oedema and hypertension owing to the so-called ‘extracellular fluid expansion’ was not borne out by a trial. Interestingly, correction of metabolic acidosis by sodium bicarbonate at a mean dose of 1.8 g/day was also associated with marked reduction in the rate of progression of CKD and development of ESKD in patients with stage 4 and 5 CKD. Calcium carbonate, also used as a calcium supplement and phosphate binder, has a beneficial effect on acidosis.

Calcium and phosphate control and suppression of PTH
Hypocalcaemia and hyperphosphataemia should be treated aggressively, preferably with regular (e.g. 3-monthly) measurements of serum PTH to assess how effectively hyperparathyroidism is being suppressed. Suppression of PTH levels to below two or three times the upper limit of ‘normal’ carries a high risk of development of a dynamic bone disease.

Dietary restriction of phosphate is seldom effective alone, because so many foods contain it. Oral calcium carbonate or acetate reduces absorption of dietary phosphate but is contraindicated where there is hypercalcaemia or hypercalciuria. Aluminium-containing gut phosphate binders are very effective but absorption of aluminium poses the risk of aluminium bone disease and development of cognitive impairment. They are now rarely used in the developed countries but are still used in the developing countries because they are extremely cheap.

Treatment
- Gut phosphate binders. The polymer sevelamer reduces the calcium load and attenuates vascular calcification and also lowers cholesterol levels by 10%. However, it has not been shown to reduce mortality. Lanthanum carbonate is a non-calcium, non-aluminium phosphate binder that is effective and has a good safety profile.
- Nicotinamide, an alternative to phosphate binders, blocks the intestinal sodium/inorganic phosphate (Na/Pi) cotransporter. It reduces phosphate levels and PTH levels alongside improvement in the lipid profile in dialysis patients.
- Calcitriol (1,25-dihydroxycholecalciferol) or a vitamin D analogue, such as alfacalcidol, used in early CKD has no deleterious effect upon renal function provided hypercalcaemia is avoided. New vitamin D metabolites (22-oxacalcitriol, paricalcitol, doxercalciferol) are less calcemic. However, with the exception of paricalcitol (19-nor-1,25 dihydroxyvitamin D₃, which may have survival advantage), their usefulness over conventional but less expensive calcitriol or alfacalcidol remains to be established. Treatment with vitamin D analogues should be started only if serum PTH level is three times or more above the upper limit of normal, in order to prevent the development of adynamic bone disease (see p. 619). Vitamin D therapy has the disadvantage that it increases not only calcium but also phosphate absorption and
may therefore exacerbate hyperphosphataemia and ectopic calcification including calciphibylaxis (calcification of small vessels).

- **Calcimimetic agents** (e.g. cinacalcet, a calcium-sensing receptor agonist, see p. 621) have also been tried in established secondary hyperparathyroidism with successful suppression of PTH levels and lowering of calcium × phosphate product. The long-term safety and efficacy of these agents has recently been confirmed and several observational studies have demonstrated that use of cinacalcet is associated with survival advantage.

### Drug therapy

This should be minimized in patients with CKD. Tetracyclines (with the possible exception of doxycycline) should be avoided in view of their anti-anabolic effect and tendency to worsen uraemia. Drugs excreted by the kidneys, such as gentamicin, should be prescribed only in the absence of any alternative and drug levels monitored if feasible. Non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided. Potassium-sparing agents, such as spironolactone and amiloride, pose particular dangers, as do artificial salt substitutes, all of which contain potassium.

Bardoxolone, an antioxidant inflammatory modulator, has shown a reduction in GFR in diabetic CKD.

### Anaemia

The anaemia of erythropoietin (EPO) deficiency can be treated with synthetic (recombinant) human EPO (epoetin-α or -β, or the longer-acting darbepoetin-α or polyethylene glycol-bound epoetin-β). The intravenous route is used, initially with 50 U/kg of epoetin-α over 1–5 min, three times weekly. Subcutaneous administration of epoetin-α can also be used (see below). Blood pressure, haemoglobin concentration and reticulocyte count are measured every 2 weeks and the dose adjusted to maintain a target haemoglobin of 110–120 g/L. Darbepoetin-α can be used once a week. Continuous erythropoiesis receptor activator (CERA), a recently licensed epoetin in Europe, is a pegylated epoetin-β and can be given once a month. In trials, CERA has a similar activity to other types of epoetin. However, CERA use is extremely limited and data about loss of flexibility of dosing, overshooting the target haemoglobin and its efficacy in combination with short-acting epoetin are required before its widespread use.

The target haemoglobin to be achieved during the treatment of anaemia is being revised to between 110 and 120 g/L as studies in pre-dialysis CKD patients have not revealed any outcome benefits in patients who were treated to achieve higher haemoglobin targets (>120 g/L).

**Failure to respond** to 300 U/kg weekly, or a fall in haemoglobin after a satisfactory response, may be due to iron deficiency, bleeding, malignancy, infection, inflammation or formation of anti-EPO neutralizing antibodies. The demand for iron by the bone marrow is enormous when erythropoietin is commenced. Patients on EPO therapy are regularly monitored for iron status and considered iron deficient if plasma ferritin is <100 μg/L, hypochromic RBCs >10%, transferrin saturation <20%. Functional iron deficiency due to poor mobilization of iron, despite adequate iron stores (ferritin >500 μg/L) and a transferrin saturation of >20%, is a common finding in patients with chronic inflammation. It is caused by hepcidin (see p. 377), an acute phase reactant produced by the liver in response to cytokines, particularly IL-6. Intravenous (rather than oral) iron supplements optimize response to EPO treatment by repletion of iron stores. A recent randomized trial has demonstrated a beneficial effect of i.v. iron even in patients with ferritin >800 μg/L and transferrin saturation of 20%.

Correction of anaemia with EPO improves quality of life, exercise tolerance and sexual and cognitive function in dialysis patients, and leads to regression of left ventricular hypertrophy. Avoidance of blood transfusion also reduces the chance of sensitization to HLA antigens, which may otherwise be a barrier to successful renal transplantation.

The **disadvantages of erythropoietin therapy** are that it is expensive and causes a rise in blood pressure in up to 30% of patients, particularly in the first 6 months. Peripheral resistance rises in all patients, owing to loss of hypoxic vasodilatation and to increased blood viscosity. A rare complication is encephalopathy with fits, transient cortical blindness and hypertension. Several reports of anti-EPO antibody-mediated pure red-cell aplasia in patients receiving subcutaneous EPO therapy (particularly EPO-α) have been described. The exact cause is unknown but interventions such as using the intravenous route and changes in manufacture of prefilled syringes have reduced the number of cases by 80%. Other causes of anaemia should be looked for and treated appropriately (see p. 375).

Several erythropoiesis-stimulating agents are in clinical trials. An EPO mimetic is an engineered peptide which stimulates EPO receptor but still has to be given by injection. Oral agents which inhibit prolyl hydroxylase and prolong the life of HIF (hypoxia inducible factors) 1α, a transcription factor for endogenous production of EPO, have shown promise in phase 2 trials.

### Male erectile dysfunction

Testosterone deficiency should be corrected. The oral phosphodiesterase inhibitors, e.g. sildenafil, tadalafil and vardenafl, are effective in ESKD and are the first-line therapy. The use of nitrates is a contraindication to this treatment. Other treatments are discussed on page 966.

### Early referral of patients with chronic kidney disease

Patients need time to adjust to the demands of CKD and its treatment, and to absorb information. Veins required in the future for fashioning of an arteriovenous fistula should not be rendered useless by cannulation (Fig. 12.49).

**DO NOT DO THIS!**

Figure 12.49 Intravenous cannula in exactly the **WRONG place**, in a right-handed patient with CKD who will in future need a left (non-dominant arm) radiocephalic fistula.
If the patient opts for regular haemodialysis, fashioning of an arteriovenous fistula should be carried out well in advance of the need for dialysis, when serum creatinine is of the order 400–500 μmol/L in non-diabetics and at an even earlier stage in diabetics with poorer vasculature. Such fistulae require several weeks to mature and become usable for vascular access.

Renal replacement therapy

Approximately 100 white individuals per million population commence renal replacement therapy in the UK each year. The corresponding figure in black Africans and Asians in the UK is three to four times higher, largely owing to diabetic and hypertensive nephropathy. The aim of all renal replacement techniques is to mimic the excretory functions of the normal kidney, including excretion of nitrogenous wastes, maintenance of normal electrolyte concentrations, and maintenance of a normal extracellular volume.

Haemodialysis

Basic principles

In haemodialysis, blood from the patient is pumped through an array of semipermeable membranes (the dialyser, often called an ‘artificial kidney’), which bring the blood into close contact with dialysate, flowing countercurrent to the blood. The plasma biochemistry changes towards that of the dialysate owing to diffusion of molecules down their concentration gradients (Fig. 12.50).

The dialysis machine comprises a series of blood pumps, with pressure monitors and bubble detectors and a proportionating unit, also with pressure monitors and blood leak detectors. Blood flow during dialysis is usually 200–300 mL/min and the dialysate flow usually 500 mL/min. The efficiency of dialysis in achieving biochemical change depends on blood and dialysate flow and the surface area of the dialysis membrane.

Dialysate is prepared by a proportionating unit, which mixes specially purified water with concentrate, resulting in fluid with the composition described in Table 12.24.

Access for haemodialysis

Adequate dialysis requires a blood flow of at least 200 mL/min. The most reliable long-term way of achieving this is surgical construction of an arteriovenous fistula (Fig. 12.51), using the radial or brachial artery and the cephalic vein. This results in distension of the vein and thickening (‘arterialization’) of its wall, so that after 6–8 weeks large-bore needles may be inserted to take blood to and from the dialysis machine. In patients with poor-quality veins or arterial disease (e.g. diabetes mellitus), arteriovenous polytetrafluoroethylene (PTFE) grafts are used for access. However, these grafts have a very high incidence of thrombosis and 2-year graft patency is only 50–60%. Dipyridamole or fish oils improve graft patency but warfarin, aspirin and clopidogrel do not and are associated with a high incidence of complications. In patients with PTFE stenosis, balloon angioplasty followed by stenting is associated with better long-term patency rates compared with angioplasty alone.

If dialysis is needed immediately, a large-bore double lumen cannula may be inserted into a central vein – usually the subclavian, jugular or femoral. Semipermanent dual-lumen venous catheters can also be used, usually inserted via a skin tunnel to lessen the risk of infection. Stenosis of the subclavian vein is common, and the jugular route is preferred. However, they are associated with particularly high rates of infection, hospitalization, and death. These catheters are prone to partial or total occlusion, which may lead to inadequate dialysis and missed dialysis sessions and should be avoided whenever possible.

In a recent study a simple regimen in which recombinant tissue plasminogen activator (rt-PA) was used for locking the dialysis catheter once a week (with heparin used for the other two treatments each week) was superior to a regimen in which heparin locks were used after all the treatments; the...
rate of access failure was halved, and access-related infection was reduced by two-thirds.

**Dialysis prescription**

Dialysis must be tailored to an individual patient to obtain optimal results.

**Initiation of dialysis**

In clinical practice there is a wide variation in the timing of the starting dialysis therapy in patients with stage 5 CKD. There is a general tendency to start dialysis earlier with eGFR close to 15 mL/min rather than below 10 mL/min, despite a recent study showing that early initiation of dialysis was not associated with an improvement in survival or clinical outcomes. This underscores the fact that decisions about the timing of starting dialysis therapy should be taken individually rather than by a numerical parameter.

**Dry weight**

This is the weight at which a patient is neither fluid overloaded nor depleted. Patients are weighed at the start of each dialysis session and the transmembrane pressure adjusted to achieve fluid removal equal to the amount by which they exceed their dry weight.

**The dialysate buffer**

The dialysate buffer is usually acetate or bicarbonate. The sodium and calcium concentrations of the dialysate buffer are carefully monitored. A high dialysate sodium causes thirst and hypertension. A high dialysate calcium causes hypercalcemia, while a low-calcium dialysate combined with poor compliance of medication with oral calcium carbonate and vitamin D may result in hyperparathyroidism.

**Frequency and duration**

Frequency and duration of dialysis are adjusted to achieve adequate removal of ureaemic metabolites and to avoid excessive fluid overload between dialysis sessions. An adult of average size usually receives 4–5 hours’ treatment three times a week. Twice-weekly dialysis is adequate only if the patient has considerable residual renal function. However, in a recent study patients treated with haemodialysis six times a week benefited more with respect to the composite outcomes of death or change in left ventricular mass and quality of life but required more frequent interventions related to vascular access.

Short-duration dialysis using very biocompatible high-flux membranes is commonly employed. Advantages include shorter duration of treatment and hence increased patient convenience. Disadvantages include higher cost of the membranes employed and, in all probability, higher prevalence of hypertension in such patients, requiring hypertensive medication. It should not be forgotten that normal kidneys work for 24 hours a day, 7 days a week, and that dialysis is a poor substitute for the natural state.

Adequate/optimal dialysis should be adjusted to individual patients’ needs. All patients are anticoagulated (usually with heparin) during treatment as contact with foreign surfaces activates the clotting cascade. In the UK, a small number of patients manage self-supervised home haemodialysis.

**Complications**

Hypotension during dialysis is the major complication. Contributing factors include: an excessive removal of extracellular fluid, inadequate ‘refilling’ of the blood compartment from the interstitial compartment during fluid removal, abnormalities of venous tone, autonomic neuropathy, acetate intolerance (acetate acts as a vasodilator) and left ventricular hypertrophy.

Very rarely, patients may develop anaphylactic reactions to ethylene oxide, which is used to sterilize most dialysers. Patients receiving ACE inhibitors are at risk of anaphylaxis if polyacrylonitrile dialysers are used.

Other potential, rare, complications include the hard-water syndrome (caused by failure to soften water resulting in a high calcium concentration prior to mixing with dialysate concentrate), haemolytic reactions and air embolism.

**Adequacy of dialysis**

Dialysis treatment is empirical since the size, number and nature of ‘uraemic toxins’ is unclear. The only true measure of adequacy is patient mortality and morbidity. Adequate nutrition of the patient, as well as adequate dialysis is necessary to reduce morbidity and mortality.

Symptoms of underdialysis are nonspecific and include insomnia, itching and fatigue, despite adequate correction of anaemia, restless legs and a peripheral sensory neuropathy.

Adequacy of dialysis may be assessed by computerized calculation of urea kinetics, requiring measurement of the residual renal urea clearance, the rate of rise of urea concentration between dialysis sessions, and the reduction in urea concentration during dialysis. The dialysis dose is normally defined in terms of urea reduction ratio (URR) and/or equilibrated urea clearance, eKt/V (where K is the dialyser clearance, t is the duration of dialysis in minutes, and V is the urea distribution volume estimated as total body water). Kt/V of 1.0–1.2 and/or URR of 65% per dialysis session is the minimum threshold required for well-nourished dialysis patients dialysed three times per week. It is unclear whether a higher eKt/V is associated with a better outcome, although no additional benefits of high (1.53) compared with standard (1.16) eKt/V were seen over 5 years’ follow-up. It is likely that duration of haemodialysis session is a factor in itself in addition to the efficiency with which small molecules such as urea are cleared. The best haemodialysis outcome data are seen in renal units where long hours (8 h per session) of dialysis are routinely practised.

Haemodialysis is the most efficient way of achieving rapid biochemical improvement, for instance in the treatment of acute kidney injury or severe hyperkalaemia. This advantage is offset by disadvantages such as haemodynamic instability, especially in acutely ill patients with multiorgan disease, and over-rapid correction of ureaemia can lead to ‘dialysis disequilibrium’. This is characterized by nausea and vomiting, restlessness, headache, hypertension, myoclonic jerking, and in severe instances seizures and coma owing to rapid changes in plasma osmolality leading to cerebral oedema. These problems have led to the increasing adoption of gentler continuous methods for the treatment of acute kidney injury (see below).

**Haemofiltration**

This involves removal of plasma water and its dissolved constituents (e.g. K+, Na+, urea, phosphate) by convective flow across a high-flux semipermeable membrane, and replacing it with a solution of the desired biochemical composition (Fig. 12.52). Lactate is used as buffer in the replacement solution because rapid infusion of acetate causes vasodilatation, and bicarbonate may cause precipitation of calcium carbonate.

Haemofiltration can be used for both acute and CKD and is used in mainland Europe for CKD patients with haemodynamic instability. High volumes need to be exchanged in
Kidney and urinary tract disease

order to achieve adequate small molecule removal, typically a 22 L exchange three times a week for maintenance treatment and 1 L per hour in acute kidney injury. Financial costs of disposable items (such as filters and replacement fluid) are high and only a selected group of patients with ESKD are managed in this way. Modern dialysis machines have built-in facilities to generate online ultrapure water, which has minimized the cost of the procedure and given an option to the clinician to use this technique either as haemofiltration or in combination with dialysis as haemodialfiltration to increase middle molecule clearance (e.g. β2-microglobulin) and prevent long-term dialysis complications such as dialysis-related amyloidosis, particularly in young, highly sensitized, non-transplantable patients.

**Peritoneal dialysis**

Peritoneal dialysis utilizes the peritoneal membrane as a semipermeable membrane, avoiding the need for extracorporeal circulation of blood. This is a very simple, low-technology treatment compared to haemodialysis. The principles are simple (Fig. 12.53).

- A tube is placed into the peritoneal cavity through the anterior abdominal wall (Fig. 12.54).
- Dialysate is run into the peritoneal cavity, usually under gravity.
- Urea, creatinine, phosphate and other uraemic toxins pass into the dialysate down their concentration gradients.
- Water (with solutes) is attracted into the peritoneal cavity by osmosis, depending on the osmolarity of the dialysate. This is determined by the glucose or polymer (icodextrin) content of the dialysate (Table 12.25).
- The fluid is changed regularly to repeat the process.

Chronic peritoneal dialysis requires insertion of a soft catheter, with its tip in the pelvis, exiting the peritoneal cavity in the midline and lying in a skin tunnel with an exit site in the lateral abdominal wall (Fig. 12.54).

This form of dialysis can be adapted in several ways.

- **Continuous ambulatory peritoneal dialysis (CAPD)**.
  Dialysate is present within the peritoneal cavity continuously, except when dialysate is being exchanged. Dialysate exchanges are performed three to five times a day, using a sterile no-touch technique to connect 1.5–3 L bags of dialysate to the peritoneal catheter; each exchange takes 20–40 min. This is the technique most often used for maintenance peritoneal dialysis in patients with ESKD.

- **Nightly intermittent peritoneal dialysis (NIPD)**, also called automated peritoneal dialysis (APD). An automated device is used to perform exchanges each night while the patient is asleep. Sometimes dialysate is left in the peritoneal cavity during the day in addition, to increase the time during which

**Figure 12.53 Principles of peritoneal dialysis.** Water is attracted into the peritoneal cavity depending on the osmolarity of the dialysate.
biochemical exchange is occurring. Few trials have demonstrated superiority of APD over CAPD with regard to complications such as peritonitis, fluid status and in anuric patients.

- **Tidal dialysis.** A residual volume is left within the peritoneal cavity with continuous cycling of smaller volumes in and out.

  Osmotic removal of excess plasma water and solutes is achieved using hypertonic dialysate (either due to high glucose concentration or icodextrin), which exerts an osmotic ‘drag’. Depending on the patient’s fluid intake and residual urine output, it may be necessary to use one or more hypertonic dialysate bags daily to achieve fluid balance in CAPD. Fluid overload is a relatively common problem in CAPD, and is due to failure of transport across the peritoneal membrane.

**Complications**

**Peritonitis**

Bacterial peritonitis is the most common serious complication of CAPD and other forms of peritoneal dialysis. Clinical presentations include abdominal pain of varying severity (guarding and rebound tenderness are unusual), and a cloudy peritoneal effluent, without which the diagnosis cannot be made. Microscopy reveals a neutrophil count above 100 cells/mL. Nausea, vomiting, fever and paralytic ileus may be seen if peritonitis is severe. The incidence of CAPD-associated peritonitis has been much reduced (to about one episode every 2 patient-years) by use of a Y-disconnect system in CAPD peritonitis must be investigated with culture of peritoneal effluent. A mixed growth of Gram-negative and Gram-positive organisms is due to failure of transport across the peritoneal membrane.

Fungal peritonitis often follows antibacterial treatment but may occur de novo. Clinical presentation is very variable. It is rare to be able to cure fungal peritonitis without catheter removal as well as antifungal treatment. Intraperitoneal amphotericin has been associated with the formation of peritoneal adhesions.

**Infection around the catheter site**

Infection where the catheter exits through the skin is relatively common. It should be treated aggressively (with systemic and/or local antibiotics) to prevent spread of the infection into the subcutaneous tunnel and the peritoneum. The most common causative organisms are staphylococci, including MRSA. Exit site infections can be reduced by routine use of mupirocin or gentamicin ointments locally and intranasally in those with colonized nares. Exit site infection due to *Pseudomonas* is treated by antibiotics and resiting the exit following catheter exchange.

**Other complications**

CAPD is often associated with constipation, which in turn may impair flow of dialysate in and out of the pelvis. Occasionally, dialysate may leak through a diaphragmatic defect into the thoracic cavity, causing a massive pleural ‘effusion’. The glucose content of the effusion is usually diagnostic, or the diagnosis may be made by instillation of methylthioninium chloride (methylene blue) with dialysate and the demonstration of a blue colour on pleural tap. Dialysate may also leak into the scrotum down a patent processus vaginalis.

Failure of peritoneal membrane function is a predictable complication of long-term CAPD, resulting in worsening biochemical exchange and decreased ultrafiltration with hypertonic dialysate. It is thought that this problem may be accelerated by excessive reliance on hypertonic dialysate to remove fluid.

Sclerosing peritonitis is a potentially fatal complication of CAPD. The cause is often unclear, but recurrent peritonitis and exposure of the peritoneum to unphysiological high glucose concentrations is responsible in most cases. Progressive thickening of the peritoneal membrane occurs in association with adhesions and strictures, turning the small bowel into a mass of matted loops and causing repeated episodes of small bowel obstruction. CAPD should be abandoned. Improvement may follow renal transplantation or treatment with prednisolone or azathioprine.

**Contraindications**

There are few absolute contraindications apart from unwillingness or inability on the patient’s part to learn the technique.

---

**Chronic kidney disease (CKD)**

627
Previous peritonitis causing peritoneal adhesions may make peritoneal dialysis impossible, but the extent of adhesions is difficult to predict and it may be worth an attempted surgical placement of a dialysis catheter.

The presence of a stoma (colostomy, ileostomy, ileal urinary conduit) makes successful placement of a dialysis catheter extremely unlikely.

Active intra-abdominal sepsis, for instance due to diverticular abscesses, is an absolute contraindication to peritoneal dialysis although diverticular disease per se is not.

Abdominal hernias may often expand during CAPD as a result of increased intra-abdominal pressure, and should ideally be repaired before or at the time of CAPD catheter insertion.

Visual impairment may make it difficult for a patient to perform dialysate exchanges, but completely blind patients can be trained in the technique if adequately motivated.

Severe arthritis makes it difficult to perform the exchanges, but a large number of mechanical aids are available. Sterilization of connections by heat or ultraviolet light reduces the risk of peritonitis.

Some studies suggest that ESKD patients with coronary artery disease or congestive heart failure have significantly higher morbidity and mortality on CAPD compared with HD. Moreover, elderly patients do worse on CAPD than younger patients. It is advisable to consider HD as the first-choice dialysis modality in these patients where it is possible.

### Adequacy of peritoneal dialysis

No consensus exists on the optimum degree of removal of urea and other waste products to be obtained in unit time but there is general agreement that minimum dose delivered should not be <1.7. Based on observational studies, weekly Kt/V of 2.0 coupled with a creatinine clearance target of 60 L per week had been recommended. However, in a randomized prospective study (ADEMEX), standard daily exchanges of 8 L in total (creatinine clearance 40 L per week) compared with a creatinine clearance of 60 L per week yielded similar patient and technique survival. Peritoneal dialysis inadequacy becomes common when residual renal function declines to zero. With increasing time on treatment, adequacy may become impaired owing to alterations in the efficiency of the peritoneal membrane in transporting waste products, fluid and electrolytes.

### Complications of all long-term dialysis

Cardiovascular disease (see p. 620) and sepsis are the leading causes of death in long-term dialysis patients.

Causes of fatal sepsis include peritonitis complicating peritoneal dialysis and Staph. aureus infection (including endocarditis) complicating the use of indwelling access devices for haemodialysis.

### Dialysis amyloidosis

This is the accumulation of amyloid protein (p. 1043) as a result of failure of clearance of β2-microglobulin, a molecule of 11.8 kDa. This protein is the light chain of the class I HLA antigens and is normally freely filtered at the glomerulus but is not removed by cellulose-based haemodialysis membranes. The protein polymerizes, possibly after modification by non-enzymic glycosylation, to form amyloid deposits, which may cause median nerve compression in the carpal tunnel or a dialysis arthropathy – a clinical syndrome of pain and disabling stiffness in the shoulders, hips, hands, wrists and knees. β2-microglobulin-related amyloid may be demonstrated in the synovium. Amyloid deposits (see p. 1043) can also cause pathological bone cysts and fractures, pseudotumours and gastrointestinal bleeding caused by amyloid deposition around submucosal blood vessels. The extent of amyloid deposition is best assessed by nuclear imaging, either using [99mTc] DMSA, or more specifically, by the use of radio-labelled serum amyloid P component.

Rapid improvement after renal transplantation is probably due to steroid therapy as low-dose prednisolone alone can also cause an improvement. A change to a biocompatible synthetic membrane has also been reported to be of benefit: again, the mechanism for this improvement is not clear. β2-microglobulin clearance is several times higher in patients treated with haemofiltration or haemodiafiltration and these techniques are increasingly used in patients at high risk of developing this complication.

### Dialysis in the elderly

Dialysis can prolong life, but the benefit to the individual and particularly elderly patients, varies widely. Outcomes in frail elderly people who are undergoing dialysis are poor. Small studies suggest that mortality or quality-of-life outcomes do not differ significantly among selected patients who elect to undergo dialysis compared to those who decide against dialysis. In one study, over 50% died within the first year of initiating dialysis and around 30% had a decrease in functional status.

Prior to the initiation of dialysis, elderly patients must be informed about its modest benefit in their age group and the possibility of conservative therapy that does not involve dialysis. Conservative therapy should be discussed, not as a last resort but as a clear option that might be more effective in promoting patient goals. There is a need for well structured palliative care infrastructure staffed by trained individuals to deal with end of life decision issues in dialysis patients.

### Transplantation

Successful renal transplantation offers the potential for almost complete rehabilitation in ESKD. This mode of renal replacement therapy has significant survival advantage compared to dialysis patients on transplant waiting lists. It allows freedom from dietary and fluid restriction; anaemia and infertility are corrected; and the need for parathyroidectomy is reduced. It is the treatment of choice for most patients with ESKD. The supply of donor organs (in the UK, 30/million per year) is greatly exceeded by demand (48/million per year), and donor organs are therefore scarce and a valuable resource that must be used optimally.

The technique involves the anastomosis of an explanted human kidney, usually either from a cadaveric donor or from a living close relative, on to the iliac vessels of the recipient (Fig. 12.55). The donor ureter is placed into the recipient’s bladder. Unless the donor is genetically identical (i.e. an identical twin), immunosuppressive treatment is needed, for as long as the transplant remains in place, to prevent rejection. Refinements in patient selection and assessment of donor–recipient compatibility, improvements in surgical techniques and the development of more efficient immunosuppressive regimens have increased patient and graft survival. Some 80% of grafts now survive for 5–10 years in the best centres, and 50% for 10–30 years. However, the half-life of renal allografts is still 13–16 years. The three most common causes of late graft loss are death with functioning graft, recurrence of renal disease and chronic allograft nephropathy.
of patients waiting for them, several countries now allow the retrieval of organs after cardiac death, with comparable results to heart beating donations. Moreover, elderly donors (age >60 years) or those between the ages of 55 and 59 years but co-morbidity such as hypertension, diabetes, preterieval AKI and intracranial haemorrhage as a cause of death known as expanded criteria donors (ECD) are increasingly used.

**Living related donation**

A close relative may volunteer as a potential donor. A sibling donor may be HLA identical or share one or no haplotypes with the potential recipient. In the UK, donor age must be 18 years or more.

Potential living related donors are subjected to an intensive preoperative evaluation, including clinical examination and measurement of renal function, tests for carriage of hepatitis B, C, HIV and cytomegalovirus, and detailed imaging of renal anatomy, to be sure that transplantation will be technically feasible.

Unrelated living donors may be accepted provided no inducement (financial or otherwise) is involved. Paid live non-related donor transplantation is illegal in the UK.

**Immunosuppression for transplantation**

Long-term drug treatment for the prevention of rejection is employed in all cases apart from living related donation from an identical twin. Some degree of immunological tolerance does develop, and the risk of rejection is highest in the first 3 months after transplantation. In the early months, rejection episodes occur in less than 30% of cadaver kidney recipients. Most are reversible. A combination of immunosuppressive drugs is usually used (Table 12.27).

**Complications**

**Acute tubular necrosis (ATN)**

ATN is the commonest cause of cadaveric graft dysfunction (up to 40–50%), particularly in kidneys from DCD or ECD donors and prolonged cold ischaemia time (>24 hours). Delayed graft function due to ATN is associated with worse long-term outcome and also predisposes the graft to rejection. It is usual practice to use induction with antibodies and use 50% of the starting dose of calcineurin inhibitors in recipients of grafts at high risk for ATN.

**Technical failures**

There may be occlusion or stenosis of the arterial anastomosis, occlusion of the venous anastomosis, and urinary leaks owing to damage to the lower ureter, or defects in the anastomosis between ureter and recipient bladder. If urine output drops, Doppler ultrasonography, DTPA scanning and/or renal angiography is used. Surgical reimplantation may be required.

**Acute rejection (AR)**

AR is seen in between 10% and 30% of transplant recipients and usually presents with declining renal function within the first 3 months. Renal biopsy confirms the diagnosis and also assesses the severity and type of rejection (cellular or vascular or antibody mediated, also called humoral rejection). Therapy in cellular rejection is high-dose pulse steroid; in acute vascular rejection (diagnosed by the presence of additional endothelial inflammation), ATG, anti-lymphocyte globulin (ALG) or OKT3 is used.

Histological appearances similar to vascular rejection are seen in a small number of patients where the culprit is an agonistic antibody directed against angiotensin receptor 1 (ATR 1), which usually presents with sudden decline in renal function.

**Factors affecting success**

ABO (blood group) compatibility between donor and recipient is required. However, in some centres, particularly in Japan where a cadaveric organ donation programme is not well established, ABO-incompatible renal transplants are increasingly performed. These transplants follow with immunoadsorption to remove preformed antibodies, splenectomy, anti-CD20 antibodies to remove B lymphocytes, and intravenous pooled immunoglobulins for immunomodulation or anti-idiotypic antibodies. In experienced hands, results are acceptable.

**Matching donor and recipient for HLA type**

Matching for HLA-DR antigens appears to have the most impact on graft survival. Studies have shown that matching at the HLA-B locus has only a minor effect on graft outcomes. Complete compatibility at A, B and DR offers the best chance of success, followed by a single HLA mismatch (i.e. antigen possessed by the donor and not possessed by the recipient).

The effect of further degrees of mismatching upon graft survival in first transplants is of modest degree. Nationwide matching schemes for kidneys retrieved from cadaver donors are in existence. However, with availability of more efficient immunosuppressive agents, the value of HLA matching in the overall transplant outcome is, if any, only modest. Transplantation with completely mismatched kidneys, particularly when the donor is the patient’s partner, is routinely practised and results are as good as, if not better than, properly matched cadaveric kidneys.

A donor factor, an allotype of the C3 complement molecule, may be associated with better long-term outcomes for cadaveric kidney grafts. This report raised the possibility that the presence of the C3F (fast) allele in a kidney allograft is associated with a better outcome. However, this finding could not be reproduced in a subsequent study, which underscores the necessity of validation of unusual findings by several groups before adopting them in the clinical practice.

**Adequate immunosuppressive treatment**

See below.

**The donor kidney**

**Cadaveric donation**

Most countries allow the removal of kidneys and other organs from patients who have suffered irretrievable brain damage (‘brainstem death’) while their hearts are still beating (see p. 897). Due to shortage of solid organs and increasing numbers

biopsy by C4 staining) (Fig. 12.56b) is usually treated empirically by a combination of i.v. polyclonal immunoglobulin infusion to neutralize and promote the clearance of anti-HLA antibodies, plasmapheresis (to remove antibodies) and anti-CD20 antibody administration (to deplete B lymphocytes) with variable success.

function but unlike vascular rejection also manifests with malignant phase hypertension and seizures. It responds to angiotensin receptor blockers in addition to conventional antirejection strategies (Fig. 12.56a). Humoral rejection (diagnosed by the presence of circulating donor-specific anti-HLA antibodies and evidence of complement activation on renal biopsy by C4 staining) (Fig. 12.56b) is usually treated empirically by a combination of i.v. polyclonal immunoglobulin infusion to neutralize and promote the clearance of anti-HLA antibodies, plasmapheresis (to remove antibodies) and anti-CD20 antibody administration (to deplete B lymphocytes) with variable success.

Table 12.27 Immunosuppressive drugs used in renal transplantation

FURTHER READING
Infections
Infections are a frequent occurrence in the first month post-transplantation. They are particularly common in recipients of deceased donor organs, and in the elderly. Infections that are both common and serious are bacterial pneumonia, Pneumocystis jiroveci (co-trimoxazole) and oral candidiasis (nystatin or amphotericin lozenges). Polyomavirus infections (BK nephropathy) result in graft dysfunction and eventual loss due to mainly tubulointerstitial nephritis diagnosed by renal biopsy and presence of cellular inclusion bodies positive for SV40 (Fig. 12.57). There is no specific treatment with the exception of tapering immunosuppression and with caution use of leflunomide and cidofovir.

Post-transplant lymphoproliferative disorders
Epstein–Barr virus-associated malignancies are common in patients who received organs from organ donors infected with EBV and in children. Tapering of cyclosporin or tacrolimus, cessation of antiproliferative agents (azathioprine or MMF) and monitoring for the reappearance of cytotoxic lymphocytes has improved the outcome.

Chronic allograft nephropathy (CAN)
CAN remains the most common cause of late graft failure. The process is mediated by immunological possibly due to chronic antibody mediated rejection due to de novo synthesis of donor specific antibodies and non-immunological factors and results in a progressive irreversible decline in graft function with mild to modest proteinuria (<3 g/day). Unfortunately there is no established therapy of proven efficiency.

Malignancy
Immunosuppressive therapy increases the risk of skin tumours, including basal and squamous cell carcinoma. In white recipients, exposure to ultraviolet light should be minimized and sun-block creams employed. Other common cancers are renal, cervical and vaginal. In female recipients, regular yearly cervical smears should be carried out.

Cardiovascular disease
Cardiovascular disease is the cause of death post transplantation in 50% of cases. This is due to increased incidence of hypertension, obesity, diabetes and insulin resistance lipid disorders. Use of a statin (fluvastatin) was associated with reduction in cardiac endpoints (myocardial infarction or revascularization) post transplantation but overall mortality remained unchanged in a randomized prospective study.

Post-transplant osteoporosis
This is common following transplantation owing to treatment with steroids. Maximum bone loss occurs within the first 3 months and regular DXA scans are necessary. Bisphosphonates (alendronate, pamidronate) and alfacalcidol with or without calcium carbonate have proven to be effective in control studies.

Recurrent disease
Recurrence of renal disease is surprisingly common. Primary FSGS often recurs and causes early graft loss. Mesangiocapillary GN, diabetic nephropathy and IgA nephropathy also commonly recur with variable effects on long-term graft survival.

Renal transplantation in HIV patients
Modern highly active antiretroviral therapy (HAART) offers patients with HIV infection a near-normal life expectancy. However, an increasing number develop end-stage CKD. Until recently, HIV was considered to be a contraindication to renal transplantation. Nevertheless, a recent study of outcomes for 150 HIV-infected patients undergoing renal transplantation has shown that kidney transplantation is safe and effective in patients, at least in the short term. The patients in the study had CD4+ T-cell counts ≥200/mL3 and undetectable plasma levels of HIV type 1 RNA while on stable HAART during the 16 weeks before renal transplantation. Median follow-up was 1.7 years. Survival rates at 1 year (95%) and 3 years (88%) were worse in HIV-infected patients than in the general population of kidney transplant recipients, but better than those in patients aged ≥65 years. Many rejection episodes were glucocorticoid-resistant, suggesting an aggressive response to donor antigens.

CYSTIC RENAL DISEASE
Solitary or multiple renal cysts are common, especially with advancing age: 50% of those aged 50 years or more have one or more such cysts. They have no special significance except in the differential diagnosis of renal tumours (see p. 634). Such cysts are often asymptomatic and are found on ultrasound examination performed for some other reason. Occasionally, they may cause pain and/or haematuria owing to their large size, or bleeding may occur into the cyst. Cystic degeneration (the formation of multiple cysts which enlarge with time) occurs regularly in the kidneys of patients with ESKD treated by dialysis and/or transplantation. Malignant tumour formation seems to be more common in such kidneys than in the general population.
Autosomal dominant polycystic kidney disease

Autosomal dominant polycystic kidney disease (ADPKD) is an inherited disorder usually presenting in adult life. It is characterized by the development of multiple renal cysts, variably associated with extrarenal (mainly hepatic and cardiovascular) abnormalities. ADPKD is by far the most common inherited nephropathy, with a prevalence rate ranging from 1:400 to 1:1000 in white populations. It accounts for 3–10% of all patients commencing regular dialysis in the West (see ciliopathies, p. 22).

In about 85% of cases, the gene responsible (PKD1) has been located on chromosome 16. A second gene, PKD2, which has been mapped to chromosome 4, accounts for the vast majority of other cases. These genetic abnormalities are distinct from the autosomal recessive form of polycystic disease (due to mutations in the PKHD1 gene on chromosome 6p21.1-p12), which is often lethal in early life.

The protein corresponding to the PKD1 gene, polycystin 1, is an integral membrane glycoprotein involved in cell-to-cell and/or cell-to-matrix interaction and functions as a mechanosensor. The protein corresponding to the PKD2 gene appears to function as a calcium ion channel, regulating calcium influx and/or release from intracellular stores. Polycystin-1 acts as the regulator of PKD2 channel activity by its co-localization on cilia of collecting tubular cells. Disruption of the polycystin pathway results in reduced cytoplasmic calcium, which in principal cells (p. 662) of the collecting duct causes an increase in cAMP via stimulation of calcium-inhibitable adenyl cyclase and inhibition of cAMP phosphodiesterases. Defective ciliary signalling results in disoriented division of the cells by upregulation of mammalian target of rapamune (mTOR) and its downstream cell cyclin kinases along the nephron, resulting in cyst formation.

In ADPKD, <1% of all nephrons acquire a second somatic mutation that in combination with a germline mutation results in cystogenesis. Progressive loss of renal function is usually attributed to mechanical compression, apoptosis of the healthy tissue and reactive fibrosis. Patients with ADPKD experience declining renal function at a variable rate which is due to discrepancy in the growth and size of the cysts; patients with rapid growth in cyst size as determined by MRI lose renal function more rapidly. Strategies to slow the growth rate of cysts have been very effective in preserving renal function in animal models. These therapies include the vasopressin V2 receptor inhibitor (vaptan, to reduce cAMP in the principal cells), rosvocitine (a cyclin-dependent kinase inhibitor) and antiproliferative therapy with sirolimus (mTOR inhibitor).

Clinical features

Clinical presentation may be at any age from the second decade. Presenting symptoms include:
- Acute loin pain and/or haematuria owing to haemorrhage into a cyst, cyst infection or urinary tract stone formation
- Loin or abdominal discomfort owing to the increasing size of the kidneys
- Subarachnoid haemorrhage associated with berry aneurysm rupture
- Complications of hypertension
- Complications of associated liver cysts
- Symptoms of anaemia associated with CKD.

Erythraemia is a rare complication and presentation of ADPKD.

The natural history of the disease is one of progressive CKD, sometimes punctuated by acute episodes of loin pain and haematuria, and commonly associated with the development of hypertension. The rate of progression to CKD (see above) is variable. The determinants of progression are both genetic and non-genetic. In the PKD2 form, renal cysts develop more slowly and ESKD occurs 10–15 years later than in the PKD1 form. Gender affects renal prognosis. Males with ADPKD reach ESKD 5–6 years earlier than females. There is a large variability in the age at end-stage renal failure within families, even between affected monozygotic twins.

Complications and associations

Pain

A minority of patients suffer chronic renal pain resistant to common analgesics, presumably owing to the pressure effect of large cysts. Surgical decompression of such cysts appears to be of benefit in about two-thirds of patients. Laparoscopic cyst decortication is a minimally invasive alternative technique.

Cyst infection

The response to standard antibacterial therapy is often poor owing to poor penetration of conventional antibiotics across the cyst wall. Lipophilic antibiotics active against Gram-negative bacteria, such as co-trimoxazole and fluoroquinolones, penetrate into the cysts better and their use has greatly improved the treatment of this complication.

Renal calculi

These are diagnosed in about 10–20% of patients with ADPKD. Frequently, they are composed of uric acid and, hence, radiolucent (see Fig. 12.39). Obstructing or painful stones are treated no differently than are stones in patients with normal urinary tracts. Percutaneous stone removal and extracorporeal lithotripsy is safe.

Hypertension

Hypertension is an early and very common feature of ADPKD. Elevation of blood pressure, still within the normal range, is detectable in young affected individuals and is associated with an increase in left ventricular mass. Left ventricular hypertrophy occurs to a greater degree for a given rise in blood pressure in ADPKD compared with other renal disorders and with essential hypertension. Intrarenal activation of the renin-angiotensin system is involved in pathogenesis, and ACE inhibitors are logical first-line agents in treatment. Early control of blood pressure is essential as cardiovascular complications are a major cause of death in ADPKD.

Progressive CKD

This is the most serious complication of ADPKD. At glomerular filtration rates below 50 mL/min, the rate of decline in GFR averages 5 mL/min each year, which is more rapid than in other primary renal disorders. The probability of being alive without requiring dialysis or transplantation by the age of 70 years is of the order of 30%. Survival rates on regular haemodialysis and after renal transplantation in ADPKD are better than those in patients with other primary renal diseases.

Hepatic cysts

Approximately 30% of patients have hepatic cysts and in a minority of the patients massive enlargement of the polycystic liver is seen. Pain, infection of cysts and, more rarely, compression of the bile duct, portal vein or hepatic venous outflow occur. Rarely, percutaneous drainage of painful cysts is performed.
cysts, laparoscopic fenestration or even partial hepatectomy is necessary. Infected cysts may require drainage.

**Intracranial aneurysm formation**

About 10% of ADPKD patients have an asymptomatic intracranial aneurysm (see p. 1105) and the prevalence is twice as high in the subgroup of patients with a family history of such aneurysms or of subarachnoid haemorrhage. Such haemorrhage is preceded in from 20% to 40% of cases by premonitory headaches from a few hours up to 2 weeks before the onset of subarachnoid bleeding. Headache of sudden onset or unusual character or severity in a patient with ADPKD should prompt investigation. Contrast-enhanced spiral CT or MR angiography are the best investigations. Screening for intracranial aneurysm in ADPKD is currently recommended for patients aged 18–40 years who have a positive family history.

**Mitr al valve prolapse**

This is found in 20% of individuals with ADPKD.

**Diagnosis**

Physical examination commonly reveals large, irregular kidneys and possibly hepatomegaly. Definitive diagnosis is established by ultrasound examination (Fig. 12.58). However, such renal imaging techniques may be equivocal, especially in subjects under the age of 15 years.

**Differential diagnosis**

A number of conditions can mimic clinical and radiological appearance of PKD (Box 12.7).

**Screening**

The children and siblings of patients with established ADPKD should, in general, be offered screening. Affected individuals should have regular blood pressure checks and should be offered genetic counselling. Screening by ultrasonography should not be carried out before the age of 15 years (Box 12.8), as excluding the condition may be difficult and hypertension is unusual before this age. Even at the age of 30 years, renal ultrasonography may give a false-negative result. Gene linkage analysis can be utilized in many families.

**Therapy**

No therapy is yet available but potential agents include vasopressin receptor antagonists, which have been studied in animal models of polycystic kidney disease, closely related to human ADPKD, where they have halted cyst progression or caused disease regression. ADPKD kidneys may be particularly vulnerable to adenyl cyclase agonists or cAMP phosphodiesterase inhibitors. Tolvaptan (which acts by inhibiting cAMP in principal cells) is already being used in clinical trials. However, in a small study, octreotide, a long-acting somatostatin analogue (which inhibits cAMP), was beneficial in halting the growth of both liver and renal cysts. Caffeine at clinically relevant concentrations has been found to enhance the effect of desmopressin to stimulate chloride secretion in cultured epithelial cells from ADPKD cysts. Two studies of mTOR inhibitor on PKD were essentially negative for primary end point of cyst growth and preservation of renal function.

**Medullary cystic disease (‘juvenile nephronophthisis’)**

Juvenile nephronophthisis that develops early in childhood is commonly inherited in an autosomal recessive manner. Mutations in the genes NPHS1–4 are present. The proteins mutated, nephrocystin and inversin, are co-localized in the cilia of the renal tubules. A similar condition developing later in childhood (medullary cystic disease) is inherited as an autosomal dominant trait, but sporadic cases occur in both conditions. Despite its name, the dominant histological finding is interstitial inflammation and tubular atrophy, with later development of medullary cysts. Progressive glomerular failure is a secondary consequence.

The dominant features are polyuria, polydipsia and growth retardation. Diagnosis is based on the family history and renal biopsy, the cysts rarely being visualized by imaging techniques.

---

**Box 12.7 Conditions that clinically and radiologically mimic polycystic kidney disease**

- **Tub erous sclerosis:** includes lymphangiomatosis and lymphangioleiomyomatosis and can be associated with the TSC2–PKD1 contiguous gene syndrome
- **von Hippel-Lindau syndrome**
- **Multicystic dysplastic kidney:** a non-heritable unilateral syndrome or a systemic syndrome (e.g. prune belly syndrome)
- **Juvenile nephronophthisis** and medullary cystic kidney disease: can be autosomal recessive (presenting in the 2nd decade of life) or autosomal dominant (presenting in the 3rd to 4th decades)
- **Glomerulocystic kidney disease:** involves the expansion of Bowman’s space and is autosomal dominant
- **Acquired cystic disease:** involves end-stage renal disease and hypokalemia
- **Renal-cell carcinoma** with cystic changes

---

**Box 12.8 Ultrasonographic diagnostic criteria for testing individuals at risk of ADPKD**

In at-risk individuals a diagnosis of ADPKD is established if patients meet the following criteria:

- 15–39 years: ≥3 cysts (unilateral or bilateral)
- 40–59 years: ≥2 cysts in each kidney
- ≥60 years: ≥4 cysts in each kidney
- ADPKD is excluded in patients meeting the following criteria:
  - ≥40 years: <2 cysts
  - 30–39 years: 0 cysts (this excludes ADPKD in 98% of cases).

At <30 years, a negative renal ultrasound scan does not exclude a diagnosis of ADPKD; other imaging techniques such as CT and MRI may be useful and molecular genetic testing might be needed.

---

**Further reading**

Medullary sponge kidney

Medullary sponge kidney is an uncommon but not rare condition that usually presents with renal colic or haematuria. Although it is most often sporadic, a few affected families have been reported. The condition is characterized by dilatation of the collecting ducts in the papillae, sometimes with cystic change. In severe cases the medullary area has a sponge-like appearance. The condition may affect one or both kidneys or only part of one kidney. Cyst formation is commonly associated with the development of small calculi within the cyst. In about 20% of patients there is associated hypercalciuria or renal tubular acidosis (see p. 664). Hemi-hypertrophy of the skeleton has been described in this condition.

The diagnosis is made by excretion urography, which shows small calculi in the papillary zones with an increase in radiodensity around these following injection of contrast medium as the dilated or cystic collecting ducts are filled with contrast (see Fig. 12.37).

The natural history is one of intermittent colic with passage of small stones or haematuria. Renal function is usually well maintained and CKD is unusual, except where obstructive nephropathy develops owing to the presence of stones in the pelvis or ureters.

**TUMOURS OF THE KIDNEY AND GENITOURINARY TRACT**

Malignant renal tumours

These comprise 1–2% of all malignant tumours, and the male to female ratio is 2:1.

Renal cell carcinoma

Renal cell carcinomas (RCC) arise from proximal tubular epithelium. They are the most common renal tumour in adults. They rarely present before the age of 40 years, the average age of presentation being 55 years.

In von Hippel–Lindau disease, an autosomal dominant disorder, bilateral renal cell carcinomas are common and haemangioblastomas, phaeochromocytomas and renal cysts are also found. Polymorphic probes from chromosome 3p, the region implicated in renal cell carcinoma, have demonstrated genetic linkage between this tumour and von Hippel–Lindau disease. It seems likely, therefore, that mutation of the same tumour suppressor gene is responsible for both renal cell carcinoma and von Hippel–Lindau disease. Deletion of the short arm of chromosome 3 is the most consistent cytogenetic finding in sporadic tumours.

Renal cell carcinomas are highly vascular tumours; microscopically most tumours are composed of large cells containing clear cytoplasm.

Clinical features

Patients are often asymptomatic but can present with haematuria, loin pain and a mass in the flank. Malaise, anorexia and weight loss (30%) occur, and 5% of patients have polycythaemia (see p. 404). Some 30% of patients have hypertension (due to secretion of renin by the tumour) and anaemia, due to depression of erythropoietin in approximately the same number. Pyrexia is present in about one-fifth of patients and approximately one-third present with metastases. Rarely, a left-sided varicocele may be associated with left-sided tumours that have invaded the renal vein and caused obstruction to drainage of the left testicular vein.

**Diagnosis**

Ultrasoundography is used to demonstrate the solid lesion and to examine the patency of the renal vein and inferior vena cava. CT scanning is used to identify the renal lesion and involvement of the renal vein or inferior vena cava. MRI is better than CT for tumour staging. Renal arteriography will reveal the tumour’s circulation but is now seldom employed. Urine cytology for malignant cells is of no value. The ESR is usually raised. Liver biochemistry may be abnormal, returning to normal after surgery.

**Treatment**

Medical management of renal cell carcinoma is discussed in Chapter 9. A nephrectomy is performed unless bilateral tumours are present or the contralateral kidney functions poorly, in which case conservative surgery such as partial nephrectomy may be indicated. If metastases are present, nephrectomy may still be warranted since regression of metastases has been reported after removal of the main tumour mass.

**Nephroblastoma (Wilms’ tumour)**

This tumour is seen mainly within the first 3 years of life and may be bilateral. It presents as an abdominal mass, rarely with haematuria. Diagnosis is established by ultrasound, CT and MRI. A combination of nephrectomy, radiotherapy and chemotherapy has much improved survival rates, even in children with metastatic disease. Overall, the 5-year survival rate is 90%.

Urothelial tumours

The calyces, renal pelvis, ureter, bladder and urethra are lined by transitional cell epithelium. Transitional cell tumours account for about 3% of deaths from all forms of malignancy. Such tumours are uncommon below the age of 40 years, and the male to female ratio is 4:1. Bladder tumours are about 50 times as common as those of the ureter or renal pelvis. Pre-disposing factors include:

- Cigarette smoking
- Exposure to industrial carcinogens such as β-naphthylamine and benzidine (workers in the chemical, cable and rubber industries are at particular risk) or ingestion of aristolochic acid found in some herbal weight-loss preparations
- Exposure to drugs (e.g. phenacetin, cyclophosphamide)
- Chronic inflammation (e.g. schistosomiasis, usually associated with squamous carcinoma).

**Presentation**

Painless haematuria is the most common presenting symptom of bladder malignancy, although pain may occur owing to clot retention. Symptoms suggestive of UTI develop in the absence of significant bacteriuria. In patients with bladder cancer, pain also results from local nerve involvement. Presenting symptoms may result from local metastases.

Transitional cell carcinomas in the kidney and ureter also present with haematuria. They may also give rise to flank pain, particularly if urinary tract obstruction is present.

**Investigations**

Cytological examination of urine for malignant cells and renal imaging (ultrasonography, CT and MRI) should be performed in all patients. Cystoscopy is necessary unless pathology is
found in the upper urinary tract. It may be omitted in men under 20 and women under 30 years if significant bacteriuria accompanies the haematuria and ceases following control of the infection, provided urine cytology and renal imaging are normal. With these exceptions, haematuria should always be investigated. In cases where the tumour is not clearly outlined on ultrasonography or CT, retrograde ureterography may be helpful.

**Tumours of the kidney and genitourinary tract**

**Diseases of the prostate gland**

**Urinary problems in the elderly**

**Prostatic carcinoma**

Prostatic carcinoma accounts for 7% of all cancers in men and is the sixth most common cancer in the world. Malignant change within the prostate becomes increasingly common with advancing age. By the age of 80 years, 80% of men have malignant foci within the gland, but most of these appear to lie dormant. Histologically, the tumour is an adenocarcinoma. Hormonal factors are thought to play a role in the aetiology.

**Clinical features**

Presentation is usually with symptoms of lower urinary tract obstruction; less common are symptoms of metastatic spread, e.g. back pain, weight loss or anaemia. The diagnosis is also made by the incidental finding of a hard irregular gland on rectal examination, or as an unexpected histological result after prostatectomy for what was believed to be benign prostatic hypertrophy.

In developed countries, patients now present as a result of screening for prostate cancer by measurement of prostate-specific antigen (PSA). However, on the evidence available, national programmes of screening are not justified. Treatment of well people carries a high morbidity of urinary incontinence and sexual dysfunction with no evidence as yet of increased overall survival. In future, screening of ‘at-risk’ groups may be useful. PSA >4 ng/mL is abnormal but between 4 and 10 ng/mL this can be due to benign hypotrophy and cancer. If PSA is over 10 ng/mL, a prostatic biopsy will show cancer in over 50% of cases.

**Investigations**

These include transrectal ultrasound of the prostate and prostatic biopsy. A histological diagnosis is essential before treatment. The Gleason scoring system is based on the histological appearances. If metastases are present, serum prostate-specific antigen levels are usually markedly elevated (>16 ng/mL) but can be normal; it is a myth that elevated levels occur as a result of rectal examination.

Ultrasonography and transrectal ultrasonography are also of value in defining the size of the gland and staging any tumour present. Endorectal coil MRI helps to detect extraprostatic extension. The upper renal tracts can be examined by ultrasonography for evidence of dilatation. Bone metastases appear as osteosclerotic lesions on X-ray and are also detected by isotopic bone scans.

**Treatment**

Non-surgical treatment of prostatic carcinoma is discussed in Chapter 9, page 481. Microscopic, impalpable tumours can sometimes be managed expectantly. Treatment for disease confined to the gland is radical prostatectomy (provided the patient is fit for the procedure) or radiotherapy. Metastatic disease can be treated with orchidectomy, but many men refuse.
Kidney and urinary tract disease

reduction in muscle mass often seen with ageing may mask this deterioration in renal function in that the serum creatinine concentration may be less than 120 μmol/L in an elderly patient whose eGFR is 50 mL/min or lower. The use of serum creatinine as a measure of renal function in the elderly must take this into account. This is especially so in the elderly when prescribing drugs whose excretion is in whole or in part by the kidney.

Urinary tract infections
UTIs are common in the elderly, in whom impaired bladder emptying due to prostatic disease in males and neuropathic bladder – especially common in females – is frequently found. Symptoms may be atypical, the major complaints being incontinence, nocturia, smelly urine or vague change in well-being with little in the way of dysuria. Demonstration of significant bacteriuria in the presence of such symptoms requires treatment.

Urinary incontinence
This is defined as involuntary passage of urine sufficient to be a health or social problem. It is common in the elderly with 25% of women and 15% of men over 65 having a problem.

- **Urge incontinence** is usually due to detrusor overactivity with leakage of urine because the bladder is perceived to be full. This is common in the elderly; it occurs as an isolated event or secondary to local factors, e.g. bladder infection or stones, or to central factors, e.g. stroke, dementia or Parkinson’s disease.

- **Stress incontinence** occurs when the intra-abdominal pressure is increased, e.g. after a cough or sneeze and there is a weak pelvic floor or urethral sphincter. It is common in women after childbirth.

- **Overflow incontinence** occurs with leakage of urine from a full distended bladder. It occurs commonly in men with prostatic obstruction, following spinal cord injury or in women with cystoceles or after gynaecological surgery.

- **Functional incontinence**. Passage of urine occurs owing to inability to get to a toilet because of disability, e.g. stroke, trauma, the unavailability of toilet facilities or dementia.

Management
- Physical examination for local problems, e.g. prostatic enlargement in men, gynaecological disorders in women, and for central problems, e.g. neurological disorders or dementia.
- Urine analysis, e.g. glycosuria and culture for UTI.
- Treatment of contributing causes, e.g. constipation, drug therapy, other co-existing disease.
- Urge incontinence – bladder training, antimuscarinics, e.g. oxybutynin, tolterodine, solifenacin and darifenacin.
- Stress incontinence – pelvic floor exercises.
- Transurethral injections of autologous myoblasts can aid in regeneration of the rhabdosphincter, and fibroblasts in reconstruction of the urethral submucosa.
- Effectiveness and tolerability of ultrasonography-guided injections of autologous cells is greatly superior compared with those of endoscopic injections of collagen for stress incontinence. Mid-urethral slings are increasingly used for the treatment of stress incontinence either by retropubic and transobturator approach with comparable efficiency.

Overflow – removal of obstruction
- Functional – improve facilities, regular urine voiding, absorbent padding.

Further evaluation with urodynamics is necessary in patients who do not respond and have a potentially curable problem. An expert and committed incontinence advisory and treatment service combining nursing and medical skills is invaluable for elderly patients with this distressing problem. Home visits to ensure the availability of commodes and toileting are essential. For established incontinence, catheterization may be necessary but should be avoided if at all possible. Incontinence and its treatment are matters of major importance and are by no means confined solely to the elderly.

**BIBLIOGRAPHY**
Current Opinion in Nephrology and Hypertension
A monthly journal with review articles, each issue devoted to one or two topics.
Journal of the American Society of Nephrology
The highest impact journal in nephrology with bimonthly self-assessment programme (SAP) supplements.
Kidney International
The major journal associated with the International Society of Nephrology – monthly with original and review articles.
Nephrology, Dialysis, Transplantation
The major European journal devoted to the subject, with review articles, editorial comments and original papers.

In normal, healthy people, the total body water constitutes 50–60% of lean body weight in men and 45–50% in women. In a healthy 70 kg male, total body water is approximately 42 L. This is contained in three major compartments:

- Intracellular fluid (28 L, about 35% of lean body weight)
- Extracellular — the interstitial fluid that bathes the cells (9.4 L, about 12%)
- Plasma (also extracellular) (4.6 L, about 4–5%)

In addition, small amounts of water are contained in bone, dense connective tissue, and epithelial secretions, such as the digestive secretions and cerebrospinal fluid.

The intracellular and interstitial fluids are separated by the cell membrane; the interstitial fluid and plasma are separated by the capillary wall. In the absence of solute, water molecules move randomly and in equal numbers in either direction across a semi-permeable membrane. However, if solutes are added to one side of the membrane, the intermolecular cohesive forces reduce the activity of the water molecules. As a result, water tends to stay in the solute-containing compartment because there is less free diffusion across the membrane. This ability to hold water in the compartment can be measured as the osmotic pressure.

Osmotic pressure

Osmotic pressure is the primary determinant of the distribution of water among the three major compartments. The concentrations of the major solutes in the compartments differ, each having one solute that is primarily limited to that compartment and therefore determines its osmotic pressure:

- The intracellular fluid contains mainly potassium (K⁺) (most of the cell Mg²⁺ is bound and osmotically inactive)
- In the extracellular compartment, Na⁺ salts predominate in the interstitial fluid, and proteins in the plasma.

Regulation of the plasma volume is somewhat more complicated because of the tendency of the plasma proteins to hold water in the vascular space by an oncotic effect which is, in part, counterbalanced by the hydrostatic pressure in the capillaries that is generated by cardiac contraction. The composition of intracellular and extracellular fluids is shown in Table 13.1.

A characteristic of an osmotically active solute is that it cannot freely leave its compartment. The capillary wall, for example, is relatively impermeable to plasma proteins, and the cell membrane is ‘impermeable’ to Na⁺ and K⁺ because the Na⁺/K⁺-ATPase pump largely restricts Na⁺ to the extracellular fluid and K⁺ to the intracellular fluid. By contrast, Na⁺ freely crosses the capillary wall and achieves similar concentrations in the interstitium and plasma; as a result, it does not contribute to fluid distribution between these compartments. Similarly, urea crosses both the capillary wall and the cell membrane and is osmotically inactive. Thus, the retention of urea in renal failure does not alter the distribution of the total body water.

A conclusion from these observations is that body Na⁺ stores are the primary determinant of the extracellular fluid volume. Thus, the extracellular volume — and therefore tissue perfusion — are maintained by appropriate alterations in Na⁺ excretion. For example, if Na⁺ intake is increased, the extra Na⁺ will initially be added to the extracellular fluid. The associated increase in extracellular osmolality will cause water to move out of the cells, leading to extracellular volume expansion. Balance is restored by excretion of the excess Na⁺ in the urine.

Distribution of different types of replacement fluids

Figure 13.2 shows the relative effects on the compartments of the addition of identical volumes of water, saline and colloid solutions. Thus, 1 L of water given intravenously as 5% glucose is distributed equally into all compartments, whereas the same amount of 0.9% saline remains in the extracellular compartment. The latter is thus the correct treatment for extracellular water depletion — sodium keeping the water in this compartment. The addition of 1 L of colloid with its high oncotic pressure stays in the vascular compartment and is a treatment for hypovolaemia.
Water, electrolytes and acid–base balance

Figure 13.1 Distribution of water between the vascular and extravascular (interstitial) spaces. This is determined by the equilibrium between hydrostatic pressure, which tends to force fluid out of the capillaries, and oncotic pressure, which acts to retain fluid within the vessel. The net flow of fluid outwards is balanced by ‘suction’ of fluid into the lymphatics, which returns it to the bloodstream. Similar principles govern the volume of the peritoneal and pleural spaces.

Figure 13.2 Relative effects of the addition of 1 L of: (a) water, (b) saline 0.9% and (c) a colloid solution.

When the EABV is expanded, the urinary Na⁺ excretion is increased and can exceed 100 mmol/L. By contrast, the urine can be rendered virtually free of Na⁺ in the presence of EABV depletion and normal renal function.

These changes in Na⁺ excretion can result from alterations both in the filtered load, determined primarily by the glomerular filtration rate (GFR), and in tubular reabsorption, which is affected by multiple factors. In general, it is changes in tubular reabsorption that constitute the main adaptive response to fluctuations in the effective circulating volume. How this occurs can be appreciated from Table 13.2 and Figure 13.4 and Figure 12.2 (see p. 563), which depicts the sites and determinants of segmental Na⁺ reabsorption.

Although the loop of Henle and distal tubules make a major overall contribution to net Na⁺ handling, transport in these segments primarily varies with the amount of Na⁺ delivered; that is, reabsorption is flow-dependent. In comparison, the neurohumoral regulation of Na⁺ reabsorption according to body needs occurs primarily in the proximal tubules and collecting ducts.

Neurohumoral regulation of extracellular volume

This is mediated by volume receptors that sense changes in the EABV rather than alterations in the sodium concentration. These receptors are distributed in both the renal and cardiovascular tissues.

Regulation of extracellular volume (Fig. 13.3)

The extracellular volume is determined by the sodium concentration. The regulation of extracellular volume is dependent upon a tight control of sodium balance, which is exerted by normal kidneys. Renal Na⁺ excretion varies directly with the effective circulating volume. In a 70 kg man:

- Plasma fluid constitutes one-third of extracellular volume (4.6 L), and of this,
- 85% (3.9 L) lies in the venous side and only 15% (0.7 L) resides in the arterial circulation.

The unifying hypothesis of extracellular volume regulation in health and disease proposed by Schrier states that the fullness of the arterial vascular compartment – or the so-called effective arterial blood volume (EABV) – is the primary determinant of renal sodium and water excretion. Thus effective arterial blood volume constitutes effective circulatory volume for the purposes of body fluid homeostasis.

The fullness of the arterial compartment depends upon a normal ratio between cardiac output and peripheral arterial resistance. Thus, diminished EABV is initiated by a fall in cardiac output or a fall in peripheral arterial resistance (an increase in the holding capacity of the arterial vascular tree).

Intrarenal receptors. Receptors in the walls of the afferent glomerular arterioles respond, via the

Juxtaglomerular apparatus, to changes in renal perfusion, and control the activity of the renin-angiotensin-aldosterone system (see p. 1006). In addition, sodium concentration in the distal tubule and sympathetic nerve activity alter renin release from the juxtaglomerular cells. Prostaglandins I₂ and E₂ are also generated within the kidney in response to angiotensin II, acting to maintain glomerular filtration rate and sodium and water excretion, modulating the sodium-retaining effect of this hormone.

Extrarenal receptors. These are located in the vascular tree in the left atrium and major thoracic veins, and in the carotid sinus body and aortic arch. These volume receptors respond to a slight reduction in effective...
circulating volume and result in increased sympathetic nerve activity and a rise in catecholamines. In addition, volume receptors in the cardiac atria control the release of a powerful natriuretic hormone – atrial natriuretic peptide (ANP) – from granules located in the atrial walls (see p. 943).

High-pressure arterial receptors (carotid, aortic arch, juxtaglomerular apparatus) predominate over low-pressure volume receptors in volume control in mammals. The low-pressure volume receptors are distributed in thoracic tissues (cardiac atria, right ventricle, thoracic veins, pulmonary vessels) and their role in the volume regulatory system is marginal.

Aldosterone and possibly ANP are responsible for day-to-day variations in Na⁺ excretion, by their respective ability to augment and diminish Na⁺ reabsorption in the collecting ducts.

A salt load, for example, leads to an increase in the effective circulatory and extracellular volume, raising both renal perfusion pressure, and atrial and arterial filling pressure. The increase in the renal perfusion pressure reduces the secretion of renin, and subsequently that of angiotensin II and aldosterone (see Fig. 12.5), whereas the rise in atrial and arterial filling pressure increases the release of ANP. These factors combine to reduce Na⁺ reabsorption in the collecting duct, thereby promoting excretion of excess Na⁺.

By contrast, in patients on a low Na⁺ intake or in those who become volume-depleted as a result of vomiting and diarrhoea, the ensuing decrease in effective volume enhances the activity of the renin-angiotensin-aldosterone system and reduces the secretion of ANP. The net effect is enhanced Na⁺ reabsorption in the collecting ducts, leading to a fall in Na⁺ excretion. This increases the extracellular volume towards normal.

With more marked hypovolaemia, a decrease in GFR leads to an increase in proximal and thin ascending limb GFR, which contributes to Na⁺ reabsorption which results in Na⁺ retention. This is brought about by enhanced sympathetic activity acting directly on the kidneys and indirectly by stimulating the secretion of renin/angiotensin II (see Fig. 13.3b) and non-osmotic release of an ATPase which contributes to Na⁺ retention. This is brought about by enhanced sympathetic activity acting directly on the kidneys and indirectly by stimulating the secretion of renin/angiotensin II (see Fig. 13.3b) and non-osmotic release of antidiuretic hormone (ADH), also called vasopressin. The pressure natriuresis phenomenon may be the final defence against changes in the effective circulating volume. Marked persistent hypovolaemia leads to systemic hypotension and increased salt and water absorption in the proximal tubules and ascending limb of Henle. This process is partly mediated by changes in renal interstitial hydrostatic pressure and local prostaglandin and nitric oxide production.

**Volume regulation in oedematous conditions**

Sodium and water are retained despite increased extracellular volume in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia. Here, the principal mediator of salt and water retention is the concept of arterial underfilling due either to reduced cardiac output or diminished peripheral arterial resistance. Arterial underfilling in these settings leads to reduction of pressure or stretch (i.e. ‘unloading’ of arterial volume receptors), which results in activation of the sympathetic nervous system, activation of the renin-angiotensin-aldosterone system and non-osmotic release of ADH. These neurohumoral mediators promote salt and water retention in the face of increased extracellular volume. The common nature of the degree of arterial fullness and neurohumoral pathway in the regulation of extracellular volume in health and disease states forms the basis of Schrier’s unifying hypothesis of volume homeostasis (Fig. 13.3a).

**Mechanism of impaired escape from actions of aldosterone and resistance to ANP**

Not only is the activity of the renin-angiotensin-aldosterone system increased in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia, but also the action of aldosterone is more persistent than in normal subjects and patients with Conn’s syndrome, who have increased aldosterone secretion (see p. 989).

In normal subjects, high doses of mineralocorticoids initially increase renal sodium retention so that the extracellular volume is increased by 1.5–2 L. However, renal sodium retention then ceases, sodium balance is re-established, and there is no detectable oedema. This escape from mineralocorticoid-mediated sodium retention explains why oedema is not a characteristic feature of primary hyperaldosteronism (Conn’s syndrome). The escape is dependent on an increase in delivery of sodium to the site of action of aldosterone in the collecting ducts. The increased distal sodium delivery is achieved by high extracellular volume-mediated arterial overfilling. This suppresses sympathetic activity and angiotensin II generation, and increases cardiac release of ANP with resultant increase in renal perfusion pressure and GFR. The net result of these events is reduced sodium absorption in the proximal tubules and increased distal sodium delivery which overwhelms the sodium-retaining actions of aldosterone.

In patients with the above oedematous conditions, e.g. heart failure, escape from the sodium-retaining actions of aldosterone does not occur and therefore they continue to retain sodium in response to aldosterone. Accordingly they have substantial natriuresis when given spironolactone,
which blocks mineralocorticoid receptors. Alpha-adrenergic
stimulation and elevated angiotensin II increase sodium
transport in the proximal tubule, and reduced renal perfusion
and GFR further increases sodium absorption from the proxim-
al tubules by presenting less sodium and water in the
tubular fluid. Sodium delivery to the distal portion of the
nephron, and thus the collecting duct, is reduced. Similarly,
increased cardiac ANP release in these conditions requires
optimum sodium concentration at the site of its action in the
collecting duct for its desired natriuretic effects. Decreased
sodium delivery to the collecting duct is therefore the most
likely explanation for the persistent aldosterone-mediated
sodium retention, absence of escape phenomenon and
resistance to natriuretic peptides in these patients (Fig.
13.3b).

Regulation of water excretion
Body water homeostasis is affected by thirst and the urine
concentrating and diluting functions of the kidney. These in
turn are controlled by intracerebral osmoreceptors, principi-
ally in the hypothalamus, to some extent by volume receptors
in capacitance vessels close to the heart, and via the
renin-angiotensin system. Of these, the major and best-
understood control is via osmoreceptors. Changes in the
plasma Na\(^+\) concentration and osmolality are sensed by
osmoreceptors that influence both thirst and the release of
ADH (vasopressin) from the supraoptic and paraventricular
nuclei of the anterior hypothalamus.

ADH plays a central role in urinary concentration by
increasing the water permeability of the normally imperme-
able cortical and medullary collecting ducts. There are three
major G-protein coupled receptors for vasopressin (ADH):
- \(V_1A\) found in vascular smooth muscle cells
- \(V_{1b}\) in anterior pituitary and throughout the brain
- \(V_2\) receptors in the principal cells of the kidney distal
convoluting tubule and collecting ducts (see below).

Activation of the \(V_{1a}\) receptors induces vasoconstriction
while \(V_{1b}\) receptors appear to mediate the effect of ADH on
the pituitary, facilitating the release of ACTH. The \(V_2\) recep-
tors mediate the antidiuretic response as well as other
functions.

The ability of ADH to increase the urine osmolality is
related indirectly to transport in the ascending limb of the
loop of Henle, which reabsorbs NaCl without water. This
process, which is the primary step in the countercurrent
mechanism, has two effects: it makes the tubular fluid dilute
and the medullary interstitium concentrated. In the absence
of ADH, little water is reabsorbed in the collecting ducts,
and a dilute urine is excreted. By contrast, the presence of
ADH promotes water reabsorption in the collecting ducts
down the favourable osmotic gradient between the tubular
fluid and the more concentrated interstitium. As a result,
there is an increase in urine osmolality and a decrease in
urine volume.

The cortical collecting duct has two cell types (see also
p. 597) with very different functions:
- **Principal cells** (about 65%) have sodium and potassium
  channels in the apical membrane and, as in all sodium-
  reabsorbing cells, Na\(^+/K^-\)\text{-ATPase} pumps in the
  basolateral membrane.
- **Intercalated cells**, in comparison, do not transport NaCl
  (since they have a lower level of Na\(^+/K^-\)\text{-ATPase} activity)
  but play a role in hydrogen and bicarbonate handling
  and in potassium reabsorption in states of potassium
depletion.

The ADH-induced increase in collecting duct water perme-
ability occurs primarily in the principal cells. ADH acts on \(V_2\)
(vasopressin) receptors located on the basolateral surface of
principal cells, resulting in the activation of adenyly cyclase.
This leads to protein kinase activation and to preformed
cytoplasmic vesicles that contain unique water channels
(called aquaporins) moving to and then being inserted into
the luminal membrane. Four renal aquaporins have been well
characterized and are localized in different areas of the cells
of the collecting duct. The water channels span the luminal
membrane and permit water movement into the cells down a
favourable osmotic gradient (Fig. 13.5). This water is then
rapidly returned to the systemic circulation across the baso-
lateral membrane. When the ADH effect has worn off, the
water channels aggregate within clathrin-coated pits, from
which they are removed from the luminal membrane by
endocytosis and returned to the cytoplasm. A defect in
any step in this pathway, such as in attachment of ADH to
its receptor or the function of the water channel, can
cause resistance to the action of ADH and an increase in
urine output. This disorder is called nephrogenic diabetes
insipidus.

Plasma osmolality
In addition to influencing the rate of water excretion, ADH
plays a central role in osmoregulation because its release
is directly affected by the plasma osmolality. At a plasma
osmolality of <275 mosmol/kg, which usually represents a
plasma Na\(^+\) concentration of <135–137 mmol/L, there is
essentially no circulating ADH. As the plasma osmolality rises
above this threshold, however, the secretion of ADH increases
progressively.

Two simple examples will illustrate the basic mechanisms
of osmoregulation, which is so efficient that the plasma Na\(^+\)
concentration is normally maintained within 1–2% of its
baseline value.

1. **Ingestion of a water load** leads to an initial reduction in
the plasma osmolality, thereby diminishing the release of
ADH. The ensuing reduction in water reabsorption in the
collecting ducts allows the excess water to be excreted
in a dilute urine.

![Figure 13.5 Aquaporin-mediated water transport in the
renal collecting duct. Stimulation of the vasopressin 2
receptor causes cAMP-mediated insertion of the aquaporin
into the apical membrane, allowing water transport down
the osmotic gradient. (Adapted from Connolly DL, Shanahan
CM, Weissberg PL. Water channels in health and disease. Lancet
1996; 347:211, with permission from Elsevier.)](image-url)
2. **Water loss** resulting from sweating is followed by, in sequence, a rise in both plasma osmolality and ADH secretion, enhanced water reabsorption, and the appropriate excretion of a small volume of concentrated urine. This renal effect of ADH minimizes further water loss but does not replace the existing water deficit. Thus, optimal osmoregulation requires an increase in water intake, which is mediated by a concurrent stimulation of thirst. The importance of thirst can also be illustrated by studies in patients with central diabetes insipidus, who are deficient in ADH. These patients often complain of marked polyuria, which is caused by the decline in water reabsorption in the collecting ducts. However, they do not typically become hyponatraemic, because urinary water loss is offset by the thirst mechanism.

**Osmoregulation versus volume regulation**

A common misconception is that regulation of the plasma Na⁺ concentration is closely correlated with the regulation of Na⁺ excretion. However, it is related to volume regulation, which has different sensors and effectors (volume receptors) from those involved in water balance and osmoregulation (osmoreceptors).

The roles of these two pathways should be considered separately when evaluating patients.

- A **water load** is rapidly excreted (in 4–6 h) by inhibition of ADH release so that there is little or no water reabsorption in the collecting ducts. This process is normally so efficient that volume regulation is not affected and there is no change in ANP release or in the activity of the renin-angiotensin-aldosterone system. Thus, a dilute urine is excreted, and there is little alteration in the excretion of Na⁺.

- **0.9% saline** administration, by contrast, causes an increase in volume but no change in plasma osmolality. In this setting, ANP secretion is increased, aldosterone secretion is reduced and ADH secretion does not change. The net effect is the appropriate excretion of the excess Na⁺ in a relatively iso-osmotic urine.

In some cases, both volume and osmolality are altered and both pathways are activated. For example, if a person with normal renal function eats salted potato chips and peanuts without drinking any water, the excess Na⁺ will increase the plasma osmolality, leading to osmotic water movement out of the cells and increased extracellular volume. The rise in osmolality will stimulate both ADH release and thirst (the main reason why many restaurants and bars supply free salted foods), whereas the hypervolaemia will enhance the secretion of ANP and suppress that of aldosterone. The net effect is increased excretion of Na⁺ without water.

This principle of separate volume and osmoregulatory pathways is also evident in the **syndrome of inappropriate ADH secretion (SIADH)**. Patients with SIADH (see p. 993) have impaired water excretion and hyponaemia (dilutional) caused by the persistent presence of ADH. However, the release of ANP and aldosterone is not impaired and, thus, Na⁺ handling remains intact. These findings have implications for the correction of the hyponaemia in this setting which initially requires restriction of water intake.

ADH is also secreted by non-osmotic stimuli such as stress (e.g. surgery, trauma), markedly reduced effective circulatory volume (e.g. cardiac failure, hepatic cirrhosis), psychiatric disturbance and nausea, irrespective of plasma osmolality. This is mediated by the effects of sympathetic overactivity on supraoptic and paraventricular nuclei. In addition to water retention, ADH release in these conditions promotes vasoconstriction owing to the activation of V₁ₐ (vasopressin) receptors distributed in the vascular smooth muscle cells.

**Regulation of cell volume**

Most cells respond to swelling or shrinkage by activating specific metabolic or membrane-transport processes that return cell volume to its normal resting state. Within minutes after exposure to hypotonic solutions and resulting cell swelling, a common feature of many cells is the increase in plasma membrane potassium and chloride conductance. Although extrusion of intracellular potassium certainly contributes to a regulatory volume decrease, the role of chloride efflux itself is modest, given the relatively low intracellular chloride concentration. Other intracellular osmolytes, such as taurine and other amino acids, are transported out of the cell to achieve a regulatory volume decrease. By contrast, these regulatory mechanisms are operative in reverse to protect cell volume under hypertonic conditions, as is the case in the renal medulla. The tubular cells at the tip of renal papillae, which are constantly exposed to a hypertonic extracellular milieu, maintain their cell volume on a long-term basis by actively taking up smaller molecules, such as betaine, taurine and myoinositol, and by synthesizing more sorbitol and glycerophosphocholine.

**Increased extracellular volume**

Increased extracellular volume occurs in numerous disease states. The physical signs depend on the distribution of excess volume and on whether the increase is local or systemic. According to Starling principles, distribution depends on:

- Venous tone, which determines the capacitance of the blood compartment and thus hydrostatic pressure
- Capillary permeability
- Oncotic pressure – mainly dependent on serum albumin
- Lymphatic drainage.

Depending on these factors, fluid accumulation may result in expansion of interstitial volume, blood volume or both.

**Clinical features**

Peripheral oedema is caused by expansion of the extracellular volume by at least 2 L (15%). The ankles are normally the first part of the body to be affected, although they may be spared in patients with lipodermatosclerosis (where the skin is tethered and cannot expand to accommodate the oedema). Oedema may be noted in the face, particularly in the morning. In a patient in bed, oedema may accumulate in the sacral area. Expansion of the interstitial volume also causes pulmonary oedema, pleural effusion, pericardial effusion and ascites. Expansion of the blood volume (overload) causes a raised jugular venous pressure, cardiomegaly, added heart sounds, basal crackles as well as a raised arterial blood pressure in certain circumstances.

**Causes**

Extracellular volume expansion is due to sodium chloride retention. Increased oral salt intake does not normally cause volume expansion because of rapid homeostatic mechanisms which increase salt excretion. However, a rapid intravenous infusion of a large volume of saline will cause volume
expansion. Most causes of extracellular volume expansion are associated with renal sodium chloride retention.

**Heart failure**
Reduction in cardiac output and the consequent fall in effective circulatory volume and arterial filling lead to activation of the renin-angiotensin-aldosterone system, non-osmotic release of ADH, and increased activity of the renal sympathetic nerves via volume receptors and baroreceptors (Fig. 13.3a). Sympathetic overdrive also indirectly augments ADH and renin-angiotensin-aldosterone response in these conditions. The cumulative effect of these mediators results in increased peripheral and renal arteriolar resistance and water and sodium retention. These factors result in extracellular volume expansion and increased venous pressure, causing oedema formation.

**Hepatic cirrhosis**
The mechanism is complex, but involves peripheral vasoconstriction (possibly owing to increased nitric oxide generation) resulting in reduced effective arterial blood volume (EABV) and arterial filling. This leads to an activation of a chain of events common to cardiac failure and other conditions with marked peripheral vasodilatation (Fig. 13.3). The cumulative effect results in increased peripheral and renal resistance, water and sodium retention, and oedema formation.

**Nephrotic syndrome**
Interstitial oedema is a common clinical finding with hypoalbuminaemia, particularly in the nephrotic syndrome. Expansion of the interstitial compartment is secondary to the accumulation of sodium in the extracellular compartment. This is due to an imbalance between oral (or parenteral) sodium intake and urinary sodium output, as well as alterations of fluid transfer across capillary walls. The intrarenal site of sodium retention is the cortical collecting duct (CCD) where Na+/K+-ATPase expression and activity are increased threefold along the basolateral surface (Fig. 13.4). In addition, amiloride-sensitive epithelial sodium channel activity is also increased in the CCD. The renal sodium retention should normally be counterbalanced by increased secretion of sodium in the inner medullary collecting duct, brought about by the release of ANP. This regulatory pathway is altered in patients with nephrotic syndrome by enhanced kidney specific catabolism of cyclic GMP (the second messenger for ANP) following phosphodiesterase activation.

Oedema generation was classically attributed to the decrease in the plasma oncotic pressure and the subsequent increase in the transcapillary oncotic gradient. However, the oncotic pressure and transcapillary oncotic gradient remain unchanged and the transcapillary hydrostatic pressure gradient is not altered. Conversely, capillary hydraulic conductivity (a measure of permeability) is increased. This is determined by intercellular macromolecular complexes between the endothelial cells consisting of tight junctions (made of occludins, claudins and ZO proteins) and adherens junctions (made of cadherin, catenins and actin cytoskeleton). Elevated TNF-α levels in nephrotic syndrome activate protein kinase C, which changes phosphorylation of occludin and capillary permeability. In addition, increased circulating ANP can increase capillary hydraulic conductivity by altering the permeability of intercellular junctional complexes. Furthermore, reduction in effective circulatory volume and the consequent fall in cardiac output and arterial filling can lead to a chain of events as in cardiac failure and cirrhosis (see above and Fig. 13.3). These factors result in extracellular volume expansion and oedema formation.

**Sodium retention**
A decreased GFR decreases the renal capacity to excrete sodium. This may be acute, as in the acute nephritic syndrome (see p. 582), or may occur as part of the presentation of chronic kidney disease. In end-stage renal failure, extracellular volume is controlled by the balance between salt intake and its removal by dialysis.

Numerous drugs cause renal sodium retention, particularly in patients whose renal function is already impaired:
- Oestrogens cause mild sodium retention, due to a weak aldosterone-like effect. This is the cause of weight gain in the premenstrual phase.
- Mineralocorticoids and liquorice (the latter potentiates the sodium-retaining action of cortisol) have aldosterone-like actions.
- NSAIDs cause sodium retention in the presence of activation of the renin-angiotensin-aldosterone system by heart failure, cirrhosis and in renal artery stenosis.
- Thiazolidinediones (TZD) (see p. 1011) are widely used to treat type 2 diabetes. Their mechanism of action is attributed to binding and activation of the PPAR-γ system. PPARs are nuclear transcription factors essential to the control of energy metabolism that are modulated via binding with tissue-specific fatty acid metabolites. Of the three PPAR isoforms, γ has been extensively studied and is expressed at high levels in adipose and liver tissues, macrophages, pancreatic-β cells and principal cells of the collecting duct. These drugs have been associated with salt and water retention and are contraindicated in patients with heart failure. Recent evidence suggests that TZD-induced oedema (like insulin) is also due to upregulation of epithelial Na transporter channel (ENaC) but by different pathways. Diuretics of choice for TZD-induced oedema are amiloride and triamterene.

Substantial amounts of sodium and water may accumulate in the body without clinically obvious oedema or evidence of raised venous pressure. In particular, several litres may accumulate in the pleural space or as ascites; these spaces are then referred to as ‘third spaces’. Bone may also act as a ‘sink’ for sodium and water.

**Other causes of oedema**
- Initiation of insulin treatment for type 1 diabetes and refeeding after malnutrition are both associated with the development of transient oedema. The mechanism is complex but involves upregulation of ENaC in the principal cell of the collecting duct. This transporter is amiloride sensitive which makes amiloride or triamterene the diuretic of choice in insulin-induced oedema.
- Oedema may result from increased capillary pressure owing to relaxation of precapillary arterioles. The best example is the peripheral oedema caused by dihydropyridine calcium-channel blockers such as nifedipine which affects up to 10% of the patients. Oedema is usually resolved by stopping the offending drug.
- Oedema is also caused by increased interstitial oncotic pressure as a result of increased capillary permeability to proteins. This can occur as part of a rare complement-deficiency syndrome; with therapeutic use of interleukin 2 in cancer chemotherapy; or in ovarian hyperstimulation syndrome (see p. 981).
**Local increase in oedema**
This does not reflect disturbances of extracellular volume control per se, but can cause clinical confusion. Examples are ankle oedema due to venous damage following thrombosis or surgery, ankle or leg oedema due to immobility, oedema of the arm due to subclavian thrombosis, and facial oedema due to superior vena caval obstruction.

### Treatment
The underlying cause should be treated where possible. Heart failure, for example, should be treated, and offending drugs such as NSAIDs withdrawn.

Sodium restriction has only a limited role, but is useful in patients who are resistant to diuretics. Sodium intake can easily be reduced to approximately 100 mmol (2 g) daily; reductions below this are often difficult to achieve without affecting the palatability of food.

Manoeuvres that increase venous return (e.g. strict bed rest or water immersion) stimulate salt and water excretion by effects on cardiac output and ANP release, but they are seldom of practical value.

The mainstay of treatment is the use of diuretic agents, which increase sodium, chloride and water excretion in the kidney (Table 13.3). These agents act by interfering with membrane ion pumps which are present on numerous cell types; they mostly achieve specificity for the kidney by being secreted into the proximal tubule, resulting in much higher concentrations in the tubular fluid than in other parts of the body.

### Clinical use of diuretics
**Loop diuretics**
These potent diuretics are useful in the treatment of any cause of systemic extracellular volume overload. They stimulate excretion of both sodium chloride and water by blocking the sodium-potassium-2-chloride (NKCC2) channel in the thick ascending limb of Henle (Fig. 13.6) and are useful in stimulating water excretion in states of relative water overload. They also act by causing increased venous capacitance, resulting in rapid clinical improvement in patients with left ventricular failure, preceding the diuresis. Unwanted effects include:
- Urate retention causing gout
- Hypokalaemia
- Hypomagnesaemia
- Decreased glucose tolerance
- Allergic tubulointerstitial nephritis and other allergic reactions
- Myalgia – especially with high-dose bumetanide
- Ototoxicity (due to an action on sodium pump activity in the inner ear) – particularly with furosemide
- Interference with excretion of lithium, resulting in toxicity.

There is little to choose between the drugs in this class. Bumetanide has a better oral bioavailability than furosemide, particularly in patients with severe peripheral oedema, and

*CCF, congestive cardiac failure; CKD, chronic kidney disease; SIADH, syndrome of inappropriate antidiuretic hormone secretion.*
Sodium chloride is generated by the Na\textsuperscript{+} low intracellular sodium and chloride concentrations (NKCC2). The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na/K-ATPase and the kidney-specific basolateral chloride channel (ClC-Kb). The availability of luminal potassium is rate-limiting for NKCC2, and recycling of potassium through the ATP-regulated potassium channel (ROMK – renal outer medulla K\textsuperscript{+} channel) ensures the efficient functioning of the NKCC2 and generates a lumen-positive transepithelial potential. Genetic studies have identified putative loss of function mutations in the genes encoding NKCC2 (ROMK 2, CIC-Kb 3, and barttin 4 in subgroups of patients with Bartter’s syndrome). In contrast to the normal condition, loss of function of NKCC2 impairs reabsorption of sodium and potassium. Inactivation of the basolateral CIC-Kb and barttin reduces transcellular reabsorption of chloride. Loss of function of any of these will reduce the transepithelial potential and thus decrease the driving force for the paracellular reabsorption of cations (K\textsuperscript{+}, Mg\textsuperscript{2+}, Ca\textsuperscript{2+} and Na\textsuperscript{+}). Paracellin-1 is necessary for the paracellular transport of Ca\textsuperscript{2+} and Mg\textsuperscript{2+}. In most patients with Bartter’s syndrome, urinary calcium excretion is increased. Hypercalciemia or increased activation of the calcium-sensing receptor inactivates ROMK and causes Bartter’s syndrome. K\textsuperscript{+} and K\textsuperscript{+}, kidney-specific basolateral chloride channel. ROMK, renal outer medullary potassium channel. Has more beneficial effects than furosemide on venous capacitance in left ventricular failure.

**Thiazide diuretics** (see p. 719)

These are less potent than loop diuretics. They act by blocking a sodium chloride channel in the distal convoluted tubule (Fig. 13.7). They cause relatively more urate retention, glucose intolerance and hypokalaemia than loop diuretics. They interfere with water excretion and may cause hyponatraemia, particularly if combined with amiloride or triamterene. This effect is clinically useful in diabetes insipidus. Thiazides reduce peripheral vascular resistance by mechanisms that are not completely understood but do not appear to depend on their diuretic action, and are widely used in the treatment of essential hypertension. They are also used extensively in mild to moderate cardiac failure. Thiazides reduce calcium excretion. This effect is useful in patients with idiopathic hypercalciuria, but may cause hypercalcaemia. Numerous agents are available, with varying half-lives but little else to choose between them. Metolazone is not dependent for its action on glomerular filtration, and therefore retains its potency in renal impairment.

**Potassium-sparing diuretics** (see Fig. 13.8)

These are of two types.

- **Aldosterone antagonists**, which compete with aldosterone in the collecting ducts and reduce sodium absorption, e.g. spironolactone and eplerenone (which has a shorter half-life). Spironolactone is used in patients with heart failure because it significantly reduces the mortality in these patients by antagonizing the fibrotic effect of aldosterone on the heart. Eplerenone is devoid of antianabolic or antiprogestrogen properties.

- **Amiloride and triamterene** inhibit sodium uptake by blocking epithelial sodium channels in the collecting duct and reduce renal potassium excretion by reducing lumen-negative transepithelial voltage. They are mainly used as potassium-sparing agents with thiazide or loop diuretics.

**Carbonic anhydrase inhibitors**

These are relatively weak diuretics and are seldom used except in the treatment of glaucoma. They cause metabolic acidosis and hypokalaemia.

**Aquaretics (vasopressin or antidiuretic hormone antagonists)**

Vasopressin V\textsubscript{2} receptor antagonists are very useful agents in the treatment of conditions associated with elevated levels...
of vasopressin, such as heart failure, cirrhosis and SIADH (see p. 993). Non-peptide vasopressin V₂ receptor antagonists are efficacious in producing free water diuresis in humans. Studies in patients with heart failure and cirrhosis suggest that such agents will allow normalization of serum osmolality with less water restriction (see p. 650).

Resistance to diuretics
Resistance may occur as a result of:

- Poor bioavailability
- Reduced GFR, which may be due to decreased circulating volume despite oedema (e.g. nephrotic syndrome, cirrhosis with ascites) or intrinsic renal disease
- Activation of sodium-retaining mechanisms, particularly aldosterone.

Management. Intravenous administration of diuretics may establish a diuresis. High doses of loop diuretics are required to achieve adequate concentrations in the tubule if GFR is depressed. However, the daily dose of furosemide must be limited to a maximum of 2 g for an adult, because of ototoxicity. Intravenous albumin solutions restore plasma oncotic pressure temporarily in the nephrotic syndrome and allow mobilization of oedema but do not increase the natriuretic effect of loop diuretics.

Combinations of various classes of diuretics are extremely helpful in patients with resistant oedema. A loop diuretic plus a thiazide inhibit two major sites of sodium reabsorption; this effect may be further potentiated by addition of a potassium-sparing agent. Metolazone in combination with a loop diuretic is particularly useful in refractory congestive cardiac failure, because its action is less dependent on glomerular filtration. However, this potent combination can cause severe electrolyte imbalance. Both aminophylline and dopamine increase renal blood flow and may be useful in refractory cardiogenic sodium retention. In addition, theophyllines, by inhibiting phosphodiesterase activity in the inner medullary collecting duct, prolong the action of cyclic GMP (a second messenger of ANP).

Effects on renal function
All diuretics may increase plasma urea concentrations by increasing urea reabsorption in the medulla. Thiazides may also promote protein breakdown. In certain situations diuretics also decrease GFR:

- Excessive diuresis causes volume depletion and prerenal failure
- Diuretics can cause allergic tubulointerstitial nephritis
- Thiazides may directly cause a drop in GFR; the mechanism is complex and not fully understood.

Decreased extracellular volume
Deficiency of sodium and water causes shrinkage both of the interstitial space and of the blood volume and may have profound effects on organ function.

Clinical features
Symptoms. Thirst, muscle cramps, nausea and vomiting, and postural dizziness occur. Severe depletion of circulating volume causes hypotension and impairs cerebral perfusion, causing confusion and eventual coma.

Signs can be divided into those due to loss of interstitial fluid and those due to loss of circulating volume.

- Loss of interstitial fluid leads to loss of skin elasticity ("turgor") – the rapidity with which the skin recoils to normal after being pinched. Skin turgor decreases with age, particularly at the peripheries. The turgor over the anterior triangle of the neck or on the forehead is a very useful sign in all ages.
- Loss of circulating volume leads to decreased pressure in the venous and (if severe) arterial compartments. Loss of up to 1 L of extracellular fluid in an adult may be compensated for by venoconstriction and may cause no physical signs. Loss of more than this causes the following:

  Postural hypotension
  Normally the blood pressure rises if a subject stands up, as a result of increased venous return due to venoconstriction (this maintains cerebral perfusion). Loss of extracellular fluid (underfill) prevents this and causes a fall in blood pressure. This is one of the earliest and most reliable signs of volume depletion, as long as the other causes of postural hypotension are excluded (Table 13.4).

  Low jugular venous pressure
  In hypovolaemic patients, the jugular venous pulsation can be seen only with the patient lying completely flat, or even head down, because the right atrial pressure is lower than 5 cmH₂O.

  Peripheral venoconstriction
  This causes cold skin with empty peripheral veins, which are difficult to cannulate just when the patient needs intravenous therapy the most! This sign is often absent in sepsis, where peripheral vasodilatation contributes to effective hypovolaemia.

  Tachycardia
  This is not always a reliable sign. Beta-blockers and other antiarrhythmics may prevent tachycardia, and hypovolaemia may activate vagal mechanisms and actually cause bradycardia.

Causes
Salt and water may be lost from the kidneys, from the gastrointestinal tract, or from the skin. Examples are given in Table 13.5.

In addition, there are a number of situations where signs of volume depletion occur despite a normal or increased body content of sodium and water.

- Septicaemia causes vasodilatation of both arterioles and veins, resulting in greatly increased capacitance of the vascular space. In addition, increased capillary permeability to plasma proteins leads to loss of fluid from the vascular space to the interstitium.
- Diuretic treatment of heart failure or nephrotic syndrome may lead to rapid reduction in plasma volume. Mobilization of oedema may take much longer.
- There may be inappropriate diuretic treatment of oedema (e.g. when the cause is local rather than systemic).

**Investigations**

Blood tests are in general not helpful in the assessment of extracellular volume. Plasma urea may be raised owing to increased water reabsorption and, later, to prerenal failure (when the creatinine rises as well), but this is very nonspecific. Urinary sodium is low if the kidneys are functioning normally, but is misleading if the cause of the volume depletion involves the kidneys (e.g. diuretics, intrinsic renal disease). Urine osmolality is high in volume depletion (owing to increased water reabsorption), but may also often mislead.

Assessment of volume status is shown in Box 13.1.

**Treatment**

The overriding principle is to replace what is missing.

**Haemorrhage**

The rational treatment of acute haemorrhage is the infusion of a combination of red cells and a plasma substitute or (if unavailable) whole blood. (Chronic anaemia causes salt and water retention rather than volume depletion by a mechanism common to conditions with peripheral vasodilatation.)

**Loss of plasma**

Loss of plasma, as occurs in burns or severe peritonitis, should be treated with human plasma or a plasma substitute (see p. 390).

**Loss of water and electrolytes**

Loss of water and electrolytes, as occurs with vomiting, diarrhoea, or excessive renal losses, should be treated by replacement of the loss. If possible, this should be with oral water and sodium salts. These are available as slow sodium (600 mg, approximately 10 mmol each of Na+ and Cl− per tablet), the usual dose of which is 6–12 tablets/day with 2–3 L of water. It is used in mild or chronic salt and water depletion, such as that associated with renal salt wasting.

Sodium bicarbonate (500 mg, 6 mmol each of Na+ and HCO3− per tablet) is used in doses of 6–12 tablets/day with 2–3 L of water. This is used in milder chronic sodium depletion with acidosis (e.g. chronic kidney disease, post-obstructive renal failure, renal tubular acidosis). Sodium bicarbonate is less effective than sodium chloride in causing positive sodium balance. Oral rehydration solutions are described in Box 4.10.

**Intravenous fluids** are sometimes required (Table 13.6). Rapid infusion (e.g. 1000 mL per hour or even faster) is necessary if there is hypotension and evidence of impaired organ perfusion (e.g. oliguria, confusion); in these situations, plasma expanders (colloids) are often used in the first instance to restore an adequate circulating volume (see p. 887). Repeated clinical assessments are vital in this situation, usually complemented by frequent measurements of central venous pressure (see p. 872, for the management of shock). Severe hypovolaemia induces vasoconstriction, which maintains venous return; over-rapid correction does not give time

“1. Volume expansion in hypovolaemic patients. Rarely to maintain fluid balance when there are large losses of sodium. The sodium (150 mmol/L) is higher than in plasma and hypernatraemia can result. It is often necessary to add KCl 20–40 mmol/L.

“3. To replace water. Can be given with or without potassium chloride. May be alternated with 0.9% saline as an alternative to (2).

“4. For volume expansion in hypovolaemic, acidotic patients alternating with (1). Occasionally for maintenance of fluid balance combined with (2) in salt-wasting, acidotic patients.”
for this to reverse, resulting in signs of circulatory overload (e.g. pulmonary oedema) even if a total body extracellular fluid (ECF) deficit remains. In less severe ECF depletion (such as in a patient with postural hypotension complicating acute tubular necrosis), the fluid should be replaced at a rate of 1000 mL every 4–6 h, again with repeated clinical assessment. If all that is required is avoidance of fluid depletion during surgery, 1–2 L can be given over 24 h, remembering that surgery is a stimulus to sodium and water retention and that over-replacement may be as dangerous as under-replacement. Regular monitoring by fluid balance charts, bodyweight and plasma biochemistry is mandatory.

**Loss of water alone**

This causes extracellular volume depletion only in severe cases, because the loss is spread evenly among all the compartments of body water. In the rare situations where there is a true deficiency of water alone, as in diabetes insipidus or in a patient who is unable to drink (e.g. after surgery), the correct treatment is to give water.

If intravenous treatment is required, water is given as 5% glucose with K+, because pure water would lead to osmotic lysis of blood cells.

### DISORDERS OF SODIUM CONCENTRATION

These are best thought of as disorders of body water content. As discussed above, sodium content is regulated by volume receptors; water content is adjusted to maintain, in health, a normal osmolality and (in the absence of abnormal osmotically active solutes) a normal sodium concentration. Disturbances of sodium concentration are caused by disturbances of water balance.

#### Hyponatraemia

Hyponatraemia (Na <135 mmol/L) is a common biochemical abnormality. The causes depend on the associated changes in extracellular volume:

- **Hyponatraemia with hypovolaemia** (Table 13.7)
- **Hyponatraemia with euovolaemia** (Table 13.8)
- **Hyponatraemia with hypervolaemia** (Table 13.9).

Rarely, hyponatraemia may be a ‘pseudo-hyponatraemia’. This occurs in hyperlipidaemia (either high cholesterol or high triglycérider or hyperproteinaemia where there is a spuriously low measured sodium concentration, the sodium being confined to the aqeous phase but having its concentration expressed in terms of the total volume of plasma. In this situation, plasma osmolality is normal and therefore treatment of ‘hyponatraemia’ is unnecessary. Note: Artefactual ‘hyponatraemia’, caused by taking blood from the limb into which fluid of low sodium concentration is being infused, should be excluded.

#### Hyponatraemia with hypovolaemia

This is due to salt loss in excess of water loss; the causes are listed in Table 13.7. In this situation, ADH secretion is initially suppressed (via the hypothalamic osmoreceptors); but as fluid volume is lost, volume receptors override the osmoreceptors and stimulate both thirst and the release of ADH. This is an attempt by the body to defend circulating volume at the expense of osmolality.

With extrarenal losses and normal kidneys, the urinary excretion of sodium falls in response to the volume depletion, as does water excretion, leading to concentrated urine containing <10 mmol/L of sodium. However, in salt-wasting kidney disease, renal compensation cannot occur and the only physiological protection is increased water intake in response to thirst.

**Clinical features**

With sodium depletion the clinical picture is usually dominated by features of volume depletion (see p. 638). The diagnosis is usually obvious where there is a history of gut losses, diabetes mellitus or diuretic abuse. Examination of the patient is often more helpful than the biochemical investigations, which include plasma and urine electrolytes and osmolality. Table 13.10 shows the potential daily losses of water and electrolytes from the gut. Losses due to renal or adenocortical disease may be less easily identified but a urinary sodium

Hyponatraemia is common when symptoms and signs evident volume depletion, suggests a renal loss.

Dilutional hyponatraemia

Clinical features

The most common iatrogenic cause is overgenerous infusion of 5% glucose with potassium supplements, i.e. 1.5–2 L 5% glucose (with 20 mmol K) and 1 L 0.9% saline over 24 h PLUS measurable losses.

Correction of acid–base abnormalities is usually not required.

Treatment

This is directed at the primary cause whenever possible.

In a healthy patient:

- Give oral electrolyte-glucose mixtures (see p. 122)
- Increase salt intake with slow sodium 60–80 mmol/day.

In a patient with vomiting or severe volume depletion:

- Give intravenous fluid with potassium supplements, i.e. 1.5–2 L 5% glucose (with 20 mmol K) and 1 L 0.9% saline over 24 h PLUS measurable losses.
- Correction of acid–base abnormalities is usually not required.

Hyponatraemia with euvolaemia

(see Table 13.8)

This results from an intake of water in excess of the kidney’s ability to excrete it (dilutional hyponatraemia) with no change in body sodium content but the plasma osmolality is low.

- With normal kidney function, dilution hyponatraemia is uncommon even if a patient drinks approximately 1 L per hour.
- The most common iatrogenic cause is overgenerous infusion of 5% glucose into postoperative patients; in this situation it is exacerbated by an increased ADH secretion in response to stress.
- Postoperative hyponatraemia is a common clinical problem (almost 1% of patients) with symptomatic hyponatraemia occurring in 20% of these patients.
- Marathon runners drinking excess water and ‘sports drinks’ can become hyponatraemic.
- Premenopausal females are at most risk for developing hyponatraemic encephalopathy postoperatively, with postoperative ADH values in young females being 40 times higher than in young males.
- To prevent hyponatraemia, avoid using hypotonic fluids postoperatively and administer 0.9% saline unless otherwise clinically contraindicated. The serum sodium should be measured daily in any patient receiving continuous parenteral fluid.
- Some degree of hyponatraemia is usual in acute oliguric kidney injury, while in chronic kidney disease (CKD) it is most often due to ill-given advice to ‘push’ fluids.

Clinical features

Dilutional hyponatraemia symptoms are common when hyponatraemia develops acutely (<48 h, often postoperatively). Symptoms rarely occur until the serum sodium is less than 120 mmol/L and are more usually associated with values around 110 mmol/L or lower, particularly when chronic. They are principally neurological and are due to the movement of water into brain cells in response to the fall in extracellular osmolality.

Hyponatraemic encephalopathy symptoms and signs include headache, confusion and restlessness leading to drowsiness, myoclonic jerks, generalized convulsions and eventually coma. MRI scan of the brain reveals cerebral oedema but, in the context of electrolyte abnormalities and neurological symptoms, it can help to make a confirmatory diagnosis.

Risk factors for developing hyponatraemic encephalopathy. The brain’s adaptation to hyponatraemia initially involves extrusion of blood and CSF, as well as sodium, potassium and organic osmolytes, in order to decrease brain osmolality. Various factors can interfere with successful adaptation. These factors rather than the absolute change in serum sodium predict whether a patient will suffer hyponatraemic encephalopathy.

- Children under 16 years are at increased risk due to their relatively larger brain-to-intracranial volume ratio compared with adults.
- Premenopausal women are more likely to develop encephalopathy than postmenopausal females and males because of inhibitory effects of sex hormones and the effects of vasopressin on cerebral circulation resulting in vasoconstriction and hypoperfusion of brain.
- Hypoxaemia is a major risk factor for hyponatraemic encephalopathy. Patients with hyponatraemia, who develop hypoxia due to either non-cardiac pulmonary oedema or hypercapnic respiratory failure, have a high risk of mortality. Hypoxia is the strongest predictor of mortality in patients with symptomatic hyponatraemia.

Investigations

The cause of hyponatraemia with apparently normal extracellular volume requires investigation:

- Plasma and urine electrolytes and osmolalities. The plasma concentrations of sodium, chloride and urea are low, giving a low osmolality. The urine sodium concentration is usually high and the urine osmolality is typically higher than the plasma osmolality. However, maximal dilution (<50 mosmol/kg) is not always present.
- Further investigations to exclude Addison’s disease, hypothyroidism, ‘syndrome of inappropriate ADH secretion’ (SIADH) and drug-induced water retention, e.g. chlorpropamide.
- Remember, potassium and magnesium depletion potentiate ADH release and are causes of diuretic-associated hyponatraemia.

</table>
The syndrome of inappropriate ADH secretion is often over-diagnosed. Some causes are associated with a lower set-point for ADH release, rather than completely autonomous ADH release – an example is chronic alcohol use.

**Treatment**

The underlying cause should be corrected where possible.

- Most cases are simply managed by restriction of water intake (to 1000 or even 500 mL/day) with review of diuretic therapy. Magnesium and potassium deficiency must be corrected. In mild sodium deficiency, 0.9% saline given slowly (1 L over 12 hours) is sufficient.

- **Acute onset with symptoms.** The most common cause of acute hyponatraemia in adults is postoperative iatrogenic hyponatraemia. Excessive water intake associated with psychosis, marathon running and use of Ecstasy (a recreational drug) are other causes. All are acute medical emergencies and should be treated aggressively and immediately. In patients in whom there are severe neurological signs, such as fits or coma or cerebral oedema, hypertonic saline (3%, 513 mmol/L) should be used. It must be given very slowly (not more than 70 mmol/h), the aim being to increase the serum sodium by 4–6 mmol/L in the first 4 hours, but the absolute change should not exceed 15–20 mmol/L over 48 hours.

In general, the plasma sodium should not be corrected to >125–130 mmol/L. 1 mL/kg of 3% sodium chloride will raise the plasma sodium by 1 mmol/L, assuming that total body water comprises 50% of total bodyweight.

- **Symptomatic hyponatraemia in patients with intracranial pathology** should be managed aggressively and immediately with 3% saline like acute hyponatraemia.

- **Chronic/asymptomatic.** If hyponatraemia has developed slowly, as it does in the majority of patients, the brain will have adapted by decreasing intracellular osmolality and the hyponatraemia can be corrected slowly (without use of hypertonic saline).

However, clinically it can be difficult to know how long the hyponatraemia has been present and 3% of hypertonic saline is still required.

**Osmotic demyelination syndrome (ODS)**

**Avoiding ODS**

A rapid rise in extracellular osmolality, particularly if there is an ‘overshoot’ to high serum sodium and osmolality, will result in the osmotic demyelination, syndrome (ODS), formally known as central pontine demyelination, which is a devastating neurologic complication. Plasma sodium concentration in patients with hyponatraemia should not rise by more than 8 mmol/L per day. The rate of rise of plasma sodium should be even lower in patients at higher risk for ODS, e.g. patients with alcohol excess, cirrhosis, malnutrition, or hypokalaemia. Other factors predisposing to demyelination are pre-existing hypoxaemia and CNS radiation (see above). ODS is diagnosed by the appearance of characteristic hypointense lesions on T2-weighted images and hyperintense on T2-weighted images on MRI; these take up to 2 weeks or longer to appear.

The pathophysiology of ODS is not fully understood. The most plausible explanation is that the brain loses organic osmolytes very quickly in order to adapt to hyponatraemia so that osmolarity is similar between the intracellular and extracellular compartments. However, neurones reclaim organic osmolytes slowly in the phase of rapid correction of hyponatraemia, resulting in an hypo-osmolar intracellular compartment and lead to shrinkage of cerebral vascular endothelial cells. Consequently the blood–brain barrier is functionally impaired, allowing lymphocytes, complement, and cytokines to enter the brain, damage oligodendrocytes, activate microglial cells and cause demyelination.

The most crucial issue in the treatment of hyponatraemia is to prevent rapid correction. A rapid rise in plasma sodium is almost always due to a water diuresis, which happens when vasopressin (ADH) action stops suddenly, for example with volume repletion in patients with intravascular volume depletion, cortisol replacement in patients with Addison disease, resolution of non-osmotic stimuli for vasopressin release such as nausea or pain. However, sometimes chronic hyponatraemia can develop in the absence of vasopressin excess. Even in these cases, water diuresis due to increased distal delivery of filtrate is the main cause of rapid rise in plasma sodium.

In the absence of vasopressin, *it is generally assumed that* the total urine volume is equal to the volume of filtrate delivered to the distal nephron, which is the GFR minus the volume reabsorbed in the proximal convoluted tubule (PCT). Approximately 80% of the GFR is reabsorbed in PCT under normal circumstance (increases even more in the presence of intravascular volume depletion). However, *in real life* water excretion will be less than the volume of distal delivery of filtrate, even in the absence of vasopressin, because a significant degree of water is reabsorbed in the inner medullary collecting duct through its residual water permeability, prompted by a very high osmotic force in the interstitium (see Fig. 12.2).

Even a modest water diuresis in the elderly with reduced muscle mass is large enough to cause a rapid rise in plasma sodium. Moreover, there is a higher risk for ODS if hypokalaemia is present. In such cases if plasma sodium rises too quickly due to anticipated water diuresis, administration of desmopressin to stop the water diuresis is beneficial. If plasma sodium rises regardless then lowering plasma sodium to the maximum limit of correction (<8 mmol/L per day) with the administration of 5% glucose solution is the best strategy.

**Reversible hyponatraemia culminating in hyponatraemia**

In many patients, the cause of water retention is reversible (e.g. hypovolaemia, thiazide diuretics). On correction of the cause, vasopressin levels fall and plasma sodium rises by up to 2 mmol/L per hour as a result of excretion of dilute urine. This excessive water diuresis should be anticipated and prevented by use of desmopressin.

Patients who are chronically hyponatraemic with concomitant hypokalaemia are especially susceptible to overcorrection. Plasma sodium is a function of the ratio of exchangeable body sodium plus potassium to total body water, so potassium administration increases sodium concentration. For example, a mildly symptomatic hyponatraemic patient with a plasma sodium of <120 mmol/L and potassium of <2 mmol/L can potentially develop ODS as a result of overcorrection of hyponatraemia simply as a direct result of replacing the large potassium deficit.

**Antidiuretic hormone antagonists (vasopressin antagonists)**

Vasopressin V2 receptor antagonists (see p. 645), which produce a free water diuresis, are being used in clinical trials.
for the treatment of hyponatraemic encephalopathy. Three oral agents, lixivaptan, tolvaptan and sartavaptan, are selective for the V₂ (antidiuretic) receptor, while conivaptan blocks both the V₁a and V₂ receptors.

These agents produce a selective water diuresis without affecting sodium and potassium excretion; they raise the plasma sodium concentration in patients with hyponatraemia caused by the SIADH, heart failure and cirrhosis.

The efficacy of oral tolvaptan in ambulatory patients has been demonstrated in patients with hyponatraemia (mean plasma sodium 129 mmol/L) caused by the SIADH, heart failure, or cirrhosis who had a sustained rise in plasma sodium to 136 mmol/L for 4 weeks. Tolvaptan is now approved for use in patients with euvolaemic hyponatraemia and those with SIADH. In addition, intravenous conivaptan is available and is also approved for the treatment of euvolaemic hyponatraemia (i.e. SIADH) in some countries. The approved dosing for conivaptan is a 20 mg bolus followed by continuous infusion of 20 mg over 1–4 days. The continuous infusion increases the risk of phlebitis, which requires the use of large veins and changing the infusion site every 24 hours.

**Hyponatraemia with hypervolaemia**

The common causes of hyponatraemia due to water excess are shown in Table 13.9. In all these conditions, there is usually an element of reduced glomerular filtration rate with avid reabsorption of sodium and chloride in the proximal tubule. This leads to reduced delivery of chloride to the ‘diluting’ ascending limb of Henle’s loop and a reduced ability to generate ‘free water’, with a consequent inability to excrete dilute urine. This is commonly compounded by the administration of diuretics that block chloride reabsorption and interfere with the dilution of filtrate either in Henle’s loop (loop diuretics) or distally (thiazides).

**Syndrome of inappropriate ADH secretion**

This is described in Chapter 19 (p. 746). There is inappropriate secretion of ADH, causing water retention and hyponatraemia.

**Hyponatraemia**

This is much rarer than hyponatraemia and nearly always indicates a water deficit. Causes are listed in Table 13.11. Hyponatraemia is always associated with increased plasma osmolality, which is a potent stimulus to thirst. None of the above cause hyponatraemia unless thirst sensation is abnormal or access to water limited. For instance, a patient with diabetes insipidus will maintain a normal serum sodium concentration by maintaining a high water intake until an intercurrent illness prevents this. Thirst is frequently deficient in elderly people, making them more prone to water depletion. Hyponatraemia may occur in the presence of normal, reduced or expanded extracellular volume, and does not necessarily imply that total body sodium is increased.

**Clinical features**

Symptoms of hyponatraemia are nonspecific. Nausea, vomiting, fever and confusion may occur. A history of long-standing polyuria, polydipsia and thirst suggests diabetes insipidus. Assessment of extracellular volume status guides resuscitation. Mental state should be assessed. Convulsions occur in severe hyponatraemia.

**Investigations**

Simultaneous urine and plasma osmolality and sodium should be measured. Plasma osmolality is high in hyponatraemia. Passage of urine with an osmolality lower than that of plasma in this situation is clearly abnormal and indicates diabetes insipidus. In pituitary diabetes insipidus, urine osmolality will increase after administration of desmopressin; the drug (a vasopressin analogue) has no effect in nephrogenic diabetes insipidus. If urine osmolality is high this suggests either an osmotic diuresis due to an unmeasured solute (e.g. in parenteral feeding) or excessive extrarenal loss of water (e.g. heat stroke).

**Treatment**

Treatment is that of the underlying cause, e.g.

- In ADH deficiency, replace ADH in the form of desmopressin, a stable non-pressor analogue of ADH
- Remember to withdraw nephrotoxic drugs where possible and replace water either orally or, if necessary, intravenously.

In severe (>170 mmol/L) hyponatraemia, 0.9% saline (150 mmol/L) should be used initially. Avoid too rapid a drop in serum sodium concentration; the aim is correction over 48 h, as over-rapid correction may lead to cerebral oedema.

In less severe (e.g. >150 mmol/L) hyponatraemia, the treatment is 5% glucose or 0.45% saline; the latter is obviously preferable in hyperosmolar diabetic coma. Very large volumes – 5 L/day or more – may need to be given in diabetics insipidus.

If there is clinical evidence of volume depletion (see p. 646), this implies that there is a sodium deficit as well as a water deficit. Treatment of this is discussed on page 647.

**Disorders of potassium concentration**

**Regulation of serum potassium concentration**

The usual dietary intake varies between 80 and 150 mmol daily, depending upon fruit and vegetable intake. Most of the...
body's potassium (3500 mmol in an adult man) is intracellular. Serum potassium levels are controlled by:

- uptake of K+ into cells
- renal excretion
- extrarenal losses (e.g. gastrointestinal).

Uptake of potassium into cells is governed by the activity of the Na'/K'-ATPase in the cell membrane and by H+ concentration.

Uptake is stimulated by:

- insulin
- β-adrenergic stimulation
- theophyllines.

Uptake is decreased by:

- α-adrenergic stimulation
- acidosis – K+ exchanged for H+ across cell membrane
- cell damage or cell death – resulting in massive K+ release.

Kidney plays the pivotal role in the maintenance of potassium balance by varying its secretion with changes in dietary intake. Over 90% of the filtered potassium is reabsorbed in the proximal tubule and the loop of Henle and only <10% of the filtered load is delivered to the early distal tubule. Potassium absorption on proximal tubule is entirely passive and follows that of sodium and water, while its reabsorption in the thick ascending limb of the loop of Henle is mediated by the sodium-potassium-2-chloride cotransporter. However, potassium is secreted by the principal cells in the cortical and outer medullary collecting tubule. Secretion in these segments is very tightly regulated in health and can be varied according to individuals needs and is responsible for most of urinary potassium excretion.

Renal excretion of potassium is increased by aldosterone, which stimulates K+ and H+ secretion in exchange for Na+ in the principal cells of the collecting duct (Fig. 13.8). Because H+ and K+ are interchangeable in the exchange mechanism, acidosis decreases and alkalosis increases the secretion of K+. Aldosterone secretion is stimulated by hyperkalaemia and increased angiotensin II levels, as well as by some drugs, and this acts to protect the body against hyperkalaemia and against extracellular volume depletion. The body adapts to dietary deficiency of potassium by reducing aldosterone secretion. However, because aldosterone is also influenced by volume status, conservation of potassium is relatively inefficient, and significant potassium depletion may therefore result from prolonged dietary deficiency.

A number of drugs affect K+ homeostasis by affecting aldosterone release (e.g. heparin, NSAIDs) or by directly affecting renal potassium handling (e.g. diuretics).

Recent evidence has shown that other endogenous proteins and metabolites also affect potassium homeostasis. Klotho, an anti-ageing protein expressed in the distal tubule (and other organs), increases potassium excretion. O633, a tetra-spanning protein, inhibits its excretion. Moreover, protein kinase A and C mediated phosphorylation inhibits conductance K channels in the principal cells of the collecting duct but the cytochrome p450-epoxigenase-mediated metabolite of arachidonic acid (11–12-epoxyeicosatrienoic acid) activates these channels and plays a role in overall potassium homeostasis.

Normally, only about 10% of daily potassium intake is excreted in the gastrointestinal tract. Vomit contains around 5–10 mmol/L of K+, but prolonged vomiting causes hypokalaemia by inducing sodium depletion, stimulating aldosterone, which increases renal potassium excretion. Potassium is secreted by the colon, and diarrhoea contains 10–30 mmol/L of K+; profuse diarrhoea can therefore induce marked hypokalaemia. Colorectal villous adenomas may rarely produce profuse diarrhoea and K+ loss.

Hypokalaemia

Common causes

Causes

The most common causes of chronic hypokalaemia are diuretic treatment (particularly thiazides) and hyperaldosteronism. Acute hypokalaemia is often caused by intravenous fluids without potassium and redistribution into cells. The common causes are shown in Table 13.12.

Rare causes

These rare causes are discussed in detail because they show the mechanisms of how diuretics can affect the kidney.

Bartter’s syndrome (clinically similar to loop diuretics)

This consists of metabolic alkalosis, hypokalaemia, hypercalciuria, occasionally hypomagnesaemia (see p. 657), normal blood pressure, and an elevated plasma renin and aldosterone. The primary defect in this disorder is an impairment in sodium and chloride reabsorption in the thick ascending limb of the loop of Henle (Fig. 13.6). Mutation in the genes encoding either the sodium-potassium-2-chloride cotransporter (NKCC2), the ATP-regulated renal outer medullary potassium channel (ROMK) or kidney-specific basolateral
These defects in sodium chloride transport are thought to initiate the following sequence, which is almost identical to that seen with chronic ingestion of a loop diuretic. The initial salt loss leads to mild volume depletion, resulting in activation of the renin-angiotensin-aldosterone system. The combination of hyperaldosteronism and increased distal flow (owing to the reabsorptive defect) enhances potassium and hydrogen secretion at the secretory sites in the collecting tubules, leading to hypokalaemia and metabolic alkalosis.

**Diagnostic pointers** include high urinary potassium and chloride despite low serum values as well as increased plasma renin (NB: in primary aldosteronism, renin levels are low). Hyperplasia of the juxtaglomerular apparatus is seen on renal biopsy (careful exclusion of diuretic abuse is necessary). Hypercalciuria is a common feature but magnesium wasting, though rare, also occurs.

**Treatment** is with combinations of potassium supplements, amiloride and indomethacin.

### Gitelman’s syndrome (similar to thiazide diuretics)

Gitelman’s syndrome is a phenotype variant of Bartter’s syndrome characterized by hypokalaemia, metabolic alkalosis, hypercalciuria, hypomagnesaemia, normal blood pressure, and elevated plasma renin and aldosterone. There are striking similarities between the Gitelman’s syndrome and the biochemical abnormalities induced by chronic thiazide diuretic administration. Thiazides act in the distal convoluted tubule to inhibit the function of the apical sodium-chloride cotransporter (NCCT) (Fig. 13.7). Analysis of the gene encoding the NCCT has identified loss of function mutations in Gitelman’s syndrome.

Like Bartter’s syndrome, defective NCCT function leads to increased solute delivery to the collecting duct, with resultant solute wasting, volume contraction and an aldosterone-mediated increase in potassium and hydrogen secretion. Unlike Bartter’s syndrome, the degree of volume depletion and hypokalaemia is not sufficient to stimulate prostaglandin E₂ production. Impaired function of NCCT is predicted to cause hypocalciuria, as does thiazide administration. Impaired sodium reabsorption across the apical membrane, coupled with continued intracellular chloride efflux across the basolateral membrane, causes the cell to become hyperpolarized. This in turn stimulates calcium reabsorption via apical, voltage-activated calcium channels. Decreased intracellular sodium also facilitates calcium efflux via the basolateral sodium-chloride exchanger. The mechanism for urinary magnesium losses is described on page 656.

**Treatment** consists of potassium and magnesium supplementation (MgCl₂) and a potassium-sparing diuretic. Volume resuscitation is usually not necessary, because patients are not dehydrated. Elevated prostaglandin E₂ does not occur (see above) and, therefore, NSAIDs are not indicated in this disorder.

### Liddle’s syndrome

This is characterized by potassium wasting, hypokalaemia and alkalosis, but is associated with low renin and aldosterone production, and high blood pressure. There is a mutation in the gene encoding for the amiloride-sensitive epithelial sodium channel in the distal tubule/collecting duct. This leads to constitutive activation of the epithelial sodium channel, resulting in excessive sodium reabsorption with
coupled potassium and hydrogen secretion. Unregulated sodium reabsorption across the collecting tubule results in volume expansion, inhibition of renin and aldosterone secretion and development of low renin hypertension (Fig. 13.8).

**Therapy** consists of sodium restriction along with amilorida or triamterene administration. Both are potassium-sparing diuretics which directly close the sodium channels. The mineralocorticoid antagonist spironolactone is ineffective, since the increase in sodium-channel activity is not mediated by aldosterone.

**Hypokalaemic periodic paralysis**

This condition may be precipitated by carbohydrate intake, suggesting that insulin-mediated potassium influx into cells may be responsible. This syndrome also occurs in association with hyperthyroidism (thyrotoxic periodic paralysis) which occurs in Asians.

**Clinical features**

Hypokalaemia is usually asymptomatic, but severe hypokalaemia (<2.5 mmol) causes muscle weakness. Potassium depletion may also cause symptomatic hyponatraemia (see p. 648).

Hypokalaemia is associated with an increased frequency of atrial and ventricular ectopic beats. This association may not always be causal, because adrenergic activation (for instance after myocardial infarction) causes both hypokalaemia and increased cardiac irritability. Hypokalaemia in patients without cardiac disease is unlikely to lead to serious arrhythmias.

Hypokalaemia seriously increases the risk of digoxin toxicity by increasing binding of digoxin to cardiac cells, potentiating its action, and decreasing its clearance.

Chronic hypokalaemia is associated with interstitial renal disease, but the pathogenesis is not completely understood.

**Treatment**

The underlying cause should be identified and treated where possible. Table 13.13 shows some examples.

Acute hypokalaemia may correct spontaneously. In most cases, withdrawal of oral diuretics or purgatives, accompanied by the oral administration of potassium supplements in the form of slow-release potassium or effervescent potassium, is all that is required. Intravenous potassium replacement is required only in conditions such as cardiac arrhythmias, muscle weakness or severe diabetic ketoacido-sis. When using intravenous therapy in the presence of poor renal function, replacement rates <2 mmol per hour should be used only, with hourly monitoring of serum potassium and ECG changes. Ampoules of potassium should be thoroughly mixed in 0.9% saline; do not use a glucose solution as this would make hypokalaemia worse.

The treatment of adrenal disorders is described on page 958.

Failure to correct hypokalaemia may be due to concurrent hypomagnesaemia. Serum magnesium should be measured and any deficiency corrected.

### Hyperkalaemia

**Causes**

Acute self-limiting hyperkalaemia occurs normally after vigorous exercise and is of no pathological significance. Hyperkalaemia in all other situations is due either to increased release from cells or to failure of excretion (Table 13.14). The most common causes are renal impairment and drug interference with potassium excretion. The combination of ACE inhibitors with potassium-sparing diuretics or NSAIDs is particularly dangerous.

**Rare causes**

**Hyporeninaemic hypoaldosteronism**

This is also known as type 4 renal tubular acidosis (see p. 664). Hyperkalaemia occurs because of acidosis and hypoaldosteronism.

**Pseudohypoaldosteronism type 1 (autosomal recessive and dominant types)**

This is a disease of infancy, apparently due to resistance to the action of aldosterone. It is characterized by hyperkalae-

*aCommon causes.
mia and evidence of sodium wasting (hyponatraemia, extracellular volume depletion). Autosomal recessive forms result from loss of function because of mutations in the gene for epithelial sodium channel activity (opposite to Liddle’s syndrome). This disorder involves multiple organ systems and is especially marked in the neonatal period. With aggressive salt replacement and control of hyperkalaemia, these children can survive and the disorder appears to become less severe with age. The autosomal dominant type is due to mutations affecting the mineralocorticoid receptor (Fig. 13.8). These patients present with salt wasting and hyperkalaemia but do not have other organ-system involvement.

**Hyperkalaemic periodic paralysis** (see p. 1153)
This is precipitated by exercise, and is caused by an autosomal dominant mutation of the skeletal muscle sodium channel gene.

**Gordon’s syndrome (familial hyperkalaemic hypertension, pseudohypoaldosteronism type 2)**
This appears to be a mirror image of Gitelman’s syndrome (see p. 653), in which primary renal retention of sodium causes hypertension, volume expansion, low renin/aldosterone, hyperkalaemia and metabolic acidosis. There is also an increased sensitivity of sodium reabsorption to thiazide diuretics, suggesting that the thiazide-sensitive sodium-chloride cotransporter (NCCT) is involved. Genetic analyses, however, have excluded abnormalities in NCCT. The involvement of two loci on chromosomes 1 and 12 and further genetic heterogeneity has also been found. These genes do not correspond to ion transporters but to unexpected proteins, WNK (With No lysine Kinase) 1 and WNK 4, which are two closely related members of a novel serine-threonine kinase family. WNK 4 normally inhibits NCCT by preventing its membrane translocation from the cytoplasm. Loss of function mutation in WNK 4 results in escape of NCCT from normal inhibition and its overactivity as seen from the patient’s phenotype. WNK 1 is an inhibitor of WNK 4 and in some patients with Gordon’s syndrome, gain of function mutation in WNK 1 results in functional deficiency of WNK 4 and overactivity of NCCT.

**Suxamethonium and other depolarizing muscle relaxants**
These cause release of potassium from cells. Induction of muscle paralysis during general anaesthesia may result in a rise of plasma potassium of up to 1 mmol/L. This is not usually a problem unless there is pre-existing hyperkalaemia.

**Clinical features**
Serum potassium of >7.0 mmol/L is a medical emergency and is associated with ECG changes. Severe hyperkalaemia may be asymptomatic and may predispose to sudden death from asystolic cardiac arrest. Muscle weakness is often the only symptom, unless (as is commonly the case) the hyperkalaemia is associated with metabolic acidosis, causing Kussmaul respiration. Hyperkalaemia causes depolarization of cell membranes, leading to decreased cardiac excitability, hypotension, bradycardia and eventual asystole.

**Treatment**
Treatment for severe hyperkalaemia requires both urgent measures to save lives and maintenance therapy to keep potassium down, as summarized in Emergency Box 13.1. The cause of the hyperkalaemia should be found and treated.

High potassium levels are cardiotoxic as they inactivate sodium channels. Divalent cations, e.g., calcium, restore the voltage dependability of the channels. Calcium ions protect the cell membranes from the effects of hyperkalaemia but do not alter the potassium concentration.

Supraphysiological insulin (20 units) drives potassium into the cell and lowers plasma potassium by 1 mmol in 60 min, but must be accompanied by glucose to avoid hypoglycaemia. Regular measurements of blood glucose for at least 6 h after use of insulin should be performed and extra glucose must be available for immediate use. The use of glucose alone in non-diabetic patients, to stimulate endogenous insulin release, does not produce the high levels of insulin required and therefore is not recommended. **Intravenous or nebulized salbutamol** (10–20 mg) has not yet found widespread acceptance and may cause disturbing muscle tremors at the doses required.

Correction of acidosis with hypertonic (8.4%) sodium bicarbonate causes volume expansion and should not be used; 1.26% is used with severe acidosis (pH <6.9). Gastric aspiration will remove potassium and leads to alkalosis.

**Ion-exchange resins** (polystyrene sulphonate resins) are used as maintenance therapy to keep potassium down after emergency treatment. They make use of the ion fluxes which occur in the gut to remove potassium from the body, and are the only way short of dialysis of removing potassium from the body. They may cause fluid overload (resinum contains Na⁺) or hypercalcaemia (calcium resinum). Resins do not appear to significantly enhance the excretion of potassium beyond the effect of diarrhoea induced by osmotic or secretory cathartics.

In general, all of these measures are simply ways of buying time either to correct the underlying disorder or to arrange...
removal of potassium by dialysis, which is the definitive treatment for hyperkalaemia in renal failure.

**DISORDERS OF MAGNESIUM CONCENTRATION**

Magnesium (Mg²⁺) plays a pivotal role in many biological processes such as enzymatic reactions, gene transcription, bone remodelling, and neuromuscular stability. Approximately 99% of the Mg²⁺ in the body is in the intracellular compartment, mainly in bone (~85%) and muscle and soft tissues (~14%). The other 1% is in the extracellular fluid.

Plasma magnesium levels are normally maintained within the range 0.7–1.1 mmol/L (1.4–2.2 mEq/L). The average daily magnesium intake is 15 mmol, which is absorbed mainly in the small intestine and to a lesser extent in the colon. In the healthy adult, there is no net gain or loss of magnesium from bone, so that balance is achieved by the urinary excretion of the net magnesium absorbed. The kidney reabsorbs between approximately 95% and 98% of the filtered Mg²⁺ and plays a major role in maintaining plasma Mg²⁺ concentrations within the normal range.

**Renal handling of magnesium**

**Cortical thick ascending limb of Henle (cTAL)**

Approximately 30% of Mg²⁺ is bound to plasma proteins but the remaining fraction is freely filterable. The major site of magnesium transport is the cortical thick ascending limb (cTAL) of the loop of Henle, where 65–70% of the filtered load is reabsorbed with only 10–20% being reabsorbed in the proximal tubule (Fig. 13.6). This transport is passive, paracellular and carried out by tight junction proteins (paracellins 1 and claudins). This process is driven by the luminal-positive electrochemical gradient, characteristic of this segment. This voltage gradient is created by the apical disproportionate net transport of two Cl⁻ to one Na⁺ (by the bumetanide-sensitive sodium-potassium-2-chloride transporter) and the secretion of K⁺ (via the ROMK) (see Fig. 13.6). Loss of function mutations in these key reabsorptive processes lead to hypomagnesaemia as part of distinctive clinical syndromes described below.

**Bartter’s syndrome** (p. 652). Hypomagnesaemia is not present in all patients with Bartter’s syndrome because expected dissipation of the luminal positive voltage gradient is prevented by lack of dilution of tubular fluid which maintains transepithelial voltage in the normal range. Compensatory increased absorption of Mg²⁺ in the distal convoluted tubule (DCT) can also partly prevent hypomagnesaemia in this condition.

**Familial hypomagnesaemia, hypercalcuria and nephrocalcinosis (FHHNC)** is characterized by excessive renal magnesium and calcium wasting. Individuals develop bilateral nephrocalcinosis and progressive chronic kidney disease. Patients also have elevated PTH levels, which precedes any reduction in GFR. A substantial proportion of patients show incomplete distal renal tubular acidosis, hypocitraturia and hyperuricaemia. Extranodal involvement such as myopia, nystagmus, chiorioretinitis has been reported. The main defect in magnesium and calcium reabsorption lies in cTAL. Ten different mutations have been identified in a novel gene which encodes for paracellin-1 and claudins 16/19 complex, members of the claudin family of tight junction proteins (see p. 23).

**Distal convoluted tubule (DCT)**

The reabsorption rate in the DCT (10%) is much lower than in the cTAL, but it defines the final urinary excretion, as there is no significant reabsorption in the collecting duct: 3–5% of filtered magnesium is finally excreted in the urine. Magnesium reabsorption in the DCT is transcellular and active (Fig. 13.7). The DCT has a slight lumen-negative voltage of approximately ~5 mV. The luminal Mg²⁺ concentration in the DCT ranges between 0.2 and 0.7 mmol/L, whereas the intracellular concentration of Mg²⁺ is estimated to be maintained around 0.2–1.0 mmol/L. Therefore the voltage difference across the apical membrane plays a key role in Mg²⁺ transport within the DCT. Magnesiotropic proteins, including the transient receptor potential channel melastatin member 6 (TRPM6), the epidermal growth factor (EGF), the potassium channels Kir4.1 as well as the hepatocyte nuclear factor 1B (HNF1B) are situated in DCT.

TRPM6 is a member of the transient receptor potential channel family. It is an Mg²⁺-permeable channel that is also expressed in the luminal membrane of the intestinal epithelium. Inactivating mutations of TRPM6, a rare autosomal recessive disease, thus cause a combination of impaired gut absorption of Mg²⁺ and renal wasting known as hypomagnesaemia with secondary hypocalcaemia (HSH). It is characterized by disturbed neuromuscular excitability, muscle spasms, tetany and generalized convulsions. Severe hypomagnesaemia is observed (0.1–0.4 mmol/L) due to impaired intestinal Mg²⁺ absorption and renal reabsorption.

**Thiazide-sensitive Na⁺-Cl⁻ cotransporter in the DCT** plays a role in sodium and chloride absorption and maintenance of lumen-negative voltage. Loss of function mutation results in an autosomal recessive form of isolated renal hypomagnesaemia (IRH). IRH presents with hypomagnesaemia (0.53–0.66 mmol/L) and an inappropriately high fractional excretion of Mg²⁺ with epileptic seizures and moderate mental retardation. In contrast to HSH, Ca²⁺ handling is not affected in these patients. Cancer therapies which inhibit EGF also cause hypomagnesaemia by the above mechanism.

**The y-subunit of the Na⁺–K⁺–ATPase** on the basolateral aspect of DCT plays a pivotal role in the sodium and chloride absorption and maintenance of lumen-negative voltage. A key requirement for magnesium absorption in this segment of the nephron. A loss of function mutation in the XFYD2 gene (transcription factor for gamma chain of Na⁺–K⁺–ATPase) causes isolated dominant hypomagnesaemia. The affected individuals present with renal Mg²⁺ wasting, accompanied by hypocalciuria.

The HNF1b gene encodes a transcription factor linked to the regulation of the FXYD2 gene. Defects in HNF1b gene have been implicated in genetic defects of beta-cell function (p. 1007). Interestingly, almost half of the carriers of a mutation in the HNF1b gene display hypomagnesaemia (<0.65 mmol/L) due to renal wasting of Mg²⁺. As in patients with FXYD2 mutations, hypocalciuria is present.

**ATP-sensitive inward rectifier potassium channel 10 (Kir4.1)** is present on the basolateral surface of DCT. It allows K⁺ ions to recycle across the basolateral membrane, thereby maintaining an adequate supply of K⁺ to sustain the high
Hypomagnesaemia
In addition to the familial causes above, hypomagnesaemia most often develops as a result of deficient intake, defective gut absorption, or excessive gut or urinary loss (Table 13.15). It can also occur with acute pancreatitis, possibly owing to the formation of magnesium soaps in the areas of fat necrosis. The serum magnesium is usually <0.7 mmol/L (1.4 mEq/L). The phenotypes can in many cases be mimicked by drug treatment such as aminoglycosides and cisplatinum compounds. Due to the severe effects of hypomagnesaemia, routine measurements of serum Mg²⁺ should be conducted in the critically ill as well as in patients who are exposed to drugs and other conditions associated with Mg²⁺ deficiency.

Clinical features
Symptoms and signs (indicating a deficit of 0.5–1 mmol/kg) include irritability, tremor, ataxia, carpopedal spasm, hyporeflexia, confusion and hallucinatory states and epileptiform convulsions. An ECG may show a prolonged QT interval, broad flattened T waves, and occasional shortening of the ST segment.

Treatment
This involves the withdrawal of precipitating agents such as diuretics or purgatives. If symptomatic (or with hypocalcaemia), give a parenteral infusion of 50 mmol of magnesium chloride in 1 L of 5% glucose or other isotonic fluid over 12–24 h. This should be repeated daily and continued for 2 days after normal plasma levels have been achieved.

SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Relationship between hypomagnesaemia and plasma calcium
Calcium deficiency usually but not always develops with hypomagnesaemia. Hypomagnesaemia can be further subdivided into three main groups:

- **Hypercalciuria** with hypomagnesaemia: this originating from defects in Mg²⁺ absorption in Cαl such as several forms of Bartter’s syndrome, loop diuretics and familial hypomagnesaemia with hypercalciuria and nephrocalcinosis (FHHNC).
- **Normocalciuria**: this includes autosomal dominant hypomagnesaemia due to mutations in Kv1.1, isolated renal hypomagnesaemia (IRH) due to mutations in the EGF gene.
- **Hypocalciuria with hypomagnesaemia**: is a hallmark feature of thiazide diuretic use, Gitelman’s syndrome (GS), and has also been reported in the EAST syndrome, due to mutations in NCC and Kir4.1, respectively. Genetic defects of beta-cell function and isolated dominant hypomagnesaemia (IDH) caused by mutations in HNF1b and FXYD2 also lead to hypomagnesaemia with accompanying hypocalciuria.

Relationship between hypomagnesaemia and plasma potassium
Magnesium depletion can lead to refractory hypokalaemia. The intracellular magnesium blocks secretory K⁺ currents through ROMK channels; therefore, magnesium depletion promotes K⁺ loss. Furthermore, this magnesium-mediated inhibition of K⁺ secretion increases as extracellular K⁺ decreases, which appropriately reduces K⁺ loss in the presence of K⁺ deficiency. Close monitoring, with potassium supplements if necessary, is required in patients presenting with primary symptomatic low plasma magnesium levels.

Hypermagnesaemia
This primarily occurs in patients with acute or chronic kidney disease given magnesium-containing laxatives or antacids. It can also be induced by magnesium-containing enemas. Mild hypermagnesaemia may occur in patients with adrenal insufficiency. Causes are given in Table 13.16.

Clinical features
Symptoms and signs relate to neurological and cardiovascular depression, and include weakness with hyporeflexia proceeding to narcosis, respiratory paralysis and cardiac conduction defects. Symptoms usually develop when the plasma magnesium level exceeds 2 mmol/L (4 mEq/L).

Treatment
Treatment requires withdrawal of any magnesium therapy. An intravenous injection of 10 mL of calcium gluconate 10% (2.25 mmol calcium) is given to antagonize the effects of hypermagnesaemia, along with glucose and insulin (as for hyperkalaemia) to lower the plasma magnesium level. Dialysis may be required in patients with severe kidney disease.

DISORDERS OF PHOSPHATE CONCENTRATION

Phosphate forms an essential part of most biochemical systems, from nucleic acids downwards. The regulation of plasma phosphate level is both direct and closely linked to calcium.

About 85% of all body phosphorus is within bone, plasma phosphate normally ranging from 0.80 to 1.15 mmol/L (2.5–3.6 mg/dL) and accounts for only 1% of the total body phosphate. However, plasma phosphate levels correlate in most circumstances with total body sodium. Phosphate reabsorption from the glomerular filtrate occurs entirely and actively in the renal proximal tubule and is hormonally regulated. It is decreased by parathyroid hormone (PTH), mediated by a cyclic AMP-dependent mechanism; thus hyperparathyroidism is associated with low plasma levels of phosphate. Other factors that are known to control phosphate reabsorption in the proximal tubule are 1,25-dihydroxyvitamin D₃, sodium delivery to the proximal tubule, and serum concentrations of calcium, bicarbonate, carbon dioxide tension, glucose, alanine, serotonin, dopamine and sympathetic activity.

Osteoblast-secreted phosphaturic factors (phosphatonin) such as fibroblast growth factor 23 (FGF23), matrix extracellular phosphoglycoprotein (MEPG) and frizzled related protein 4 (FRP-4) play a role in phosphate homeostasis. FGF23 is the most extensively investigated phosphatonin which binds to its receptors FGFR1 in the kidney and causes phosphaturia and also regulates vitamin D by inactivation of 1α-hydroxylase (CYP27B1) and upregulation of 24 hydroxylase (CYP24A1) enzymes with the net result of low 1,25-dihydroxyvitamin D₃ synthesis. Moreover, FGF23 requires Klotho to act as a coreceptor with FGFR1 for its activity. Loss of function mutation in either FGF23 or Klotho results in a similar phenotype of shortened lifespan, premature ageing (p. 652) including hyperphosphataemia and as expected from mode of action increased 1–25 vitamin D levels. Klotho can also inhibit phosphate absorption directly in the absence of FGF23 or PTH.

Phosphate absorption is an active process carried out by a family of sodium-phosphate cotransporters (NPT) in the gut and kidneys. NPT2a and NPT2c are expressed in the brush border of the renal proximal tubule whilst NPT2b is expressed in lungs and intestine. NPT2a plays a central role in the renal reabsorption of phosphate but essentially requires a companion protein called sodium hydrogen exchanger regulatory factor 1 (NHERF1) for membrane sorting. Intestinal absorption is carried out by NPT2b but its mutation does not cause any phosphate abnormalities because of the compensation taking place by the renal expression of NPT2a and possibly NPT2c. Under normal circumstances plasma phosphate levels are kept constant, e.g. after a phosphate-rich meal, the intestinal bone axis releases FGF23 from bone which inhibits NPT2a and causes phosphate excretion. Moreover, phosphate in the plasma either directly or indirectly by lowering ionized calcium causes the release of PTH which also inhibits NPT2a and NHERF1 resulting in phosphaturia (Fig. 13.9). These two principal mechanisms keep plasma phosphate levels within normal limits on a daily basis.

Hypophosphataemia

Significant hypophosphataemia (<0.4 mmol/L or <1.25 mg/dL) occurs in a number of clinical situations, owing to redistribution into cells, to renal losses, or to decreased intake (Table 13.17).

Clinical features include:

- Muscle weakness, e.g. diaphragmatic weakness, decreased cardiac contractility, skeletal muscle rhabdomyolysis
- A left shift in the oxymhaemoglobin dissociation curve (reduced 2,3-bisphosphoglycerate, 2,3-BPG) and rarely haemolysis
- Confusion, hallucinations and convulsions.

Mild hypophosphataemia often resolves without specific treatment. However, diaphragmatic weakness may be severe in acute hypophosphataemia, and may impede weaning a patient from a ventilator. Interestingly, chronic hypophosphataemia (in X-linked hypophosphataemia) is associated with normal muscle power.

Causes

Primary hyperparathyroidism is a common cause of hypophosphataemia. Very rarely, gain of function mutations of PTH1 receptor cause hypophosphataemia and Jansen’s metaphyseal chondrodysplasia due to constitutive activation of PTH signaling even in the presence of low or absent circulating PTH levels.

Hypophosphataemia can be part of osteomalacia and rickets due to vitamin D deficiency either dietary (globally the commonest cause) or genetic and is usually accompanied by hypocalcaemia (calcipenic) and secondary hyperparathyroidism.

Vitamin D-dependent rickets type I

Also known as pseudovitamin D-deficient rickets, this is caused by 1α-hydroxylase deficiency due to inactivating mutations in its gene. It can be corrected with high daily doses of vitamin D. This condition manifests clinically in
the first year of life with severe hypocalcaemia often complicated by tetany, moderate hypophosphataemia and enamel hypoplasia. The characteristic biochemical findings are normal serum levels of 25-hydroxyvitamin D and low values of 1,25-dihydroxyvitamin D and usually relatively high PTH levels. The treatment of choice is replacement therapy with calcitriol.

**Vitamin D-dependent rickets type II**

This is a form of vitamin D resistance and is now known as *hereditary vitamin D-resistant rickets*. It is an autosomal recessive disorder and is usually caused by loss of function mutations in the gene encoding the vitamin D receptor. The clinical manifestations vary widely, depending upon the type of mutation within the vitamin D receptor and the amount of residual vitamin D receptor activity. Affected children usually develop rickets within the first 2 years of life with alopecia in two-thirds of cases which is due to lack of vitamin D receptor action within keratinocytes. The treatment involves a therapeutic trial of calcitriol and calcium supplementation. Long-term infusion of calcium into a central vein is a possible alternative for severely resistant patients. Oral calcium therapy may be sufficient once radiographic healing has been observed.

**Decreased renal reabsorption of phosphate**

**Excessive phosphatohnins (FGF23)**

This condition also occurs in patients with *tumour-induced osteomalacia* (TIO), *X-linked dominant hypophosphataemic rickets* (XLR), and *autosomal-dominant hypophosphataemic rickets* (ADHR). These syndromes have similar biochemical and osseous phenotypes. Patients have osteomalacia or rickets, reduced tubular phosphate reabsorption, hypophosphataemia, normal or low serum calcium, normal PTH and PTH-related protein concentrations, and normal or low 1,25-dihydroxyvitamin D₃. Urinary cyclic AMP levels are generally in the normal range.

In TIO, there is excessive production of phosphaturic agents (which are normally produced by osteoblasts and act as hormones by acting on kidneys and regulating phosphate absorption and vitamin D activation), e.g., fibroblast growth factor 23 (FGF23), matrix extracellular phosphoglycoprotein (MEPG) and frizzled related protein 4 (FRP-4). These cannot be degraded by normal concentrations of PHEX (phosphate regulating gene with homologies to endopeptidases on the Med36 family, member D) proteinuria. This urinary profile is associated with progressive renal fibrosis and more rapid decline in renal function.

In ADHR, FGF-23 is mutated so that it is resistant to PHEX proteolysis. In XLR, mutations in PHEX prevent binding to FGF23 and FRP-4, resulting in a net relative excess of phosphatohnins.

Normal adaptive increases in 1,25-dihydroxyvitamin D₃ synthesis in response to low phosphate levels do not occur in TIO, ADHR and XLR, aggravating phosphaturia (Fig. 13.9).

** Autosomal recessive hypophosphataemia with high FGF23 levels** has been described in patients with mutations in the gene encoding dentin matrix protein 1 (DMP1), which is a transcription factor produced by dental cells, osteoblasts and osteocytes. It is also secreted and can modulate the formation of mineralized matrix.

**Reduced NPT2a/NHERF1 activity**

Mutations in NPT2a (sodium phosphate cotransporter 2a) and NHERF1 (sodium hydrogen regulator factor 1) have been identified in patients with low phosphate levels and reduced ratio of the maximum tubular reabsorption of phosphate (TmP) normalised for GFR (TmP/GFR ratio). Heterozygous loss of function mutation in NPT2a and NHERF1 in patients is characterized by hypophosphataemia, low TmP/GFR and normal PTH. Carriers of these mutations do not have hypocalcaemia, which means these mutation do not affect the action of PTH on bones.

**Dent’s disease**

Dent’s disease is the generally accepted name for a group of hereditary tubular disorders including X-linked recessive nephrolithiasis with renal failure, X-linked recessive hypophosphataemic rickets, and idiopathic low-molecular-weight proteinuria. It is characterized by low-molecular-weight proteinuria, hypercalciuria, hyperphosphaturia, nephrocalcinosis, kidney stones and eventual renal failure, with some patients developing rickets or osteomalacia.

Dent’s disease is caused by loss of function mutation of a proximal tubular endosomal chloride channel, CIC5. This chloride channel, along with the proton pump, is essential for acidification of proximal tubular endosomes. The process is linked with normal endocytosis, degradation and recycling of absorbed proteins, vitamins and hormones. Defective endosomal acidification (owing to the mutated CIC5 gene) results in impaired endosomal degradation and recycling of endocytosed hormones such as PTH with clinical phenotype of hyperparathyroidism. Moreover, the receptors (megalin and cubilin) for reabsorption of low-molecular-weight proteins and albumin in the proximal tubules are decreased in Dent’s disease. This explains low-molecular-weight proteinuria and excessive urinary leaks of cytokines, hormones and chemokines. This urinary profile is associated with progressive renal fibrosis and more rapid decline in renal function.

**Diagnostic approach**

Patients with hypophosphataemia should have their TmP/GFR measured. A value of <0.7 mmol/L indicates renal phosphate wasting. If PTH levels are high then it is very likely to be hyperparathyroidism either primary or secondary to vitamin D deficiency (acquired or genetic) or Dent’s disease. If PTH levels are low then the only possibility is gain of function mutation in PTH1R. If PTH levels are normal then assess FGF23 levels. High FGF23 levels will indicate possible mutated genes in FGF23/Klotho, PHEX and DMP1. Normal FGF23 and PTH levels point to mutations in NPT2a, NPT2c and NHERF1.

**Treatment**

Treatment for hypophosphataemia includes combined therapy with phosphate supplementation and calcitriol (1,25-dihydroxyvitamin D) administration.

**Treatment of acute hypophosphataemia**, if warranted, is with intravenous phosphate at a maximum rate of 9 mmol every 12 hours, with repeated measurements of calcium and phosphate, as over-rapid administration of phosphate may lead to severe hypocalcaemia, particularly in the presence of alkalosis. **Chronic hypophosphataemia** can be corrected, if warranted, with oral effervescent sodium phosphate.

**Hyperphosphataemia**

Hyperphosphataemia is common in patients with CKD (see p. 618 and Table 13.18). Hyperphosphataemia is usually asymptomatic but may result in precipitation of calcium phosphate, particularly in the presence of a normal or raised calcium or of alkalosis. Uraemic itching may be caused by a
blood pH is tightly regulated and is normally maintained at between 7.38 and 7.42. Any deviation from this range indicates a change in the hydrogen ion concentration \([H^+]\) because blood pH is the negative logarithm of \([H^+]\) (Table 13.19). The \([H^+]\) at a physiological blood pH of 7.40 is 40 nmol/L. An increase in the \([H^+]\) – a fall in pH – is termed acidaemia. A decrease in \([H^+]\) – a rise in the blood pH – is termed alkalaemia. The disorders that cause these changes in the blood pH are acidosis and alkalosis, respectively.

**Normal acid–base physiology**

The normal adult diet contains 70–100 mmol of acid. Throughout the body, there are buffers that minimize any changes in blood pH that these ingested hydrogen ions raised calcium phosphate product. Prolonged hyperphosphataemia causes hyperparathyroidism, and periarticular and vascular calcification.

Familial tumoral calcinosis is characterized by calcifications of muscles, skin, eyelids and vessels as well hyperostosis. Absence of glycosylation of FGF23 makes it unstable and more sensitive to proteolysis. This results in its deficiency and hyperphosphataemia due to increased renal phosphate reabsorption through increased NPT2a activity.

Usually, no treatment is required for acute hyperphosphataemia, as the causes are self-limiting. Treatment of chronic hyperphosphataemia is with gut phosphate binders and dialysis (see p. 622).

**ACID–BASE DISORDERS**

The concentration of hydrogen ions in both extracellular and intracellular compartments is extremely tightly controlled, and very small changes lead to major cell dysfunction. The
Renal reabsorption of bicarbonate

The plasma [HCO₃⁻] is normally maintained at approximately 25 mmol/L. In individuals with a normal glomerular filtration rate (120 mL/min), about 4500 mmol of bicarbonate is filtered each day. If this filtered bicarbonate were not reabsorbed, the plasma [HCO₃⁻] would fall, along with blood pH. Thus, maintenance of normal plasma [HCO₃⁻] requires that essentially all of the bicarbonate in the glomerular filtrate be reabsorbed (Fig. 13.10).

The proximal convoluted tubule reclaims 85–90% of filtered bicarbonate; by contrast, the distal nephron reclaims very little. This difference is caused by the greater quantity of luminal (brush border) carbonic anhydrase in the proximal tubule than in the distal nephron. As a result of these quantitative differences, bicarbonate that escapes reabsorption in the proximal tubule is excreted in the urine.

Proximal tubular bicarbonate reabsorption is catalysed by the Na⁺/K⁺-ATPase pump located in the basolateral cell membrane. By exchanging peritubular potassium ions for intracellular sodium ions, the pump keeps the intracellular sodium concentration low, allowing sodium ions to enter the cell by moving down the sodium concentration gradient from the tubule lumen to the cell interior. Hydrogen ions are transported in the opposite direction (at the Na⁺-H⁺ antiporter), thereby maintaining electroneutrality. Before bicarbonate enters the proximal tubule, it combines with secreted hydrogen ions to form carbonic acid. In the presence of luminal carbonic anhydrase (CA-IV), carbonic acid rapidly dissociates into carbon dioxide and water, which can then rapidly enter the proximal tubular cell. In the cell, carbon dioxide is hydrated by cytosolic carbonic anhydrase (CA-II), ultimately forming bicarbonate, which is then transported down an electrical gradient from the cell interior, across the membrane into the peritubular fluid, and into the blood. In this process, each hydrogen ion secreted into the proximal tubular cell is reabsorbed and can be resecreted; there is no net loss of hydrogen ions or net gain of bicarbonate ions.

Renal excretion of [H⁺] (Fig. 13.11)

More acid is secreted into the proximal tubule (up to 4500 nmol of hydrogen ions each day) than into any other nephron segment. However, the hydrogen ions secreted into the proximal tubule are almost completely reabsorbed with bicarbonate; consequently, proximal tubular hydrogen ion secretion does not contribute significantly to hydrogen ion elimination from the body. The excretion of the daily acid load requires hydrogen ion secretion in more distal nephron segments.

Most dietary hydrogen ions come from sulphur-containing amino acids that are metabolized to sulphuric acid (H₂SO₄), which then reacts with sodium bicarbonate as follows:

\[ \text{H}_2\text{SO}_4 + 2\text{NaHCO}_3 \rightarrow \text{Na}_2\text{SO}_4 + 2\text{CO}_2 + 2\text{H}_2\text{O}. \]

Excess sulphate is excreted in the urine, whereas excess hydrogen ions are buffered by bicarbonate and lower the plasma [HCO₃⁻]. This fall in plasma [HCO₃⁻] leads to a slight decrease in the blood pH, although a smaller decrease in the blood pH than would have occurred if buffer were

\[ \text{H}^+ + \text{HCO}_3^- \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}_2\text{O} + \text{CO}_2. \]

In these buffer systems, the dissociation constant of carbonic acid is given by the Henderson–Hasselbalch equation:

\[ \text{pH} = \text{pK}_a + \log\left(\frac{\text{HCO}_3^-}{\text{H}_2\text{CO}_3}\right) \]

where [H⁺] is expressed in mmol/L, \( P_{\text{CO}_2} \) in kPa, and \( \text{pK}_a \) is 6.1. Thus, the bicarbonate used in the buffering process must be regenerated to maintain normal acid–base balance.

Although the acidaemia stimulates an increase in ventilation, which blunts this change in pH, increased ventilation does not regenerate the bicarbonate used in the buffering process. Consequently, the kidney must excrete hydrogen ions to return the plasma [HCO₃⁻] to normal. Maintenance of normal plasma [HCO₃⁻] under physiological conditions depends not only on daily regeneration of bicarbonate but also on reabsorption of all bicarbonate filtered across the glomerular capillaries.

Acid–base disorders

Figure 13.10 Resorption of sodium bicarbonate in the renal (mainly proximal) tubule. Bicarbonate is reabsorbed by the secretion of H⁺ in exchange for Na⁺ in the proximal tubule, and then converted back to H₂CO₃, which dissociates into H⁺ and HCO₃⁻. This net result is reabsorption of Na⁺ and HCO₃⁻, which is dependent on carbonic anhydrase within the cells and on the luminal surface of the tubular cell.

\[ \text{H}^+ + \text{HCO}_3^- \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}_2\text{O} + \text{CO}_2. \]
Renal excretion of H\(^+\): Secretion of H\(^+\) from the cortical collecting ducts is indirectly linked to Na\(^+\) reabsorption. Intracellular potassium is exchanged for sodium in the principal cell. Aldosterone stimulates H\(^+\) secretion by entering the principal cell, where it opens Na\(^+\) channels in the luminal membrane and increases Na\(^+\)-K\(^+\)-ATPase activity. The movement of cationic Na\(^+\) into the principal cells then creates a negative charge within the tubule lumen. K\(^+\) moves from the electrochemical gradient and into the lumen. Aldosterone also stimulates the H\(^+\)-ATPase directly in the intercalated cell, further enhancing H\(^+\) secretion. When the urinary pH falls to 4.0–4.5, further H\(^+\) secretion by the α-intercalated cells ceases. The filtration of titratable acids (e.g., phosphoric acid, H\(_2\)PO\(_4\)) raises the intraluminal pH and permits this process to continue. Secreted H\(^+\) binds to the conjugate anion of a titratable acid (HPO\(_4^{2-}\) in this case) and is excreted in the urine. The H\(^+\) to be secreted arises from the reassociation of H\(_2\)O and CO\(_2\) in the presence of carbonic anhydrase; thus, a bicarbonate ion is regenerated each time an H\(^+\) is eliminated in the urine.

Figure 13.11

Buffer systems in acid excretion

Two buffer systems are involved in acid excretion: the titratable acids such as phosphate and the ammonia system. Each system is responsible for excreting about half of the daily acid load of 50–100 mmol under physiological conditions (Fig. 13.11).

Titratable acid

A titratable acid is a filtered buffer substance having a conjugate anion that can be titrated within the pH range occurring physiologically in the urine. Phosphoric acid (pK\(_a\) 6.8) is the usual titratable urinary buffer. Hydrogen ions bind to the conjugate anions of the titratable acids and are excreted in the urine. For each hydrogen ion excreted in this form, a bicarbonate ion is regenerated within the cell and returned to the blood (Fig. 13.11).

Ammonium (NH\(_4^{+}\))

In the setting of metabolic acidosis, titratable acids cannot increase significantly because the availability of titratable acid is fixed by the plasma concentration of the buffer and by the GFR. The ammonia buffer system, by contrast, can increase several hundred-fold when necessary. Consequently, impaired renal excretion of hydrogen ions is always associated with a defect in ammonium excretion (Fig. 13.12).

All ammonia used to buffer urinary hydrogen ions in the collecting tubule is synthesized in the proximal convoluted tubule. Glutamine is the primary source of ammonia. It undergoes deamination catalysed by glutaminase, resulting in α-ketoglutaric acid (Fig. 13.12) and ammonia. Once formed, ammonia can diffuse into the proximal tubule lumen and become acidified, forming ammonium. Once in the proximal tubule lumen, ammonium flows along the tubule to the thick ascending limb of Henle’s loop. Here, it is transported out of the tubule into the medullary interstitium. Ammonium then dissociates to ammonia, leading to a high interstitial ammonia concentration. The notion that ammonia diffuses down its concentration gradient into the lumen of the collecting tubule
Acid–base disorders

Figure 13.12 The ammonia buffering system in the kidney. All ammonia used to buffer H+ in the collecting duct is synthesized in the proximal convoluted tubule, and glutamine is the main source of this ammonia. As glutamine is metabolized, α-ketoglutarate (α-KG) is formed, which ultimately breaks down to bicarbonate that is then secreted into the peritubular fluid at an Na+-HCO3− cotransporter.

Figure 13.13 The Flenley acid–base nomogram. This was derived from a large number of observations in patients with ‘pure’ respiratory or metabolic disturbances. The bands show the 95% confidence limits representing the individual varieties of acid–base disturbance. The central white box shows the approximate limits of arterial pH and PCO2 in normal individuals.

Diagnosis

Clinical history and examination usually point to the correct diagnosis. Table 13.20 shows the typical blood changes, but in complicated patients the acid–base nomogram (Fig. 13.13) is invaluable. The [H+] and P_aCO2 are measured in arterial blood (for precautions see p. 659) as well as the bicarbonate. If the values from a patient lie in one of the bands in the diagram, it is likely that only one abnormality is present. If the [H+] is high (pH low) but the P_aCO2 is normal, the intercept lies between two bands: the patient has respiratory dysfunction, leading to failure of CO2 elimination, but this is partly compensated for by metabolic acidosis, stimulating respiration and CO2 removal (this is the most common ‘combined’ abnormality in practice).

Respiratory acidosis and alkalosis

Respiratory acidosis

This is caused by retention of CO2. The P_aCO2 and [H+] rise. Renal retention of bicarbonate may partly compensate, returning the [H+] towards normal (see p. 876).
Respiratory alkalosis
Increased removal of CO₂ is caused by hyperventilation, so there is a fall in PₕCO₂ and [H⁺] (see p. 876).

Metabolic acidosis
This is due to the accumulation of any acid other than carbonic acid, and there is a primary decrease in plasma [HCO₃⁻]. Several disorders can lead to metabolic acidosis: acid administration, acid generation (e.g. lactic acidosis during shock or cardiac arrest), impaired acid excretion by the kidneys, or bicarbonate losses from the gastrointestinal tract or kidneys. Calculation of the plasma anion gap is extremely useful in narrowing this differential diagnosis.

The anion gap
The first step is to identify whether the acidosis is due to retention of H⁺Cl⁻ or to another acid. This is achieved by calculation of the anion gap.
- The normal cations present in plasma are Na⁺, K⁺, Ca²⁺, Mg²⁺.
- The normal anions present in plasma are Cl⁻, HCO₃⁻, negative charges present on albumin, phosphate, sulphate, lactate, and other organic acids.
- The sums of the positive and negative charges are equal.
- Measurement of plasma [Na⁺], [K⁺], [Cl⁻] and [HCO₃⁻] is usually easily available.

\[ \text{ANION GAP} = ([Na⁺] + [K⁺]) - ([HCO₃⁻] + [Cl⁻]) \]

Because there are more unmeasured anions than cations, the normal anion gap is 10–18 mmol/L, although calculations with more sensitive methods place this at 6–12 mmol/L. Albumin normally makes up the largest portion of these unmeasured anions. As a result, a fall in the plasma albumin concentration from the normal value of about 40 g/L to 20 g/L may reduce the anion gap by as much as 6 mmol/L, because each 1 g/L of albumin has a negative charge of 0.2–0.28 mmol/L.

Metabolic acidosis with a normal anion gap
If the anion gap is normal in the presence of acidosis, this suggests that H⁺Cl⁻ is being retained or that Na⁺HCO₃⁻ is being lost. Causes of a normal-anion-gap acidosis are given in Table 13.21. In these conditions, plasma bicarbonate decreases and is replaced by chloride to maintain electroneutrality. Consequently, these disorders are sometimes referred to collectively as hyperchloraemic acidoses.

Renal tubular acidosis (RTA)
This term refers to systemic acidosis caused by impairment of the ability of the renal tubules to maintain acid-base balance. This group of disorders is uncommon and only rarely a cause of significant clinical disease.

Type 4 renal tubular acidosis
Also called ‘hyporeninaemic hypoaldosteronism’, this is probably the most common of these disorders. The cardinal features are hyperkalaemia and acidosis occurring in a patient with mild chronic kidney disease, usually caused by tubulo-interstitial disease (e.g. reflux nephropathy) or diabetes. Gordon’s syndrome (see p. 655) shares biochemical abnormalities but differs in having normal GFR and hypertension. Plasma renin and aldosterone are found to be low, even after measures which would normally stimulate their secretion. The features for the diagnosis are shown in Table 13.22. An identical syndrome is caused by chronic ingestion of NSAIDs, which impair renin and aldosterone secretion. In the presence of acidosis, urine pH may be low. Treatment is with fludrocortisone, sodium bicarbonate, diuretics, or ion exchange resins to remove potassium, or a combination of these. Dietary potassium restriction alone is ineffective.

Type 3 renal tubular acidosis (RTA)
This condition is vanishingly rare, and represents a combination of type 1 and type 2. Inherited type 3 RTA is caused by mutations resulting in carbonic anhydrase type II deficiency, which is characterized by osteopetrosis, RTA of mixed type, cerebral calcification, and mental retardation.

Type 2 (‘proximal’) renal tubular acidosis
This is very rare in adult practice. It is caused by failure of sodium bicarbonate reabsorption in the proximal tubule. The cardinal features are acidosis, hypokalaemia, an inability to lower the urine pH below 5.5 despite systemic acidosis, and the appearance of bicarbonate in the urine despite a subnormal plasma bicarbonate. This disorder normally occurs as part of a generalized tubular defect, together with other features such as glycosuria and amino-aciduria. Inherited forms of isolated type 2 RTA are described as both autosomal dominant and recessive patterns of inheritance, where putative mutations are in the Na⁺HCO₃⁻ cotransporter in the basolateral membrane of proximal tubular cells respectively (see Fig. 13.10). Treatment is with sodium bicarbonate: massive doses may be required to overcome the renal ‘leak’.

**Practical Box 13.1**

Diagnosis of renal tubular acidosis

Type 1 (‘distal’) renal tubular acidosis

This is due to a failure of H⁺ excretion in the distal tubule (Table 13.23). It consists of:

- Acidosis
- Hypokalaemia (few exceptions)
- Inability to lower the urine pH below 5.3 despite systemic acidosis
- Low urinary ammonium production.

These features may be present only in the face of increased acid production; hence the need for an acid load test in diagnosis (Practical Box 13.1). Other features include:

- Low urinary citrate (owing to increased citrate absorption in the proximal tubule where it can be converted to bicarbonate)
- Hypercalciuria.

These abnormalities result in osteomalacia, renal stone formation and recurrent urinary infections. Osteomalacia is caused by buffering of H⁺ by Ca²⁺ in bone, resulting in depletion of calcium from bone. Renal stone formation is caused by hypercalciuria, hypocitraturia (citrate inhibits calcium phosphate precipitation), and alkaline urine (which favours precipitation of calcium phosphate). Recurrent urinary infections are caused by renal stones.

Both autosomal dominant and recessive inheritance patterns have been reported in primary distal RTA. In the autosomal recessive distal RTA, a substantial proportion of patients have sensorineural deafness, and this is associated with a loss of function mutation in the H⁺-ATPase at the apical surface of intercalated cells.

**Treatment** is with sodium bicarbonate, potassium supplements and citrate. Thiazide diuretics are useful by causing volume contraction and increased proximal sodium bicarbonate reabsorption.

**Urinary anion gap**

Another useful tool in the evaluation of metabolic acidosis with a normal anion gap is the urinary anion gap:

$$\text{URINARY ANION GAP} = \left[ \frac{\text{urinary [Na}^+\text{] + urinary [K}^+\text{]} - \text{urinary [Cl}^-\text{]}}{2} \right]$$

This calculation can be used to distinguish the normal anion-gap acidosis caused by diarrhoea (or other gastrointestinal alkalai loss) from that caused by distal renal tubular acidosis. In both disorders, the plasma [K⁺] is characteristically low. In patients with renal tubular acidosis, urinary pH is always greater than 5.3.

Although excretion of urinary hydrogen ions in the patient with diarrhoea should acidify the urine, hypokalaemia leads to enhanced ammonia synthesis by the proximal tubular cells. Despite acidemia, the excess urinary buffer increases the urine pH to a value above 5.3 in some patients with diarrhoea.

Whenever urinary acid is excreted as ammonium chloride, the increase in urinary chloride excretion decreases the urinary anion gap. Thus, the urinary anion gap should be negative in the patient with diarrhoea, regardless of the urine pH. On the other hand, although hypokalaemia may result in enhanced proximal tubular ammonia synthesis in distal renal tubular acidosis, the inability to secrete hydrogen ions into the collecting duct in this condition limits ammonium chloride formation and excretion; thus, the urinary anion gap is positive in distal renal tubular acidosis.

**Metabolic acidosis with a high anion gap**

If the anion gap is increased, there is an unmeasured anion present in increased quantities. This is either one of the acids normally present in small, but unmeasured quantities, such as lactate, or an exogenous acid. Causes of a high-anion-gap acidosis are given in Table 13.24.

**Uraemic acidosis**

Kidney disease causes acidosis in several ways. Reduction in the number of functioning nephrons decreases the capacity to excrete ammonia and H⁺ in the urine. In addition, tubular disease may cause bicarbonate wasting. Acidosis is a particular feature of those types of CKD in which the tubules are particularly affected, such as reflux nephropathy and chronic obstructive uropathy.

**Chronic acidosis** is most often caused by chronic kidney disease, where there is a failure to excrete fixed acid. Up to 40 mmol of hydrogen ions may accumulate daily. These are buffered by bone, in exchange for calcium. Chronic acidosis is therefore a major risk factor for renal osteodystrophy and hypercalciuria.

Chronic acidosis has also been shown to be a risk factor for muscle wasting in renal failure, and may also contribute to the inexorable progression of some types of renal disease.

Uraemic acidosis should be corrected because of these effects on growth, muscle turnover and bones. Oral sodium bicarbonate 2–3 mmol/kg daily is usually enough to maintain serum bicarbonate above 20 mmol/L, but may contribute to sodium overload. Calcium carbonate improves acidosis and
Lactic acidosis
Increased lactic acid production occurs when cellular respiration is abnormal, because of either a lack of oxygen in the tissues (‘type A’) or a metabolic abnormality, such as drug-induced (‘type B’) (Table 13.24). The most common cause in clinical practice is type A lactic acidosis, occurring in septic or cardiogenic shock. Significant acidosis can occur despite a normal blood pressure and PaCO₂, owing to splanchnic and peripheral vasoconstriction. Acidosis worsens cardiac function and vasoconstriction further, contributing to a downward spiral and fulminant production of lactic acid.

Diabetic ketoacidosis (see p. 1017)
There is a high-anion-gap acidosis due to the accumulation of acetoacetic and hydroxybutyric acids, owing to increased production and some reduced peripheral utilization.

Mixed metabolic acidosis
Both types of acidosis can co-exist. For instance, cholera would be expected to cause a normal-anion-gap acidosis owing to massive gastrointestinal losses of bicarbonate, but the anion gap is often increased owing to renal failure and lactic acidosis as a result of hypovolaemia.

Clinical features
Clinically, the most obvious effect is stimulation of respiration, leading to the clinical sign of ‘air hunger’, or Kussmaul respiration. Interestingly, patients with profound hyperventilation may not complain of breathlessness, although in others it may be a presenting complaint.

Acidosis increases delivery of oxygen to the tissues by shifting the oxyhaemoglobin dissociation curve to the right, but it also leads to inhibition of 2,3-BPG production, which returns the curve towards normal (see p. 870). Cardiovascular dysfunction is common in acidic patients, although it is often difficult to dissociate the numerous possible causes of this. Acidosis is negatively inotropic. Severe acidosis also causes vasoconstriction, resulting in redistribution of blood from the peripheries to the central circulation, and increased systemic venous pressure, which may worsen pulmonary oedema caused by myocardial depression. Arteriolar vasodilatation also occurs, further contributing to hypotension.

Cerebral dysfunction is variable. Severe acidosis is often associated with confusion and fits, but numerous other possible causes are usually present.

As mentioned earlier, acidosis stimulates potassium loss from cells, which may lead to potassium deficiency if renal function is normal, or to hyperkalaemia if renal potassium excretion is impaired.

General treatment of acidosis
Treatment should be aimed at correcting the primary cause. In lactic acidosis caused by poor tissue perfusion (‘type A’), treatment should be aimed at maximizing oxygen delivery to the tissues by protecting the airway, improving breathing and circulation. This usually requires inotropic agents, mechanical ventilation and invasive monitoring. In ‘type B’ lactic acidosis, treatment is that of the underlying disorder; e.g.:

- Insulin in diabetic ketoacidosis
- Treatment of methanol and ethylene glycol poisoning with ethanol
- Removal of salicylate by dialysis.

The question of whether severe acidosis should be treated with bicarbonate is extremely controversial:

- Rapid correction of acidosis may result in tetany and fits owing to a rapid decrease in ionized calcium.
- Administration of sodium bicarbonate (8.4%) provides 1 mmol/mL of sodium, which may lead to extracellular volume expansion, exacerbating pulmonary oedema.
- Bicarbonate therapy increases CO₂ production and will therefore correct acidosis only if ventilation can be increased to remove the added CO₂ load.
- The increased amounts of CO₂ generated may diffuse more readily into cells than bicarbonate, worsening intracellular acidosis.

Administration of sodium bicarbonate (50 mmol, as 50 mL of 8.4% sodium bicarbonate intravenously) is still occasionally given during cardiac arrest and is often necessary before arrhythmias can be corrected. Correction of hyperkalaemia associated with acidosis is also of undoubted benefit. In other situations there is no clinical evidence to show that correction of acidosis improves outcome, but it is standard practice to administer sodium bicarbonate when [H⁺] is above 126 mmol/L (pH <6.9), using intravenous 1.26% (150 mmol/L) bicarbonate infused over 2–3 h with electrolyte and pH monitoring. Intravenous sodium lactate should never be given.

Metabolic alkalosis
Metabolic alkalosis is common, comprising half of all the acid–base disorders in hospitalized patients. This observation should not be surprising since vomiting, the use of diuretics, and nasogastric suction are common among hospitalized patients. The mortality associated with metabolic alkalosis is substantial; the mortality rate is 45% in patients with an arterial pH of 7.55 and 80% when the pH is >7.65. Although this relationship is not necessarily causal, severe alkalosis should be viewed with concern.

Classification and definitions
Metabolic alkalosis has been classified on the basis of underlying pathophysiology (Table 13.25).

Water, electrolytes and acid-base balance

The most common group is due to chloride depletion which can be corrected without potassium repletion. The other major grouping is that due to potassium depletion, usually with mineralocorticoid excess. Metabolic alkalosis due to both potassium and chloride depletion also occurs. Chloride may be lost from the gut, kidney or skin. The loss of gastric fluid rich in acid results in alkalosis because bicarbonate generated during the production of gastric acid returns to the circulation. In Zollinger–Ellison syndrome (see p. 370) or gastric outflow obstruction these losses can be massive. Although sodium and potassium loss in the gastric juice is variable, the obligate urinary loss of these cations is intensified by bicarbonaturia, which occurs during disequilibrium.

Chloruretic agents all directly produce loss of chloride, sodium and fluid in the urine. These losses in turn promote metabolic alkalosis by several mechanisms:

- Diuretic-induced increases in sodium delivery to the distal nephron enhance potassium and hydrogen ion secretion
- Extracellular volume contraction stimulates renin and aldosterone secretion, which blunts sodium losses but accelerates potassium and hydrogen ion secretion
- Potassium depletion augments bicarbonate reabsorption in the proximal tubule and
- Stimulates ammonia production which in turn will increase urinary net acid excretion.

Urinary losses of chloride exceed those for sodium and are associated with alkalosis even when potassium depletion is prevented. The cessation of events that generate alkalosis is not necessarily accompanied by resolution of the alkalosis. A widely accepted hypothesis for the maintenance of alkalosis is chloride depletion rather than volume depletion. Although normal functioning of the proximal tubule is essential for bicarbonate absorption, the collecting duct appears to be the major nephron site for altered electrolyte and proton transport in both maintenance and recovery from metabolic alkalosis. During maintenance, the α-intercalated cells in the cortical collecting duct do not secrete bicarbonate because insufficient chloride is available for bicarbonate exchange. When chloride is administered and luminal or cellular chloride concentration increases, bicarbonate is promptly excreted and alkalosis is corrected.

Metabolic alkalosis in hypokalaemia is generated primarily by an increased intracellular shift of hydrogen ion causing intracellular acidosis. Potassium depletion is also associated with enhanced ammonia production with increased obligated net acid excretion. However, the role of intracellular acidosis is supported by the correction of the alkalosis by infusion of potassium without any suppression of renal net excretion. The correction is assumed to occur by the movement of potassium into and hydrogen ion out of the cell, which titrates extracellular fluid bicarbonate.

Milk-alkali syndrome in which both bicarbonate and calcium are ingested produces alkalosis by vomiting, calcium-induced bicarbonate absorption and reduced GFR. Cationic antibiotics in high doses can cause alkalosis by obligatory bicarbonate loss in the urine.

### Clinical features

The symptoms of metabolic alkalosis per se are difficult to separate from those of chloride, volume or potassium depletion. Tetany (see p. 997), apathy, confusion, drowsiness, cardiac arrhythmias and neuromuscular irritability are common when alkalosis is severe. The oxyhaemoglobin dissociation curve is shifted to the left. Respiration may be depressed.

### Treatment

**Chloride-responsive metabolic alkalosis**

Although replacement of the chloride deficit is essential in chloride depletion states, selection of the accompanying cation – sodium, potassium or proton – is dependent on the assessment of extracellular fluid volume status (see p. 646), the presence or absence of associated potassium depletion, and the degree and reversibility of any depression of GFR. If kidney function is normal, bicarbonate and base equivalents will be excreted with sodium or potassium, and metabolic alkalosis will be rapidly corrected as chloride is made available.

If chloride and extracellular depletion co-exist then isotonic saline solution is appropriate therapy.

In the clinical settings of fluid overload, saline is contraindicated. In such situations, intravenous use of hydrochloride acid or ammonium chloride can be given. If GFR is adequate, acetazolamide, which causes bicarbonate diuresis by inhibiting carbonic anhydrase, can also be used. When the kidney is incapable of responding to chloride repletion, dialysis is necessary.

**Chloride-resistant metabolic alkalosis**

Metabolic alkalosis due to potassium depletion is managed by the correction of the underlying cause (see hypokalaemia). Mild to moderate alkalosis requires oral potassium chloride administration. However, the presence of cardiac arrhythmia or generalized weakness requires intravenous potassium chloride.

Note: The table and text are from a textbook on medical physiology. The table lists causes of metabolic alkalosis, and the text discusses the mechanisms and treatments for these conditions.
BIBLIOGRAPHY
ESSENTIAL ANATOMY, PHYSIOLOGY AND EMBRYOLOGY OF THE HEART

Introduction
Myocardial cells constitute 75% of the heart mass but only about 25% of the cell number. They are designed to perform two fundamental functions: initiation and conduction of electrical impulses and contraction. Although most myocardial cells are able to perform both these functions, the vast majority are predominantly contractile cells (myocytes) and a small number are specifically designed as electrical cells. The latter, collectively known as the conducting system of the heart, are not nervous tissue but modified myocytes lacking myofibril components. They have the ability to generate electrical impulses which are then conducted to the myocytes, leading to contraction by a process known as excitation-contraction coupling. The rate of electrical impulse generation and the force of myocardial contraction are modified by numerous factors including autonomic input and stretch.

Three epicardial coronary arteries supply blood to the myocardium, and a more complex network of veins is responsible for drainage. In the face of continuous arterial pressure fluctuations, blood vessels, especially in the cerebral circulation, maintain constant tissue perfusion by a process known as ‘autoregulation’; blood vessel control is, however, complex involving additional local and central mechanisms.

The conduction system of the heart

The sinus node
The sinus node is a complex spindle-shaped structure that lies in the lateral and epicardial aspects of the junction between the superior vena cava and the right atrium (Fig. 14.1). Physiologically, it generates impulses automatically by spontaneous depolarization of its membrane at a rate quicker than any other cardiac cell type. It is therefore the natural pacemaker of the heart.

A number of factors are responsible for the spontaneous decay of the sinus node cell membrane potential (‘the pacemaker potential’), the most significant of which is a small influx of sodium ions into the cells. This small sodium current
Cardiovascular disease

14

670

fast, self-inactivating sodium channels, resulting in a sharp depolarization spike. This is followed by a partial repolarization of the membrane due to activation of ‘transient outward’ potassium channels. The plateau phase which follows is unique to myocytes and results from a small, but sustained inward calcium current through L-type calcium channels ($I_{CaL}$) lasting 200–400 ms. This calcium influx is caused by a combined increase in permeability of the cell, especially the sarcolemmal membranes to calcium (Fig. 14.3). This plateau (or refractory) phase in myocyte action potential prevents early reactivation of the myocytes and directly determines the strength of contraction. The gradual inactivation of the calcium channels activates delayed rectifier potassium channels ($I_K$) repolarizing the membrane.

Atrial and ventricular myocyte action potentials

Action potentials in the sinus node trigger depolarization of the atrial and subsequently the ventricular myocytes. These cells have a different action potential from that of sinus node cells (Fig. 14.2). Their resting membrane potential is a consequence of a small flow of potassium into the cells through open ‘inward rectifier’ channels ($I_{K1}$); at this stage sodium and calcium channels are closed. The arrival of adjacent action potentials triggers the opening of voltage-gated,
The atrioventricular node, His bundle and Purkinje fibres

The depolarization continues to conduct slowly through the atrioventricular (AV) node. This is a small, bean-shaped structure that lies beneath the right atrial endocardium within the lower interatrial septum. The AV node continues as the His bundle, which penetrates the annulus fibrosus and conducts the cardiac impulse rapidly towards the ventricle. The His bundle reaches the crest of the interventricular septum and divides into the right bundle branch and the main left bundle branch.

The right bundle branch continues down the right side of the interventricular septum to the apex, from where it radiates and divides to form the Purkinje network, which spreads throughout the subendocardial surface of the right ventricle. The main left bundle branch is a short structure, which fans out into many strands on the left side of the interventricular septum. These strands can be grouped into an anterior superior division (the anterior hemi-bundle) and a posterior inferior division (the posterior hemi-bundle). The anterior hemi-bundle supplies the subendocardial Purkinje network of the anterior and superior surfaces of the left ventricle, and the inferior hemi-bundle supplies the inferior and posterior surfaces. Impulse conduction through the AV node is slow and depends on action potentials largely produced by slow transmembrane calcium flux. In the atria, ventricles and His-Purkinje system, conduction is rapid and is due to action potentials generated by rapid transmembrane sodium diffusion.

The cellular basis of myocardial contraction – excitation-contraction coupling

Each myocyte, approximately 100 μm long, branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction to adjacent cells. Myocytes contain bundles of parallel myofibrils. Each myofibril is made up of a series of sarcomeres (Fig. 14.4). A sarcomere (which is the basic unit of contraction) is bound by two transverse Z lines, to each of which is attached a perpendicular filament of the protein actin. The actin filaments from each of the two Z bands overlap with thicker parallel protein filaments known as myosin. Actin and myosin filaments are attached to each other by cross-bridges that contain ATPase, which breaks down adenosine triphosphate (ATP) to provide the energy for contraction.

Two chains of actin molecules form a helical structure, with another molecule, tropomyosin, in the grooves of the actin helix, and a further molecule, troponin, is attached to every seven actin molecules. During cardiac contraction the length of the actin and myosin monofilaments does not change. Rather, the actin filaments slide between the myosin filaments when ATPase splits a high-energy bond of ATP. To supply the ATP, the myocyte (which cannot stop for a rest) has a very high mitochondrial density (35% of the cell volume). As calcium ions bind to troponin C, the activity of troponin I is inhibited, which induces a conformational change in tropomyosin. This event unlocks the active site between actin and myosin, enabling contraction to proceed.

Calcium is made available during the plateau phase of the action potential by calcium ions entering the cell and being mobilized from the sarcoplasmic reticulum through the ryanodine receptor (RyR2) calcium-release channel. RyR2 activity is regulated by the protein calstabin 2 (see p. 770) and nitric oxide. The force of cardiac muscle contraction (‘inotropic state’) is thus regulated by the influx of calcium ions into the cell through calcium channels (Fig. 14.3). T (transient) calcium channels open when the muscle is more depolarized, whereas L (long-lasting) calcium channels require less depolarization. The extent to which the sarcomere can shorten determines the stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or severe exercise.

Starling’s law of the heart

The contractile function of an isolated strip of cardiac tissue can be described by the relationship between the velocity of muscle contraction, the load that is moved by the contracting muscle, and the extent to which the muscle is stretched before contracting. As with all other types of muscle, the velocity of contraction of myocardial tissue is reduced by increasing the load against which the tissue must contract. However, in the non-failing heart, pre-stretching of cardiac muscle improves the relationship between the force and velocity of contraction (Fig. 14.5).

This phenomenon was described in the intact heart as an increase of stroke volume (ventricular performance) with an enlargement of the diastolic volume (preload), and is known as the Starling phenomenon.
as ‘Starling’s law of the heart’ or the ‘Frank-Starling relationship’. It has been transcribed into more clinically relevant indices. Thus, stroke work (aortic pressure × stroke volume) is increased as ventricular end-diastolic volume is raised. Alternatively, within certain limits, cardiac output rises as pulmonary capillary wedge pressure increases. This clinical relationship is described by the ventricular function curve (Fig. 14.5), which also shows the effect of sympathetic stimulation.

Nerve supply of the myocardium

Adrenergic nerves supply atrial and ventricular muscle fibres as well as the conduction system, β1-adrenergic receptors predominate in the heart with both epinephrine (adrenaline) and norepinephrine (noradrenaline) having positive inotropic and chronotropic effects. Cholinergic nerves from the vagus supply mainly the SA and AV nodes via M2 muscarinic receptors. The ventricular myocardium is sparsely innervated by the vagus. Under basal conditions, vagal inhibitory effects predominate over the sympathetic excitatory effects, resulting in a slow heart rate.

Adrenergic stimulation and cellular signalling

β1-Adrenergic stimulation enhances Ca2+ flux in the myocyte and thereby strengthens the force of contraction (Fig. 14.3). Binding of catecholamines, e.g. norepinephrine (noradrenaline), to the myocyte β1-adrenergic receptor stimulates membrane-bound adenylyl cyclase. These enzymes enhance production of cyclic adenosine monophosphate (cAMP) that activates intracellular protein kinases, which in turn phosphorylate cellular proteins, including L-type calcium channels within the cell membrane. β1-Adrenergic stimulation of the myocyte also enhances myocyte relaxation.

The return of calcium from the cytosol to the sarcoplasmic reticulum (SR) is regulated by phospholamban (PL), a low-molecular-weight protein in the SR membrane. In its dephosphorylated state, PL inhibits Ca2+ uptake by the SR ATPase pump (Fig. 14.3). However, β1-adrenergic activation of protein kinase phosphorylates PL, and blunts its inhibitory effect. The subsequently greater uptake of Ca2+ ions by the SR hastens Ca2+ removal from the cytosol and promotes myocyte relaxation.

The increased cAMP activity also results in phosphorylation of troponin I, an action that inhibits actin-myosin interaction, and further enhances myocyte relaxation.

The cardiac cycle

The cardiac cycle (Fig. 14.6) consists of precisely timed rhythmic electrical and mechanical events that propel blood into the systemic and pulmonary circulations. The first event in the cardiac cycle is atrial depolarization (a P wave on the surface ECG) followed by right atrial and then left atrial contraction. Ventricular activation (the QRS complex on the ECG) follows after a short interval (the PR interval). Left ventricular contraction starts and shortly thereafter right ventricular contraction begins. The increased ventricular pressures exceed the atrial pressures, and close first the mitral and then the tricuspid valves.

Until the aortic and pulmonary valves open, the ventricles contract with no change of volume (isovolumetric contraction). When ventricular pressures rise above the aortic and pulmonary artery pressures, the pulmonary valve and then the aortic valve open and ventricular ejection occurs. As the ventricles begin to relax, their pressures fall below the aortic and pulmonary arterial pressures, and aortic valve closure is followed by pulmonary valve closure.

Isovolumetric relaxation then occurs. After the ventricular pressures have fallen below the right atrial and left atrial pressures, the tricuspid and mitral valves open. The cardiac cycle can be graphically depicted as the relationship between the pressure and volume of the ventricle. This is shown in Figure 14.7, which illustrates the changing pressure-volume relationships in response to increased contractility and to exercise.

The coronary circulation

The coronary arterial system (Fig. 14.8) consists of the right and left coronary arteries. These arteries branch from the aorta, arising immediately above two cusps of the aortic valve. These arteries are unique in that they fill during diastole, when not occluded by valve cusps and when not squeezed by myocardial contraction. The right coronary artery arises from the right coronary sinus and courses through the right side of the AV groove, giving off vessels

Blood vessel control and functions of the vascular endothelium

In functional terms, the tunica intima with the vascular endothelium and the smooth-muscle-cell-containing tunica media are the main constituents of blood vessels. These two structures are closely interlinked by a variety of mechanisms to regulate vascular tone. The central control of blood vessels is achieved via the neuroendocrine system. Sympathetic vasoconstrictor and parasympathetic vasodilator nerves regulate vascular tone in response to daily activity. Where neural control is impaired, or in various pathological states, e.g. haemorrhage, endocrine control of blood vessels mediated through epinephrine (adrenaline), angiotensin and vasopressin takes over.

At a local level, tissue perfusion is maintained automatically and by the effect of various factors synthesized and/or released in the immediate vicinity. In the face of fluctuating arterial pressures, blood vessels vasoconstrict independently of nervous input when blood pressure drops and vice versa. This process of autoregulation is a consequence of:

- The Bayliss myogenic response – the ability of blood vessels to constrict when distended
- The vasodilator washout effect – the vasoconstriction triggered by a decrease in the concentration of tissue metabolites.

The vascular endothelium is a cardiovascular endocrine organ, which occupies a strategic interface between blood and other tissues. It produces various compounds (e.g. nitric oxide (NO), prostacyclin (PGI₂), endothelin, endothelial-derived hyperpolarizing factor (ERHF), adhesion molecules, vascular endothelial growth factor (VEGF)) and has enzymes located on the surface controlling the levels of circulating compounds such as angiotensin, bradykinin and serotonin. It has many regulatory roles:

Vasomotor control

Nitric oxide is a diffusible gas with a very short half-life, produced in endothelial cells from the amino acid L-arginine
via the action of the enzyme NO synthase (NOS), which is controlled by cytoplasmic calcium/calmodulin (Fig. 14.9). It is produced in response to various stimuli (Table 14.1), triggering vascular smooth muscle relaxation through activation of guanylate cyclase, leading to an increase in the intracellular levels of cyclic 3,5-guanine monophosphate (cGMP). Its cardiovascular effects protect against atherosclerosis, high blood pressure, heart failure and thrombosis. NO is also the neurotransmitter in various ‘nitrergic’ nerves in the central and peripheral nervous systems and may play a role in the central regulation of vascular tone. The class of drugs used to treat erectile dysfunction, the phosphodiesterase (PDE5) inhibitors, prevent the breakdown of cGMP and promote vasodilatation.

PGI₂ is synergistic to NO and also plays a role in the local regulation of vasomotor tone.

Endothelin is a 21-amino-acid peptide that counteracts the effects of NO. Its production is inhibited by shear stress, i.e. the stress exerted on the vessel wall by the flowing blood, and it causes profound vasoconstriction and vascular smooth muscle hypertrophy. It is thought to play a role in the genesis of hypertension and atheroma.

Angiotensin-converting enzyme located on the endothelial cell membrane converts circulating angiotensin I (synthesized by the action of renin on angiotensinogen) to angiotensin II which has vasoconstrictor properties and leads to aldosterone release (Fig. 12.5). Aldosterone promotes sodium absorption from the kidney and together with the angiotensin-induced vasoconstriction provides haemodynamic stability.

Other factors which influence vasomotor tone include histamine (released by mast cells), bradykinin (synthesized from kininogen by the action of coagulation factor Xlla) and serotonin released by platelets.

Anti- and pro-thrombotic mechanisms
PGI₂, produced from arachidonic acid in the endothelial cell membrane by the action of the enzyme cyclo-oxygenase, inhibits platelet aggregation. Low-dose aspirin prevents activation of the cyclo-oxygenase pathway in platelets but only to a degree that does not affect PGI₂ synthesis, unlike higher doses. Other antithrombotic agents such as clopidogrel (ADP receptor antagonist) and glycoprotein IIb/IIIa inhibitors achieve their effects by acting directly on platelet receptors. The antithrombotic effect of PGI₂ is aided by NO, affecting platelets via activation of guanylate cyclase. The endothelial cell membrane also produces other anticoagulant molecules such as thrombomodulin, heparin sulphate and various fibrinolytic factors. Clinically used, fast-acting, heparin preparations are identical to this naturally occurring molecule.

In addition to their ability to prevent clotting, endothelial cells also aid thrombosis. They are responsible for the production of Von Willebrand factor through a unique organelle called the Weibel–Palade body, which not only acts as a carrier for factor VIII but also promotes platelet adhesion by binding to exposed collagen (p. 414).

Modulation of immune responses
In response to various inflammatory mediators, the vascular endothelium expresses various so-called ‘adhesion molecules’ which promote leucocyte attraction, adhesion and infiltration into the blood vessel wall (Chapter 3).

Regulation of vascular cell growth
The endothelial cells are also responsible for the development of new blood vessels (‘angiogenesis’) in the placenta, wound healing, tissue repair and tumour growth. This process is facilitated by VEGF.

SYMPTOMS OF HEART DISEASE

The following symptoms occur with heart disease:

- Chest pain
- Breathlessness
- Palpitations
- Syncope
- Fatigue
- Peripheral oedema.

The severity of cardiac symptoms or fatigue is classified according to the New York Heart Association (NYHA) grading of cardiac status (see Table 14.19). The differential diagnosis of chest pain is given in Table 14.2.

Central chest pain
This is the most common symptom associated with heart disease. The pain of angina pectoris and myocardial infarction is due to myocardial hypoxia. Types of pain include:

- Retrosternal or gripping sensation with radiation to the left arm or neck that is provoked by exertion and eased with rest or nitrates – angina (p. 729)
- Similar pain at rest – acute coronary syndrome (p. 734)
- Severe tearing chest pain radiating through to the back – aortic dissection (p. 787)
- Sharp central chest pain that is worse with movement or respiration but relieved with sitting forward – pericarditis (p. 774)
- Sharp stabbing left submammary pain associated with anxiety – Da Costa’s syndrome.

Dyspnoea
Left ventricular failure causes dyspnoea due to oedema of the pulmonary interstitium and alveoli. This makes the lungs stiff (less compliant), thus increasing the respiratory effort required to ventilate the lungs. Tachypnoea (increased respiratory rate) is often present owing to stimulation of pulmonary stretch receptors.

Orthopnoea refers to breathlessness on lying flat. Blood is redistributed from the legs to the torso, leading to an increase in central and pulmonary blood volume. The patient uses an increasing number of pillows to sleep.

Paroxysmal nocturnal dyspnoea (PND) is when a patient is woken from sleep fighting for breath. It is due to the same mechanisms as orthopnoea. However, as sensory awareness is reduced whilst asleep, the pulmonary oedema can become quite severe before the patient is awoken.

Hyperventilation with alternating episodes of apnoea (Cheyne–Stokes respiration) occurs in severe heart failure.

Central sleep apnoea syndrome (CSAS). If hypopnoea occurs rather than apnoea, the phenomenon is termed ‘periodic breathing’, but the two variations are known together as CSAS. This occurs due to malfunctioning of the respiratory centre in the brain, caused by poor cardiac output with concurrent cerebrovascular disease. The symptoms of CSAS, such as daytime somnolence and fatigue, are similar to those of obstructive sleep apnoea syndrome (OSAS, p. 818) and there is considerable overlap with the symptoms of heart failure. CSAS is believed to lead to myocardial hypertrophy and fibrosis, deterioration in cardiac function and complex arrhythmias, including non-sustained ventricular tachycardia, hypertension and stroke. Patients with CSAS have a worse prognosis compared to similar patients without CSAS.

Palpitations
These represent an increased awareness of the normal heart beat or the sensation of slow, rapid or irregular heart rhythms. The most common arrhythmias felt as palpitations are premature ectopic beats and paroxysmal tachycardias. A useful trick is to ask patients to tap out the rate and rhythm of their palpitations, as the different arrhythmias have different characteristics:

- Premature beats (ectopics) are felt by the patient as a pause followed by a forceful beat. This is because premature beats are usually followed by a pause before the next normal beat, as the heart resets itself. The next beat is more forceful as the heart has had a longer

### Syncope

Syncope is a transient loss of consciousness due to inadequate cerebral blood flow. The cardiovascular causes are listed in Table 14.3.

#### Vascular

- **A vasovagal attack** is a simple faint and is the most common cause of syncope. The mechanism begins with peripheral vasodilation and venous pooling of blood, leading to a reduction in the amount of blood returned to the heart. The near-empty heart responds by contracting vigorously, which in turn stimulates mechanoreceptors (stretch receptors) in the inferoposterior wall of the left ventricle. These in turn trigger reflexes via the central nervous system, which act to reduce ventricular stretch (i.e., further vasodilation and sometimes profound bradycardia), but this causes a drop in blood pressure and therefore syncope. These episodes are usually associated with a prodrome of dizziness, nausea, sweating, tinnitus, yawning and a sinking feeling. Recovery occurs within a few seconds, especially if the patient lies down.

- **Postural (orthostatic) hypotension** is a drop in systolic blood pressure of 20 mmHg or more on standing from a sitting or lying position. Usually, reflex vasoconstriction prevents a drop in pressure but if this is absent or the patient is fluid depleted or on vasodilating or diuretic drugs, hypotension occurs.

- **Postprandial hypotension** is a drop in systolic blood pressure of ≥20 mmHg or the systolic blood pressure drops from above 100 mmHg to under 90 mmHg within 2 hours of eating. The mechanism is unknown but may be due to pooling of blood in the splanchnic vessels. In normal subjects, this elicits a homeostatic response via activation of baroreceptors and the sympathetic system, peripheral vasoconstriction and an increase in cardiac output.

- **Micturition syncope** refers to loss of consciousness whilst passing urine.

- **Carotid sinus syncope** occurs when there is an exaggerated vagal response to carotid sinus stimulation, provoked by wearing a tight collar, looking upwards or turning the head.

#### Obstructive

The obstructive cardiac causes listed in Table 14.3 all lead to syncope due to restriction of blood flow from the heart into the rest of the circulation, or between the different chambers of the heart.

#### Arrhythmias

Stokes–Adams attacks (p. 700) are a sudden loss of consciousness unrelated to posture and due to intermittent high-grade AV block, profound bradycardia or ventricular standstill. The patient falls to the ground without warning, is pale and deeply unconscious. The pulse is usually very slow or absent. After a few seconds the patient flushes brightly and recovers consciousness as the pulse quickens. Often there are no sequelae, but patients may injure themselves during falls. Occasionally a generalized convulsion may occur if the period of cerebral hypoxia is prolonged, leading to a misdiagnosis of epilepsy.

### Fatigue

Fatigue may be a symptom of inadequate systemic perfusion in heart failure. It is due to poor sleep, a direct side-effect of medication, particularly beta-blockers, electrolyte imbalance due to diuretic therapy and as a systemic manifestation of infection such as endocarditis.

### Peripheral oedema

Heart failure results in salt and water retention due to renal underperfusion and consequent activation of the renin-angiotensin-aldosterone system (p. 566). This leads to dependent pitting oedema.

### EXAMINATION OF THE CARDIOVASCULAR SYSTEM

#### General examination

General features of the patient’s wellbeing should be noted as well as the presence of conjunctival pallor, obesity, jaundice and cachexia.

- **Clubbing** (p. 799) is seen in congenital cyanotic heart disease, particularly Fallot’s tetralogy and also in 10% of patients with subacute infective endocarditis.

- **Splinter haemorrhages**. These small, subungual linear haemorrhages are frequently due to trauma, but are also seen in infective endocarditis.

- **Cyanosis** is a dusky blue discoloration of the skin (particularly at the extremities) or of the mucous membranes when the capillary oxygen saturation is less than 85%. *Central cyanosis* (p. 799) is seen with shunting of deoxygenated venous blood into the systemic circulation, as in the presence of a right-to-left heart shunt. *Peripheral cyanosis* is seen in the hands and feet, which are cold. It occurs in conditions associated with peripheral vasoconstriction and stasis of blood in the extremities leading to increased peripheral oxygen extraction. Such conditions include congestive heart failure, circulatory shock, exposure to cold temperatures and abnormalities of the peripheral circulation, e.g. Raynaud’s, p. 788.
The arterial pulse

The first pulse to be examined is the right radial pulse. A delayed femoral pulsation occurs because of a proximal stenosis, particularly of the aorta (coarctation).

Pulse rate

The pulse rate should be between 60 and 80 beats per minute (b.p.m.) when an adult patient is lying quietly in bed.

Rhythm

The rhythm is regular except for a slight quickening in early inspiration and a slowing in expiration (sinus arrhythmia).

- Premature beats occur as occasional or repeated irregularities superimposed on a regular pulse rhythm. Similarly, intermittent heart block is revealed by occasional beats dropped from an otherwise regular rhythm.
- Atrial fibrillation produces an irregularly irregular pulse. This irregular pattern persists when the pulse quickens in response to exercise, in contrast to pulse irregularity due to ectopic beats, which usually disappears on exercise.

Character of pulse

- Carotid pulsations are not normally apparent on inspection of the neck but may be visible (Corrigan’s sign) in conditions associated with a large-volume pulse, including high output states (such as thyrotoxicosis, anaemia or fever) and in aortic regurgitation.
- A ‘collapsing’ or ‘water hammer’ pulse (Fig. 14.10) is a large-volume pulse characterized by a short duration with a brisk rise and fall. This is best appreciated by palpating the radial artery with the palmer aspect of four fingers while elevating the patient’s arm above the level of the heart. A collapsing pulse is characteristic of aortic valvular regurgitation or a persistent ductus arteriosus.
- A small-volume pulse is seen in cardiac failure, shock and obstructive valvar or vascular disease. It may also be present during tachyarrhythmias.
- A plateau pulse is small in volume and slow in rising to a peak due to aortic stenosis (Fig. 14.10).
- Alternating pulse (pulsus alternans). This is characterized by regular alternate beats that are weak and strong. It is a feature of severe myocardial failure and is due to the prolonged recovery time of damaged myocardium; it indicates a very poor prognosis. It is easily noticed when taking the blood pressure because the systolic pressure may vary from beat to beat by as much as 50 mmHg (Fig. 14.10).
- Bigeminal pulse (pulsus bigeminus). This is due to a premature ectopic beat following every sinus beat. The rhythm is not regular (Fig. 14.10) because every weak pulse is premature.
- Pulsus bisferiens (Fig. 14.10). This is a pulse that is found in hypertrophic cardiomyopathy and in mixed aortic valve disease (regurgitation combined with stenosis). The first systolic wave is the ‘percussion’ wave produced by the transmission of the left ventricular pressure in early systole. The second peak is the ‘tidal’ wave caused by recoil of the vascular bed. This normally happens in diastole (the dicrotic wave), but when the left ventricle empties slowly or is obstructed from emptying completely, the tidal wave occurs in late systole. The result is a palpable double pulse.
- Dicrotic pulse (Fig. 14.10) results from an accentuated dicrotic wave. It occurs in sepsis, hypovolaemic shock and after aortic valve replacement.
- Paradoxical pulse. Paradoxical pulse is a misnomer, as it is actually an exaggeration of the normal pattern. In normal subjects, the systolic pressure and the pulse pressure (the difference between the systolic and diastolic blood pressures) fall during inspiration. The normal fall of systolic pressure is <10 mmHg, and this can be measured using a sphygmomanometer. It is due to increased pulmonary intravascular volume during inspiration. In severe airflow limitation (especially severe asthma) there is an increased negative intrathoracic pressure on inspiration which enhances the normal fall in blood pressure. In patients with cardiac tamponade, the fluid in the pericardium increases the intrapericardial pressure, thereby impeding diastolic filling of the heart. The normal inspiratory increase in venous return to the right ventricle is at the expense of the left ventricle, as both ventricles are confined by the accumulated pericardial fluid within the pericardial space. Paradox can occur through a similar mechanism in constrictive pericarditis but is less common.

The blood pressure

The peak systemic arterial blood pressure is produced by transmission of left ventricular systolic pressure. Vascular tone and an intact aortic valve maintain the diastolic blood pressure. How to take the blood pressure is outlined in Practical Box 14.1.

Jugular venous pressure

There are no valves between the internal jugular vein and the right atrium. Observation of the column of blood in the
Practical Box 14.1

Taking the blood pressure

Use a properly calibrated machine.
1. The blood pressure is taken in the (right) arm with the patient relaxed and comfortable.
2. The sphygmomanometer cuff is wrapped around the upper arm with the inflation bag placed over the brachial artery.
3. The cuff is inflated until the pressure exceeds the arterial pressure – when the radial pulse is no longer palpable.
4. The diaphragm of the stethoscope is positioned over the brachial artery just below the cuff.
5. The cuff pressure is slowly reduced until sounds (Korotkoff sounds) can be heard (phase 1). This is the systolic pressure.
6. The pressure is allowed to fall further until the Korotkoff sounds become suddenly muffled (phase 4).
7. The pressure is allowed to fall still further until they disappear (phase 5).

The diastolic pressure is usually taken as phase 5 because this phase is more reproducible and nearer to the intravascular diastolic pressure. The Korotkoff sounds may disappear (phase 2) and reappear (phase 3) between the systolic and diastolic pressures. Do not mistake phase 2 for the diastolic pressure or phase 3 for the systolic pressure.

Practical Box 14.2

Measurement of jugular venous pressure

- The patient is positioned at about 45° to the horizontal (between 30° and 60°), wherever the top of the venous pulsation can be seen in a good light.
- The jugular venous pressure is measured as the vertical distance between the manubriosternal angle and the top of the venous column.
- The normal jugular venous pressure is usually -3 cmH₂O, which is equivalent to a right atrial pressure of 8 cmH₂O when measured with reference to a point midway between the anterior and posterior surfaces of the chest.
- The venous pulsations are not usually palpable (except for the forceful venous distension associated with tricuspid regurgitation).
- Compression of the right upper abdomen causes a temporary increase in venous pressure and makes the JVP more visible (hepatojugular reflux).

The internal jugular system is therefore a good measure of right atrial pressure. The external jugular cannot be relied upon because of its valves and because it may be obstructed by the fascial and muscular layers through which it passes; it can only be used if typical venous pulsation is seen, indicating no obstruction to flow.

Measurement of jugular venous pressure (JVP)

See Practical Box 14.2.

Elevation of the jugular venous pressure occurs in heart failure. It is also produced by an elevated jugular venous pressure which occurs in constrictive pericarditis and cardiac tamponade (increases in inspiration – Kussmaul’s sign), renal disease with salt and water retention, overtransfusion or excessive infusion of fluids, congestive cardiac failure and superior vena cava obstruction. A reduced jugular venous pressure occurs in hypovolaemia.

The jugular venous pressure wave

This consists of three peaks and two troughs (Fig. 14.11). The peaks are described as a, c and v waves and the troughs are known as x and y descents:

- **The a wave** is produced by atrial systole and is increased with right ventricular hypertrophy secondary to pulmonary hypertension or pulmonary stenosis. Giant cannon waves occur in complete heart block and ventricular tachycardia.
- **The x descent** occurs when atrial contraction finishes.
- **The c wave** occurs during the x descent and is due to transmission of right ventricular systolic pressure before the tricuspid valve closes.
- **The v wave** occurs with venous return filling the right atrium. Giant v waves occur in tricuspid regurgitation.
- **The y descent** follows the v wave when the tricuspid valve opens. A steep y descent is seen in constrictive pericarditis and tricuspid incompetence.

Examination of the precordium

- With the patient at 45°, the cardiac apex is located in the 5th intercostal space mid-clavicular line. Left ventricular dilatation will displace the apex downwards and laterally. It may be impalpable in patients with emphysema, obesity, pericardial or pleural effusions.
- **A tapping apex** is a palpable first sound and occurs in mitral stenosis.
- **A vigorous apex** may be present in diseases with volume overload, e.g. aortic regurgitation.
- **A heaving apex** may occur with left ventricular hypertrophy – aortic stenosis, systemic hypertension and hypertrophic cardiomyopathy.
- **A double pulsation** may occur in hypertrophic cardiomyopathy.
- **A sustained left parasternal heave** occurs with right ventricular hypertrophy or left atrial enlargement.
- **A palpable thrill** may be felt overlying an abnormal cardiac valve, e.g. systolic thrill with aortic stenosis.

Auscultation

The bell of the stethoscope is used for low-pitched sounds (heart sounds and mid-diastolic murmur in mitral stenosis). The diaphragm is used for high-pitched sounds (systolic murmurs, aortic regurgitation, ejection clicks and opening snaps). The areas of auscultation are described in (Fig. 14.12). Left-sided valve murmurs may be more prominent in...
Cardiac investigations

Blood tests
Routine haematology, urea/creatinine and electrolytes, liver biochemistry, cardiac enzymes, thyroid function and brain natriuretic peptides (BNP).

Chest X-ray
Ideally, this is taken in the postero-anterior (PA) direction at maximum inspiration with the heart close to the X-ray film to minimize magnification with respect to the thorax. A lateral may give additional information if the PA is abnormal. The cardiac structures and great vessels that can be seen on these X-rays are indicated in Figure 14.13. An antero-posterior (AP) view is only taken in an emergency.

Heart size
Heart size can be reliably assessed only from the PA chest film. The maximum transverse diameter of the heart is compared with the maximum transverse diameter of the thorax measured from the inside of the ribs (the cardiothoracic ratio). The cardiothoracic ratio (CTR) is usually <50%, except in neonates, infants, athletes and patients with skeletal abnormalities such as scoliosis and funnel chest. A transverse cardiac diameter of more than 15.5 cm is abnormal. Pericardial effusion or cardiac dilatation causes an increase in the ratio.

A pericardial effusion produces a globular heart (see Fig. 14.115, p. 775). This enlargement may occur quite suddenly and, unlike in heart failure, there is no associated change in the pulmonary vasculature. The echocardiogram is more specific (p. 776).

Certain patterns of specific chamber enlargement may be seen on the chest X-ray:

Left atrial dilatation. This results in prominence of the left atrial appendage and a straightening or convex bulging of the upper left heart border, a double atrial shadow to the right of the sternum, and splaying of the carina because a large left atrium elevates the left main bronchus (Fig. 14.14). On a
There is a paucity of vascular markings.

This is seen in chest X-ray as a results from left-to-right shunts (e.g., in the right lower lung field). This results in an increase in the vascularity of the lung fields and as an increase in the size of hilar vessels (e.g., in the right lower lung field).

**Pulmonary plethora** is a paucity of vascular markings and a reduction in the width of the arteries. It occurs in situations where there is reduced pulmonary blood flow, such as pulmonary embolism, severe pulmonary stenosis and Fallot’s tetralogy.

**Pulmonary hypertension** may result from pulmonary embolism, chronic lung disease or chronic left heart disease, e.g., left ventricular failure or mitral valve disease such as shunts due to a ventricular septal defect or mitral valve stenosis. In addition to X-ray features of these conditions, the pulmonary arteries are prominent close to the hilum but are reduced in size (pruned) in the peripheral lung fields. This pattern is usually symmetrical. Normal pulmonary capillary pressure is 5–14 mmHg at rest. Mild pulmonary capillary hypertension (15–20 mmHg) produces isolated dilatation of the upper zone vessels.

**Interstitial oedema** occurs when the pressure is between 21 and 30 mmHg. This manifests as fluid collections in the interlobar fissures, interlobular septa (Kerley B lines) and plural spaces. This gives rise to indistinctness of the hilar regions and haziness of the lung fields.

**Alveolar oedema** occurs when the pressure exceeds 30 mmHg, appearing as areas of consolidation and mottling of the lung fields (Fig. 14.15) and pleural effusions. Patients with long-standing elevation of the pulmonary capillary pressure have reactive thickening of the pulmonary arteriolar intima, which protects the alveoli from pulmonary oedema. Thus, in these patients the pulmonary venous pressure may increase to well above 30 mmHg before frank pulmonary oedema develops.

### Electrocardiography

The electrocardiogram (ECG) is a recording of the electrical activity of the heart. It is the vector sum of the depolarization and repolarization potentials of all myocardial cells (see Fig. 14.2, p. 670). At the body surface these generate potential differences of about 1 mV, and the fluctuations of these potentials create the familiar P-QRS-T pattern. At rest the intracellular voltage of the myocardium is polarized at ~90 mV compared with that of the extracellular space. This diastolic voltage difference occurs because of the high intracellular potassium concentration, which is maintained by the sodium potassium pump despite the free membrane permeability to potassium. Depolarization of cardiac cells occurs when there is a sudden increase in the permeability of the membrane to sodium. Sodium rushes into the cell and the negative resting voltage is lost (phase 0 in Fig. 14.37, p. 698). The depolarization of a myocardial cell causes the depolarization of adjacent cells and, in the healthy heart, the entire myocardium is depolarized in a coordinated fashion. During repolarization, cellular electrolyte balance is slowly restored (phases 1, 2 and 3). Slow diastolic depolarization (phase 4) follows until the threshold potential is reached. Another action potential then follows.

The ECG is recorded from two or more simultaneous points of skin contact (electrodes). When cardiac activation proceeds towards the positive contact, an upward deflection is produced on the ECG. Correct representation of a three-dimensional spatial vector requires recordings from three mutually perpendicular (orthogonal) axes. The shape of the human torso does not make this easy, so the practical ECG records 12 projections of the vector, called ‘leads’ (Fig. 14.16).

Six of the leads are obtained by recording voltages from the limbs (I, II, III, AVR, AVL and AVF). The other six leads
Cardiac investigations

Figure 14.15 Acute pulmonary oedema. This pair of chest X-rays were taken from a patient before (a) and after (b) treatment of acute pulmonary oedema. The X-ray taken when the oedema was present demonstrates hilar haziness, Kerley B lines, upper lobe venous engorgement and fluid in the right horizontal interlobar fissure. These abnormalities are resolved on the film taken after successful treatment.

Figure 14.16 The connections or directions that comprise the 12-lead electrocardiogram.

Figure 14.16 The connections or directions that comprise the 12-lead electrocardiogram.

record potentials between points on the chest surface and an average of the three limbs: RA, LA and LL. These are designated $V_{1}$–$V_{6}$ and aim to select activity from the right ventricle ($V_{1}$–$V_{2}$), interventricular septum ($V_{3}$–$V_{4}$) and left ventricle ($V_{5}$–$V_{6}$). Note that leads AVR and $V_{1}$ are oriented towards the cavity of the heart, leads II, III and AVF face the inferior surface, and leads I, AVL and $V_{6}$ face the lateral wall of the left ventricle. A $V_{4}$ on the right side of the chest (V.R) is occasionally useful (e.g., for the diagnosis of right ventricular infarction).

Most ECG machines are simultaneous three-channel recorders with output either as a continuous strip or with automatic channel switching. Many ECG machines also analyse the recordings and print the analysis on the record. Usually the machine interpretation is correct, but many arrhythmias still defy automatic analysis.

The ECG waveform

The shape of the normal ECG waveform (Fig. 14.17) has similarities, whatever the orientation. The first deflection is caused by atrial depolarization, and it is a low-amplitude slow deflection called a $P$ wave. The QRS complex reflects ventricular activation or depolarization and is sharper and larger in amplitude than the $P$ wave. An initial downward deflection is called the $Q$ wave. An initial upward deflection is called an $R$ wave. The $S$ wave is the last part of ventricular activation.
The mean QRS vector can be calculated from the six standard leads (Fig. 14.19):
- Normal between $-30^\circ$ and $+90^\circ$
- Left axis deviation between $-30^\circ$ and $-90^\circ$
- Right axis deviation between $+90^\circ$ and $+150^\circ$
Calculation of this vector is useful in the diagnosis of some cardiac disorders.

**Exercise electrocardiography**
This is less used than previously (see p. 730) because of its low sensitivity. The ECG is recorded whilst the patient walks or runs on a motorized treadmill. The test is based upon the principle that exercise increases myocardial demand on coronary blood supply, which may be inadequate during exercise, and at peak stress can result in relative myocardial ischaemia. Most exercise tests are performed according to a standardized method, e.g. the Bruce protocol. Recording an ECG after exercise is not an adequate form of stress test.

Normally there is little change in the T wave or ST segment during exercise.
The patient’s exercise capacity (the total time achieved) will depend on many factors; however, patients who can only exercise for $<6$ min generally have a poorer prognosis.

Myocardial ischaemia provoked by exertion results in ST segment depression (>1 mm) in leads facing the affected area. The form of ST segment depression provoked by ischaemia is characteristic: it is either planar or shows downsloping depression (Fig. 14.20). Up-sloping depression is a nonspecific finding. The degree of ST segment depression is positively correlated to the degree of myocardial ischaemia.

ST segment elevation during an exercise test is induced much less frequently than ST depression. When it occurs, it reflects transmural ischaemia caused by coronary spasm or critical stenosis.

Although most abnormalities are detected in leads V_5 (anterior and lateral ischaemia) or AVF (inferior ischaemia), it
is best to record a full 12-lead ECG. During an exercise test the blood pressure and rhythm responses to exercise are also assessed. Exercise normally causes an increase in heart rate and blood pressure. A sustained fall in blood pressure usually indicates severe coronary artery disease. A slow recovery of the heart rate to basal levels has also been reported to be a predictor of mortality.

Frequent premature ventricular depolarizations during the test are associated with a long-term increase in the risk of death from cardiovascular causes and further testing is required in these patients. Use of the exercise test in angina is described on page 682.

24-Hour ambulatory taped electrocardiography

This records transient changes such as a brief paroxysm of tachycardia, an occasional pause in the rhythm, or intermittent ST segment shifts (Fig. 14.21). A conventional 12-lead ECG is recorded in less than a minute and usually samples less than 20 complexes. In a 24-hour period, over 100 000 complexes are recorded. Such a large amount of data must be analysed by automatic or semi-automatic methods. This technique is called ‘Holter’ electrocardiography after its inventor.

Event recording is another technique that is used to record less frequent arrhythmias. The patient is provided with a pocket-sized device that can record and store a short segment of the ECG. The device may be kept for several days or weeks until the arrhythmia is recorded. Most units of this kind will also allow transtelephonic ECG transmission so that the physician can determine the need for treatment or the continued need for monitoring.

A very small event recorder, known as an implantable loop recorder (ILR), can also be implanted subcutaneously, triggered by events or a magnet, and interrogated by the physician.

Other tests

Non-invasive methods that make use of digitalized Holter recordings to identify increased risk of ventricular arrhythmias include assessment of heart rate variability, signal averaged ECG (SAECG) and T wave alternans.

Heart rate variability (HRV) can be assessed from a 24 hour ECG. HRV is decreased in some patients following myocardial infarction and represents an abnormality of autonomic tone or cardiac responsiveness. Low HRV is a major risk factor for sudden death and ventricular arrhythmias in patients discharged from hospital following myocardial infarction.

Signal-averaged ECG (SAECG) is a technique that requires amplification and averaging of abnormal low-amplitude signals which occur beyond the end of the QRS complex and extend well into the ST segment. These signals are therefore also known as late potentials and are too small to be detected on a surface ECG. They arise in areas of slow conduction in the myocardium, such as the border zone of an infarct, where re-entrant ventricular arrhythmias can originate.

T wave alternans (TWA) is a valuable technique used as a non-invasive marker of susceptibility to ventricular arrhythmias and sudden cardiac death. TWA represents microvolt level changes in the morphology of the T waves in every other beat and can be detected during acute myocardial ischaemia using amplification techniques. Visible TWA on an ordinary surface ECG is quite a rare phenomenon, except in patients with long QT syndromes, particularly during emotion or exercise.
Tilt testing

Patients with suspected neurocardiogenic (vasovagal) syncope should be investigated by upright tilt testing. The patient is secured to a table which is tilted to +60° to the vertical for ≥45 minutes. The ECG and blood pressure are monitored throughout. If neither symptoms nor signs develop, isoprenaline may be slowly infused or glyceryl trinitrate inhaled and the tilt repeated. A positive test results in hypotension, sometimes bradycardia (Fig. 14.22) and presyncope/syncope, and supports the diagnosis of neurocardiogenic syncope. If symptoms and signs appear, placing the patient flat can quickly reverse them. The effect of treatment can be evaluated by repeating the tilt test, but it is not always reproducible. The overall sensitivity, specificity and reproducibility is low.

Carotid sinus massage

Carotid sinus massage (Practical Box 14.3) may lead to asystole (>3 s) and/or a fall of systolic blood pressure (>50 mmHg). This hypersensitive response occurs in many of the normal (especially elderly) population, but may also be responsible for loss of consciousness in some patients with carotid sinus syndrome (p. 676). In one-third of cases, carotid sinus massage is only positive when the patient is standing. Atherosclerosis can cause narrowing and stenosis of carotid arteries. Carotid sinus massage should thus be avoided in patients with carotid bruits.

Echocardiography

Echocardiography is a non-invasive diagnostic technique that is widely used in clinical cardiology. It involves the use
of ultrasound (either alone or with contrast agent) to assess cardiac structure and function. A physician or technician performs the studies and a comprehensive examination takes 15–45 minutes. The ultrasound machines are either mobile on wheels, or are handheld.

**Physics**

Echocardiography uses transmitted ultrasound wavelengths of \( \leq 1 \text{ mm} \), which correspond to frequencies of approximately \( \geq 2 \text{ MHz} \) (\( \geq 2 \) million cycles per second). At such high frequencies, the ultrasound waves can be focused into a ‘beam’ and aimed at a particular region of the heart. The waves are generated in very short bursts or pulses a few microseconds long by a crystal transducer, which also detects returning echoes and converts them into electrical signals.

When the handheld crystal transducer is placed on the body surface the emitted ultrasound pulses encounter interfaces between various body tissues as they pass through the body. In crossing each interface, some of the wave energy is reflected, and if the beam path is approximately at right angles to the plane of the interface, the reflected waves return to the transducer as an echo. Since the velocity of sound in body tissues is almost constant (1550 m/s), the time delay for the echo to return measures the distance of the reflecting interface. Thus, if a single ultrasound pulse is transmitted, a series of echoes return, the first of which is from the closest interface.

**Echocardiographic modalities**

**M mode and two-dimensional echocardiography**

M-mode echocardiography is a technique that details the changing motion of structures along the ultrasound beam with time. Thus the motion of the interventricular septum during the cardiac cycle (either towards or away from the transducer placed on the chest wall) can be assessed and quantified. Stationary structures thus generate horizontal straight lines, the distances of which from the top of the screen indicate their depths, and movements, such as those of heart valves, are indicated by zigzag lines (Fig. 14.23c). Alternatively, a series of views from different positions can be obtained in the form of a two-dimensional image (cross-sectional 2-D echocardiography) (Fig. 14.23a,b). This method is useful for delineating anatomical structures and for quantifying volumes of cardiac chambers. M mode can be used to estimate LV systolic function by comparing end-diastolic...
and end-systolic dimensions. For example, the percentage reduction in the left ventricular cavity size ('shortening fraction' – SF) is given by:

\[
SF = \frac{\text{LVDD} - \text{LVSD}}{\text{LVDD}} \times 100\%
\]

where LVDD is left ventricular diastolic diameter and LVSD is left ventricular systolic diameter, at the base of the heart. The normal range is 30–45%.

This method is easy to perform, but is an inaccurate measure of ejection fraction (EF) because it does not take account of reduced regional function of the mid or apical myocardium, due to infarction for example. For this reason, estimation of EF based upon the difference in LV volumes from systole to diastole, derived from planimetered measurements of LV area in at least two planes, is more accurate. A normal EF is >55%. This method is helpful in assessing the response of the patient with heart failure to therapy. It also permits estimation of LV mass.

Three-dimensional echocardiography
Three-dimensional echocardiography is a novel development in cardiac imaging in which a volumetric dataset is acquired using a multipane probe rotating around a fixed axis. Clinical uses include accurate volumetric assessment of ventricular function and mass, assessment of mitral and aortic valve disease and assessment of adult congenital heart disease (Fig. 14.24).

Doppler echocardiography
Echocardiography imaging utilizes echoes from tissue interfaces. Using high amplification, it is also possible to detect weak echoes scattered by small targets, including those from red blood cells. Blood velocity in the heart chambers is typically much more rapid (>1 m/s) than the movement of myocardial tissue. If the blood is moving in the same direction as the direction of the ultrasound beam, the frequency of the returning echoes will be changed according to the Doppler phenomenon. The Doppler shift frequency is directly proportional to the blood velocity. Blood velocity data can be acquired and displayed in several ways.

Pulsed-wave (PW) Doppler extracts velocity data from the pulse echoes used to form a 2-D image and gives useful qualitative information. PW echoes can be specified from locations within an image identified by a sample volume cursor placed on the screen. Such information from the left ventricular outflow tract (LVOT) and right ventricular outflow tract provides the stroke distance, and is used to estimate cardiac output (CO) and also to quantify intracardiac shunts. Cardiac output can then be derived using the formula:

\[
\text{CO} = \text{stroke volume} \times \text{heart rate}
\]

Stroke volume is the stroke distance multiplied by the area of the LVOT, which can also be measured echocardiographically. PW Doppler of the flow across the mitral valve and into the left atrium through the pulmonary veins can be used as part of the estimation of left ventricular filling pressure.

Colour flow Doppler. Doppler colour flow imaging uses one colour for blood flowing towards the transducer and another colour for blood flowing away. This technique allows the direction, velocity and timing of the flow to be measured with a simultaneous view of cardiac structure and function. Colour flow Doppler is used to help assess valvar regurgitation (Fig. 14.25) and may be useful in the assessment of coronary blood flow.

Continuous-wave (CW) Doppler collects all the velocity data from the path of the beam and analyses it to generate a spectral display. This is unlike PW Doppler, which provides information from a particular sample volume at one location along a line. Thus, CW Doppler does not provide any depth information.

The outline of the envelope of the spectral display is used to estimate the value of peak velocity throughout the cardiac cycle. CW Doppler is used typically to assess valvular obstruction, which then causes increased velocities. For example, normal flow velocities are of the order of 1 m/s across the normal aortic valve, but if there is a severe obstructive lesion, such as a severely stenotic aortic valve, velocities of 4 m/s or more can occur. These velocities are generated by the pressure gradient that exists across the lesion.

According to the Bernoulli equation, the pressure difference between two chambers is calculated as: 4 multiplied by the square of the CW Doppler velocity between chambers. Thus a velocity of 5 m/s across the aortic valve suggests a peak gradient of \(4 \times 5 \times 5 = 100\) mmHg between the ascending aorta and the left ventricle. This equation has been validated in a wide variety of clinical situations, including valve stenoses, ventricular septal defects and intraventricular obstruction (as in hypertrophic cardiomyopathy). It is often clinically unnecessary to resort to invasive methods such as...
cardiac catheterization to measure intracardiac pressure gradients.

Similarly, pulmonary artery (PA) systolic pressure and right ventricular diastolic pressure can be calculated using the Bernoulli equation. In this case, CW Doppler tracing of the tricuspid regurgitant jet is used to estimate the pressure gradient between the right ventricle and the right atrium. The PA systolic pressure is then calculated by adding the estimated right atrial pressure to the pressure gradient between the right ventricle and the right atrium.

Tissue Doppler is similar to PW Doppler. It measures myocardial tissue velocities within a particular sample volume placed on the image. Such velocities are of the order of 1 cm/s. Currently, tissue Doppler of the mitral annulus is used as part of the estimation of left ventricular filling pressure.

Other ultrasound modalities. Harmonic power Doppler, pulse inversion Doppler and ultraharmonics are used to detect and amplify microsphere-specific signals as part of the echocardiographic assessment of myocardial perfusion.

Transoesophageal echocardiography (TOE)
A transducer mounted on a flexible tube is placed into the oesophagus. This involves the use of local anaesthesia and sometimes intravenous sedation. High-resolution images can be obtained because of the close proximity of the heart to the transducer in the oesophagus, and also because of the higher frequencies that are used relative to transthoracic imaging. TOE is most commonly used in the assessment of valve structure and function (to assess for reparable of mitral valve prolapse), for features and complications of infective endocarditis, to assess the aorta for aortic dissection and to assess for a cardiac source of embolus.

Wall motion stress echocardiography
Echocardiography can be used clinically to evaluate the patient for the presence of myocardial scars and of reversible ischaemia. Since ultrasound cannot directly detect red blood cells in capillaries, myocardial wall motion is used as a surrogate for perfusion. Myocardial segments that demonstrate a change in function (defined as a change or reduction in thickening) from rest to stress can be assumed to be supplied by a flow-limiting stenosis in the epicardial artery or graft.

Stress for this indication needs to be inotropic to induce true ischaemia. Physiological stress includes treadmill exercise, which is complicated by the difficulty in obtaining reliable images rapidly as the patient comes off the treadmill, before heart rate reduces back to sub-maximal levels. Alternatively, pharmacological stress can be induced with dobutamine at graded doses. This is relatively safe but complications such as ventricular arrhythmia have been reported. This technique can also be used to assess for viability of the myocardium and for hibernating or stunned myocardium (p. 721).

Myocardial perfusion echocardiography
In order to assess myocardial perfusion by echocardiography (MPE), microspheres of similar size to red blood cells are used as an intravenous contrast agent. Microsphere-specific ultrasound modes such as harmonic power Doppler can be used for detection. MPE involves the use of intravenous infusion of contrast to fill the myocardium. A pulse of ultrasound destroys microspheres within the capillaries (and not the LV cavity), and the time taken to replenish the capillaries is a measure of myocardial blood flow. The time taken to fill should be significantly shorter at stress than at rest.

Contrast echo for LV opacification
Intravenous contrast agents opacify the left ventricle and can define the endocardial border. Their clinical utility has reduced with the advent of harmonic imaging, which has improved image quality in previously ‘difficult to image’ patients.

Intravascular (coronary) ultrasound
Intravascular (coronary) ultrasound probes can be used to image proximal coronary arteries as part of a percutaneous transluminal coronary angioplasty (PTCA) procedure, e.g. to assess for adequacy of deployment of intracoronary stents.

Nuclear imaging
Nuclear imaging is used to detect myocardial infarction or to measure myocardial function, perfusion or viability, depending on the radiopharmaceutical used and the technique of imaging. These data are particularly valuable when used in combination. All involve a significant radiation dose (p. 688).

Image type
Gamma cameras produce a planar image in which structures are superimposed as in a standard radiograph. Single-photon-emission computed tomography (SPECT) imaging uses similar raw data to construct tomographic images, just as a CT image is reconstructed from X-rays. This gives finer anatomical resolution, but is technically demanding. These methods may be used with any of the radiopharmaceuticals.

Myocardial perfusion and viability
Thallium-201 is rapidly taken up by the myocardium, so an image taken immediately after injection reflects the distribution of blood flow to the myocardium. Areas of ischaemia or infarction receive less 201Tl and appear dark. Between 2 and 24 h after injection, 201Tl is redistributed so that all cardiac myocytes contain a comparable concentration. Images at this time show dark areas where the myocardium has infarcted, but normal density in ischaemic areas. Comparison of the early and late images is one method of predicting whether an ischaemic area of myocardium contains enough viable tissue to justify coronary bypass or angioplasty. Technetium-99-labelled tetrofosmin (Fig. 14.26) is also taken up rapidly by cardiac myocytes, but does not undergo redistribution. When this substance is injected during exercise, its distribution in the myocardium reflects the distribution of blood at the time of the exercise, even if the image is taken several hours later. This is a sensitive method of detecting myocardial viability. Images produced following injection of 99mTc-tetrofosmin during exercise can be compared to images produced following injection at rest to decide which areas of ischaemia are reversible (p. 721). In patients unable to exercise, the heart can be stressed with drugs, e.g. dipyridamole or dobutamine.

Infarct imaging
Perfusion images produced using compounds labelled with 201Tl or 99mTc-sestamibi show a myocardial infarction as a perfusion defect or ‘cold spot’. These methods are sensitive for detecting and localizing the infarct, but give no information about its age. 99mTc-Pyrophosphate is preferentially taken up by myocardium which has undergone infarction within the previous few days. Images are difficult to interpret because the isotope is also concentrated by bone and cartilage.

FURTHER READING

Computed tomography is useful for the assessment of the thoracic aorta and mediastinum. The development of 64-slice multidetector CT (MDCT) scanners has enabled accurate non-invasive imaging of the coronary arteries.

### Coronary artery calcification

Calcium is absent in normal coronary arteries but is present in atherosclerosis and increases with age. Studies have demonstrated a positive correlation between calcification and the presence of coronary artery stenoses, although the relationship is non-linear. Electron beam CT (EBT) and MDCT scanners are used to obtain multiple thin axial slices through the heart and then the calcium score is calculated. The calcium score is based on the X-ray attenuation coefficient or CT number measured in Hounsfield units. Meta-analyses have demonstrated that a higher calcium score is associated with higher event rate and higher relative risk ratios, although currently no study has shown a net effect on health outcomes of calcium scoring. The current NICE chest pain guidelines demonstrated that a higher calcium score is associated with a very high positive predictive value (85%) and specificity (90%) for the detection of coronary artery disease with a very high negative predictive value (>95%). CTCA may become part of an acute chest pain service in the emergency medicine department to exclude aortic dissection, pulmonary embolism and coronary artery disease. However CT coronary angiography does expose the patient to ionizing radiation.

### Cardiovascular magnetic resonance

Cardiovascular magnetic resonance (CMR), a non-invasive imaging technique that does not involve harmful radiation, is increasingly used in the investigation of patients with cardiovascular disease.

CMR is usually performed with multiple breath-holds to minimize respiratory motion artefacts and cardiac gating to reduce blurring during the cardiac cycle. Several different...
Cine imaging can accurately assess systemic and non-systemic ventricular function and mass. Extracardiac conduits, anomalous pulmonary venous return and aortic coarctations pre- and post-repair can be studied by CMR and the studies repeated for long-term follow-up without the risk of ionizing radiation.

**Cardiomyopathies, pericardial disease and cardiac masses**

In hypertrophic cardiomyopathy CMR accurately defines the extent and distribution of myocardial hypertrophy and can be used in patients with sub-optimal echocardiograms. Intravenous gadolinium can be used to demonstrate regional myocardial fibrosis which is associated with an adverse prognosis. In patients with suspected arrhythmogenic right ventricular cardiomyopathy, CMR is the imaging investigation of choice to detect global and regional wall motion abnormalities of the right ventricle and right ventricular outflow tract, and to detect fatty or fibro-fatty infiltration of the right and left ventricles. In constrictive pericarditis and restrictive cardiomyopathy CMR can demonstrate the effects of the impaired ventricular filling common to both conditions (dilated right atrium and inferior vena cava), but can also determine the thickness of the pericardium (usually 4 mm in normal individuals) (Fig. 14.28). In patients with dilated cardiomyopathy CMR can accurately quantify bi-ventricular function and with gadolinium can demonstrate myocardial fibrosis. In inflammatory and infiltrative conditions of the myocardium, such as myocarditis, sarcoidosis and amyloidosis, CMR is increasingly used as a diagnostic investigation due to different patterns of signal enhancement seen with gadolinium. In patients with thalassaemia, CMR can detect iron deposition within the myocardium and guide chelation therapy. CMR can be useful in patients with cardiac masses to differentiate benign from malignant tumours and to identify thrombus not visualized on echocardiography.

**Diseases of the aorta**

CMR is an excellent technique for assessing patients with aortic dissection and can detect the clinical features of an aortic dissection; the intimal flap, thrombosis in a false lumen, aortic regurgitation, pericardial effusion and aortic dilatation.
Cardiovascular disease

14

690

patients with suspected coronary disease and to assess myocardial viability prior to revascularization in patients with impaired cardiac function (Figs 14.29, 14.30).

Magnetic resonance angiography with gadolinium can provide high quality images of the pulmonary veins which can be fused with electrical data during pulmonary vein isolation for the treatment of atrial fibrillation.

Positron emission tomography (PET)

This is a technique based on detection of high-energy emissions caused by annihilation of positrons released from unstable isotopes. There are several advantages of PET over other techniques, e.g. improved spatial resolution, accurate quantification, the use of biological isotopes of carbon, nitrogen and oxygen. However, PET is expensive and requires a cyclotron to produce the short-lived tracers. PET has become a useful investigation in the detection of viable myocardium in patients who are suitable for revascularization.

As it does not involve radiation or need contrast, CMR is an ideal method of surveillance of patients with dilated thoracic aortas or repaired coarctation.

Valvular heart disease

Valvular stenosis produces signal void on gradient-echo CMR. CMR can quantify the velocity across a stenosed valve using phase-contrast velocity mapping. Valvular regurgitation can be accurately quantified using phase-contrast velocity mapping across the valve, or by calculating the stroke volumes of the left and right ventricle which are equal in the absence of significant regurgitation. However, in most patients, transthoracic and transoesophageal echocardiography should provide sufficient information.

Coronary artery disease

CMR can be used to assess coronary artery anatomy, left ventricular function, myocardial perfusion and viability in a ‘one-stop’ approach to the assessment of patients with coronary artery disease. Coronary artery anatomy and stenoses can be identified with ultra-fast breath-hold or respiratory-gated sequences with high accuracies. Global left ventricular function and wall motion abnormalities can be detected with cine imaging performed at rest and during dobutamine stress. Myocardial perfusion can be assessed with gadolinium and first-pass imaging; ischaemia can be demonstrated with adenosine for coronary vasodilatation. Myocardial viability can be determined using gadolinium and ‘delayed enhancement’ images. With these techniques CMR is increasingly used both for the assessment of ischaemia in patients with suspected coronary disease and to assess myocardial viability prior to revascularization in patients with impaired cardiac function (Figs 14.29, 14.30).

Positron emission tomography (PET)

This is a technique based on detection of high-energy emissions caused by annihilation of positrons released from unstable isotopes. There are several advantages of PET over other techniques, e.g. improved spatial resolution, accurate quantification, the use of biological isotopes of carbon, nitrogen and oxygen. However, PET is expensive and requires a cyclotron to produce the short-lived tracers. PET has become a useful investigation in the detection of viable myocardium in patients who are suitable for revascularization.

Myocardial perfusion and ischaemia can be determined using PET with \(^{13}\)N-ammonia or oxygen-15 with greater sensitivity than SPECT. Myocardial metabolism and viability can be detected with the use of \(^{18}\)F-fluorodeoxyglucose (FDG), which the cardiac myocyte utilizes for energy production in the presence of reduced oxygen supply and blood flow. There may be reduced perfusion to infarcted or fibrotic myocardium, but also reduced FDG uptake. In hibernating

Figure 14.28 Short-axis cardiac magnetic resonance (CMR) in a patient with constrictive pericarditis. The pericardium is thickened (*) and on ciné imaging (c) there is septal bounce. LV, left ventricle; RV, right ventricle.

Figure 14.29 Cardiac magnetic resonance (CMR). A diagnostic coronary angiography in a patient with type 2 diabetes mellitus and exertional breathlessness demonstrates a severe stenosis (*) in the right coronary artery (RCA), a sub-totally occluded (+) circumflex coronary artery (LCX), and a long segment of disease (X) in the left anterior descending coronary artery (LAD).
Cardiac catheterization

Cardiac catheterization is the introduction of a thin radio-opaque tube (catheter) into the circulation. The right heart is catheterized by introducing the catheter into a peripheral vein (usually the right femoral or internal jugular vein) and advancing it through the right atrium and ventricle into the pulmonary artery. The pressures in the right heart chambers, and pulmonary artery can be measured directly. An indirect measure of left atrial pressure can be obtained by ‘wedging’ a catheter into the distal pulmonary artery (p. 874). In this position the pressure from the right ventricle is obstructed by the catheter and only the pulmonary venous and left atrial pressures are recorded. Left heart catheterization is usually performed via the right femoral or radial artery. A pigtail catheter is advanced up the aorta and manipulated through the aortic valve into the left ventricle. Pressure tracings are taken from the left ventricular cavity. The end-diastolic pressure is invariably elevated in patients with left ventricular dysfunction. A power injection of radio-opaque contrast material is used to opacify the left ventricular cavity (left ventriculography) and thereby assesses left ventricular systolic function. The catheter is then withdrawn across the aortic valve into the aorta and the ‘pullback’ gradient across the valve is measured. Aortography (a power injection into the aortic root) can be performed to assess the aortic root and the presence and severity of aortic regurgitation. Specially designed catheters are then used to selectively engage the left and right coronary arteries, and contrast cine-angiograms are taken in order to define the coronary circulation and identify the presence and severity of any coronary artery disease. During the procedure intracoronary nitrate or adenosine may be used to dilate the coronary arteries. During cardiac catheterization, blood samples may be withdrawn to measure the oxygen content. These estimations are used to quantify intracardiac shunts and measure cardiac output.

THERAPEUTIC PROCEDURES

Cardiac resuscitation

When cardiac arrest occurs, basic life support must be started immediately. The longer the period of respiratory and circulatory arrest, the lower is the chance of restoring healthy life. The chain of survival (Fig. 14.31) includes early recognition of cardiac arrest; early activation of emergency services; early cardiopulmonary resuscitation (CPR); early defibrillation and early advanced life support; and high quality post resuscitation care.

Basic life support (BLS)

The first step is to ensure the safety of the victim and rescuer. The next is to ascertain that the victim is unresponsive by shaking him/her and shouting into one ear. If no response is obtained, help should be sought immediately prior to commencement of basic life support. If the victim has absent or abnormal breathing then cardiac arrest is confirmed and basic life support should be started (Emergency Box 14.1).

Airway

Debris (e.g. blood and mucus) in the mouth and pharynx should be removed. Loose or ill-fitting dentures should be removed. The airway should be opened gently by flexing the neck and extending the head (‘sniffing the morning air’
Cardiovascular disease

Circulation

Most adult cardiac arrest is due to a primary cardiac disorder, e.g. acute coronary syndrome, and results in circulatory collapse. Pulse detection can be difficult and if the victim is unresponsive with absent or abnormal breathing then external chest compression should be started immediately:

- The heel of one hand is placed over the centre of the chest and the heel of the second hand is placed over the first with the fingers interlocked.
- The arms are kept straight and the sternum is rhythmically depressed by 5–6 cm at a rate of approximately 100–120/min allowing for complete recoil between compressions.

Chest compressions do not massage the heart. The thorax acts as a pump and the heart provides a system of one-way valves to ensure forward circulation. Respiratory and circulatory support is continued by providing two effective breaths for every 30 cardiac compressions (30:2 for one or two persons, 15:2 in paediatric patients). Compressions alone is as good as compressions with rescue breaths (American Heart Association updated guidelines). This maintains adequate cerebral and coronary perfusion pressures. There is evidence to suggest that if the person performing compressions tires, the quality of resuscitation deteriorates.

Breathing

After 30 compressions the rescuer opens the victim’s airway by tilting the head backwards (head tilt) and pulling the chin pulled forward (chin lift) or (jaw thrust). The rescuer then pinches the nostrils firmly and takes a deep breath and seals his/her lips around the mouth of the victim. Two effective breaths are given over 1 s each. In paediatric patients respiratory arrests are more common and patients should be given five rescue breaths and a minute of CPR before a sole rescuer leaves the victim to seek help. CPR should not be interrupted to reassess the victim unless they start to show signs of life and start to breathe normally.

Advanced cardiac life support

By the time effective life support has been established, more help should have arrived and advanced cardiac life support can begin. This consists of ECG monitoring, advanced airway management (endotracheal intubation or supraglottic airway tube) and setting up an intravenous infusion in a large peripheral or central vein (an intraosseous needle may be used if i.v. access is not possible). As soon as possible the cardiac rhythm should be established as this determines which pathway of the European Resuscitation Council and the Resuscitation Council UK ACLS Algorithm is followed (Fig. 14.32). This can be determined with an automated external defibrillator (AED), or the paddles or limb leads of a standard defibrillator.

If the ECG shows a shockable rhythm – ventricular fibrillation or pulseless ventricular tachycardia then an unsynchronized shock of 150–200 J biphasic (360 J monophasic) is delivered without delay via paddles or self-adhesive pads followed immediately by 2 minutes of CPR. For a non-shockable rhythm – asystole or pulseless electrical activity,
Therapeutic procedures

Hypothermia should be excluded with a low reading thermometer and treated with external or internal warming.

Tension pneumothorax may occur during central venous cannulation or following chest trauma. Clinical diagnosis (deviated trachea, hyperresonant chest, absent breath-sounds, ultrasound) and needle thoracocentesis/thoracostomy may be required.

Tamponade should be excluded with echocardiography and if present treated with pericardiocentesis.

Toxins may have been ingested by accident or deliberate self-harm and specific antidotes should be considered in appropriate patients.

Thromboembolism and massive pulmonary embolism may cause pulseless electrical activity and patients should be considered for intravenous thrombolysis.

Causes of unexpected cardiac arrest

Each year in the UK, there are approximately 100 000 unexpected deaths occurring within 24 hours of the development of shock.

2 minutes of CPR is delivered with 1 mg of intravenous adrenaline (epinephrine).

For both sides of the algorithm, it is necessary to maintain CPR, ensure oxygenation, and to exclude/treat reversible causes – the ‘4 Hs and 4Ts’:

- **Hypoxia** should be minimized by ventilating the patient with oxygen and a bag-valve mask or advanced airway (endotracheal intubation or supraglottic airway tube) insuring that there is bilateral air entry and chest expansion. With an advanced airway CPR should continue with a ventilation rate of 10/min without interrupting cardiac massage.

- **Hypovolaemia** is a frequent cardiac of pulseless electrical activity due to haemorrhage. Intravenous volume should be replaced.

- **Hyper- or hypokalaemia** may cause ECG abnormalities and should be detected by biochemical testing. Intravenous calcium chloride may be helpful in hyperkalaemia or hypocalcaemia. Acidosis should be managed with effective ventilation.

- **Hypothermia** should be excluded with a low reading thermometer and treated with external or internal warming.

- **Tension pneumothorax** may occur during central venous cannulation or following chest trauma. Clinical diagnosis (deviated trachea, hyperresonant chest, absent breath-sounds, ultrasound) and needle thoracocentesis/thoracostomy may be required.

- **Tamponade** should be excluded with echocardiography and if present treated with pericardiocentesis.

- **Toxins** may have been ingested by accident or deliberate self-harm and specific antidotes should be considered in appropriate patients.

- **Thromboembolism** and massive pulmonary embolism may cause pulseless electrical activity and patients should be considered for intravenous thrombolysis.

**Figure 14.32 Adult advanced life support algorithm.** CPR, cardiopulmonary resuscitation; PEA, pulseless electrical activity; VF, ventricular fibrillation. (Reproduced with permission from the Resuscitation Council: http://www.resus.org.uk/pages/alsalgo.pdf)
of cardiac symptoms. About half of these deaths are almost instantaneous. There are several causes (Table 14.6).

Most deaths are due to ventricular fibrillation or rapid ventricular tachycardia, and a small proportion are due to severe bradyarrhythmias. Coronary artery disease accounts for approximately 80% of sudden cardiac deaths in western society. Transient ischaemia is suspected as the major trigger factor; however, only a small proportion of survivors have clinical evidence of acute myocardial infarction.

There are two mechanisms of sudden unexpected cardiac arrest:

- Ventricular fibrillation or pulseless ventricular tachycardia (VF/VT)
- Non-VF/VT (asystole and pulseless electrical activity also known as electromechanical dissociation).

The principal difference in the management of these two groups of arrhythmias is the need for attempted defibrillation in those patients with VF/VT (Fig. 14.32).

Three-quarters of arrests are due to ventricular fibrillation or rapid ventricular tachycardia. Only a very small proportion is due to pulseless electrical activity. The remainder is due to asystole. An agonal rhythm is characterized by an inexorable slowing and widening of the QRS complexes associated with falling blood pressure and cardiac output. This type of arrhythmia is very difficult to reverse and usually no attempt should be made because it is the result rather than the cause of death.

 Arrests are treated in the following ways:

- Ventricular fibrillation or pulseless ventricular tachycardia is readily treated with IMMEDIATE defibrillation, cardio pulmonary resuscitation (CPR) and drugs. Intravenous amiodarone is the first-line drug in refractory VF/pulseless VT. When treating VF/VT cardiac arrest, adrenaline 1 mg is given after the third shock and then every 3–5 min. Amiodarone 300 mg is also given after the third shock, particularly if VT/VF have recurred after defibrillation.
- Asystole is more difficult to treat but the heart may respond to atropine. However atropine is not longer recommended for routine use. More recently, vasopressin has been shown to be successful. If there is any sign of slow electromechanical activity (e.g. bradycardia with a weak pulse), emergency pacing should be used. Continued CPR is critical and drug management is rarely effective.
- Pulseless electrical activity: several potentially reversible causes are listed in the universal algorithm (Fig. 14.32). It carries a very poor prognosis. Effective treatment involves continued CPR and addressing the underlying cause.

Defibrillation

This technique is used to convert ventricular fibrillation to sinus rhythm. When the defibrillator is discharged, a high-voltage field envelopes the heart which depolarizes the myocardium and allows an organized heart rhythm to emerge.

Electrical energy is discharged through two paddles with gel pads or adhesive pads placed on the chest wall. The paddles are placed in one of two positions:

- One paddle is placed to the right of the upper sternum and the other over the cardiac apex.
- One paddle is placed under the tip of the left scapula and the other is placed over the anterior wall of the left chest.

All personnel should stand clear of the patient. The person performing defibrillation has the responsibility for ensuring the safety of the patient and other people present. Conventional defibrillators employ a damped monophasic waveform. Biphasic defibrillators which require less energy are increasingly common. Automated external defibrillators (AEDs) which recognize ventricular fibrillation automatically deliver a shock if indicated. These are available in some public places (in the UK their location is noted by a specific sign as shown).

It is the responsibility of all healthcare practitioners to be familiar with the range of defibrillators they may be called on to use in their workplace. Provision of AEDs in residential areas or in the homes of patients at risk has not proved an effective therapy.

Table 14.6 Causes of unexpected cardiac arrest

| Cardiac arrhythmias (e.g. ventricular fibrillation) |
| Sudden pump failure (e.g. acute myocardial infarction) |
| Acute circulatory obstruction (e.g. pulmonary embolism) |
| Cardiovascular rupture (e.g. aortic dissection, myocardial rupture) |
| Vasomotor collapse (e.g. in pulmonary hypertension) |

Post resuscitation – therapeutic hypothermia

Randomized studies have supported the use of therapeutic hypothermia in unconscious adult patients with spontaneous circulation after an out-of-hospital cardiac arrest due to ventricular fibrillation. These patients should be cooled with careful temperature monitoring to 32–34°C for 12–24 h. External cooling methods include the use of cooling blankets; ice packs to the groin, axillae and neck; wet towels; and a cooling helmet. Invasive methods include intravenous infusions and peritoneal and pleural lavage. Shivering should be prevented by the use of a neuromuscular blocker and sedation to reduce oxygen consumption. Neurological recovery is more favourable in patients with purposeful movements and EEG activity within 3 days of a cardiac arrest.

DC cardioversion (DCC)

Tachyarrhythmias that do not respond to medical treatment or that are associated with haemodynamic compromise (e.g. hypotension, worsening heart failure) may be converted to sinus rhythm by the use of a transvenous electric shock. A short-acting general anaesthetic or powerful sedation is used. Muscle relaxants are not usually given.

When the arrhythmia has definite QRS complexes, the delivery of the shock should be timed to occur with the downstroke of the QRS complex (synchronization) (Fig. 14.33). The machine being used to perform the cardioversion will do this automatically if the appropriate button is pressed. There is a crucial difference between defibrillation and cardioversion: a non-synchronized shock is used to defibrillate. Accidental defibrillation of a patient who does not require it may itself precipitate ventricular fibrillation.

Typical indications for DCC include:

- Atrial fibrillation
- Atrial flutter
- Sustained ventricular tachycardia
- Junctional tachyarrhythmias.

If atrial fibrillation or flutter has been present for >48 hours, it is necessary to anticoagulate the patient adequately for 3 weeks before elective cardioversion to reduce the risk of embolization. Alternatively, cardioversion may be performed if intra-atrial thrombus is ruled out using a transoesophageal
Therapeutic procedures

Echocardiogram. The duration of anticoagulation after successful cardioversion for atrial fibrillation is a complex issue and depends on a number of factors: it should be for at least 4 weeks after the procedure and should be indefinite if risk factors for stroke exist.

Digoxin toxicity may lead to ventricular arrhythmias or asystole following cardioversion. Therapeutic digitalization does not increase the risks of cardioversion, but it is conventional to omit digoxin several days prior to elective cardioversion in order to be sure that toxicity is not present.

Cardiac enzyme levels may rise after a cardioversion.

Temporary pacing

Therapeutic cardiac pacing is employed in any patient with sustained symptomatic or haemodynamically compromising bradycardia. Bradycardias may be due to either a slow intrinsic heart rate (e.g. sinus node dysfunction) or atrioventricular block. Prophylactic cardiac pacing is employed in asymptomatic patients with either bradycardia or conduction abnormalities in whom the risk of progression to symptomatic bradycardia justifies such a strategy.

Temporary pacing is the preferred method in patients with symptomatic bradycardias. In summary, a thin (French gauge 5 or 6), bipolar pacing electrode wire is inserted via an internal jugular vein, a femoral vein or a subclavian vein and is positioned at the right ventricular apex using cardiac fluoroscopy. The energy needed for successful pacing (the pacing threshold) is assessed by reducing the energy until the pacemaker fails to stimulate the tissue (loss of capture). The output energy is then set at three times the threshold value to prevent inadvertent loss of capture. If the threshold increases above 5 V, the pacemaker wire should be resited. A temporary pacemaker unit (Fig. 14.34a) is almost always set to work ‘on demand’ – to fire only when a spontaneous beat has not occurred. The rate of temporary pacing is usually 60–80/minute.

Transcutaneous pacing is the preferred method in selected patients with asymptomatic bradycardia or conduction abnormalities and may be life-saving for patients in whom a cardiac arrest is precipitated by bradycardia. In this method the myocardium is depolarized by current flow between two large adhesive electrodes positioned anteriorly and posteriorly on the chest wall. Transcutaneous pacing is uncomfortable for the conscious patient. However, it can usually be tolerated until a temporary transvenous pacemaker is inserted.

Permanent pacing

Permanent pacemakers are fully implanted in the body and connected to the heart by one or two electrode leads (Fig. 14.34b). The pacemaker is powered by solid-state lithium batteries, which usually last 5–10 years. Pacemakers are ‘programmable’ in that their operating characteristics (e.g. the pacing rate) can be changed by a programmer that

Figure 14.33 DC-cardioversion of a supraventricular tachycardia to sinus rhythm. The direct current shock is delivered synchronously with the QRS complex.

Figure 14.34 Pacemakers. (a) A temporary pacemaker unit. (b) A permanent pacemaker with atrial (placed in the right atrium, usually in its high lateral wall) and ventricular (placed in the right ventricular apex) leads. (c) An electrocardiogram showing dual (atrial and ventricular) chamber pacing. A wide QRS complex results from abnormal activation of the ventricles from the right ventricular apex.
transmits specific electromagnetic signals through the skin. The pacemaker leads are passed transvenously to the right heart chambers.

Pacemakers are designed to both pace and sense either the ventricles or the atria or more commonly both chambers. A single chamber ventricular pacemaker is described as a ‘VI’ unit because it paces the ventricle (V), senses the ventricle (V) and is inhibited (I) by a spontaneous ventricular signal. Occasionally (e.g. in symptomatic sinus bradycardia), an atrial pacemaker (AAI) may be implanted. Pacemakers that are connected to both the right atrium and ventricle (‘dual chamber’ pacemakers) are used to simulate the natural pacemaker and activation sequence of the heart. This form of pacemaker is called DDD because it paces the two (dual) chambers, senses both (D) and reacts in two (D) ways – pacing in the same chamber is inhibited by spontaneous atrial and ventricular signals, and ventricular pacing is triggered by spontaneous atrial events (Fig. 14.34c).

In addition, pacemakers may be ‘rate responsive’ (R). A rate-responsive pacemaker detects motion (level of vibration or acceleration), respiration, or changes in QT interval, and by employing one or more biosensors, changes its rate of pacing so that it is appropriate to the level of exertion.

The choice of pacemaker mostly depends on the underlying rhythm abnormality and the general condition of the patient. For example, complete heart block in patients with sinus rhythm should be treated with a dual-chamber device in order to maintain AV synchrony, whereas inactive or infirm patients may not benefit from the most sophisticated units. Specialized biventricular pacemakers are used for the treatment of severe heart failure.

Permanent pacemakers are inserted under local anaesthetic using fluoroscopy to guide the insertion of the electrode leads via the cephalic or subclavian veins. Perioperative prophylactic antibiotics are routinely prescribed. The pacemaker is usually positioned subcutaneously in front of the pectoral muscle. Following surgery, which usually takes 60–90 minutes, the patient rests in bed for 6–12 hours before being discharged. Patients may not drive for at least 1 week after implantation, and must inform the licensing authorities and their motor insurers.

Complications are few but can prove to be very difficult to manage, and patients should be referred to the pacemaker clinic. They include the following:
- Infection
- Erosion
- Pocket haematoma
- Lead displacement
- Electromagnetic interference.

**Pericardiocentesis**

A pericardial effusion is an accumulation of fluid between the parietal and visceral layers of pericardium. Fluid is removed to relieve symptoms that are due to haemodynamic embarrassment or for diagnostic purposes. This can be a technically difficult procedure, particularly in the acute setting. In an emergency it can be performed at the bedside.

Pericardial aspiration or pericardiocentesis is performed by inserting a needle into the pericardial space, usually via a subxiphisternal route under ultrasound guidance. Certain effusions, particularly posterior ones, require surgical drainage under a general anaesthetic. If a large volume of fluid is to be removed, a wide-bore needle and cannula are inserted. The needle may be removed and the cannula left in situ to drain the fluid. Fluid that is removed is sent for chemical analysis, microscopy, including cytology, Gram-stain and culture. If a reaccumulation of pericardial fluid is anticipated, the cannula may be left in place for several days, or an operation can be performed to cut a window in the parietal pericardium (fenestration) or to remove a large section of the pericardium.

**Right-heart bedside catheterization**

Bedside catheterization (Fig. 16.18) of the pulmonary artery with a pulmonary artery balloon flotation catheter (Swann–Ganz catheter) is performed in patients with:
- Cardiac failure
- Cardiogenic shock
- Doubtful fluid status.

**Intra-aortic balloon pumping**

This is a technique used to assist temporarily the failing left ventricle. A catheter with a long sausage-shaped balloon at its tip is introduced percutaneously into the femoral artery and manipulated under X-ray control so that the balloon lies in the descending aorta just below the aortic arch (Fig. 14.35). The balloon is rhythmically deflated and inflated with carbon dioxide gas. Using the ECG or intra-aortic pressure changes, the inflation is timed to occur during ventricular diastole to increase diastolic aortic pressure and consequently to improve coronary and cerebral blood flow. During systole the balloon is deflated, resulting in a reduction in the resistance to left ventricular emptying. Intra-aortic balloon pumping is used for circulatory support in the following acute situations:

![Figure 14.35 Intra-aortic balloon pump – inflated in aorta on the left and deflated on the right.](image-url)
Acute heart failure. Balloon pumping is used to improve cardiac output when there is a transient or reversible depression of left ventricular function, such as in a patient with severe mitral valve regurgitation who is awaiting surgical replacement of the mitral valve, or in a patient with a ventricular septal defect that is due to septal infarction. It may also be used to support patients awaiting heart transplantation.

Unstable angina pectoris. Balloon pumping is used to treat unstable angina pectoris by improving coronary flow and decreasing myocardial oxygen consumption by reducing the ‘afterload’. This technique may be successful, even when medical therapy has failed. It is followed by early angiography and appropriate definitive therapy such as surgery or coronary angioplasty.

Balloon pumping should not be used when there is no remediable cause of cardiac dysfunction. It is also unsuitable in patients with severe aortic regurgitation, aortic dissection and severe peripheral vascular disease.

Complications of balloon pumping occur in about 20% of patients and include aortic dissection, leg ischaemia, emboli from the balloon and balloon rupture. Embolic complications are reduced by anticoagulation with heparin.

CARDIAC ARRHYTHMIAS

An abnormality of the cardiac rhythm is called a cardiac arrhythmia. Arrhythmias may cause sudden death, syncope, heart failure, chest pain, dizziness, palpitations or no symptoms at all. There are two main types of arrhythmia:

- **Bradyarrhythmias**: the heart rate is slow (<60 b.p.m. during the day or <50 b.p.m. at night)
- **Tachyarrhythmias**: the heart rate is fast (>100 b.p.m.)

Tachyarrhythmias are more symptomatic when the arrhythmia is fast and sustained. Tachyarrhythmias are subdivided into supraventricular tachycardias, which arise from the atrium or the atrioventricular junction, and ventricular tachycardias, which arise from the ventricles.

Some arrhythmias occur in patients with apparently normal hearts, and in others arrhythmias originate from diseased tissue, such as scar, as a result of underlying structural heart disease. When myocardial function is poor, arrhythmias are more symptomatic and are potentially life-threatening.

### Sinus node function

The normal cardiac pacemaker is the sinus node (p. 669) and, like most cardiac tissue, it depolarizes spontaneously.

The rate of sinus node discharge is modulated by the autonomic nervous system. Normally the parasympathetic system predominates, resulting in slowing of the spontaneous discharge rate from approximately 100 to 70 b.p.m. A reduction of parasympathetic tone or an increase in sympathetic stimulation leads to tachycardia; conversely, increased parasympathetic tone and decreased sympathetic stimulation produces bradycardia. The sinus rate in women is slightly faster than in men. Normal sinus rhythm is characterized by P waves that are upright in leads I, and II of the ECG (Fig. 14.18), but inverted in the cavity leads AVR and V1 (Fig. 14.36a).

### Sinus bradycardia

A sinus rate of <60 b.p.m. during the day or <50 b.p.m. at night is known as sinus bradycardia. It is usually asymptomatic unless the rate is very slow. It is normal in athletes owing to increased vagal tone. Other causes may be divided into systemic or cardiac and are discussed below in the section entitled ‘Bradycardias and heart block’ (see p. 698).

### Sinus tachycardia

Sinus rate acceleration to more than 100 b.p.m. is known as sinus tachycardia. Again, causes may be divided into...
Mechanisms of arrhythmia production

Abnormalities of automaticity, which could arise from a single cell, and abnormalities of conduction, which require abnormal interaction between cells, account for both bradyarrhythmias and tachyarrhythmias. Sinus bradycardia is a result of abnormally slow automaticity while bradycardia due to AV block is caused by abnormal conduction within the AV node or the intraventricular conduction system. The mechanisms generating tachycardia are shown in Figure 14.37.

**Accelerated automaticity** (Fig. 14.37a)

The normal mechanism of spontaneous cardiac rhythmicity is slow depolarization of the transmembrane voltage during diastole until the threshold potential is reached and the action potential of the pacemaker cells takes off. This mechanism may be accelerated by increasing the rate of diastolic depolarization or changing the threshold potential. For example, sympathetic stimulation releases epinephrine (adrenaline), which enhances automaticity. Such changes are thought to produce sinus tachycardia, escape rhythms and accelerated AV nodal (junctional) rhythms.

**Figure 14.37 Mechanisms of arrhythmogenesis.** (a,b)

Action potentials (i.e. the potential difference between intracellular and extracellular fluid) of ventricular myocardium after stimulation. (a) Increased (accelerated) automaticity due to reduced threshold potential or an increased slope of phase 4 depolarization (see p. 680). (b) Triggered activity due to early (E) or delayed (D) ‘after depolarizations’ reaching threshold potential. (c) Mechanism of circus movement or re-entry. In panel (1) the impulse passes down both limbs of the potential tachycardia circuit. In panel (2) the impulse is blocked in one pathway (α) but proceeds slowly down pathway β, returning along pathway α until it collides with refractory tissue. In panel (3) the impulse travels so slowly along pathway β that it can return along pathway α and complete the re-entry circuit, producing a circus movement tachycardia.

**Triggers of arrhythmia**

Myocardial damage can result in oscillations of the transmembrane potential at the end of the action potential. These oscillations, which are called ‘after depolarizations’, may reach threshold potential and produce an arrhythmia. If they occur before the transmembrane potential reaches its threshold (at the end of phase 3 of the action potential), they are called ‘early after depolarizations’ (E in Fig. 14.37b). When they develop after the transmembrane potential is completed, they are called ‘delayed after depolarizations’ (D in Fig. 14.37b).

The abnormal oscillations can be exaggerated by pacing, catecholamines, electrolyte disturbances, hypoxia, acidosis and some medications, which may then trigger arrhythmia. The atrial tachycardias produced by digoxin toxicity are due to triggered activity. The initiation of ventricular arrhythmia in the long QT syndrome (p. 708) may be caused by this mechanism.

**Re-entry (or circus movements)** (Fig. 14.37c)

The mechanism of re-entry occurs when a ‘ring’ of cardiac tissue surrounds an inexcitable core (e.g. in a region of scarred myocardium). Tachycardia is initiated if an ectopic beat finds one limb refractory (α), resulting in unidirectional block, and the other limb excitable. Provided conduction through the excitable limb (β) is slow enough, the other limb (α) will have recovered and will allow retrograde activation to complete the re-entry loop. If the time to conduct around the ring is longer than the recovery times (refractory periods) of the tissue within the ring, circus movement will be maintained, producing a run of tachycardia. The majority of regular paroxysmal tachycardias are produced by this mechanism.

**Bradycardia and heart block**

Bradycardias may be due to failure of impulse formation (sinus bradycardia) or failure of impulse conduction from the atria to the ventricles (atrioventricular block).

**Bradycardia**

Sinus bradycardia

Sinus bradycardia is due to extrinsic factors influencing a relatively normal sinus node or due to intrinsic sinus node disease. The mechanism can be acute and reversible or chronic and degenerative. Common causes of sinus bradycardia include:

**Extrinsic causes**

- Hypothermia, hypothyroidism, cholestatic jaundice and raised intracranial pressure
- Drug therapy with beta-blockers, digitalis and other antiarrhythmic drugs
- Neuromediated syndromes (see below).

**Intrinsic causes**

- Acute ischaemia and infarction of the sinus node (as a complication of acute myocardial infarction)
- Chronic degenerative changes such as fibrosis of the atrium and sinus node (sick sinus syndrome).

**Sick sinus syndrome or sinoatrial disease** is usually caused by idiopathic fibrosis of the sinus node. Other causes of fibrosis such as ischaemic heart disease, cardiomyopathy or myocarditis can also cause the syndrome. Patients develop episodes of sinus bradycardia or sinus arrest (Fig. 14.36) and commonly, owing to diffuse atrial disease, experience paroxysmal atrial tachyarrhythmias (tachy-brady syndrome).
Neurally mediated syndromes

Neurally mediated syndromes are due to a reflex (called Bezold–Jarisch) that may result in both bradycardia (sinus bradycardia, sinus arrest and AV block) and reflex peripheral vasodilatation. These syndromes usually present as syncope or pre-syncope (dizzy spells).

**Carotid sinus syndrome** occurs in the elderly and mainly results in bradycardia. Syncope occurs (see p. 676).

**Neurocardiogenic (vasovagal) syncope (syndrome)** usually presents in young adults but may present for the first time in elderly patients (see p. 676). It results from a variety of situations (physical and emotional) that affect the autonomic nervous system. The efferent output may be predominantly bradycardic, predominantly vasodilatory or mixed.

**Postural orthostatic tachycardia syndrome (POTS)** is a sudden and significant increase in heart rate associated with normal or mildly reduced blood pressure produced by standing. The underlying mechanism is a failure of the peripheral vasculature to appropriately constrict in response to orthostatic stress, which is compensated by an excessive increase in heart rate.

Many medications, such as antihypertensives, tricyclic antidepressants and neuroleptics, can be the cause of syncope, particularly in the elderly. Careful dose titration and avoidance of combining two agents with potential to cause syncope help to prevent iatrogenic syncope.

**Treatment**

The management of sinus bradycardia is first to identify and if possible remove any extrinsic causes. Temporary pacing may be employed in patients with reversible causes until a normal sinus rate is restored and in patients with chronic degenerative conditions until a permanent pacemaker is implanted.

Chronic symptomatic sick sinus syndrome requires permanent pacing (DDD), with additional antiarrhythmic drugs (or ablation therapy) to manage any tachycardia element. Thromboembolism is common in tachy-brady syndrome and patients should be anticoagulated unless there is a contraindication.

Patients with carotid sinus hypersensitivity (asystole >3 s), especially if symptoms are reproduced by carotid sinus massage, and in whom life-threatening causes of syncope have been excluded, benefit from pacemaker implantation.

Treatment options in vasovagal attacks include avoidance, if possible, of situations known to cause syncope in a particular patient, and sitting/lying down and applying counter pressure manoeuvres (pushing palms together or crossing legs) if an attack threatens. Increased salt intake, compression of the lower legs with hose and drugs such as beta-blockers, alpha-agonists, e.g. midodrine, or myocardial negative inotropes (such as disopyramide) may be helpful.

In selected patients with ‘malignant’ neurocardiogenic syncope (syncope associated with injuries and demonstrated asystole) permanent pacemaker therapy is helpful. These patients benefit from dual chamber pacemakers with a feature called ‘rate drop response’ which, once activated, paces the heart at a fast rate for a set period of time in order to prevent syncope.

**Heart block**

Heart block or conduction block may occur at any level in the conducting system. Block in either the AV node or the His bundle results in AV block, whereas block lower in the conduction system produces bundle branch block.

**Atrioventricular block**

There are three forms:

**First-degree AV block**

This is simple prolongation of the PR interval to >0.22 s. Every atrial depolarization is followed by conduction to the ventricles but with delay (Fig. 14.38).

**Second-degree AV block**

This occurs when some P waves conduct and others do not. There are several forms (Fig. 14.39):

- **Mobitz I block** (Wenckebach block phenomenon) is progressive PR interval prolongation until a P wave fails to conduct. The PR interval before the blocked P wave is much longer than the PR interval after the blocked P wave.
- **Mobitz II block** occurs when a dropped QRS complex is not preceded by progressive PR interval prolongation. Usually the QRS complex is wide (>0.12 s).
- **2:1 or 3:1 (advanced) block** occurs when every second or third P wave conducts to the ventricles. This form of second-degree block is neither Mobitz I nor II. Wenckebach AV block in general is due to block in the AV node, whereas Mobitz II block signifies block at an infra-nodal level such as the His bundle. The risk of progression to complete heart block is greater and the reliability of the resultant escape rhythm is less with Mobitz II block. Therefore pacing is usually indicated in Mobitz II block, whereas patients with Wenckebach AV block are usually monitored.

**Acute myocardial infarction** may produce second-degree heart block. In inferior myocardial infarction, close monitoring and transcutaneous temporary back-up pacing are all that is required. In anterior myocardial infarction, second-degree heart block is associated with a high risk of progression to complete heart block, and temporary pacing followed by permanent pacemaker implantation is usually indicated; 2:1 Heart block may either be due to block in the AV node or at an infra-nodal level. Management depends on the clinical setting in which it occurs.

**Third-degree (complete) AV block**

Complete heart block occurs when all atrial activity fails to conduct to the ventricles (Fig. 14.40). In patients with complete heart block the aetiology needs to be established (Table 14.7). In this situation life is maintained by a spontaneous escape rhythm.

**Narrow complex escape rhythm** (<0.12 s QRS complex) implies that it originates in the His bundle and therefore that the region of block lies more proximally in the AV node. The escape rhythm occurs with an adequate rate (50–60 b.p.m.) and is relatively reliable.

**Treatment** depends on the aetiology. Recent-onset narrow-complex AV block due to transient causes may respond to intravenous atropine, but temporary pacing
AV block may also be caused by ischaemic heart disease, myocarditis or cardiomyopathy. Permanent pacemaker implantation (p. 695) is indicated, as pacing considerably reduces the mortality. Because ventricular arrhythmias are not uncommon, an implantable cardioverter-defibrillator (ICD) may be indicated in those with severe left ventricular dysfunction (>0.30 s).

Bundle branch block

The His bundle gives rise to the right and left bundle branches. The left bundle subdivides into the anterior and posterior divisions of the left bundle. Various conduction disturbances can occur.

Bundle branch conduction delay

This produces slight widening of the QRS complex (up to 0.11 s). It is known as incomplete bundle branch block.
Complete block of a bundle branch

This is associated with a wider QRS complex (≥0.12 s). The shape of the QRS depends on whether the right or the left bundle is blocked.

**Right bundle branch block** (Fig. 14.41a) produces late activation of the right ventricle. This is seen as deep S waves in leads I and V6 and as a tall late R wave in lead V1 (late activation moving towards right- and away from left-sided leads).

**Left bundle branch block** (Fig. 14.42) produces the opposite – a deep S wave in lead V1 and a tall late R wave in leads I and V6. Because left bundle branch conduction is normally responsible for the initial ventricular activation, left bundle branch block also produces abnormal Q waves.

**Hemiblock**

Delay or block in the divisions of the left bundle branch produces a swing in the direction of depolarization (electrical axis) of the heart. When the anterior division is blocked (left anterior hemiblock), the left ventricle is activated from inferior to superior. This produces a superior and leftwards movement of the axis (left axis deviation). Delay or block in the postero-inferior division swings the QRS axis inferiorly to the right (right axis deviation).

**Bifascicular block** (Fig. 14.41b)

This is a combination of a block of any two of the following: the right bundle branch, the left antero-superior division and the left postero-inferior division. Block of the remaining fascicle will result in complete AV block.

**Clinical features of heart blocks**

Bundle branch blocks are usually asymptomatic. Right bundle branch block causes wide but physiological splitting of the second heart sound. Left bundle branch block may cause reverse splitting of the second sound. Patients with intraventricular conduction disturbances may complain of syncope. This is due to intermittent complete heart block or

to ventricular tachyarrhythmias. ECG monitoring and electrophysiological studies are needed to determine the cause of syncope in these patients.

**Causes**

Right bundle branch block occurs as an isolated congenital anomaly or is associated with cardiac or pulmonary conditions (Table 14.8). Right bundle branch block alone does not alter the electrical axis of the heart. Axis deviations signify right ventricular hypertrophy (RV overload) or co-existent fascicular block. The combination of right bundle branch block with left axis deviation is associated with ostium primum atrial septal defects. Complete left bundle branch block is often associated with extensive left ventricular disease. The most common causes are listed in Table 14.8 and are similar to those of complete heart block.

**Supraventricular tachycardias**

Supraventricular tachycardias (SVTs) arise from the atrium or the atrioventricular junction. Conduction is via the His–Purkinje system; therefore the QRS shape during tachycardia is usually similar to that seen in the same patient during baseline rhythm. A classification of supraventricular tachycardia is listed in Table 14.9. Some of these are discussed in more detail below.

**Inappropriate sinus tachycardia**

Inappropriate sinus tachycardia is a persistent increase in resting heart rate unrelated to or out of proportion with the level of physical or emotional stress. It is found predominantly in young women and is not uncommon in health professionals. Sinus tachycardia due to intrinsic sinus node abnormalities such as enhanced automaticity, or abnormal autonomic regulation of the heart with excess sympathetic and reduced parasympathetic input, is extremely rare.

In general, sinus tachycardia is a secondary phenomenon and the underlying causes need to be actively investigated. Depending on the clinical setting, acute causes include exercise, emotion, pain, fever, infection, acute heart failure, acute pulmonary embolism and hypovolaemia. Chronic causes include pregnancy, anaemia, hyperthyroidism and catecholamine excess. The underlying cause should be found and treated, rather than treating the compensatory physiological response. If necessary, beta-blockers may be used to slow the sinus rate, e.g. in hyperthyroidism (p. 937); ivabradine, an If (pacemaker current) blocker, may be useful when beta-blockade cannot be tolerated.

**Atrioventricular junctional tachycardias**

AV nodal re-entry and AV re-entry tachycardias are usually referred to as paroxysmal SVTs and are often seen in young patients with no or little structural heart disease, although congenital heart abnormalities (e.g. Ebstein’s anomaly, atrial septal defect, Fallot’s tetralogy) can co-exist in a small proportion of patients with these arrhythmias. The first presentation is commonly between ages 12 and 30, and the prevalence is approximately 2.5/1000.

In these tachycardias the AV node is an essential component of the re-entry circuit.

**Atrioventricular nodal re-entry tachycardia (AVNRT)**

This tachycardia is twice as common in women. Clinically, the tachycardia often strikes suddenly without obvious provocation, but exertion, coffee, tea and alcohol may aggravate

</table>
or induce the arrhythmia. An attack may stop spontaneously or may continue indefinitely until medical intervention.

In AVNRT, there are two functionally and anatomically different pathways predominantly within the AV node: one is characterized by a short effective refractory period and slow conduction, and the other has a longer effective refractory period and conducts faster. In sinus rhythm, the atrial impulse that depolarizes the ventricles usually conducts through the fast pathway. If the atrial impulse (e.g., an atrial premature beat) occurs early when the fast pathway is still refractory, the slow pathway takes over in propagating the atrial impulse to the ventricles. It then travels back through the fast pathway which has already recovered its excitability, thus initiating the most common ‘slow-fast’, or typical, AVNRT.

The rhythm is recognized on ECG by normal regular QRS complexes, usually at a rate of 140–240/minute (Fig. 14.43a). Sometimes the QRS complexes will show typical bundle branch block. P waves are either not visible or are seen immediately before or after the QRS complex because of simultaneous atrial and ventricular activation. Less commonly observed (5–10%) is atrial tachycardia when the atrial impulse conducts anterogradely through the fast pathway and returns through the slow pathway, producing a long RP interval (‘fast-slow’, or long RP tachycardia).

**Atrioventricular reciprocating tachycardia (AVRT)**

This large circuit comprises the AV node, the His bundle, the ventricle and an abnormal connection of myocardial fibres from the ventricle back to the atrium. It is called an accessory pathway or bypass tract and results from an incomplete separation of the atria and the ventricles during fetal development.

In contrast to AVNRT, this tachycardia is due to a macro-reentry circuit and each part of the circuit is activated sequentially. As a result atrial activation occurs after ventricular activation and the P wave is usually clearly seen between the QRS and T wave (Fig. 14.43b).

Accessory pathways are most commonly situated on the left but may occur anywhere around the AV groove. The most common accessory pathways, known as *Kent bundles*, are in the free wall or septum. In about 10% of cases multiple pathways occur. *Mahaim fibres* are atrio-fascicular or nodo-fascicular fibres entering the ventricular myocardium in the region of the right bundle branch. Accessory pathways that conduct from the ventricles to the atria only are not visible on the surface ECG during sinus rhythm and are therefore ‘concealed’. Accessory pathways that conduct bidirectionally usually are manifest on the surface ECG. If the accessory pathway conducts from the atrium to the ventricle during sinus rhythm, the electrical impulse can conduct quickly over this abnormal connection to depolarize part of the ventricles abnormally (pre-excitation). A pre-excited ECG is characterized by a short PR interval and a wide QRS complex that begins as a slurred part known as the δ wave (Fig. 14.43c). Patients with a history of palpitations and a pre-excited ECG have a syndrome known as Wolff–Parkinson–White (WPW) syndrome.

During AVRT the AV node and ventricles are activated normally (orthodromic AVRT), resulting usually in a narrow QRS complex. Less commonly, the tachycardia circuit can be reversed, with activation of the ventricles via the accessory pathway and atrial activation via retrograde conduction through the AV node (antidromic AVRT). This results in a broad complex tachycardia. These patients are also prone to atrial fibrillation.

During atrial fibrillation, the ventricles may be depolarized by impulses travelling over both the abnormal and the normal pathways. This results in pre-excited atrial fibrillation, a characteristic tachycardia that is characterized by irregularly irregular broad QRS complexes (Fig. 14.43d). If an accessory pathway has a short antegrade effective refractory period (<250 ms), it may conduct to the ventricles at an extremely high rate and may cause ventricular fibrillation. The incidence of sudden death is 0.15–0.39% per patient-year and it may be a first manifestation of the disease in younger individuals. Verapamil and digoxin may allow a higher rate of conduction over the abnormal pathway and precipitate ventricular fibrillation. Therefore, neither verapamil nor digoxin should be used to treat atrial fibrillation associated with the WPW syndrome.

![Figure 14.43 Atrioventricular junctional tachycardia. (a) Atrioventricular nodal re-entry tachycardia. The QRS complexes are narrow and the P waves cannot be seen. Note tachycardia with broad QRS complexes with fast and irregular ventricular rate.](image-url)
Symptoms
The leading symptom of most SVTs, in particular AV node re-entry and AV re-entry tachycardias, is rapid regular palpitations, usually with abrupt onset and sudden termination, which can occur spontaneously or be precipitated by simple movements. A common feature is termination by Valsalva manoeuvres. In younger individuals with no structural heart disease, the rapid heart rate can be the main pathological finding.

Irregular palpitations may be due to atrial premature beats, atrial flutter with varying AV conduction block, atrial fibrillation or multifocal atrial tachycardia. In patients with depressed ventricular function, uncontrolled atrial fibrillation can reduce cardiac output and cause hypotension and congestive heart failure.

Other symptoms may include anxiety, dizziness, dyspnoea, neck pulsation, central chest pain and weakness. Polyuria may occur because of release of atrial natriuretic peptide in response to increased atrial pressures during the tachycardia, especially during AVNRT and atrial fibrillation. Prominent jugular venous pulsations due to atrial contractions against closed atrioventricular valves may be observed during AVNRT.

Syncope has been reported in 10–15% of patients, usually just after initiation of the arrhythmia or in association with a prolonged pause following its termination. It is more common if the patient is standing. However, in older patients with concomitant heart disease, such as aortic stenosis, hypertrophic cardiomyopathy and cerebrovascular disease, significant hypotension and syncope may result from moderately fast ventricular rates.

Acute management
In an emergency, distinguishing between AVNRT and AVRT may be difficult, but it is usually not critical as both tachycardias respond to the same treatment. Patients presenting with SVTs and haemodynamic instability (e.g. hypotension, pulmonary oedema) require emergency cardioversion. If the patient is haemodynamically stable, vagal manoeuvres, including right carotid massage (Practical Box 14.3), Valsalva manoeuvre (Practical Box 14.4) and facial immersion in cold water may be observed during AVNRT.

In some patients, adenosine can induce atrial fibrillation. An alternative treatment is verapamil 5–10 mg i.v. over 5–10 min, i.v. diltiazem, or beta-blockers (esmolol, propranolol, metoprolol). Verapamil (or diltiazem) must not be given after beta-blockers or if the tachycardia presents with broad (>0.12 s) QRS complexes.

Long-term management
Patients with suspected cardiac arrhythmias should always be referred to the cardiologist for electrophysiological evaluation and long-term management, as both pharmacological and non-pharmacological alternatives, including ablation of an accessory pathway, are readily available. Verapamil, diltiazem and beta-blockers have proven efficacy in 60–80% of patients. Sodium-channel blockers (flecainide and propafenone), potassium repolarization current blockers (sotalol, dofetilide, azimilide), and the multichannel blocker amiodarone may also prevent the occurrence of tachycardia.

Refinement of catheter ablation techniques has rendered many AV junctional tachycardias entirely curable. Modification of the slow pathway is successful in 96% of patients with AVNRT, although a 1% risk of AV block is present. In AVRT, the target for catheter ablation is the accessory pathway(s). The success rate for ablation of a single accessory pathway is approximately 95%, with a recurrence rate of 5%, requiring a repeat procedure.

Atrial tachyarrhythmias
Atrial tachyarrhythmias including atrial fibrillation, atrial flutter, atrial tachycardia and atrial ectopic beats all arise from the atrial myocardium (Fig. 14.44). They share common aetiologies, which are listed in Table 14.10.

Atrial fibrillation
This is a common arrhythmia, occurring in 1–2% of the general population and 5–10% of patients over 75 years of age. It also occurs, particularly in a paroxysmal form, in younger patients. Any condition resulting in raised atrial pressure, increased atrial muscle mass, atrial fibrosis, inflammation and infiltration of the atrium, may cause atrial fibrillation. There are also many genetic and systemic causes of atrial fibrillation (Table 14.10).

Although rheumatic heart disease, alcohol intoxication and thyrotoxicosis are the ‘classic’ causes of atrial fibrillation, hypertension and heart failure are the most common causes.
Hyperthyroidism may provoke atrial fibrillation, sometimes as virtually the only feature of the disease, and thyroid function tests are mandatory in any patient with unaccounted atrial fibrillation. Atrial fibrillation occurs in one-third of patients after cardiac surgery. It usually manifests during the first hospital stay, and later recurrences.

In some patients no cause can be found, and this group is labelled as ‘lone’ atrial fibrillation. The pathogenesis of ‘lone’, or ‘idiopathic’, atrial fibrillation is unknown but genetic predisposition or even specific genetically predetermined forms of the arrhythmia have been proposed. About 30–40% of those with AF, especially those who present at a young age, have at least one parent with AF and genes associated with the sodium channel, the potassium channel, gap junction proteins and right left isomerism) have been implicated. Gene defects linked to chromosomes 10, 6, 5 and 4 have been associated with familial AF.

Atrial fibrillation is maintained by continuous, rapid (300–600/min) activation of the atria by multiple meandering re-entry wavelets, often driven by rapidly depolarizing automatic foci, located predominantly within the pulmonary veins. The atria respond electrically at this rate but there is no coordinated mechanical action and only a proportion of the impulses are conducted to the ventricles. The ventricular response depends on the rate and regularity of atrial activity, particularly at the entry to the AV node, the refractory properties of the AV node itself, and the balance between sympathetic and parasympathetic tone.

**Symptoms and signs**

Symptoms attributable to atrial fibrillation are highly variable. In some patients (about 30%) it is an incidental finding, whilst others attend hospital as an emergency with rapid palpitations dyspnoea and/or chest pain following the onset of atrial fibrillation. Most patients with ongoing atrial fibrillation experience some deterioration of exercise capacity or wellbeing, but this may only be appreciated once sinus rhythm is restored. When caused by rheumatic mitral stenosis, the onset of atrial fibrillation results in considerable worsening of cardiac failure.

The patient has a very irregular pulse, as opposed to a basically regular pulse with an occasional irregularity (e.g. extrasystoles) or recurring irregular patterns (e.g. Wenckebach block). The irregular nature of the pulse in atrial fibrillation is maintained during exercise. The ECG shows fine oscillations of the baseline (so-called fibrillation or f waves) and no clear P waves. The QRS rhythm is rapid and irregular. Untreated, the ventricular rate is usually 120–180/minute, but it slows with treatment.

The clinical classification of atrial fibrillation includes first detected, paroxysmal (stops spontaneously within 7 days), persistent (requires cardioversion to stop), and permanent (no spontaneous or induced cardioversion) forms of the arrhythmia and is helpful for the decision-making between rhythm restoration and rate control. Atrial fibrillation may be asymptomatic and the ‘first detected episode’ should not be regarded as necessarily the true onset.
Management

When atrial fibrillation is due to an acute precipitating event such as alcohol toxicity, chest infection or hyperthyroidism, the provoking cause should be treated. Strategies for the acute management of AF are:

- **Ventricular rate control**: this is achieved by drugs which block the AV node (see below)

- **Cardioversion** (β: anticoagulation): this is achieved electrically by DC shock (p. 694) or medically either by intravenous infusion of an antiarrhythmic drug such as flecaïnide, propafenone, vernakalant or amiodarone or by taking an oral agent (flecainide or propafenone) previously tested in hospital and found to be safe in a particular patient (‘pill-in-pocket’ approach).

  The choice depends upon:

  - how well the arrhythmia is tolerated (is cardioversion urgent?)
  - whether anticoagulation is required before considering elective cardioversion
  - whether spontaneous cardioversion is likely (previous history? reversible cause?).

  Conversion to sinus rhythm can be achieved by electrical DC cardioversion (p. 694) in about 80% of patients. Biphasic waveform defibrillation is more effective than conventional (monophasic) defibrillation, and biphasic defibrillators are now standard. To minimize the risk of thromboembolism associated with cardioversion patients are fully anticoagulated with warfarin (INR 2.0–3.0) or with dabigatran 150 mg twice daily for 3 weeks before cardioversion (unless atrial fibrillation is of < 48 hours duration) and at least 4 weeks after the procedure. The patient is then assessed for the necessity for long-term anticoagulation. If cardioversion is urgent, transoesophageal echocardiography may be used to document the presence or absence of atrial thrombus as a guide to possibly avoiding pre-cardioversion anticoagulation.

Long-term management of atrial fibrillation

Two strategies are available:

- **‘Rate control’** (AV nodal slowing agents plus oral anticoagulation)

- **‘Rhythm control’** (antiarrhythmic drugs plus DC cardioversion plus oral anticoagulation).

  Major randomized studies in patients predominantly over the age of 65 years (AFFIRM) or in patients with heart failure (AF-CHF) have shown that there is no net mortality or vascular outcome but it does successfully treat symptoms due to atrial fibrillation. The ectopic triggers for atrial fibrillation are generally found in the pulmonary veins which can be isolated from the atria using radiofrequency or cryothermal energy. Occasionally, more extensive ablation within the left atrium is needed. These techniques are more successful than antiarrhythmic drugs and may represent a ‘cure’ in some patients. However, the procedure is invasive and carries some hazard of serious complications such as stroke, and bleeding in about 2% of cases. In the long term, recurrence is not uncommon and an apparently successful ablation does not remove the obligation for appropriate anticoagulation. Ablation has not been shown to improve long-term cardiovascular outcome but it does successfully treat symptoms due to atrial fibrillation.

Rate control

As a primary strategy this is appropriate in patients who:

- have the permanent form of the arrhythmia associated with symptoms which can be further improved by slowing heart rate or are older than 65 years with recurrent atrial tachyarrhythmias (‘accepted’ atrial fibrillation)

- have persistent tachyarrhythmias and have failed cardioversion(s) and serial prophylactic antiarrhythmic drug therapy and in whom the risk/benefit ratio from using specific antiarrhythmic agents is shifted towards increased risk.

Rate control is usually achieved by a combination of digoxin, beta-blockers or nondihydropyridine calcium-channel blockers (verapamil or diltiazem). Digoxin monotherapy may be sufficient for elderly non-ambulant patients. In younger patients the effect of catecholamines easily overwhelms the vagotonic effect of digoxin and additional AV nodal slowing agents are needed. The ventricular rate response is generally considered controlled if the resting heart rate is < 110 b.p.m. but a more strict control between 60 and 80 b.p.m. at rest and < 110 b.p.m. during moderate exercise may be needed if symptoms persist. To assess the adequacy of rate control, an ECG rhythm strip may be sufficient in an elderly patient but ambulatory 24-hour Holter monitoring and an exercise stress test (treadmill) are needed in younger individuals. Older patients with poor rate control despite optimal medical therapy should be considered for AV node ablation and pacemaker implantation (‘ablate and pace’ strategy). These patients usually experience a marked symptomatic improvement but because of the ongoing risk of thromboembolism require life-long anticoagulation.

Anticoagulation

This is indicated in patients with atrial fibrillation related to rheumatic mitral stenosis or in the presence of a mechanical prosthetic heart valve. A scoring system known as CHADS2 is used as the first step to determine the need for anticoagulation. CHADS2 is an acronym standing for Congestive heart failure, Hypertension, Age ≥ 75, Diabetes mellitus and previous Stroke or TIA. Each factor scores 1 except previous stroke or TIA which scores 2. A total score of 2 implies that oral anticoagulation is needed. When the score is ≥ 2 the CHADS2VASc scoring system should be applied. CHADS2VASc adds Vascular disease (aorta, coronary or peripheral arteries), Age 65–74, and female Sex category. Each factor scores 1 except previous Age ≥ 75 and stroke or TIA which score 2. A CHADS2VASc score of 2 requires oral anticoagulation and a score of 1 merits consideration for oral anticoagulation or aspirin. A score of 0 should not require any antithrombotic prophylaxis.
Cardiac arrhythmias

When oral anticoagulation is required either warfarin (dose adjusted to maintain an INR between 2.0 and 3.0) or dabigatran 150 mg two times daily (or 110 mg two times daily in elderly patients (>75 years), those with moderate renal impairment (creatinine clearance: 30 to 50 mL/min) or those taking P-glycoprotein inhibitors such as amiodarone and verapamil) can be considered. Other new oral anticoagulants, such as apixaban and rivaroxaban, are now also being used.

Atrial flutter
Atrial flutter is often associated with atrial fibrillation and often requires a similar initial therapeutic approach. Atrial flutter is usually an organized atrial rhythm with an atrial rate typically between 250 and 350 b.p.m. Typical, or isthmus-dependent, atrial flutter involves a macro re-entrant right atrial circuit around the tricuspid annulus. The wavefront circulates down the lateral wall of the right atrium, through the Eustachian ridge between the tricuspid annulus and the inferior vena cava, and up the interatrial septum, giving rise to the most frequent pattern, referred to as counter-clockwise flutter. Re-entry can also occur in the opposite direction (clockwise or reverse flutter).

The ECG shows regular sawtooth-like atrial flutter waves (F waves) between QRS complexes (Fig. 14.44c). In typical counter-clockwise atrial flutter, the F waves are negative in the inferior leads and positive in leads V1 and V2. In clockwise atrial flutter, the deflection of the F waves is the opposite. If F waves are not clearly visible, it is worth trying to reveal them by slowing AV conduction by carotid sinus massage or by the administration of AV nodal blocking drugs such as adenosine or verapamil.

Symptoms are largely related to the degree of AV block. Most often, every second flutter beat conducts, giving a ventricular rate of 150 b.p.m. Occasionally, every beat conducts, producing a heart rate of 300 b.p.m. More often, especially when patients are receiving treatment, AV conduction block reduces the heart rate to approximately 75 b.p.m.

Management
Treatment of a symptomatic acute paroxysm is electrical cardioversion. Patients who have been in atrial flutter more than 1–2 days should be treated in a similar manner to patients with atrial fibrillation and anticoagulated for 3 weeks prior to cardioversion.

Recurrent paroxysms may be prevented by class III antiarrhythmic agents. AV nodal blocking agents may be used to control the ventricular rate if the arrhythmia persists. However, the treatment of choice for patients with recurrent atrial flutter is catheter ablation (p. 712), which permanently interrupts re-entry by creating a line of conduction block within the isthmus between the inferior vena cava and the tricuspid valve ring. This technique offers patients whose only arrhythmia is typical atrial flutter an almost certain chance of a cure, although the later occurrence of atrial fibrillation is not uncommon.

Atrial tachycardia
This is an uncommon arrhythmia. Its prevalence is believed to be <1% in patients with arrhythmias. It is usually associated with structural heart disease but in many cases it is referred to as idiopathic. Macro re-entrant tachycardia often occurs after surgery for congenital heart disease. Atrial tachycardia with block is often a result of digitals poisoning.

The mechanisms of atrial tachycardia are attributed to enhanced automaticity, triggered activity or intra-atrial reentry. Atrial re-entry tachycardia is usually relatively slow (125–150 b.p.m.) and can be initiated and terminated by atrial premature beats. The P’P intervals are regular. The PR interval depends on the rate of tachycardia and is longer than in sinus rhythm at the same rate.

Automatic tachycardia usually presents with higher rates (125–250 b.p.m.) and is often characterized by a progressive increase in the atrial rate with onset of the tachycardia ("warm-up") and progressive decrease prior to termination ("cool-down"). Atrial tachycardia is typically caused by a focus which is frequently located along the crista terminals in the right atrium, adjacent to a pulmonary vein in the left atrium, or around one of the atrial appendages. Automatic atrial tachycardia may also present as an incessant variety leading to tachycardia-induced cardiomyopathy. Short runs of atrial tachycardia may provoke more sustained episodes of atrial fibrillation.

Figure 14.44b demonstrates an atrial tachycardia at an atrial rate of 150/minute. The P waves are abnormally shaped and occur in front of the QRS complexes. Carotid sinus massage may increase AV block during tachycardia, thereby facilitating the diagnosis, but does not usually terminate the arrhythmia. Treatment options include cardioversion, antiarrhythmic drug therapy to maintain sinus rhythm, AV nodal slowing agents to control rate and, in selected cases, radiofrequency catheter ablation.

Atrial ectopic beats
These often cause no symptoms, although they may be sensed as an irregularity or heaviness of the heart beat. On the ECG they appear as early and abnormal P waves, and are usually, but not always, followed by normal QRS complexes (Fig. 14.44a). Treatment is normally not required unless the ectopic beats provoke more significant arrhythmias, when beta-blockers may be effective.

Ventricular tachyarrhythmias
Ventricular tachyarrhythmias can be discussed under the following headings:

- Life-threatening ventricular tachyarrhythmias
- Torsades de pointes
- Normal heart ventricular tachycardia
- Non-sustained ventricular tachycardia
- Ventricular premature beats.

Life-threatening ventricular tachyarrhythmias
Sustained ventricular tachycardia and ventricular fibrillation with haemodynamic instability (e.g. syncope, hypotension) are life-threatening ventricular tachyarrhythmias.

Sustained ventricular tachycardia
Sustained ventricular tachycardia (>30 s) often results in pre-syncope (dizziness), syncope, hypotension and cardiac arrest, although it may be remarkably well tolerated in some patients. Examination reveals a pulse rate typically between 120 and 220 b.p.m. Usually, there are clinical signs of atrio-ventricular dissociation (i.e. intermittent cannon ‘a’ waves in the neck) and variable intensity of the first heart sound.

The ECG shows a rapid ventricular rhythm with broad (often ≥0.14 s) abnormal QRS complexes. AV dissociation may result in visible P waves which appear to march through the tachycardia, capture beats (interruption narrow QRS complex owing to normal ventricular activation via the AV node and conducting system) and fusion beats (intermediate between ventricular tachycardia beat and capture beat).
Ventricular fibrillation

This is very rapid and irregular ventricular activation with no mechanical effect. The patient is pulseless and becomes rapidly unconscious, and respiration ceases (cardiac arrest). The ECG shows shapeless, rapid oscillations and there is no hint of organized complexes (Fig. 14.45). It is usually provoked by a ventricular ectopic beat. Ventricular fibrillation rarely reverses spontaneously. The only effective treatment is electrical defibrillation. Basic and advanced cardiac life support is needed (p. 691).

If the attack of ventricular fibrillation occurs during the first day or two of an acute myocardial infarction, it is probable that prophylactic therapy will be unnecessary. If the ventricular fibrillation was not related to an acute infarction, the long-term risk of recurrent cardiac arrest and sudden death is high.

Survivors of these ventricular tachyarrhythmias are, in the absence of an identifiable reversible cause (e.g. acute myocardial infarction, severe metabolic disturbance), at high risk of sudden death. Implantable cardioverter-defibrillators (ICDs) are first-line therapy in the management of these patients (p. 713).

The Brugada syndrome

This inheritable condition accounts for part of a group of patients with idiopathic ventricular fibrillation who have no evidence of causative structural cardiac disease. It is more common in young male adults and in South-east Asia. The diagnosis is made by identifying the classic ECG changes that may be present spontaneously or be provoked by the administration of a class I antiarrhythmic (flecainide or ajmaline): right bundle branch block with coved ST elevation in leads V₁–V₃ (Fig. 14.46). Atrial fibrillation may occur.

In 20% of cases it is a monogenic inheritable condition associated with loss of sodium channel function due to a mutation in the SCN5A gene. Recently other mutations in the SCN1B gene, glycerol-3-phosphate dehydrogenase-1-like gene (GPD1LL-type) and genes related to calcium channel subunits CACNA1C and CACNB2 have also been implicated in the genesis of this syndrome. It can present with sudden death during sleep, resuscitated cardiac arrest and syncope, or the patient may be asymptomatic and diagnosed incidentally or during familial assessment. There is a high risk of sudden death, particularly in the symptomatic patient or those with spontaneous ECG changes. The only successful treatment is an ICD. Beta-blockade is not helpful and may be harmful in this syndrome.

Long QT syndrome

This describes an ECG where the ventricular repolarization (QT interval) is greatly prolonged. The causes of long QT syndrome are listed in Table 14.12.

Congenital long QT syndrome

Two major syndromes have been described, which may (Jervell and Lange–Nielsen syndrome) or may not (Romano–Ward syndrome) be associated with congenital deafness.
Cardiac arrhythmias

The molecular biology of the congenital long QT syndromes has been shown to be heterogeneous. It is usually a monogenic disorder and has been associated with mutations in cardiac potassium and sodium channel genes (Table 14.13). The different genes involved appear to correlate with different phenotypes (Fig. 14.47b) that can exhibit such variable penetrance that carriers may have completely normal ECGs. There are three major subtypes: LQT1 in which the arrhythmia is usually provoked by exercise, particularly swimming; LQT2 with provocation associated with emotion and acoustic stimuli; and LQT3 where the arrhythmias occur during rest or when asleep. It is likely that identification of the mutation involved will not only improve diagnostic accuracy, particularly with cascade screening in affected families, but also guide future therapy for the congenital long QT syndrome.

**Figure 14.47 Prolonged QT.** (a) An ECG demonstrating a supraventricular rhythm with a long QT (LQT) interval giving way to atypical ventricular tachycardia (torsades de pointes). The tachycardia is short-lived and is followed by a brief period of idioventricular rhythm. (b) Further three examples of a prolonged QT interval corresponding to three different types of LQT.
Acquired long QT syndrome

QT prolongation and torsades de pointes are usually provoked by bradycardia.

Clinical features

Patients with a long QT develop syncope and palpitations as a result of polymorphic ventricular tachycardia (torsades de pointes). They usually terminate spontaneously but may degenerate to ventricular fibrillation, resulting in sudden death.

_Torsades de pointes_ is characterized on the ECG by rapid, irregular, sharp complexes that continuously change from an upright to an inverted position (Fig. 14.47a).

Between spells of tachycardia or immediately preceding the onset of tachycardia the ECG shows a prolonged QT interval; the corrected QT (Table 14.4, p. 682) is usually $>0.50$ s.

Management

**Acute (acquired):**

- Any electrolyte disturbance is corrected
- Causative drugs are stopped
- The heart rate is maintained with atrial or ventricular pacing
- Magnesium sulphate $8$ mmol (Mg$^{2+}$) over $10–15$ min for acquired long QT
- Intravenous isoprenaline may be effective when QT prolongation is acquired (isoprenaline is contraindicated for congenital long QT syndrome).

_Long-term_, congenital long QT syndrome is generally treated by beta-blockade, pacemaker therapy and occasionally left cardiac sympathetic denervation. LQT1 patients seem to respond well to beta-blockade and LQT3 patients are better treated with sodium channel blockers. All LQT patients should avoid drugs known to prolong the QT interval. Patients who remain symptomatic despite conventional therapy and those with marked QT prolongation or a strong family history of sudden death usually need ICD therapy.

Short QT syndrome

Five types have been described caused by genetic abnormalities leading to faster repolarization. Ventricular arrhythmias and sudden death may occur and an ICD is the best treatment.

Normal heart ventricular tachycardia

Monomorphic ventricular tachycardia in patients with structurally normal hearts (idiopathic VT) is usually a benign condition with an excellent long-term prognosis. Occasionally, it is incessant (so called Galavardin’s tachycardia) and if untreated may lead to cardiomyopathy.

Normal heart VT either arises from a focus in the right ventricular outflow tract or in the left ventricular septum. Treatment of symptoms is usually with beta-blockers. There is a special form of verapamill-sensitive tachycardia that responds well to non-dihydropyridine calcium antagonists. In symptomatic patients, radiofrequency catheter ablation is highly effective, resulting in a cure in $>90\%$ cases. It is sometimes difficult to distinguish arrhythmogenic right ventricular hypertrophy (p. 770) from this seemingly benign disorder.

Non-sustained ventricular tachycardia

Non-sustained ventricular tachycardia (NSVT) is defined as ventricular tachycardia that is $\geq 5$ consecutive beats but lasts $<30$ s (Fig. 14.48d). NSVT can be found in $6\%$ of patients with normal hearts and usually does not require treatment. NSVT is documented in up to $60–80\%$ of patients with heart disease. There is insufficient evidence on prognosis, but an ICD has been shown to improve survival of patients with particularly poor left ventricular function (ejection fraction $<30\%$) by preventing arrhythmic death. Antiarrhythmic suppression of NSVT is not usually advocated but beta-blockers may improve quality-of-life in symptomatic individuals.

Ventricular premature beats

These may be uncomfortable, especially when frequent. The patient complains of extra beats, missed beats or heavy beats because it may be the premature beat, the post-ectopic pause or the next sinus beat that is noticed by the patient. The pulse is irregular owing to the premature beats. Some early beats may not be felt at the wrist. When a premature beat occurs regularly after every normal beat, ‘pulsus bigeminus’ may occur. If premature ventricular beats are highly symptomatic, treatment with beta-blockade may be
Is the principal aim of treatment symptom relief or prevention of sudden death?
Is maintaining sinus rhythm or controlling ventricular rates the treatment goal?

Commonly employed treatment strategies for the management of specific tachyarrhythmias are outlined in Table 14.14.

### Antiarrhythmic drugs

Drugs that modify the rhythm and conduction of the heart are used to treat cardiac arrhythmias. Antiarrhythmic drugs may aggravate or produce arrhythmias (proarrhythmia) and they may also depress ventricular contractility and must therefore be used with caution. They are classified according to their effect on the action potential (Vaughan Williams classification; Table 14.15 and Fig. 14.49).

### Class I drugs

These are membrane-depressant drugs that reduce the rate of entry of sodium into the cell (sodium-channel blockers). They may slow conduction, delay recovery or reduce the spontaneous discharge rate of myocardial cells. Class Ia drugs (e.g. disopyramide) lengthen the action potential, class Ib drugs (e.g. lidocaine) shorten the action potential, and class Ic (flecainide, propafenone) do not affect the duration of the action potential. Class I agents have been found to increase mortality compared to placebo in post-myocardial infarction patients with ventricular ectopy (Cardiac Arrhythmia Suppression Trial (CAST) trials – class Ic agents) and in helpful. If the ectopics are very frequent left ventricular dysfunction may develop, and if the ectopics stem from a single focus, especially when in the right ventricle, catheter ablation can be very effective.

These premature beats (Fig. 14.48a–c) have a broad (>0.12 s) and bizarre QRS complex because they arise from an abnormal (ectopic) site in the ventricular myocardium. Following a premature beat there is usually a complete compensatory pause because the AV node or ventricle is refractory to the next sinus impulse. Early ‘R-on-T’ ventricular premature beats (occurring simultaneously with the upstroke or peak of the T wave of the previous beat) may induce ventricular fibrillation in patients with heart disease, particularly in patients following myocardial infarction.

Ventricular premature beats are usually treated only if symptomatic. Usually simple measures such as reassurance and beta-blocker therapy are all that is required.

### Long-term management of cardiac tachyarrhythmias

Options for the long-term management of cardiac tachyarrhythmias include:

- Antiarrhythmic drug therapy
- Ablation therapy
- Device therapy.

To determine the optimal strategy for a given patient the following questions must be addressed:

patients treated for atrial fibrillation (class Ia agent, quinidine). In view of this, class Ic agents such as flecainide and all other class I drugs should be reserved for patients who do not have significant coronary artery disease, left ventricular dysfunction, or other forms of significant structural heart disease.

**Class II drugs**
These antisympathetic drugs prevent the effects of catecholamines on the action potential. Most are β-adrenoceptor antagonists. Cardioselective beta-blockers (β1) include metoprolol, bisoprolol, atenolol and acebutolol. Beta-blockers suppress AV node conduction, which may be effective in preventing attacks of junctional tachycardia, and may help to control the ventricular rate during paroxysms of other forms of SVT (e.g. atrial fibrillation). In general beta-blockers are anti-ischaemic and anti-arrhythmic, and have proven beneficial effects in patients post-myocardial infarction (by preventing ventricular fibrillation) and in patients with congestive heart failure. It is therefore advisable to use beta-blocker therapy either alone or in combination with other antiarrhythmic drugs in patients with symptomatic tachyarrhythmias, particularly in patients with coronary artery disease.

**Class III drugs**
These prolong the action potential, usually by blocking the rapid component of the delayed rectifier potassium current (IKr) and do not affect sodium transport through the membrane. The drugs in this class are amiodarone and sotalol. Sotalol is also a β-blocker.

Some drugs, such as ibutilide and dofetilide, are only available in some countries. Sotalol may result in acquired long QT syndrome and torsades de pointes. The risk of torsades is increased in the setting of hypokalaemia, and particular care should be taken in patients taking diuretic therapy. Amiodarone therapy in contrast to most other antiarrhythmic drugs carries a low risk of proarrhythmia in patients with significant structural heart disease. Because it has many toxic and potentially serious side-effects, patients need to be counselled prior to commencing amiodarone and monitored at regular follow-up intervals. Dofetilide has been used to treat atrial fibrillation and flutter in patients with recent myocardial infarction and poor LV function. Dronedarone is a multichannel blocking drug which suppresses the recurrence of atrial fibrillation and reduces hospital admissions in patients with cardiovascular risk (ATHENA). However, it has proven harmful in patients with left ventricular dysfunction and heart failure (ANDROMEDA and PALLAS) and must not be used when heart failure is present.

Vernakalant is a multichannel blocker which is approved for the rapid intravenous medical cardioversion of new onset atrial fibrillation.

**Class IV drugs**
The non-dihydropyridine calcium channel blockers that reduce the plateau phase of the action potential are particularly effective at slowing conduction in nodal tissue. Verapamil and diltiazem are two drugs in this group. These drugs can prevent attacks of junctional tachycardia (AVNRT and AVRT) and may help to control ventricular rates during paroxysms of other forms of SVT (e.g. atrial fibrillation).

**Drug therapy** is commonly used for symptomatic relief in patients who do not have life-threatening tachyarrhythmias. Antiarrhythmic drugs have not been shown to prolong life. Patient safety is the main factor determining the choice of antiarrhythmic therapy and proarrhythmic risks need to be carefully assessed prior to initiating therapy. As a generalization, class Ic agents are employed in patients with structurally normal hearts and class III agents are used in patients with structural heart disease, although exceptions occur.

In order to administer antiarrhythmic agents as safely as possible it is helpful to be familiar with the different proarrhythmia mechanisms and their main predisposing risk factors (Table 14.16).

Patients with structurally normal hearts and normal QT intervals, or with implantable defibrillators, are either at very low risk of proarrhythmia or are protected from any life-threatening consequences, and in these patients it is possible to persevere with drug therapy until an efficacious, well-tolerated agent is identified.

**Catheter ablation**
Radiofrequency catheter ablation is frequently employed in the management of symptomatic tachyarrhythmias. Ablations are performed by placing three or four electrode catheters into the heart chambers in order to record and pace from various sites. Pacing the atria or the ventricles is used to trigger the tachycardia and to study the tachycardia mechanism. Successful ablation depends on accurate identification of either the site of origin of a focal tachycardia or of a critical component of a macro-re-entry tachycardia. The following tachyarrhythmias can be readily ablated:
into the veins from the atrium (pulmonary vein isolation). The arrhythmogenic atrial myocardium surrounding or extending radiofrequency energy in or around the pulmonary veins in ablation of this ectopic focus includes the application of in the pulmonary veins, may trigger atrial fibrillation. Catheter ectopic beats, which commonly arise from a focus situated

- AV node re-entry tachycardia (AVNRT)
- AV re-entry tachycardia (AVRT) with an accessory pathway, including WPW syndrome
- Normal heart VT
- Atrial flutter
- Atrial tachycardia
- Atrial fibrillation.

Symptomatic patients with a pre-excited ECG because of accessory pathway conduction (WPW syndrome) are advised to undergo catheter ablation as first-line therapy, owing to the risk of sudden death associated with this condition. This is especially the case in patients with pre-excited atrial fibrillation. Patients with accessory pathways that only conduct retrogradely from the ventricles to the atrium are not at increased risk of sudden death but experience symptoms due to AVRT. These patients are commonly offered an ablation procedure if simple measures such as AV nodal slowing agents fail to suppress tachycardia. Asymptomatic patients with the WPW ECG pattern are now frequently offered an ablation procedure for prophylactic reasons. The main risk associated with accessory pathway ablation is thromboembolism in patients with left-sided accessory pathways. The success rate for catheter ablation of AVNRT and accessory pathways is >95%.

Patients with normal hearts and documented ventricular tachycardia should be referred for specialist evaluation. Unlike VT in patients with structural heart disease, normal heart VT is not associated with increased risk of sudden death and is easily cured by catheter ablation.

**Catheter ablation** is recommended in patients with atrial flutter that is not easily managed medically. Ablation of typical flutter is effective in 90–95% cases. In the direct comparison of catheter ablation and antiarrhythmic therapy, the rate of recurrence was significantly lower following ablation. Atrial tachycardia, especially in patients with structurally normal hearts, may also be cured by catheter ablation. In atrial fibrillation, adequate control of ventricular rates is sometimes not possible despite optimal medical therapy. These patients experience a marked symptomatic improvement following AV node ablation and pacemaker implantation. Unlike other forms of catheter ablation this does not cure the arrhythmia; atrial fibrillation continues and anticoagulation is still required following ablation.

In younger patients with structurally normal hearts, atrial ectopic beats, which commonly arise from a focus situated in the pulmonary veins, may trigger atrial fibrillation. Catheter ablation of this ectopic focus includes the application of radiofrequency energy in or around the pulmonary veins in order to abolish the connection between the sleeves of arrhythmogenic atrial myocardium surrounding or extending into the veins from the atrium (pulmonary vein isolation). The trigger is therefore eliminated and the arrhythmia does not recur. These techniques appear to be highly effective, especially in young patients with paroxysmal atrial fibrillation, normal atrial size and no underlying heart disease (70–80% long-term success), but are presently time-consuming procedures (4 h or more) and are associated with some serious complications such as stroke, pericardial haemorrhage, pulmonary vein stenosis and atrio-oesophageal fistula in a small minority of patients (in experienced centres <2% altogether).

**Implantable cardioverter-defibrillator (ICD)**

Life-threatening ventricular arrhythmias (ventricular fibrillation or rapid ventricular tachycardia with hypotension) result in death in up to 40% within 1 year of diagnosis. Large multicentre prospective trials such as the Antiarrhythmics (amiodarone) Versus Implantable Defibrillator (AVID) trial and the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), both in patients who have experienced a spontaneous episode of life-threatening ventricular tachyarrrhythmia.

The ICD recognizes ventricular tachycardia or fibrillation and automatically delivers pacing or a shock to the heart to cause cardioversion to sinus rhythm. Modern ICDs are only a little larger than a pacemaker and are implanted in a pectoral position (Fig. 14.50). The device may have leads to sense and pace both the right atrium and ventricle, and the lithium batteries employed are able to provide energy for over 100 shocks each of around 30 J. ICD discharges are painful if the patient is conscious. However, ventricular tachycardia may often be terminated by overdrive pacing the heart, which is painless. The ICD is superior to all other treatment options at preventing sudden cardiac death. The use of this device has cut the sudden death rate in patients with a history of serious ventricular arrhythmias to approximately 2% per year. However, the majority of these patients have significant structural heart disease and overall cardiac mortality due to progressive heart failure remains high. As a result the ICD is now first-line therapy in the secondary prevention of sudden death.

Implantable cardioverter-defibrillators are also employed in the primary prevention of sudden cardiac death. The chances of surviving an out-of-hospital cardiac arrest are as low as 10%. Therefore selected patients who have never experienced a spontaneous episode of life-threatening ventricular tachyarrrhythmia but who are assessed to be at high risk of sudden death are advised to undergo ICD implantation. In two large primary prevention ICD trials, Multicenter Automated Defibrillator Implantation Trial (MADIT II) and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), therapy with an ICD reduced mortality by 23–31% on top of...
conventional treatment, which included revascularization, beta-blockers and angiotensin-converting enzyme inhibitors. ICD combined with cardiac resynchronization therapy may improve both symptoms and life expectancy of patients with any degree of heart failure (COMPANION, CARE-HF and MADIT-CRT).

The following groups of patients may merit prophylactic ICD placement:

- Those with coronary artery disease; significant impairment of left ventricular function (LVEF ≤35–40%), spontaneous non-sustained ventricular tachycardia in whom sustained ventricular tachycardia was induced by pacing the heart during an electrophysiological study
- Those with NYHA class III–IV heart failure (LVEF ≤35%) in combination with cardiac resynchronization therapy, and in class I–II NYHA heart failure (LVEF ≤35%) when LBBB is present
- Those with very poor LV function post-MI (LVEF ≤30%)
- Those with dilated and hypertrophic cardiomyopathy, long QT syndrome and Brugada syndrome or other channelopathies who have a strong family history of sudden cardiac death.

The prognosis of heart failure has improved over the past 10 years, but the mortality rate is still high with approximately 50% of patients dead at 5 years. Heart failure accounts for 5% of admissions to hospital medical wards. The cost of managing heart failure in the UK exceeds £1 billion per year. Coronary artery disease is the commonest cause of heart failure in western countries.

The causes of heart failure are shown in Table 14.17.

Pathophysiology
When the heart fails, considerable changes occur to the heart and peripheral vascular system in response to the haemodynamic changes associated with heart failure (Table 14.18). These physiological changes are compensatory and maintain cardiac output and peripheral perfusion. However, as heart failure progresses, these mechanisms are overwhelmed and
become pathophysiological. The development of pathologi-
cal peripheral vasoconstriction and sodium retention in heart
care by activation of the renin-angiotensin-aldosterone
system are a loss of beneficial compensatory mechanisms
and represent cardiac decompensation. Factors involved are
venous return, outflow resistance, contractility of the myo-
cardium, and salt and water retention.

Venous return (preload)
In the intact heart, myocardial failure leads to a reduction of
the volume of blood ejected with each heart beat and an
increase in the volume of blood remaining after systole. This
increased diastolic volume stretches the myocardial fibres
and, as Starling’s law of the heart (p. 671) would suggest,
myocardial contraction is restored. However, the failing myo-
cardium results in depression of the ventricular function
curve (cardiac output plotted against the ventricular diastolic
volume) (Fig. 16.6, p. 871).

Mild myocardial depression is not associated with a reduc-
tion in cardiac output because it is maintained by an increase
in venous pressure (and hence diastolic volume). However,
the proportion of blood ejected with each heart beat (ejection
fraction) is reduced early in heart failure. Sinus tachycardia
also ensures that any reduction of stroke volume is compen-
sated for by the increase in heart rate; cardiac output (stroke
volume × heart rate) is therefore maintained.

When there is more severe myocardial dysfunction, cardiac
output can be maintained only by a large increase in venous
pressure and/or marked sinus tachycardia. The increased
venous pressure contributes to the development of dysp-
noea, owing to the accumulation of interstitial and alveolar
fluid, and to the occurrence of hepatic enlargement, ascites
and dependent oedema, due to increased systemic venous
pressure. However, the cardiac output at rest may not be
much depressed, but myocardial and haemodynamic reserve
is so compromised that a normal increase in cardiac output
cannot be produced by exercise.

In very severe heart failure, the cardiac output at rest is
depressed, despite high venous pressures. The inadequate
cardiac output is redistributed to maintain perfusion of vital
organs, such as the heart, brain and kidneys, at the expense of
the skin and muscle.

Outflow resistance (afterload) (see Fig. 14.5)
This is the load or resistance against which the ventricle
contracts. It is formed by:

- Pulmonary and systemic resistance
- Physical characteristics of the vessel walls
- The volume of blood that is ejected.

An increase in afterload decreases the cardiac output. This
results in a further increase of end-diastolic volume and
dilitation of the ventricle itself, which further exacerbates the
problem of afterload. This is expressed by Laplace’s law:

\[ T = \frac{P \times R^2}{2} \]

where \( T \) is the tension of the myocardium, \( P \) is the intraventricular pressure, \( R \) is the radius of the ventricular chamber, and \( 2 \) is the radius of the ventricular chamber.

The increase in venous pressure that occurs when the ven-
tricles fail leads to retention of salt and water and their accu-
mulation in the interstitium, producing many of the physical
signs of heart failure. Reduced cardiac output also leads to
diminished renal perfusion, activating the renin-angiotensin
system and enhancing salt and water retention (Fig. 12.5, p.
566), which further increases venous pressure (Fig. 14.51).
The retention of sodium is in part compensated by the action
of circulating atrial natriuretic peptides and antidiuretic
hormone (see p. 650).

The interaction of haemodynamic and neurohumoral
factors in the progression of heart failure remains unclear.
Increased ventricular wall stress promotes ventricular dilata-
tion and further worsens contractile efficiency. In addition,
prolonged activation of the sympathetic nervous and renin-
angiotensin-aldosterone systems exerts direct toxic effects
on myocardial cells.

Myocardial remodelling in heart failure
Left ventricular remodelling is a process of progressive alter-
ation of ventricular size, shape and function owing to the

influence of mechanical, neurohormonal and possibly genetic factors in several clinical conditions, including myocardial infarction, cardiomyopathy, hypertension and valvular heart disease. Its hallmarks include hypertrophy, loss of myocytes and increased interstitial fibrosis. Remodelling continues for months after the initial insult, and the eventual change in the shape of the ventricle becomes responsible for significant impairment of overall function of the heart as a pump (Fig. 14.52a). In cardiomyopathy, the process of progressive ventricular dilatation or hypertrophy occurs without ischaemic myocardial injury or infarction (Fig. 14.52b).

Changes in myocardial gene expression

Haemodynamic overload of the ventricle stimulates changes in cardiac contractile protein gene expression. The overall effect is to increase protein synthesis, but many proteins also switch to fetal and neonatal isoforms. Human myosin is composed of a pair of heavy chains and two pairs of light chains. Myosin heavy chains (MHC) exist in two isoforms, α and β, that have different contractile properties and ATPase activity. α-MHC predominates in the atria and β-MHC in the ventricles. In animal models, pressure overload results in a shift from αβ-MHC in the atria, in parallel with atrial size. This results in reduction in atrial contractility but reduced energy demands. This shift is less significant in the human ventricle, as the β-MHC isoform already predominates. Other genes affected in heart failure include those encoding Na+/K+-ATPase, Ca2+-ATPase and β1-adrenoceptors.

Abnormal calcium homeostasis

Calcium ion flux within myocytes plays a pivotal role in the regulation of contractile function. Excitation of the myocyte cell membrane causes the rapid entry of calcium into myocytes from the extracellular space via calcium channels. This triggers the release of intracellular calcium from the sarcoplasmic reticulum and initiates contraction (see Fig. 14.3, p. 670). Relaxation results from the uptake and storage of calcium by the sarcoplasmic reticulum (see Fig. 14.9, p. 674) controlled by changes in nitric oxide. In heart failure, there is a prolongation of the calcium current in association with prolongation of contraction and relaxation.

Apoptosis

Apoptosis (or ‘programmed cell death’) of myocytes has been demonstrated in animal models of ischaemic reperfusion, rapid ventricular pacing, mechanical stretch and pressure overload. Apoptosis is associated with irreversible congestive heart failure, and the spiral of ventricular dysfunction, characteristic of heart failure, results from the initiation of apoptosis by cytokines, free radicals and other triggers.

Natriuretic peptides (ANP, BNP and C-type)

Atrial natriuretic peptide (ANP) is released from atrial myocytes in response to stretch. ANP induces diuresis, natriuresis, vasodilatation and suppression of the renin-angiotensin system. Levels of circulating ANP are increased in congestive cardiac failure and correlate with functional class, prognosis and haemodynamic state. The renal response to ANP is attenuated in heart failure, probably secondarily to reduced renal perfusion, receptor downregulation, increased peptide breakdown, renal sympathetic activation and excessive renin-angiotensin activity.

Brain natriuretic peptide (BNP) (so called because it was first discovered in brain) is predominantly secreted by the ventricles, and has an action similar to that of ANP but greater diagnostic and prognostic value (p. 943).

C-type peptide, which is limited to vascular endothelium and the central nervous system, has similar effects to those of ANP and BNP.

The therapeutic benefits of the natriuretic peptides have been investigated in two ways:

- The administration of synthetic BNP (nesitide) has no effect on dyspnoea and is no longer recommended.
- Neutral endopeptidase (NEP) is a metalloendopeptidase involved in the degradation of a variety of vasoactive peptides (including ANP, BNP, CNP and bradykinin). In animal studies NEP inhibitors can produce diuresis and natriuresis. Omapatrilat is a combined angiotensin-converting enzyme inhibitor (ACEI) and NEP-I that is an effective antihypertensive agent, but it has not received FDA approval because of an increased risk of severe angio-oedema.

Endothelial function in heart failure

The endothelium has a central role in the regulation of vaso-motor tone. In patients with heart failure, endothelium-dependent vasodilatation in peripheral blood vessels is impaired and may be one mechanism of exercise limitation. The cause of abnormal endothelial responsiveness relates to abnormal release of both nitric oxide and vasoconstrictor...
substances, such as endothelin (ET). The activity of nitric oxide, a potent vasodilator, is blunted in heart failure. ET secretion from a variety of tissues is stimulated by many factors, including hypoxia, catecholamines and angiotensin II. The plasma concentration of ET is elevated in patients with heart failure, and levels correlate with the severity of haemodynamic disturbance. The major source of circulating ET in heart failure is the pulmonary vascular bed.

ET has many actions that potentially contribute to the pathophysiology of heart failure: vasoconstriction, sympathetic stimulation, renin-angiotensin system activation and left ventricular hypertrophy. Acute intravenous administration of endothelin antagonists improves haemodynamic abnormalities in patients with congestive cardiac failure, and oral endothelin antagonists are being developed. Plasma concentrations of some cytokines, in particular TNF, are increased in patients with heart failure.

**Antidiuretic hormone (vasopressin)**

Antidiuretic hormone (ADH) is raised in severe chronic heart failure, particularly in patients on diuretic treatment. High ADH concentration precipitates hyponatraemia which is an ominous prognostic indicator.

### Clinical syndromes of heart failure

There are many causes of heart failure (Table 14.17) that can present suddenly with acute heart failure (AHF) or more insidiously with chronic heart failure (CHF).

**Left ventricular systolic dysfunction (LVSD)** is commonly caused by ischaemic heart disease but can also occur with valvular heart disease and hypertension.

**Right ventricular systolic dysfunction (RVSD)** may be secondary to chronic LVSD but can occur with primary and secondary pulmonary hypertension, right ventricular infarction, arrhythmogenic right ventricular cardiomyopathy and adult congenital heart disease.

**Diastolic heart failure** is a syndrome consisting of symptoms and signs of heart failure with preserved left ventricular ejection fraction above 45–50% and abnormal left ventricular relaxation assessed by echocardiography. There is increased stiffness in the ventricular wall and decreased left ventricular compliance, leading to impairment of diastolic ventricular filling and hence decreased cardiac output. Diastolic heart failure is more common in elderly hypertensive patients but may occur with primary cardiomyopathies (hypertrophic, restrictive, infiltrative).

The symptoms and signs of heart failure are:

**Symptoms:**
- Exertional dyspnoea
- Orthopnoea
- Paroxysmal nocturnal dyspnoea
- Fatigue.

**Signs:**
- Cardiomegaly
- Third and fourth heart sounds
- Elevated JVP
- Tachycardia
- Hypotension
- Bi-basal crackles
- Pleural effusion
- Peripheral ankle oedema
- Ascites
- Tender hepatomegaly.

The New York Heart Association classification of heart failure (Table 14.19) can be used to describe the symptoms of heart failure and limitation of exercise capacity, and is useful to assess response to therapy. It does not include left ventricular ejection fraction to determine severity of heart failure.

### Diagnosis of heart failure

The diagnosis of heart failure should not be based on history and clinical findings; it requires evidence of cardiac dysfunction with appropriate investigation using objective measures of left ventricular structure and function (usually echocardiography). Similarly, the underlying cause of heart failure should be established in all patients (Table 14.20 and Fig. 14.53).

**Table 14.20** Diagnosis of heart failure (European Society of Cardiology guidelines)

1. Symptoms and signs of heart failure (e.g. breathlessness, fatigue, ankle swelling)
2. Objective evidence of cardiac dysfunction (at rest, e.g. echocardiogram)

### Choose treatment

Heart failure suspected because of symptoms and signs

- Assess presence of cardiac disease by ECG, CXR or natriuretic peptides (normal < 100pg/mL)

**Normal:** heart failure unlikely

**Abnormal:** imaging by echocardiography

**Normal:** heart failure unlikely

**Abnormal:** Assess aetiology, degree, precipitating factors, and type of cardiac dysfunction. Additional diagnostic tests where appropriate

Figure 14.53 Algorithm for the diagnosis of heart failure. (Based on the European Society of Cardiology and NICE guidelines.)
Investigations in heart failure

- **Blood tests.** Full blood count, liver biochemistry, urea and electrolytes, cardiac enzymes in acute heart failure, BNP or N-terminal portion of proBNP (NPproBNP), thyroid function
- **Chest X-ray.** Look for cardiomegaly, pulmonary congestion with upper lobe diversion, fluid in fissures, Kerley B lines, and pulmonary oedema.
- **Electrocardiogram** for ischaemia, hypertension or arrhythmia.
- **Echocardiography.** Cardiac chamber dimension, systolic and diastolic function, regional wall motion abnormalities, valvular heart disease, cardiomyopathies.
- **Stress echocardiography.** Assessment of viability in dysfunctional myocardium – dobutamine identifies contractile reserve in stunned or hibernating myocardium.
- **Nuclear cardiology.** Radionuclide angiography (RNA) can quantify ventricular ejection fraction, single-photon-emission computed tomography (SPECT) or positron emission tomography (PET) can demonstrate myocardial ischaemia and viability in dysfunctional myocardium.
- **CMR (cardiac MRI).** Assessment of viability in dysfunctional myocardium with the use of dobutamine for contractile reserve or with gadolinium for delayed enhancement (‘infarct imaging’).
- **Cardiac catheterization.** Diagnosis of ischaemic heart failure (and suitability for revascularization), measurement of pulmonary artery pressure, left atrial (wedge) pressure, left ventricular end-diastolic pressure.
- **Cardiac biopsy.** Diagnosis of cardiomyopathies, e.g. amyloid, follow-up of transplanted patients to assess rejection.
- **Cardiopulmonary exercise testing.** Peak oxygen consumption (VO\textsubscript{2}) is predictive of hospital admission and death in heart failure. A 6-minute exercise walk is an alternative.
- **Ambulatory 24-hour ECG monitoring (Holter).** In patients with suspected arrhythmia. May be used in patients with severe heart failure or inherited cardiomyopathy to determine if a defibrillator is appropriate (non-sustained ventricular tachycardia).

Treatment of heart failure

Treatment is aimed at relieving symptoms, prevention and control of disease leading to cardiac dysfunction and heart failure, retarding disease progression and improving quality and length of life.

Measures to prevent heart failure include cessation of smoking, alcohol and illicit drugs, effective treatment of hypertension, diabetes and hypercholesterolaemia, and pharmacological therapy following myocardial infarction.

The management of heart failure requires that any factor aggravating the failure should be identified and treated. Similarly, the cause of heart failure must be elucidated and where possible corrected. Community nursing programmes to help with drug compliance and to detect early deterioration may prevent acute hospitalization.

General lifestyle advice

**Education**

Effective counselling of patients and family, emphasizing weight monitoring and dose adjustment of diuretics, may prevent hospitalization.

**Obesity control**

Maintain desired weight and body mass index.

**Dietary modification**

Large meals should be avoided and, if necessary, weight reduction instituted. Salt restriction is necessary and foods rich in salt or added salt in cooking and at the table should be avoided. A low-sodium diet is unpalatable and of questionable value. In severe heart failure fluid restriction is necessary. Alcohol has a negative inotropic effect and heart failure patients should moderate consumption. Omega-3 polyunsaturated fatty acids reduce mortality and admission to hospital.

**Smoking**

Smoking should be stopped, with help from anti-smoking clinics (p. 807) if necessary.

**Physical activity, exercise training and rehabilitation**

For patients with exacerbations of congestive cardiac failure, bed rest reduces the demands on the heart and is useful for a few days. Migration of fluid from the interstitium promotes a diuresis, reducing heart failure. Prolonged bed rest may lead to development of deep vein thrombosis; this can be avoided by daily leg exercises, low-dose subcutaneous heparin and elastic support stockings. Low-level endurance exercise (e.g. 20–30 min walking three or five times per week or 20 or 20 min cycling at 70–80% of peak heart rate five times per week) is actively encouraged in patients with compensated heart failure in order to reverse ‘deconditioning’ of peripheral muscle metabolism. Strenuous isometric activity should be avoided.

**Vaccination**

While prospective clinical trials are lacking, it is recommended that patients with heart failure be vaccinated against pneumococcal disease and influenza.

**Air travel**

This is possible for most patients, subject to clinical circumstances. Check with the airline – most have guidelines on who should travel.

**Sexual activity**

Tell patients on nitrates not to take phosphodiesterase type 5 inhibitors (e.g. sildenafil) as it may induce profound hypotension.

**Driving**

Driving motor cars and motorcycles may continue provided there are no symptoms that distract the driver’s attention. The DVLA in the UK does not need to be notified. Symptomatic heart failure disqualifies patients from driving large lorries and buses. Re-licensing may be permitted provided that the LV ejection fraction is good (i.e. LVEF is >0.4), the exercise test requirements can be met and there is no other disqualifying condition.

**Monitoring of heart failure patients**

The clinical condition of a person with heart failure fluctuates, and repeated admissions to hospital is common. Monitoring of clinical status is necessary and this responsibility should be shared between primary and secondary care health professionals.

- Essential monitoring includes assessment of:
  - functional capacity (e.g. VO\textsubscript{2} max, exercise tolerance test, echocardiography)
Heart failure must be monitored regularly (risk of hypokalaemia and hypomagnesaemia).

Angiotensin-converting enzyme inhibitors (ACEI)
Trials have shown that in addition to producing considerable symptomatic improvement in patients with symptomatic heart failure, prognosis is markedly improved and development of heart failure is slowed. ACEI also benefit patients with asymptomatic heart failure following myocardial infarction (Fig. 12.5, p. 566). Thus ACEI improve survival in patients in all functional classes (NYHA I-IV) and are recommended in all patients at risk of developing heart failure. The main adverse effects of ACE inhibitors are cough, hypotension, hyperkalaemia and renal dysfunction. The contraindications to their use include renal artery stenosis, pregnancy and previous angioedema. In patients with heart failure ACEI should be introduced gradually with a low initial dose and gradual titration with regular blood pressure monitoring. Serum creatinine should be measured concomitantly; potassium-sparing diuretics should be discontinued.

Angiotensin II receptor antagonists (ARA)
The angiotensin II receptor antagonists (ARA) (candesartan and valsartan) are indicated as second-line therapy in patients intolerant of ACEI. Unlike ACEI they do not affect bradykinin metabolism and do not produce a cough. The CHARM Alternative Trial showed that candesartan reduced the risk of heart failure hospitalization compared to placebo in patients intolerant to ACEI. Other trials (Val HeFT and ELITE II) have assessed other ARAs.

Fluid status (body weight, U&Es, clinical)
Cardiac rhythm (ECG, 24-hour tape).

Multidisciplinary team approach
Heart failure care should be delivered by a multidisciplinary team with an integrated approach across the healthcare community. The use of multiple biomarkers, e.g. troponins and CRP, is of prognostic value. The multidisciplinary team should involve specialist healthcare professionals: heart failure nurse, dietitian, pharmacist, occupational therapist, physiotherapist and palliative care adviser.

Understanding the information needs of patients and carers is vital. Good communication is essential for best clinical management, which should include advice on anxiety, depression and ‘end-of-life’ issues.

Drug management (Table 14.21)

Serum electrolytes and renal function must be monitored regularly (risk of hypokalaemia and hypomagnesaemia).

Multidisciplinary team approach
Heart failure care should be delivered by a multidisciplinary team with an integrated approach across the healthcare community. The use of multiple biomarkers, e.g. troponins and CRP, is of prognostic value. The multidisciplinary team should involve specialist healthcare professionals: heart failure nurse, dietitian, pharmacist, occupational therapist, physiotherapist and palliative care adviser.

Understanding the information needs of patients and carers is vital. Good communication is essential for best clinical management, which should include advice on anxiety, depression and ‘end-of-life’ issues.

Drug management (Table 14.21)

Figure 14.54 shows the stages of heart failure and the treatment options.

Diuretics
These act by promoting the renal excretion of salt and water by blocking tubular reabsorption of sodium and chloride (p. 644). Loop diuretics (e.g. furosemide and bumetanide) and thiazide diuretics (e.g. bendroflumethiazide, hydrochlorothiazide) should be given in patients with fluid overload. Although diuretics provide symptomatic relief of dyspnoea and improve exercise tolerance, there is limited evidence that they affect survival. In severe heart failure patients, the combination of a loop and thiazide diuretic may be required.

Angiotensin II receptor antagonists (ARA)
The angiotensin II receptor antagonists (ARA) (candesartan and valsartan) are indicated as second-line therapy in patients intolerant of ACEI. Unlike ACEI they do not affect bradykinin metabolism and do not produce a cough. The CHARM Alternative Trial showed that candesartan reduced the risk of heart failure hospitalization compared to placebo in patients intolerant to ACEI. Other trials (Val HeFT and ELITE II) have assessed other ARAs.

Further reading

**Beta-blockers**

Beta-blockers have been shown to improve functional status and reduce cardiovascular morbidity and mortality in patients with heart failure. Several trials (CIBIS, CIBIS II, MERIT-HF, COMET, SENOIRS) have assessed the effects of beta-blockers in varying degrees of heart failure. Bisoprolol and carvedilol reduce mortality in any grade of heart failure. Nebivolol is used in the treatment of stable mild-moderate heart failure in patients over 70 years old. In patients with heart failure, only evidence-based beta-blockers from successful trials should be used. In patients with significant heart failure, beta-blockers are started at a low dose and gradually increased.

**Aldosterone antagonists**

The aldosterone antagonists spironolactone and eplerenone have been shown to improve survival in patients with heart failure. In RALES, spironolactone reduced total mortality by 30% in patients with severe heart failure. However, gynaecomastia or breast pain occurred in 1 in 10 men taking spironolactone. In EPHESUS, eplerenone given to patients with an acute myocardial infarction and heart failure reduced total mortality by 15% and sudden cardiac death by 21%, with no gynaecomastia.

**Cardiac glycosides**

Digoxin is a cardiac glycoside that is indicated in patients in atrial fibrillation with heart failure. It is used as add-on therapy in symptomatic heart failure patients already receiving ACEI and beta-blockers. The DIG study demonstrated that digoxin reduced hospital admissions in patients with heart failure.

**Vasodilators and nitrates**

The combination of hydralazine and nitrates reduces afterload and pre-load and is used in patients intolerant of ACEI or ARA. The Veterans Administration Cooperative Study demonstrated that the combination of hydralazine (with nitrates) improved survival in patients with chronic heart failure. The A-HeFT trial showed that the same combination reduced mortality and hospitalization for heart failure in black patients with heart failure.

**Inotropic and vasopressor agents**

Intravenous inotropes and vasopressor agents (see Table 14.25) are used in patients with chronic heart failure who are not responding to oral medication. Although they produce haemodynamic improvements they have not been shown to improve long-term mortality when compared with placebo.

**Other medications**

In hospital, all patients require prophylactic anticoagulation. Heart failure is associated with a four-fold increase in the risk of a stroke. Oral anticoagulants are recommended in patients with atrial fibrillation and in patients with sinus rhythm with a history of thromboembolism, left ventricular thrombus or aneurysm. In patients with known ischaemic heart disease antiplatelet therapy (aspirin, clopidogrel) and statin therapy should be continued. Arrhythmias are frequent in heart failure and are implicated in sudden death. Although treatment of complex ventricular arrhythmias might be expected to improve survival, there is no evidence to support this and it may increase mortality. In the Sudden Cardiac Death Heart Failure Trial (SCD-HeFT), amiodarone showed no benefit compared to placebo in patients with impaired left ventricular function and mild-moderate heart failure (whereas an ICD reduced mortality by 23% compared to placebo). Patients with heart failure and symptomatic ventricular arrhythmias should be assessed for suitability for an ICD.

Ivabradine, which inhibits the If channel in the sincatrial node, slows the heart rate and in the SHIFT study was associated with a reduction in cardiovascular mortality and hospital admission for worsening heart failure in patients in sinus rhythm with chronic heart failure and left ventricular dysfunction (LVEF ≤35%) when compared to placebo.
Non-pharmacological treatment of heart failure

Revascularization
While coronary artery disease is the most common cause of heart failure, the role of revascularization in patients with heart failure is unclear. Patients with angina and left ventricular dysfunction have a higher mortality from surgery (10–20%), but have the most to gain in terms of improved symptoms and prognosis. Factors that must be considered before recommending surgery include age, symptoms and evidence for reversible myocardial ischaemia.

Hibernating myocardium and myocardial stunning
‘Hibernating’ myocardium can be defined as reversible left ventricular dysfunction due to chronic coronary artery disease that responds positively to inotropic stress and indicates the presence of viable heart muscle that may recover after revascularization. It is due to reduced myocardial perfusion, which is just sufficient to maintain viability of the heart muscle. Myocardial hibernation results from repetitive episodes of cardiac stunning that occur, e.g. with repeated exercise in a patient with coronary artery disease.

Myocardial stunning is reversible ventricular dysfunction that persists following an episode of ischaemia when the blood flow has returned to normal, i.e. there is a mismatch between flow and function.

The prevalence of hibernating myocardium in patients with coronary artery disease can be estimated from the frequency of improvement in regional abnormalities in wall motion after revascularization and is estimated to be 33% of such patients. Techniques to try to identify hibernating myocardium include stress echocardiography, nuclear imaging techniques, cardiovascular magnetic resonance and positron emission tomography.

The clinical relevance of the hibernating and stunned myocardium is that ventricular dysfunction due to these mechanisms may be wrongly ascribed to myocardial necrosis and scarring which seems untreatable, whereas reversible hibernating and stunning respond to coronary revascularization.

Biventricular pacemaker or implantable cardioverter-defibrillator
Pacemakers (Fig. 14.55) are indicated in patients with sinoatrial disease and atrioventricular conduction block. Pacemakers are also valuable in patients without AV block but with prolonged PR intervals, left bundle branch block and severe mitral regurgitation. In patients with heart failure and left bundle branch block and NYHA class III heart failure (MUSTIC study) biventricular pacing was more beneficial than conventional right ventricular pacing. The results showed an improvement in symptoms and exercise tolerance. The effect on prognosis is being addressed by an ongoing trial (CARE HF).

Biventricular pacing can also be used in patients not responding to therapy in the following situations:
- Systolic heart failure
- Non-reversible cause
- Highly symptomatic (New York Heart Association class III/IV)
- On optimal medical therapy
- Ventricular dys-synchrony: left bundle branch block (QRS >120 ms)
- Sinus rhythm, and possibly atrial fibrillation
- Significant mitral regurgitation.

New guidelines recommend advanced pacing technologies should be used for cardiac resynchronisation therapy (CRT) in selected patients with heart failure. Atrio-biventricular pacing has been shown to improve symptoms and reduce admission to hospital in patients with left bundle branch block and heart failure with poor LV function. The use of combined implantable defibrillators and atrio-biventricular pacemakers for patients with heart failure is likely to increase. One large trial (COMPANION) shows 21% reduction in all-cause mortality and all-cause admissions to hospital in the groups receiving biventricular pacing. ICD therapy in patients with NYHA (classes I and II, see Table 14.19) has shown a reduction in mortality compared with placebo and amiodarone.

Cardiac transplantation
Cardiac transplantation has become the treatment of choice for younger patients with severe intractable heart failure, whose life expectancy is <6 months. With careful recipient selection, the expected 1-year survival for patients following transplantation is over 90%, and is 75% at 5 years. Irrespective of survival, quality of life is dramatically improved for the majority of patients. The availability of heart transplantation is limited.

Heart allografts do not function normally. Cardiac denervation results in a high resting heart rate, loss of diurnal blood pressure variation and impaired renin-angiotensin-aldosterone regulation. Some patients develop a ‘stiff heart’ syndrome, caused by rejection, denervation and ischaemic injury during organ harvest and implantation. Transplantation of an inappropriately small donor heart can also result in elevated right and left heart pressure.

The complications of heart transplantation are summarized in Table 14.22. Many (infection, malignancy, hypertension and hyperlipidaemia) are related to immunosuppression. Allograft coronary atherosclerosis is the major cause of long-term graft failure and is present in 30–50% of patients at 5 years. It is due to a ‘vascular’ rejection process in conjunction with hypertension and hyperlipidaemia.

There are specific contraindications to cardiac transplantation (Table 14.23); notably, high pulmonary vascular resistance is an absolute contraindication. Several options to transplantation are available: cardiomyoplasty (augmentation of left ventricular contraction by wrapping a latissimus dorsi muscle flap around the ventricle) and the Batista procedure (surgical ventricular size reduction and remodelling the

Figure 14.55 Implanted biventricular pacing with ICD device.
Acute heart failure (AHF) occurs with the rapid onset of symptoms and signs of heart failure secondary to abnormal cardiac function, causing elevated cardiac filling pressures. This causes severe dyspnoea and fluid accumulates in the interstitium and alveolar spaces of the lung (pulmonary oedema). AHF has a poor prognosis with a 60-day mortality rate of nearly 10% and a rate of death or rehospitalization of 35% within 60 days. In patients with acute pulmonary oedema the in-hospital mortality rate is 12% and by 12 months this rises to 30%. Poor prognostic indicators include a high (>16 mmHg) pulmonary capillary wedge pressure (PCWP), low serum sodium concentration, increased left ventricular end-diastolic dimension on echo and low oxygen consumption.

The aetiology of AHF is similar to chronic heart failure:

- People with ischaemic heart disease present with an acute coronary syndrome or develop a complication of a myocardial infarct, e.g. papillary muscle rupture or ventricular septal defect requiring surgical intervention.
- People with valvular heart disease also present with AHF due to valvular regurgitation in endocarditis or prosthetic valve thrombosis. A thoracic aortic dissection may produce severe aortic regurgitation.
- People with hypertension present with episodes of ‘flash’ pulmonary oedema despite preserved left ventricular systolic function.
- In both acute and chronic kidney disease fluid overload and a reduced renal excretion will produce pulmonary oedema.

**Atrial fibrillation** is frequently associated with AHF and may require emergency cardioversion. Several clinical syndromes of AHF can be defined (Table 14.24). In a clinical environment both the Killip score (p. 739, based on a cardiorespiratory clinical assessment) and Forrester (based on right catheterization findings) classification are used to provide therapeutic and prognostic information.

### Pathophysiology

The pathophysiology of AHF is similar to chronic heart failure with activation of the renin-angiotensin-aldosterone axis and sympathetic nervous system. In addition, prolonged ischaemia (e.g. in acute coronary syndromes) results in myocardial stunning (p. 721) that exacerbates myocardial dysfunction but may respond to inotropic support. If myocardial ischaemia persists the myocardium may exhibit hibernation (persistently impaired function due to reduced coronary blood flow) that may recover with successful revascularization.

### Diagnosis

In a patient presenting with symptoms and signs of heart failure a structured assessment should result in the clinical diagnosis of AHF and direct initial treatment to stabilize the patient. Initial investigations performed in the emergency room should include the following:

- A 12-lead ECG for acute coronary syndromes, left ventricular hypertrophy, atrial fibrillation, valvular heart disease, left bundle branch block
- A chest X-ray (cardiomegaly, pulmonary oedema, pleural effusion, non-cardiac disease)
- Blood investigations (serum creatinine and electrolytes, full blood count, blood glucose, cardiac enzymes and troponin, CRP and D-dimer)
- Plasma BNP or NTproBNP (BNP >100 pg/mL or NTproBNP >300 pg/mL indicates heart failure
- Transthoracic echocardiography should be performed without delay to confirm the diagnosis of heart failure (p. 686) and possibly identify the cause.

If the baseline investigations confirm AHF, then treatment should be commenced.

**FURTHER READING**

Treatment
The goals of treatment in a patient with AHF include:
- Immediate relief of symptoms and stabilization of haemodynamics (short-term benefits)
- Reduction in length of hospital stay and hospital readmissions
- Reduction in mortality from heart failure.

Patients with AHF should be managed in a high-care area with regular measurements of temperature, heart rate, blood pressure and cardiac monitoring. All patients require prophylactic anticoagulation with low molecular weight heparin, e.g. enoxaparin 1 mg/kg s.c. ×2 daily.

Patients with haemodynamic compromise may require arterial lines (invasive blood pressure monitoring and arterial gases), central venous cannulation (intravenous medication, inotropic support, monitoring of central venous pressure) and pulmonary artery cannulation (calculation of cardiac output/index, peripheral vasoconstriction and pulmonary wedge pressure).

Initial therapy (Fig. 14.56, Table 14.25) includes oxygen, diuretics (e.g. i.v. furosemide 50 mg) and vasodilator therapy (e.g. glyceryl trinitrate infusion 10–200 μg/min) if the blood pressure is maintained (systolic >85 mmHg). Inotropic support (see p. 887) with dobutamine, phosphodiesterase inhibitors or levosimendan can be added in patients who do not respond to the initial therapy (Fig. 14.56). If blood pressure is low, use noradrenaline (norepinephrine).

Patients with profound hypotension may require inotropes and vasopressors to improve the haemodynamic status and alleviate symptoms, but these have not been shown to improve mortality. Non-invasive CPAP/NIPPV (see p. 895) has been shown to provide earlier improvement in dyspnoea and respiratory distress than standard oxygen via masks; mortality is however unaffected.

Mechanical assist devices
Mechanical assist devices can be used in patients who fail to respond to standard medical therapy but in whom there is either transient myocardial dysfunction with likelihood of recovery (e.g. post anterior myocardial infarction treated with coronary angioplasty) or a bridge is needed to cardiac surgery, including transplantation.

Ventricular assist devices (VAD) (Fig. 14.57) Ventricular assist devices are mechanical devices that replace or help the failing ventricles in delivering blood around the body. A left ventricular assist device (LVAD) receives blood from the left ventricle and delivers it to the aorta; a right ventricular assist device (RVAD) receives blood from the right ventricle and delivers it to the pulmonary artery. The devices can be extracorporeal (suitable for short-term support) or intracorporeal (suitable for long-term support as a bridge to transplantation or as destination therapy in patients with end-stage heart failure not candidates for transplantation). The main problems with VADs include thromboembolism, bleeding, infection and device malfunction.

**CORONARY ARTERY DISEASE**

Myocardial ischaemia occurs when there is an imbalance between the supply of oxygen (and other essential

</tbody>
</table>
myocardial nutrients) and the myocardial demand for these substances.

Coronary blood flow to a region of the myocardium may be reduced by a mechanical obstruction that is due to:

- Atheroma
- Thrombosis
- Spasm
- Embolus
- Coronary ostial stenosis
- Coronary arteritis (e.g. in SLE).

There can be a decrease in the flow of oxygenated blood to the myocardium that is due to:

- Anaemia
- Carboxyhaemoglobinemia
- Hypotension causing decreased coronary perfusion pressure.

An increased demand for oxygen may occur owing to an increase in cardiac output (e.g. thyrotoxicosis) or myocardial hypertrophy (e.g. from aortic stenosis or hypertension).

Myocardial ischaemia most commonly occurs as a result of obstructive coronary artery disease (CAD) in the form of coronary atherosclerosis. In addition to this fixed obstruction, variations in the tone of smooth muscle in the wall of a coronary artery may add another element of dynamic or variable obstruction.

CAD is the largest single cause of death in the UK and many parts of the world. However, over the last decade, the mortality rate in the UK has fallen considerably. In 2009, 1 in 5 male and 1 in 8 female deaths were from coronary artery disease; approximately 82,000 deaths in the UK (www.bhf.org.uk/heart-health/statistics/mortality.aspx). It has been estimated that by 2010, 60% of the world’s heart disease occurred in India. Sudden cardiac death is a prominent feature of CAD. One in every six coronary attacks present with sudden death as the first, last and only symptom.

**Process of coronary atherosclerosis**

Coronary atherosclerosis is a complex inflammatory process characterized by the accumulation of lipid, macrophages and smooth muscle cells in intimal plaques in the large and medium-sized epicardial coronary arteries. The vascular endothelium plays a critical role in maintaining vascular integrity and homeostasis. Mechanical shear stresses (e.g. from morbidity hypertension), biochemical abnormalities (e.g. elevated LDL, diabetes mellitus), immunological factors (e.g. free radicals from smoking), inflammation (e.g. infection such as *Chlamydia pneumoniae*) and genetic alteration may contribute to the initial endothelial ‘injury’ or dysfunction, which is believed to trigger atherogenesis.

The development of atherosclerosis follows the endothelial dysfunction, with increased permeability to and accumulation of oxidized lipoproteins, which are taken up by macrophages at focal sites within the endothelium to produce lipid-laden foam cells. Macroscopically, these lesions are seen as flat yellow dots or lines on the endothelium of the artery and are known as ‘fatty streaks’. The ‘fatty streak’ progresses with the appearance of extracellular lipid within the endothelium (‘transitional plaque’). Release of cytokines such as platelet-derived growth factor and transforming growth factor-β (TGF-β) by monocytes, macrophages or the damaged endothelium promotes further accumulation of macrophages as well as smooth muscle cell migration and proliferation. The proliferation of smooth muscle with the formation of a layer of cells covering the extracellular lipid separates it from the

![Figure 14.58 The mechanisms for the development of thrombosis on plaques.](image-url)

Adaptive smooth muscle thickening in the endothelium. Collagen is produced in larger and larger quantities by the smooth muscle and the whole sequence of events cumulates as an ‘advanced or raised fibrolipid plaque’. The ‘advanced plaque’ may grow slowly and encroach on the lumen or become unstable, undergo thrombosis and produce an obstruction (‘complicated plaque’).

Two different mechanisms are responsible for thrombosis on the plaques (Fig. 14.58):

- **The first process** is superficial endothelial injury, which involves denudation of the endothelial covering over the plaque. Subendocardial connective tissue matrix is then exposed and platelet adhesion occurs because of reaction with collagen. The thrombus is adherent to the surface of the plaque.
- **The second process** is deep endothelial fissuring, which involves an advanced plaque with a lipid core. The plaque cap tears (ulcerates, fissures or ruptures), allowing blood from the lumen to enter the inside of the plaque itself. The core with lamellar lipid surfaces, tissue factor (which triggers platelet adhesion and activation) produced by macrophages and exposed collagen, is highly thrombogenic. Thrombus forms within the plaque, expanding its volume and distorting its shape. Thrombosis may then extend into the lumen.

A 50% reduction in luminal diameter (producing a reduction in luminal cross-sectional area of approximately 70%) causes a haemodynamically significant stenosis. At this point the smaller distal intramyocardial arteries and arterioles are maximally dilated (coronary flow reserve is near zero), and any increase in myocardial oxygen demand provokes ischaemia.

CAD gives rise to a wide variety of clinical presentations, ranging from relatively stable angina through to the acute coronary syndromes of unstable angina and myocardial infarction (Fig. 14.59). Figure 14.60 shows an actual plaque rupture.

**Risk factors for coronary artery disease – primary and secondary prevention**

CAD is an atherosclerotic disease that is multifactorial in origin, giving rise to the risk factor concept. Certain living habits promote atherogenic traits in genetically susceptible persons. A number of ‘risk’ factors are known to predispose to the condition (Table 14.26). Some of these, such as age, gender, race and family history, cannot be changed, whereas
The disease can be asymptomatic in its most severe form, with one in three myocardial infarctions going unrecognized. Some 30–40% of individuals who present with an acute coronary syndrome have had no prior warning symptom to suggest the presence of underlying disease.

**Primary prevention** can be defined as the prevention of the atherosclerotic disease process and **secondary prevention** as the treatment of the atherosclerotic disease process (i.e. treatment of the disease or its complications). The objective of prevention is to reduce the incidence of first or recurrent clinical events due to CAD, ischaemic stroke and peripheral artery disease.

other major risk factors, such as serum cholesterol, smoking habits, diabetes and hypertension, can be modified.

Atherosclerotic disease manifest in one vascular bed is often advanced in other territories. Patients with intermittent claudication have a two- to four-fold increased risk of CAD, stroke, or heart failure. Following initial myocardial infarction (MI), there is a 3–6-fold increase in the risk of heart failure and stroke. After stroke, the risk of heart failure and MI is increased two-fold.

The disease can be asymptomatic in its most severe form, with one in three myocardial infarctions going unrecognized. Some 30–40% of individuals who present with an acute coronary syndrome have had no prior warning symptom to suggest the presence of underlying disease.

**Primary prevention** can be defined as the prevention of the atherosclerotic disease process and **secondary prevention** as the treatment of the atherosclerotic disease process (i.e. treatment of the disease or its complications). The objective of prevention is to reduce the incidence of first or recurrent clinical events due to CAD, ischaemic stroke and peripheral artery disease.

**Traditional risk factors**

**Age**

CAD rates increase with age. Atherosclerosis is rare in childhood, except in familial hyperlipidaemia, but is often detectable in young men between 20 and 30 years of age. It is almost universal in the elderly in the West. Atheromatous lesions in the elderly are often complicated by calcification.

**Gender**

Men have a higher incidence of coronary artery disease than premenopausal women. However, after the menopause, the incidence of atheroma in women approaches that in men. The reasons for this gender difference are not clearly understood, but probably relate to the loss of the protective effect of oestrogen.

**Family history**

CAD is often found in several members of the same family. Because the disease is so prevalent and because other risk factors are familial, it is uncertain whether family history, per se, is an independent risk factor. A positive family history is generally accepted to refer to those in whom a first-degree relative has developed ischaemic heart disease before the age of 50 years.

**Smoking**

In men, the risk of developing CAD is directly related to the number of cigarettes smoked (see p. 807). It is estimated that about 20% of deaths from CAD in men and 17% of deaths from CAD in women are due to smoking. Evidence suggests that each person stopping smoking will reduce his/her own risk by 25%. The risk from smoking declines to almost normal after 10 years of abstinence.

**Diet and obesity**

Diet high in fats are associated with ischaemic heart disease, as are those with low intakes of antioxidants (i.e. fruit and vegetables). Supplementation with antioxidants has been shown to be unhelpful in RCTs (p. 211).
It is estimated that up to 30% of deaths from CAD are due to unhealthy diets (see p. 200). The dietary changes which would help to reduce rates of CAD include a reduction in fat, particularly saturated fat intake, a reduction in salt intake and an increase in carbohydrate intake. The consumption of fruit and vegetables should be increased by 50%, to about 400 g/day, which is equivalent to at least five daily portions (see Box 5.2).

There is overwhelming evidence from clinical trials that modification of the diet has a significant impact on the risk of CVD in both the primary and secondary prevention settings.

**Weight.** Patients who are overweight and those who are obese have an increased risk of CAD. It is estimated that about 5% of deaths from CAD in men and 6% of such deaths in women are due to obesity (a body mass index (BMI) of $>30$ kg/m$^2$).

The adverse effect of excess weight is more pronounced when the fat is concentrated mainly in the abdomen. This is known as central obesity (visceral fat) and can be identified when the fat is concentrated mainly in the abdomen. This is directly related to the activity needs to be regular and aerobic. Aerobic activity can lower the incidence of CVD but also diabetes/insulin resistance. It is estimated that about 36% of deaths from CAD in men and 38% of deaths from CAD in women are due to lack of physical activity. To produce the maximum benefit the activity needs to be regular and aerobic. Aerobic activity involves using the large muscle groups in the arms, legs and back steadily and rhythmically so that breathing and heart rate are significantly increased.

It is recommended that adults should participate in a minimum of 30 minutes of at least moderate intensity activity (such as brisk walking, cycling or climbing the stairs) on ≥5 days of the week.

**Hypertension**

Both systolic and diastolic hypertension are associated with an increased risk of CAD. Both drug treatment and lifestyle changes – particularly weight loss, an increase in physical activity and a reduction in salt and alcohol intake – can effectively lower blood pressure.

It is estimated that 14% of deaths from CAD in men and 12% of deaths from CAD in women are due to a raised blood pressure (defined as a systolic blood pressure of $≥140$ mmHg, or a diastolic blood pressure of $≥90$ mmHg) and that 6% of deaths from CAD in the UK could be avoided if the numbers of people who have high blood pressure were to be reduced by 50%.

**Hyperlipidaemia**

High serum cholesterol, especially when associated with a low value of high-density lipoproteins (HDL), is strongly associated with coronary atheroma. There is increasing evidence that high serum triglyceride (TG) is also independently linked with coronary atheroma (see p. 1034).

Familial hypercholesterolaemia combined with hypertriglyceridaemia and remnant hyperlipidaemia are also associated with increased risk of coronary atherosclerosis.

Measurement of the fasting lipid profile (total cholesterol, low- and high-density lipoproteins and triglycerides) should be performed on all people with an increased risk of cardiac disease.

The risk of CAD is directly related to serum cholesterol levels. Serum cholesterol levels can be reduced by drugs, physical activity and by dietary changes, in particular a reduction in the consumption of saturated fat. It is estimated that 45% of deaths from CAD in men and 47% of deaths from CAD in women are due to a raised serum cholesterol level (in this case $>5.2$ mmol/L) and that 10% of deaths from CAD in the UK could be avoided if everyone in the population had a serum cholesterol level of $<6.5$ mmol/L.

Different guidelines give slightly different advice for managing high levels of serum cholesterol (hyperlipidaemia). The National Service Framework for coronary heart disease in England includes guidelines on the prevention of CAD in clinical practice and suggests a cholesterol target of $<5.0$ mmol/L for both primary and secondary prevention.

High-density lipoprotein cholesterol (HDL-cholesterol) is the fraction of cholesterol that removes cholesterol (via the liver) from the blood. Low levels of HDL-cholesterol are associated with an increased risk of CAD and a worse prognosis after a heart attack. Guidelines on HDL-cholesterol generally recommend treatment for those with concentrations $<1.0$ mmol/L. HDL increases with exercise, alcohol in moderation, not smoking and when TG is lowered.

A 1% reduction in cholesterol levels reduces risks of CAD by 2–3%. Hyperlipidaemia can be treated as follows:

- **Statins:** 24–30% reduction in mortality in primary and secondary prevention will be achieved if a statin (pravastatin or simvastatin) is given. Up to 50% reduction is achieved if the dose of statin (e.g. atorvastatin) is titrated to achieve a target LDL of $<2.6$ mmol/L.
- **Fibrates** result in a significant reduction in CAD events in diabetics and patients with high TG and low HDL.
- **Diet:** the so-called Mediterranean diet (p. 198) has resulted in a 75% reduction in CAD events in post-myocardial infarction patients.

Angiographic studies have shown that lowering the serum cholesterol can slow the progression of coronary atherosclerosis, and can cause regression of disease. Large clinical trials have shown that lipid lowering, usually with a statin, can decrease total mortality and new coronary events, and reduce the need for revascularization. Management of hypercholesterolaemia is described in detail on page 1037.

**Diabetes mellitus**

Diabetes, an abnormal glucose tolerance or raised fasting glucose, is strongly associated with vascular disease.

Diabetes substantially increases the risk of CAD. Men with type 2 diabetes have a two- to four-fold greater annual risk of CAD, with an even higher (3–5-fold) risk in women with type 2 diabetes.

Diabetes not only increases the risk of CAD but also magnifies the effect of other risk factors for CAD such as raised cholesterol levels, raised blood pressure, smoking and obesity.

**Other risk factors**

Although there is general agreement on established cardiovascular risk factors, epidemiological research continues to identify or evaluate additional risk factors that contribute to the occurrence of atherosclerotic CVD and warrant further clarification.

**Sedentary lifestyle**

Lack of exercise is an independent risk factor for CAD equal to hypertension, hyperlipidaemia and smoking. Regular exercise probably protects against its development (see above).

**Psychosocial wellbeing**

Four different types of psychosocial factors have been found to be most consistently associated with an increased risk of...
CAD: work stress, lack of social support, depression (including anxiety) and personality (particularly hostility).

**Alcohol**
Moderate alcohol consumption (one or two drinks per day) is associated with a reduced risk of CAD. At high levels of intake – particularly in ‘binges’ – the risk of CAD is increased. It is currently advised that ‘regular consumption of between three and four units a day by men’ and ‘between two and three units a day by women of all ages will not lead to any significant health risk’.

**Genetic factors**
A number of genetic factors have been linked with coronary artery disease. The angiotensin-converting enzyme (ACE) gene contains an insertion/deletion (I/D) polymorphism, the DD genotype of which has been associated with a predisposition to CAD and myocardial infarction.

**Lipoprotein(a)**
High plasma Lp(a) concentrations are associated with CAD and, although probably not an independent risk factor, elevated plasma Lp(a) increases the CAD risk associated with more traditional risk factors.

**Coagulation factors**
Serum fibrinogen is strongly, consistently and independently related to CAD risk. The pathophysiological mechanism by which fibrinogen levels mediate coronary disease risk is related to its effect on the coagulation cascade, platelet aggregation, endothelial function and smooth muscle cell proliferation and migration.

High levels of coagulation factor VII are also a risk factor. Polymorphisms of the factor VII gene may increase the risk of myocardial infarction.

Homocysteine, an amino acid regulated by vitamins B12, B6 and folate, is another factor that has been associated with CAD and atherosclerosis (see p. 212). Homocysteinaemia is a major risk factor in the pathogenesis of CAD and a strong predictor of mortality in this group. Plasma levels of homocysteine are influenced by a variety of genetic and non-genetic factors. The mechanism associating hyperhomocysteinaemia with atherosclerosis is its adverse effect on vascular endothelium. Folic acid in low doses may ameliorate this process.

**C-reactive protein (CRP)**
CRP is linked with future risk of coronary events independently of the traditional risk factors but its use as a marker for subclinical atherosclerosis and cardiovascular risk has been questioned.

**Non-steroidal anti-inflammatory drugs (NSAIDs)**
NSAIDs that are specific inhibitors of cyclo-oxygenase-2 (COX-2) have been shown to increase cardiovascular risk and mortality. Rofecoxib has already been withdrawn.

**Prevention policy**
The priorities for CVD prevention in clinical practice are:

- Patients with established CAD, PVD and cerebrovascular atherosclerotic disease
- Asymptomatic individuals who are at high risk of developing atherosclerotic disease because of multiple risk factors resulting in a 10-year risk of >5% now (or if extrapolated to age 60) for developing a fatal event, i.e. those with markedly raised levels of single risk factors:
  - cholesterol >8 mmol/L
  - LDL cholesterol >6 mmol/L
  - BP >180/110 mmHg.

- All patients with diabetes.
- Close relatives of:
  - patients with early-onset atherosclerotic cardiovascular disease
  - asymptomatic individuals at a particularly high risk.
- Other individuals encountered in routine clinical practice.

**Risk estimation for CVD prevention in the asymptomatic population**
Patients with established CVD have declared themselves to be at high total risk of further vascular events. Therefore they require the most intense lifestyle intervention, and where appropriate drug therapies.

However, in the majority of asymptomatic, apparently healthy people, preventative actions should be guided in accordance with the total CVD risk level. Indeed, risk factor management decisions should usually not be based on considerations of a single modestly raised factor.

To evaluate candidates for the major cardiovascular events cost-effectively, multivariate risk profiles have been formulated; these facilitate targeting those at high risk for preventative measures.

The Joint British Societies, the European Society of Cardiology and the American Heart Association have emphasized the importance of these risk profiles for motivating as well as reassuring patients and in assisting in selecting therapy. They concluded that these scores direct healthcare professionals to look at the whole patient and to recognize the cumulative nature of risk factors (Fig. 14.61). However, not all practitioners agree with this approach (see p. 1038).

**National Service Framework (NSF)**
The UK’s NSF includes a nurse-led audited approach to reduce CAD by lowering saturated fat intake, increasing exercise and, most relevant, decreasing/stop smoking. The hypertension treatment targets are 140/85 mmHg in patients at risk of or with established coronary artery disease and 130/80 mmHg in diabetics. The cholesterol target is either total cholesterol of ≤5.0 mmol/L (LDL-cholesterol <3 mmol/L) or a reduction of 30% (whichever is greater).

**Angina**
The diagnosis of angina (see also p. 675 and Table 14.27) is largely based on the clinical history. The chest pain is generally described as ‘heavy’, ‘tight’ or ‘gripping’. Typically, the pain is central/retrosternal and may radiate to the jaw and/or arms. Angina can range from a mild ache to a most severe pain that provokes sweating and fear. There may be associated breathlessness.

| Table 14.27 Canadian cardiovascular society functional classification of angina |
|-------------------------|--------------------------------------------------------------------------|
| Class I                 | No angina with ordinary activity. Angina with strenuous activity         |
| Class II                | Angina during ordinary activity, e.g. walking up hills, walking rapidly up stairs, with mild limitation of activities |
| Class III               | Angina with low levels of activity, e.g. walking 50–100 yards on the flat, walking up one flight of stairs, with marked restriction of activities |
| Class IV                | Angina at rest or with any level of exercise                              |
Coronary artery disease

Typical angina has all three features, atypical angina two out of the three, and non-anginal chest pain one or less of these features.

Angina is stable when it is not a new symptom and when there is no change in the frequency or severity of attacks.

Unstable angina refers to angina of recent onset (< 24 h) or a deterioration in previous stable angina with symptoms frequently occurring at rest, i.e. acute coronary syndrome (p. 730).

Refractory angina refers to patients with severe coronary disease in whom revascularization is not possible and angina is not controlled by medical therapy.

Variant (Prinzmetal’s) angina refers to an angina that occurs without provocation, usually at rest, as a result of coronary artery spasm. It occurs more frequently in women.

Figure 14.61 Cardiovascular risk prediction charts. (Cardiovascular risk prediction charts reproduced with permission from the University of Manchester, Department of Medical Illustration.)

The Health Survey for England 2006 reported a prevalence of angina of 14.2% in men aged 65–74 years and 8.3% in women aged 65–74 years old. In the UK, an estimated 2 million people over the age of 35 years have had angina.

Classical or exertional angina pectoris is characterized by:

- constricting discomfort in the front of the chest, arms, neck, jaw;
- provoked by physical exertion, especially after meals and in cold, windy weather or by anger or excitement and
- relieved (usually within minutes) with rest or glyceryl trinitrate. Occasionally, it disappears with continued exertion (‘walking through the pain’).

Typical angina has all three features, atypical angina two out of the three, and non-anginal chest pain one or less of these features.

Angina is stable when it is not a new symptom and when there is no change in the frequency or severity of attacks.

Unstable angina refers to angina of recent onset (< 24 h) or a deterioration in previous stable angina with symptoms frequently occurring at rest, i.e. acute coronary syndrome (p. 730).

Refractory angina refers to patients with severe coronary disease in whom revascularization is not possible and angina is not controlled by medical therapy.

Variant (Prinzmetal's) angina refers to an angina that occurs without provocation, usually at rest, as a result of coronary artery spasm. It occurs more frequently in women.
Characteristically, there is ST segment elevation on the ECG during the pain. Specialist investigation using provocation tests (e.g., hyperventilation, cold-pressor testing or ergometrine challenge) may be required to establish the diagnosis.

Cardiac syndrome X refers to those patients with a good history of angina, a positive exercise test and angiographically normal coronary arteries. They form a heterogeneous group, and the syndrome is much more common in women than in men. Whilst they have a good prognosis, they are often highly symptomatic and can be difficult to treat. In women with this syndrome the myocardium shows an abnormal metabolic response to stress, consistent with the suggestion that the myocardial ischaemia results from abnormal dilator responses of the coronary microvasculature to stress. See Table 14.27 for the Canadian Cardiovascular Society Functional Classification of Angina.

Examination

There are usually no abnormal findings in angina, although occasionally a fourth heart sound may be heard. Signs to suggest anaemia, thyrotoxicosis or hyperlipidaemia (e.g., lipid arcus, xanthelasma, tendon xanthoma) should be sought. It is essential to exclude aortic stenosis (i.e., slow-rising carotid impulse and ejection systolic murmur radiating to the neck) as a possible cause for the angina. The blood pressure should be taken to identify co-existent hypertension.

Diagnosis and investigations for angina

Patients presenting with chest pain should have a 12-lead ECG performed to exclude an acute coronary syndrome. In many patients the ECG is normal between attacks although evidence of old myocardial infarction (e.g., pathological Q waves), left ventricular hypertrophy or left bundle branch block may be present. During an attack, transient ST depression, T wave inversion or other changes of the shape of the T wave may appear.

The diagnosis of stable angina can be made on clinical assessment alone OR by clinical assessment combined with anatomical (cardiac catheterization or CT coronary angiography) or functional imaging (SPECT, stress-echocardiography, stress-magnetic resonance imaging).

UK NICE guidance recommends assessing the likelihood of coronary artery disease in patients without known coronary artery disease who present with typical angina, atypical angina, or non-anginal chest pain (Table 14.28).

- Patients with non-anginal chest pain (more likely if the pain is continuous, is unrelated to exertion, is exacerbated by respiration, is associated with dizziness, palpitations or difficulty in swallowing) should have alternate diagnoses considered and be investigated appropriately.
- Patients with typical angina and a risk of disease of >90% do not need further diagnostic investigation and should be managed for stable angina.
- Patients with typical or atypical angina and a risk of disease of 61–90% should have cardiac catheterization if appropriate.
- Patients with typical or atypical angina and a risk of disease of 30–60% should be referred for functional testing (SPECT, stress-echocardiography, stress-magnetic resonance imaging).
- Patients with typical or atypical angina and a risk of disease of 10–29% should be referred for CT coronary angiography. If CT calcium score is zero then angina is unlikely and other causes of chest pain should be sought (although young patients may have non-calcified plaque and CT angiography may be appropriate if symptomatic). If CT calcium score is 1–400, proceed to CT angiography but if the score is >400, invasive coronary angiography or functional imaging would be appropriate.
- If stable angina cannot be diagnosed in patients with known coronary artery disease then functional assessment would be appropriate.

NICE does not recommend exercise ECG as a diagnostic test in patients with chest pain symptoms although it has been present in the ESC guidelines from 2006. Using ST depression of <0.1 mV or 1 mm as a positive result, exercise ECG has a reported sensitivity of 67% and specificity of 72% for the detection of significant coronary disease in patients without prior myocardial infarction although interpretation of the findings is dependent on the prevalence of disease in the population and their presenting symptoms.

Management of stable angina

Patients should be informed as to the nature of their condition and reassured that the prognosis is good (annual mortality <2%). Underlying problems, such as anaemia or hyperthyroidism, should be treated. Management of co-existent conditions, such as diabetes and hypertension, should be optimized. Risk factors should be evaluated and steps made to correct them where possible; e.g., smoking must be stopped, hypercholesterolaemia should be identified and treated (see below), weight loss, where appropriate, and regular exercise should be encouraged. The stable angina

Men >70 years with atypical or typical angina: assume risk >90%.
Women >70 years: assume risk 61–90% unless high risk and typical angina (risk >90%).
Hi, high risk – diabetes, smoking, hyperlipidaemia (total cholesterol >6.47 mmol/L); Lo, low risk – none of the above.
Resting ECG abnormalities (ST-T changes, Q waves, LBBB) increases likelihood.
algorithm in Figure 14.62 should be used to guide initial patient management, as well as Table 14.29.

Low-dose aspirin is indicated. Symptomatic treatment should be started with the vasodilator sublingual or buccal nitrate to relieve acute episodes. Prophylaxis should be started with either a beta-adrenoceptor antagonist (e.g. atenolol) OR calcium channel receptor antagonist (e.g. diltiazem). If patients remain symptomatic then a beta-blocker can be combined with a dihydropyridine calcium channel receptor antagonist (e.g. amlopidine). Patients intolerant of beta-blockers and/or calcium channel blockers are treated with long-acting nitrates (e.g. isosorbide mononitrate) or 1 current inhibitor ivabradine or potassium channel activator nicorandil or sodium channel inhibitor ranolazine.

The COURAGE Trial published in April 2007 randomized patients with stable but significant coronary artery disease and inducible ischaemia to percutaneous coronary intervention with stenting (n=1149) or optimal medical therapy (n=1138). The primary composite outcome (all-cause death and non-fatal myocardial infarction) occurred in 211 (18.3%) of the PCI patients and 202 (17.8%) of the medically treated patients. This supports an initial strategy of optimal medical therapy in patients with stable angina symptoms although revascularization should be used in patients who remain symptomatic despite two anti-anginals.

Revascularization

Percutaneous coronary intervention

Percutaneous coronary intervention (PCI) is the process of dilating a coronary artery stenosis using an inflatable balloon and metallic stent introduced into the arterial circulation via the femoral, radial or brachial artery (Fig. 14.63). A discrete, soft lesion in a straight vessel without involving a bifurcation has the best outcome. Unfavourable lesions are occluded vessels, stenoses that are calcified, tortuous, long, or involve a bifurcation. Complications of the procedure include bleeding, haematoma, dissection and pseudoaneurysm from the arterial puncture site although the use of the radial artery may reduce the risks. Serious complications include acute myocardial infarction (2%), stroke (0.4%) and death (1%). Thrombotic complications are reduced with the use of heparin or the direct thrombin inhibitor bivalirudin together with the antiplatelet agents, aspirin and the thienopyridine clopidogrel. In very high-risk acute coronary syndrome or diabetic patients the antiplatelet GPIIb/IIIa antagonists (tirofiban, eptifibatide and abciximab) are also used. Reductions in the need for repeat revascularization have been seen with the introduction of covered stents lined with substances that reduce coronary artery restenosis. The Cypher stent contains sirolimus, which is an immunosuppressant agent that reduces cellular proliferation; everolimus is a derivative of sirolimus which is used in the Xience V stent. The Taxus stent contains paclitaxel, which is a mitotic inhibitor drug that inhibits neointima formation. Some concerns have been raised about late-stent thrombosis (>6 months post-insertion) in patients with drug-eluting stents leading to acute myocardial infarction and frequently death. It has been suggested that inadequate endothelialization of the stent leads to exposure of thrombus stimulating surface when the patient discontinues clopidogrel therapy, leading to recommendations that patients take prolonged dual therapy (aspirin and clopidogrel) and avoid discontinuing therapy within 6–12 months of implantation.

Coronary artery bypass grafting

With coronary artery bypass grafting (CABG) autologous veins or arteries are anastomosed to the ascending aorta and to the native coronary arteries distal to the area of stenosis (Fig. 14.64). Improved graft survival can be obtained with in situ internal mammary and gastroepiploic arteries grafted onto the stenosed coronary artery. Three major randomized controlled trials compared CABG with medical therapy; the Coronary Artery Surgery Study (CASS); the Veterans Administration (VA) Cooperative Study and the European Coronary Surgery Study (ECSS). A meta-analysis has been performed that demonstrated that compared to medical therapy, CABG significantly improved angina symptoms, exercise capacity and reduced the need for antianginal therapy. Operative mortality is well below 1% in patients with normal left ventricular function. Perioperative strokes occur in up to 2% of cases, and more subtle neurological deficits are common. Off-pump coronary surgery is now performed; results show that it is as safe as on-pump surgery and causes less myocardial damage, but the graft patency rate is lower. Minimal invasive operative procedures for bypass grafting (‘MIDCAB’) are being developed, including laparoscopic approaches, and may be of use in certain subgroups of patients (e.g. previous CABG and those with co-existent medical conditions which would increase the operative risks of ‘full’ CABG).

CABG versus PCI

Comparative trials between CABG and PCI have now been performed. All demonstrate a higher need for repeat revascularization with PCI than with CAGB. In the ERACI II study, PCI patients had fewer major adverse events initially and better 18-month survival than the CAGB group. The SoS Trial

Figure 14.62 Algorithm for management of patients with stable angina. CABG, coronary artery bypass grafting; PCI, percutaneous coronary intervention. (From NICE draft guideline: http://www.nice.org.uk/nicemedia/live/11878/52141/52141.pdf.)

FURTHER READING

**Figure 14.63** Percutaneous transluminal coronary angioplasty (PTCA). (a) Coronary angiography demonstrates an occluded right coronary artery (arrow). (b) A soft wire passed through the guide catheter reopens the artery but a severe stenosis remains (arrow). (c) A balloon (X) is inflated to dilate the stenosis. The soft guide-wire can be seen in the distal posterior descending artery (arrow). (d) The right coronary artery has now been successfully reopened with good antegrade flow.

**Figure 14.64** Relief of coronary obstruction by surgical techniques: coronary artery vein bypass grafting (CAVBG) or internal mammary arterial implantation (IMA). In both of these examples, the graft bypasses a coronary obstruction in the left coronary artery (LCA).

reported a 2-year incidence of death or Q wave myocardial infarction of 9% in PCI versus 10% in CABG patients but fewer deaths in with CAGB (2% vs 5%). The SYNTAX study compared PCI with drug-eluting stents with CABG in patients with three-vessel disease and/or left main stem disease. The primary end-point (all cause death, stroke, myocardial infarction or repeat revascularization) occurred in more PCI patients. Although the draft guidance of stable angina from NICE recommends PCI for young patients with single or multi-vessel disease (and no diabetes), the European Society of Cardiology has recommended PCI ONLY in cases of single or double vessel disease NOT involving the proximal left anterior descending artery.

**Patients with intractable angina**

Some patients remain symptomatic despite medication and are not suitable for (further) revascularization. These patients need a pain management programme.
Coronary artery disease

Acute coronary syndromes (ACS) include:

- **ST-elevation myocardial infarction (STEMI)**
- **Non-ST-elevation myocardial infarction (NSTEMI)**
- **Unstable angina (UA).**

The difference between UA and NSTEMI is that in the latter there is occluding thrombus, which leads to myocardial necrosis and a rise in serum troponins or CK-MB. Myocardial infarction (MI) occurs when cardiac myocytes die due to myocardial ischaemia, and can be diagnosed on the basis of appropriate clinical history, 12-lead ECG and elevated biochemical markers – troponin I and T, CK-MB. There are three types of MIs:

- **Type 1** – spontaneous MI with ischaemia due to a primary coronary event, e.g. plaque erosion/rupture, fissuring or dissection
- **Type 2** – MI secondary to ischaemia due to increased oxygen demand or decreased supply, such as coronary spasm, coronary embolism, anaemia, arrhythmias, hypertension, or hypotension
- **Type 3,4,5** – diagnosis of MI in sudden cardiac death, after percutaneous coronary intervention (PCI) and after coronary artery bypass graft (CABG), respectively.

Pathophysiology

The common mechanism to all ACS is rupture or erosion of the fibrous cap of a coronary artery plaque. This leads to platelet aggregation and adhesion, localized thrombosis, vasoconstriction and distal thrombus embolization. The presence of a rich lipid pool within the plaque and a thin fibrous cap are associated with an increased risk of rupture. Thrombus formation and the vasoconstriction produced by platelet release of serotonin and thromboxane A₂, results in myocardial ischaemia due to reduction of coronary blood flow.
Diagnosis

Clinical presentation

Patients with an ACS may complain of a new onset of chest pain, chest pain at rest, or a deterioration of pre-existing angina. However, some patients present with atypical features including indigestion, pleuritic chest pain or dyspnoea. Physical examination can detect alternative diagnoses such as aortic dissection, pulmonary embolism or peptic ulceration. In addition it can also detect adverse clinical signs such as hypotension, basal crackles, fourth heart sounds and cardiac murmurs.

Electrocardiogram

Although the 12-lead ECG may be normal in patients with an ACS, ST depression and T wave inversion are highly suggestive for an ACS, particularly if associated with anginal chest pain. The ECG should be repeated when the patient is in pain, and continuous ST-segment monitoring is recommended. With a STEMI, complete occlusion of a coronary vessel will result in persistent ST-elevation or left bundle branch block pattern, although transient ST elevation is seen with coronary vasospasm or Prinzmetal’s angina.

Biochemical markers

- The cardiac troponin complex is made up of three distinct proteins (I, T and C) that are situated with tropomyosin on the thin actin filament that forms the skeleton of the cardiac myofilament. Troponin T attaches the complex to tropomyosin, troponin C binds calcium during excitation-contraction coupling, and troponin I inhibits the myosin binding site on the actin. The cardiac troponins are not detectable in normal people and so monoclonal antibody tests to cardiac-specific troponin I and cardiac-specific troponin T are highly sensitive markers of myocyte necrosis. If the initial troponin assay is negative, then it should be repeated 6–12 h after admission. The troponin assay has prognostic information, i.e. a high serum troponin level has an increased mortality risk in ACS (Box 14.1), and defines which patients may benefit from aggressive medical therapy and early coronary revascularization.

- The measurement of the creatine-kinase-MB level was, until recently, the standard marker for myocyte death used in ACS. However, the presence of low levels of CK-MB in the serum of normal individuals and in patients with significant skeletal muscle damage, has limited its accuracy. It can be used to determine reinfarction as levels drop back to normal after 36–72 hours.

- Myoglobin may be useful for a rapid diagnosis of an ACS as the levels become elevated very early in the time course of an MI, but because of the presence of myoglobin in skeletal muscle the test has poor specificity for ACS.

NSTE MI and unstable angina

Risk stratification in NSTE MI and unstable angina

Initial risk in ACS is determined by complications of the acute thrombosis. This may produce recurrent myocardial ischaemia, marked ST depression, dynamic ST changes, a raised troponin level and be demonstrated with coronary angiography.

Long-term risks defined by clinical risk factors; age, prior myocardial infarction or bypass surgery, diabetes or heart failure. Biological markers, such as C-reactive protein, fibrinogen, brain natriuretic peptide, modified albumin and serum creatinine, can be used to further stratify patient risk. Left ventricular dysfunction and the presence of left main or triple vessel disease significantly increase the future cardiovascular risk. Both the Thrombolysis In Myocardial Infarction (TIMI) score and the Global Registry of Acute Coronary Events (GRACE) prediction score can be used in patients with ACS to define risk. TIMI is shown in Table 14.30. The GRACE score is based on age, heart rate, systolic blood pressure, serum creatinine and the Killip score.

Investigation and treatment of NSTE MI and UA

All patients require immediate management of their chest pain as outlined on page 738 and in Table 14.31.

High-risk patients for progression to myocardial infarction or death require urgent coronary angiography. These patients include those with persistent or recurrent angina with ST changes ≥2 mm or deep negative T wave changes, clinical signs of heart failure or haemodynamic instability, life-threatening arrhythmias (VF, VT).

Patients with immediate or high-risk TIMI or GRACE scores, elevated troponins, dynamic ST or T wave changes, diabetes mellitus, renal dysfunction, reduced left ventricular function, early post-infarction angina, previous myocardial infarction, PCI within 6 months, or previous CABG, should have early (<72 h) coronary angiography and interventions.
Low-risk patients can be managed with oral aspirin, clopidogrel, beta-blockers and nitrates. These include patients with no recurrence of chest pain during observation, no signs of heart failure, normal ECG or minor T wave changes on arrival and at 6–12 h, normal troponins on the initial assays and at 6–12 h post admission. An exercise test should be performed – a negative result has a good prognosis and an early positive test should direct the patient to an invasive strategy. If the patient is unable to exercise satisfactorily, or if the baseline ECG is abnormal (e.g. left ventricular hypertrophy or LBBB), then dobutamine stress echocardiography or myocardial perfusion scintigraphy are recommended. These tests are often used as the first line investigation.

Antiplatelet agents
The platelet is a key part of the thrombosis cascade involved in ACS. Rupture of the atheromatous plaque exposes the circulating platelets to ADP (adenosine diphosphate), thromboxane A2 (TxA2), epinephrine (adrenaline), thrombin and collagen tissue factor. This causes platelet activation, with thrombin as an especially potent stimulant of such activity. Platelet activation stimulates the expression of glycoprotein (GP) IIb/IIIa receptors on the platelet surface. These receptors bridge fibrinogen between adjacent platelets, causing platelet aggregates (Fig. 8.41).

Aspirin blocks the formation of thromboxane A2 and so prevents platelet aggregation. In ACS patients, 75–150 mg aspirin reduced the relative risk of death or myocardial infarction by about 35–50%. Ticagrelor, a nucleoside analogue, is used in combination with aspirin for the acute coronary syndrome.

Clopidogrel is a thienopyridine that inhibits ADP-dependent activation of the GPIIb/IIIa complex that allows platelet aggregates to form. In the CURE study of 12562

**Low-risk patients** can be managed with oral aspirin, clopidogrel, beta-blockers and nitrates. These include patients with no recurrence of chest pain during observation, no signs of heart failure, normal ECG or minor T wave changes on arrival and at 6–12 h, normal troponins on the initial assays and at 6–12 h post admission. An exercise test should be performed – a negative result has a good prognosis and an early positive test should direct the patient to an invasive strategy. If the patient is unable to exercise satisfactorily, or if the baseline ECG is abnormal (e.g. left ventricular hypertrophy or LBBB), then dobutamine stress echocardiography or myocardial perfusion scintigraphy are recommended. These tests are often used as the first line investigation.
ACS patients, 9 months of 75 mg clopidogrel reduced the primary end-point of cardiovascular death, myocardial infarction, or stroke from 11.4% to 9.3% (p<0.0001), compared with placebo. However, clopidogrel is a pro-drug requiring conversion by hepatic cytochrome P450 enzymes to an active moiety that binds irreversibly to the P2Y12 receptor on platelet membranes and inhibits the ADP-dependent pathway of platelet activation. Proton-pump inhibitors, e.g. omeprazole, and genetic variation in the cytochrome P450 enzymes may theoretically reduce the effectiveness of clopidogrel. This has not been a problem in clinical practice. The TRITON-TIMI 38 study found that the thienopyridine prasugrel reduced ischemic events (12.1% with clopidogrel and 9.9% with prasugrel) but increased the risk of major bleeding (1.8% with clopidogrel and 2.4% with prasugrel).

**Activated GP (glycoprotein) IIb/IIIa receptors** on platelets bind to fibrinogen initiating platelet aggregation. Receptor antagonists have been developed that are powerful inhibitors of platelet aggregation. Abciximab is a monoclonal antibody that binds tightly and has a long half-life. Eptifibatide is a cyclic peptide that selectively inhibits GPIIb/IIIa receptors, but has a short half-life and wears off in 2–4 h. Tirofiban is a small non-peptide that rapidly blocks the GPIIb/IIIa receptors and is reversible in 4–6 h.

In the GUSTO-IV ACS study of 7800 patients, abciximab was administered but coronary intervention discouraged. At 30 days, 8.2% of abciximab patients and 8.0% of placebo patients had reached the composite end-point of death or myocardial infarction. In the PRISM study of 3232 patients with angina, tirofiban reduced the 30-day death or myocardial infarction rate from 7.1% with placebo to 5.8%. Troponin-positive patients with diabetes scheduled to have coronary intervention benefit most from GPIIb/IIIa receptor antagonists.

**Antithrombins**

In ACS patients off aspirin, unfractionated heparin (UFH) produces a lower rate of refractory angina/myocardial infarction and death than placebo, and when used with aspirin reduces death and myocardial infarction from 10.3% to 7.9%. However, because of poor bioavailability and variable effects, frequent monitoring of aPTT is necessary to ensure therapeutic levels. Low-molecular-weight heparins and in particular enoxaparin appear superior to UFH and can be given subcutaneously twice daily. Bivalirudin is a direct thrombin inhibitor that reversibly binds to thrombin and inhibits clot-bound thrombin. In the ACUTY trial, bivalirudin appeared as effective as heparin plus GPIIb/IIIa inhibitors in reducing ischaemic events in patients pretreated with a thienopyridine and undergoing diagnostic angiography or percutaneous intervention, but with less bleeding. Fondaparinux is a synthetic pentasaccharide that selectively binds to antithrombin, which inactivates factor Xa resulting in a strong inhibition of thrombin generation and clot formation. It does not inactivate thrombin and has no effect on platelets. The OASIS-5 trial evaluated the efficacy and safety of fondaparinux and enoxaparin in 20,078 high-risk patients with unstable angina or myocardial infarction without ST-segment elevation. Thrombotic endpoints were similar with both agents but fondaparinux was associated with less bleeding end-points at 2.2% compared with 4.1% with enoxaparin patients.

Rivaroxaban, a factor Xa inhibitor, is effective in reducing the risk of further cardiac events but with a risk of bleeding.

**Anti-ischaemia agents**

In patients with no contraindications (asthma, AV-block, acute pulmonary oedema), beta-blockers are administered intravenously or orally, to reduce myocardial ischaemia by blocking circulating catecholamines. This will reduce the heart rate and blood pressure, reducing myocardial oxygen consumption. The dose can be titrated to produce a resting heart rate of 50–60 b.p.m. In patients with ongoing angina, nitrates should be given either sublingually or intravenously. They effectively reduce preload and produce coronary vasodilation. However, tolerance can become a problem and patients should be weaned off intravenous administration if symptoms resolve.

**Plaque stabilization/remodelling**

HMG-CoA reductase inhibitor drugs (statins) and ACE inhibitors are routinely administered to patients with ACS. These agents may produce plaque stabilization, improve vascular and myocardial remodelling, and reduce future cardiovascular events. Starting the drugs whilst the patient is still in hospital increases the likelihood of patients receiving secondary drug therapy.

**Coronary intervention**

Coronary revascularization is recommended in high-risk patients with ACS. Coronary stenting may stabilize the disrupted coronary plaque; in the BENESTENT II trial it was demonstrated that stenting was superior to PTCA in reducing angiographic restenosis rates. Subgroup analysis of patients with unstable angina in the EPIC, EPILOG and CAPTURE trials confirmed the benefit of GPIIb/IIIa inhibitors at reducing the complication rate during PCI. The PCI-CURE study demonstrated that pretreatment with clopidogrel reduces the rate of cardiovascular death and MI. The current rate of CABG in ACS is low (5.4%). The mortality rates with CABG are greater in the high-risk group patients, particularly with a recent myocardial infarction. Single vessel lesions are usually treated with PCI, unless the anatomy is unfavourable. Conversely in patients with left main stem or triple vessel disease with impaired left ventricular function are best managed with surgery. Two studies have compared a conservative versus an invasive strategy in the modern era. In the FRISC-II study 2457 high-risk ACS patients were randomized to PTCA or CABG at 4 and 8 days, respectively, or a conservative approach with intervention only for severe angina. Revascularization within 10 days was performed in 71% of the invasive arm and 9% of the conservative arm. After 1 year, there was a significant reduction in total mortality (2.2% vs 3.9%) in the invasive arm, as well a significant reduction in MI (8.6% vs 11.6%). In addition, the rate of angina or readmission was reduced by 50%. In the TACTICS study of 2220 high-risk ACS patients, similar findings were obtained with the rate of death or MI reduced from 9.5% to 7.3% by an invasive strategy. Patients with a troponin T $>$ 0.01 ng/mL obtained benefit, but not those who were troponin T negative.

**ST elevation myocardial infarction (STEMI)**

Myocardial infarction occurs when cardiac myocytes die due to prolonged myocardial ischaemia. The diagnosis can be made in patients with an appropriate clinical history together with findings from repeated 12-lead ECGs and elevated biochemical markers – troponin I and T, CK-MB.

**Pathophysiology**

Rupture or erosion of a vulnerable coronary artery plaque can produce prolonged occlusion of a coronary artery leading...
Coronary artery disease

737

14

to myocardial necrosis within 15–30 minutes. The subendocardial myocardium is initially affected but with continued ischaemia the infarct zone extends through to the subepicardial myocardium, producing a transmural Q wave myocardial infarction. Early reperfusion may salvage regions of the myocardium, reducing future mortality and morbidity.

The 1-month mortality in patients with a myocardial infarction may be as high as 50% in the community, with 50% of deaths occurring in the first 2 hours of the event. In the prethrombolytic era the in-hospital mortality rate was nearly 20% but with modern therapy it may be as low as 6–7% at 1 month. Several risk factors can be identified that predict death rate at 30 days (TIMI STEMI score; Table 14.32).

Diagnosis

Symptoms and signs

Any patient presenting with severe chest pain lasting more than 20 minutes may be suffering from a myocardial infarction. The pain does not usually respond to sublingual GTN, and opiate analgesia is required. The pain may radiate to the left arm, neck or jaw. However, in some patients, particularly elderly or diabetic patients, the symptoms may be atypical and include dyspnoea, fatigue, pre-syncope or syncope. Autonomic symptoms are common and on examination the patient is pale and clammy, with marked sweating. In addition, the pulse is thready with significant hypotension, bradycardia or tachycardia.

Electrocardiography

An ECG in patients with chest pain should be performed on admission to A&E. The baseline ECG is rarely normal, but if so should be repeated every 15 minutes, while the patient remains in pain. Continuous cardiac monitoring is required because of the high likelihood of significant cardiac arrhythmias. ECG changes (Table 14.33) are usually confined to the ECG leads that “face” the infarction. The presence of new ST elevation (due to opening of the K⁺ channels) ≥0.2 mV at the J-point in leads V₁–V₃, and ≥0.1 mV in other leads, suggests anterior MI (Fig. 14.65). An inferior wall MI is diagnosed when ST elevation is seen in leads II, III and AVF (Fig. 14.66). Lateral MI produces changes in leads I, AVL and V₄/V₆. In patients with a posterior MI, there may be ST depression in leads V₁–V₃ with a dominant R wave, and ST elevation in lead V₅/V₆. New LBBB or presumed new LBBB is compatible with coronary artery occlusion requiring urgent reperfusion therapy. The evolution of the ECG during the course of STEMI is illustrated in Figure 14.67.

Investigations

Blood samples should be taken for cardiac troponin I or T levels, although treatment should not be deferred until the

Cardiovascular disease

Early medical management

**Accident and emergency**

Rapid triage for chest pain (Note: time is muscle):

- Aspirin 150–300 mg chewed and clopidogrel 300 mg oral gel
- Sublingual glyceryl trinitrate 0.3–1 mg. Repeat
- Oxygen – nasal cannula 2–4 L/min (Fig. 16.21) if hypoxia is present
- Brief history/risk factors. Examination
- Intravenous access + blood for markers (plus FBC, biochemistry, lipids, glucose)
- 12-lead ECG
- Intravenous opiate, e.g. diamorphine (or morphine) 2.5–5 mg + antiemetic, e.g. metoclopramide 10 mg
- Beta-blocker (if no contraindication) for ongoing chest pain, hypertension, tachycardia
- If primary PCI available (see p. 738), give GP IIb/IIIa inhibitor. Alternatively, give thrombolysis (see below).

Pre-hospital treatment, including thrombolysis, can be given by trained healthcare professionals under strict guidelines.

**Percutaneous coronary intervention (PCI)**

PCI performed within 90 minutes is the preferred reperfusion therapy in interventional cardiology centres that have the expertise available. In the PAMI (Primary Angioplasty in Myocardial Infarction) trial, patients with a myocardial infarction who presented within 12 hours of the onset of STEMI were randomized to primary PTCA or t-PA followed by conservative care. At 2-year follow-up the primary PTCA group had less recurrent ischaemia, lower re-intervention rates and reduced hospital readmission rates. Primary PTCA produced a combined end-point of death or re-infarction of 14.9% compared to 23% for t-PA. PCI with thrombus aspiration has recently been shown to result in better reperfusion and clinical outcomes.

The DANAMI 2 study investigated if rapid transfer of patients with STEMI for primary angioplasty in an intervention centre was superior to thrombolysis. Patients within 12 hours of a high-risk STEMI (>4 mm elevation) received front-loaded t-PA, primary angioplasty at a local centre, or primary angioplasty at an intervention centre after transfer.
Primary PCI significantly reduced the death rate in both local and transferred patients as compared to thrombolytic therapy (8.0% vs 13.7%). The majority of the benefits with primary PCI are obtained by a reduction in recurrent myocardial infarction.

Coronary stenting in primary PCI reduces the need for repeat target vessel revascularization but did not appear to reduce mortality rates. However, one study using drug-eluting stents showed a decreased 2-year mortality rate.

The use of abciximab in STEMI patients undergoing primary angioplasty reduces immediate outcome (death, myocardial infarction, urgent revascularization), but this benefit is minimal by 6 months.

PCI following thrombolysis was initially discouraged but a trial has suggested that it is safe and improves the 1-year clinical outcome. Randomized trials have compared a strategy of thrombolysis (in hospitals without PCI capability) versus transfer to a PCI centre and have demonstrated a significant reduction in the combined end-point of death, reinfarction and stroke (although with a non-significant reduction in mortality) with transfer. The strategy of transfer for primary PCI is appropriate if the intervention can be performed within 90 minutes of presentation and this is now optimal therapy.

**Fibrinolysis**

Fibrinolytic agents (p. 426) enhance the breakdown of occlusive thromboses by the activation of plasminogen to form plasmin. Fibrinolysis is still used if PCI is unavailable.

A meta-analysis of fibrinolytics (FTT), fibrinolysis within 6 h of STEMI or LBBB MI, prevented 30 deaths in every 1000 patients treated. Between 7 and 12 hours, 20 in every 1000 deaths were prevented. After 12 hours, the benefits are limited, and there is evidence to suggest less benefit for older patients, possibly because of the increased risk of strokes.

Prompt reperfusion therapy (door to needle time <30 min) will reduce the death rate following myocardial infarction. Double bolus r-PA (reteplase) and single bolus TNK-t-PA (tenecteplase) facilitate rapid administration of fibrinolytic therapy and can be used for pre-hospital thrombolysis. In patients who fail to reperfuse by 60–90 minutes, as demonstrated by 50% resolution of the ST segment elevation, rethrombolysis or referral for rescue coronary angioplasty is recommended.

Aspirin therapy should be prescribed with fibrinolysis, but there is little additional benefit in combining clopidogrel or abciximab therapy in patients with STEMI/new LBBB. Heparin is recommended with t-PA or tenecteplase, but not with streptokinase. Enoxaparin (low-molecular-weight heparin) appears to be superior to unfractionated i.v. heparin in patients receiving TNK-t-PA, with less reocclusion and better late patency (ASSENT 3).

The contraindications to thrombolysis are provided in Table 14.34.

**Coronary artery bypass surgery**

Cardiac surgery is usually reserved for the complications of myocardial infarction, such as ventricular septal defect or mitral regurgitation.

**Complications of myocardial infarction**

**Heart failure**

Cardiac failure post STEMI is a poor prognostic feature that necessitates medical and invasive therapy to reduce the death rate (see Table 14.36). The Killip classification is used to assess patients with heart failure post-MI:

- **Killip I** – no crackles and no third heart sound
- **Killip II** – crackles in <50% of the lung fields or a third heart sound
- **Killip III** – crackles in >50% of the lung fields
- **Killip IV** – cardiogenic shock.

Mild heart failure may respond to intravenous furosemide 40–80 mg i.v., with GTN administration if the blood pressure is satisfactory. Oxygen is required, with regular oxygen monitoring. ACE inhibitors can be given in 24–48 hours if the blood pressure is satisfactory. Patients with severe heart failure may require Swan–Ganz catheterization to determine the pulmonary wedge pressure. Intravenous inotropes such as dopamine or dobutamine are used in patients with severe heart failure. If the patient is in cardiogenic shock, then revascularization ± intra-aortic balloon pump insertion may be required.

**Myocardial rupture and aneurysmal dilatation**

Rupture of the free wall of the left ventricle is usually an early, catastrophic and fatal event. The patient will have a haemodynamic collapse, then an electromechanical cardiac arrest. A subacute rupture may allow for pericardiocentesis followed by the surgical repair of the rupture. Myocardial aneurysm, shown in Fig. 14.68, is a late complication that may require surgical repair.

**Ventricular septal defect (VSD)**

A VSD may occur in 1–2.0% of patients with STEMI, and may be associated with delayed or failed fibrinolysis. However, mortality is very high with a 12-month unoperative mortality of 92%. An intra-aortic balloon pump (IABP) and coronary angiography may allow for patient optimization prior to surgery. A post-infarct VSD is demonstrated in Figure 14.69.

**Mitral regurgitation**

Severe mitral regurgitation can occur early in the course of STEMI. Three mechanisms may be responsible for the mitral regurgitation, and a transoesophageal echocardiogram (TOE) may be necessary to confirm the aetiology:

- Severe left ventricular dysfunction and dilatation, causing annular dilatation of the valve and subsequent regurgitation
- Myocardial infarction of the inferior wall, producing dysfunction of the papillary muscle that may respond to coronary intervention

**FURTHER READING**

Cardiovascular disease

Post-MI pericarditis and Dressler’s syndrome
See section entitled ‘Pericardial disease’, below.

Post-ACS lifestyle modification
After recovery from an ACS patients should be encouraged to participate in a cardiac rehabilitation programme that provides education and information appropriate to the patients’ requirements. An exercise programme forms part of the rehabilitation.

- Patients should be encouraged to eat a Mediterranean-style diet and to consume >7 g of omega-3 fatty acids/week from oily fish or >1 g daily of omega-3-acid ethyl esters.
- Patients should maintain alcohol consumption within safe limits (≤21 units/week for men or <14 units for women) and avoid binge drinking.
- Patients should be physically active for 20–30 min/day.
- Patients should stop smoking.
- Overweight and obese patients should be offered advice and support to achieve and maintain a healthy weight.
- Patients with hypertension should be treated to <140/90 or <130/80 if chronic kidney disease or diabetes.
- Patients with diabetes should be treated to maintain HbA1c<7%.

Post-MI pericarditis and Dressler’s syndrome

Post-ACS drug therapy and assessment
Extensive clinical trial evidence has been gathered in post-myocardial infarction patients, demonstrating that a range of pharmaceuticals are advantageous in reducing mortality over the following years. Therefore, post-MI most patients should be taking most of the following medications:

- Aspirin 75–100 mg/day
- A beta-blocker to maintain heart rate <60 b.p.m., e.g. metoprolol 50 mg twice daily
- ACE inhibitors, e.g. ramipril 2.5 mg twice daily, titrated to maximum tolerated or target dose (if intolerant of ACE inhibitors use ARB, e.g. valsartan 20 mg twice daily titrated to maximum tolerated or target dose)
- Statins, e.g. simvastatin 20–80 mg/day
- Clopidogrel 75 mg/day for 9–12 months should be added in moderate–high-risk patients with non-ST elevation acute coronary syndrome (NST-ACS)
- Aldosterone antagonist, e.g. spironolactone 25 mg/day, should be given in patients post-MI with clinical evidence of heart failure and reduced ejection fraction (renal function and potassium levels should be monitored).

VALVULAR HEART DISEASE

Mitrval valve
The mitral valve consists of the fibrous annulus, anterior and posterior leaflets, chordae, tendinae and the papillary muscles (Fig. 14.70).
Valvular heart disease

Mitral stenosis

The most common cause of mitral stenosis is rheumatic heart disease secondary to previous rheumatic fever due to infection with group A β-hemolytic streptococcus which in the developing world affects nearly 20 million people. The condition is more common in women than men. Inflammation leads to commissural fusion and a reduction in mitral valve orifice area leading to the characteristic doming pattern seen on echocardiography. Over many years the condition progresses to valve thickening, cusp fusion, calcium deposition, a severely narrowed (stenotic) valve orifice and progressive immobility of the valve cusps.

Other causes of mitral stenosis include:

- Lutembacher’s syndrome, which is the combination of acquired mitral stenosis and an atrial septal defect
- a rare form of congenital mitral stenosis
- in the elderly, a syndrome similar to mitral stenosis, which develops because of calcification and fibrosis of the valve, valve ring and subvalvular apparatus (chordae tendineae)
- carcinoid tumours metastasizing to the lung, or primary bronchial carcinoid.

Pathophysiology

When the normal valve orifice area of 4–6 cm² is reduced to <1 cm², severe mitral stenosis is present. In order that sufficient cardiac output will be maintained, the left atrial pressure increases and left atrial hypertrophy and dilatation occur. Consequently, pulmonary venous, pulmonary arterial and right heart pressures also increase. The increase in pulmonary capillary pressure is followed by the development of pulmonary oedema particularly when the rhythm deteriorates to atrial fibrillation with tachycardia and loss of coordinated atrial contraction. This is partially prevented by alveolar and capillary thickening and pulmonary arterial vasoconstriction (reactive pulmonary hypertension). Pulmonary hypertension leads to right ventricular hypertrophy, dilatation and failure with subsequent tricuspid regurgitation.

Symptoms

Usually there are no symptoms until the valve orifice is moderately stenosed (i.e. has an area of 2 cm²). In Europe, this does not usually occur until several decades after the first attack of rheumatic fever, but children of 10–20 years of age in the Middle or Far East may have severe calcific mitral stenosis.

Because of pulmonary venous hypertension and recurrent bronchitis, progressively severe dyspnoea develops. A cough productive of blood-tinged, frothy sputum or frank haemoptysis may occur. The development of pulmonary hypertension eventually leads to right heart failure and its symptoms of weakness, fatigue and abdominal or lower limb swelling.

The large left atrium favours atrial fibrillation, giving rise to symptoms such as palpitations. Atrial fibrillation may result in systemic emboli, most commonly to the cerebral vessels resulting in neurological sequelae, but mesenteric, renal and peripheral emboli are also seen.

Signs

See Clinical memo in Figure 14.71.

Face

Severe mitral stenosis with pulmonary hypertension is associated with the so-called mitral facies or malar flush. This is
a bilateral, cyanotic or dusky pink discoloration over the upper cheeks that is due to arteriovenous anastomoses and vascular stasis.

**Pulse**

Mitrail stenosis may be associated with a small-volume pulse which is usually regular early on in the disease process when most patients are in sinus rhythm. However, as the severity of the disease progresses, many patients develop atrial fibrillation resulting in an irregularly irregular pulse. The development of atrial fibrillation in these patients often causes a dramatic clinical deterioration.

**Jugular veins**

If right heart failure develops, there is obvious distension of the jugular veins. If pulmonary hypertension or tricuspid stenosis is present, the ‘a’-wave will be prominent provided that atrial fibrillation has not supervened.

**Palpation**

There is a tapping impulse felt parasternally on the left side. This is the result of a palpable first heart sound combined with left ventricular backward displacement produced by an enlarging right ventricle. A sustained parasternal impulse due to right ventricular hypertrophy may also be felt.

**Auscultation**

Auscultation (Fig. 14.71) reveals a loud first heart sound if the mitral valve is pliable, but it will not occur in calcific mitral stenosis. As the valve suddenly opens with the force of the increased left atrial pressure, an ‘opening snap’ will be heard. This is followed by a low-pitched ‘rumbling’ mid-diastolic murmur best heard with the bell of the stethoscope held lightly at the apex with the patient lying on the left side. If the patient is in sinus rhythm, the murmur becomes louder at the end of diastole as a result of atrial contraction (pre-systolic accentuation).

The severity of mitral stenosis is judged clinically on the basis of several criteria:

- The presence of pulmonary hypertension implies that mitral stenosis is severe. Pulmonary hypertension is recognized by a right ventricular heave, a loud pulmonary component of the second heart sound, eventually with signs of right-sided heart failure, such as oedema and hepatomegaly. Pulmonary hypertension results in pulmonary valvular regurgitation that causes an early diastolic murmur in the pulmonary area known as a Graham Steell murmur.
- The closeness of the opening snap to the second heart sound is proportional to the severity of mitral stenosis.
- The length of the mid-diastolic murmur is proportional to the severity.
- As the valve cusps become immobile, the loud first heart sound softens and the opening snap disappears. (For recordings of heart sounds, see online at Student Consult.) When pulmonary hypertension occurs, the pulmonary component of the second sound is increased in intensity and the mitral diastolic murmur may become quieter because of the reduction of cardiac output.

**Investigations**

**Chest X-ray**

The chest X-ray usually shows a generally small heart with an enlarged left atrium (Fig. 14.14). Pulmonary venous hypertension is usually also present. Late in the course of the disease a calcified mitral valve may be seen on a penetrated or lateral view. The signs of pulmonary oedema or pulmonary hypertension may also be apparent when the disease is severe.

**Electrocardiogram**

In sinus rhythm the ECG shows a bifid P wave owing to delayed left atrial activation (Fig. 14.72). However, atrial fibrillation is frequently present. As the disease progresses, the ECG features of right ventricular hypertrophy (right axis deviation and perhaps tall R waves in lead V1) may develop (Fig. 14.73).

**Imaging**

**Echocardiogram** (Fig. 14.74) 

**Transthoracic echocardiography** should be used to determine left and right atrial and ventricular size and function. The severity of the mitral stenosis (Table 14.35) can be defined by planimetry of the mitral valve area on 2-dimensional echocardiography; with continuous wave (CW) Doppler use to measure the pressure half time (the time taken for the pressure to halve from the peak value) and mean pressure drop across the valve. The Wilkins score can be used to determine if the valve is suitable for percutaneous valvotomy. Continuous wave (CW) Doppler may also be used to estimate of pulmonary artery pressure through measurement of the degree of tricuspid regurgitation.

---

**Figure 14.72 A bifid P wave as seen on the ECG in mitral stenosis (P mitrale).** Also shown for comparison are other P wave abnormalities.

---

**Figure 14.73 Severe mitral stenosis shown by a 12-lead ECG.** Note the right axis deviation (frontal plane axis = +120°), the left atrial conduction abnormality (large terminal negative component of the P wave in V1), and the right ventricular hypertrophy (R wave in V1 and right axis deviation).

British Society of Echocardiography.

Transoesophageal echocardiography (TOE) is performed to detect the presence of left atrial thrombus (p. 687) or prior to consideration of surgical or percutaneous intervention.

Cardiac magnetic resonance (CMR; see p. 688)
This can accurately show mitral valve anatomy although it is rarely used in mitral stenosis.

Cardiac catheterization
This is now seldom required and is only used if co-existing cardiac problems (e.g. mitral regurgitation or coronary artery disease) are suspected. Right heart catheterization may be required to determine pulmonary artery pressure in patients referred for valve intervention.

Treatment
Mild mitral stenosis may need no treatment other than prompt therapy of attacks of bronchitis. Infective endocarditis in pure mitral stenosis is uncommon. Early symptoms of mitral stenosis such as mild dyspnoea can usually be treated with low doses of diuretics. The onset of atrial fibrillation requires treatment with digoxin and anticoagulation to prevent atrial thrombus and systemic embolization. If pulmonary hypertension develops or the symptoms of pulmonary congestion persist despite therapy, surgical relief of the mitral stenosis is advised. There are four operative measures.

Trans-septal balloon valvotomy
A catheter is introduced into the right atrium via the femoral vein under local anaesthesia in the cardiac catheter laboratory. The interatrial septum is then punctured and the catheter advanced into the left atrium and across the mitral valve. A balloon is passed over the catheter to lie across the valve, and then inflated briefly to split the valve commissures. As with other valvotomy techniques, significant regurgitation may result, necessitating valve replacement (see below). This procedure is ideal for patients with pliable valves in whom there is minimal mitral regurgitation. Contraindications include heavy calcification or more than mild mitral regurgitation and thrombus in the left atrium. Transoesophageal echocardiography must be performed prior to this technique in order to exclude left atrial thrombus.

Closed valvotomy
This operation is advised for patients with mobile, non-calcified and non-regurgitant mitral valves. The fused cusps are forced apart by a dilator introduced through the apex of the left ventricle and guided into position by the surgeon’s finger inserted via the left atrial appendage. Cardiopulmonary bypass is not needed for this operation. Closed valvotomy may produce a good result for 10 years or more. The valve cusps often re-fuse and eventually another operation may be necessary.

Open valvotomy
This operation is often preferred to closed valvotomy. The cusps are carefully dissected apart under direct vision. Cardiopulmonary bypass is required. Open dissection reduces the likelihood of causing traumatic mitral regurgitation.

Mitral valve replacement
Replacement of the mitral valve is necessary if:
- Mitral regurgitation is also present
- There is a badly diseased or badly calcified stenotic valve that cannot be reopened without producing significant regurgitation
- There is moderate or severe mitral stenosis and thrombus in the left atrium despite anticoagulation.

Artificial valves (see p. 750) may work successfully for >20 years. Anticoagulants are generally necessary to prevent the formation of thrombus, which might obstruct the valve or embolize.

Mitral regurgitation
Mitral regurgitation (MR) can occur due to abnormalities of the valve leaflets, the annulus, the chordae tendineae or papillary muscles, or the left ventricle. The most frequent causes of mitral regurgitation are degenerative (myxomatous) disease, ischemic heart disease, rheumatic heart disease, and infectious endocarditis. Mitral regurgitation is also seen in diseases of the myocardium (dilated and hypertrophic cardiomyopathy), rheumatic autoimmune diseases, e.g. systemic lupus erythematosus, collagen diseases, e.g. Marfan’s and Ehlers-Danlos syndromes, and drugs including centrally acting appetite suppressants (fenfluramine) and dopamine agonists (cabergoline).

Pathophysiology
Regurgitation into the left atrium produces left atrial dilatation but little increase in left atrial pressure if the regurgitation is long-standing, as the regurgitant flow is accommodated by the large left atrium. With acute mitral regurgitation the normal compliance of the left atrium does not allow much dilatation and the left atrial pressure rises. Thus, in acute mitral regurgitation the left atrial v-wave is greatly increased and pulmonary venous pressure rises to produce pulmonary oedema. Since a proportion of the stroke volume is regurgitated, the stroke volume increases to maintain the forward cardiac output and the left ventricle therefore enlarges.

The Carpentier classification (Fig. 14.75) uses mitral leaflet motion to divide patients into different classes according to the mechanism of regurgitation which can be useful when considering surgical intervention.

Symptoms
Mitral regurgitation can be present for many years and the cardiac dimensions greatly increased before any symptoms occur. The increased stroke volume is sensed as a...
the symptoms of right heart failure also occur and eventually lead to congestive cardiac failure. Cardiac cachexia may develop. Thromboembolism is less common than in mitral stenosis, but subacute infective endocarditis is much more common.

**Signs**

See Clinical memo in Figure 14.71.

The physical signs of uncomplicated mitral regurgitation are:

- Laterally displaced (forceful) diffuse apex beat and a systolic thrill (if severe)
- Soft first heart sound, owing to the incomplete apposition of the valve cusps and their partial closure by the time ventricular systole begins
- Pansystolic murmur, owing to the occurrence of regurgitation throughout the whole of systole, being loudest at the apex but radiating widely over the precordium and into the axilla
- With a floppy mitral valve (see below) there may be a mid-systolic click, which is produced by the sudden prolapse of the valve and the tensing of the chordae tendineae that occurs during systole. This may be followed by a late systolic murmur owing to some regurgitation.
- Prominent third heart sound, owing to the sudden rush of blood back into the dilated left ventricle in early diastole (sometimes a short mid-diastolic flow murmur may follow the third heart sound).

The signs related to atrial fibrillation, pulmonary hypertension, and left and right heart failure develop later in the disease. The onset of atrial fibrillation has a much less dramatic effect on symptoms than in mitral stenosis.

**Investigations**

**Chest X-ray**

The chest X-ray may show left atrial and left ventricular enlargement. There is an increase in the CTR, and valve calcification is seen.

**Electrocardiogram**

The ECG shows the features of left atrial delay (bifid P waves) and left ventricular hypertrophy (Fig. 14.76) as manifested by tall R waves in the left lateral leads (e.g. leads I and V6) and deep S waves in the right-sided precordial leads, (e.g. leads V1 and V2). (Note that SV, plus RV, or RV2 +SV3 mm indicates left ventricular hypertrophy.) Left ventricular hypertrophy occurs in about 50% of patients with mitral regurgitation. Atrial fibrillation may be present.
Valvular heart disease

Echocardiogram

The echocardiogram shows a dilated left atrium and left ventricle. There may be specific features of chordal or papillary muscle rupture. The severity of regurgitation can be assessed with the use of colour Doppler looking at the jet area and the size of the vena contracta and by calculating the regurgitant fraction, volume or orifice area. Useful information regarding the severity of the condition can be obtained indirectly by observing the dynamics of ventricular function. Transoesophageal echocardiography can be helpful to identify structural valve abnormalities before surgery (Fig. 14.77) and intraoperative TOE can aid assessment of the efficacy of valve repair.

Cardiac catheterization

This demonstrates a prominent left atrial systolic pressure wave, and when contrast is injected into the left ventricle it is seen regurgitating into an enlarged left atrium during systole.

Treatment

Mild mitral regurgitation in the absence of symptoms can be managed conservatively by following the patient with serial echocardiograms. Prophylaxis against endocarditis is discussed in Chapter 4 (see p. 87). Any evidence of progressive cardiac enlargement generally warrants early surgical intervention by either mitral valve repair or replacement. The current ESC guidelines recommend surgical intervention in patients with symptomatic severe mitral regurgitation, left ventricular ejection fraction >30% and end-diastolic dimension of under 55 mm; and in asymptomatic patients with left ventricular dysfunction (end-systolic dimension >45 mm and/or ejection fraction of under 60%). Surgery should also be considered in patients with asymptomatic severe mitral regurgitation with preserved left ventricular function and atrial fibrillation and/or pulmonary hypertension. The advantages of surgical intervention are diminished in more advanced disease. (Sudden torrential mitral regurgitation, as seen with chordal or papillary muscle rupture or infective endocarditis, necessitates emergency mitral valve replacement.) In patients who are not appropriate for surgical intervention, or in whom surgery will be performed at a later date, management involves treatment with ACE inhibitors, diuretics and possibly anticoagulants. More recently a percutaneous mitral valve repair (MitraClip) has been compared to cardiac surgery in the EVEREST II trial and appears effective in the short-term at reducing the severity of mitral regurgitation and providing symptomatic relief. It is appropriate in patients unsuitable for cardiac surgery.

Prolapsing (billowing) mitral valve

This is also known as Barlow’s syndrome or floppy mitral valve. It is due to excessively large mitral valve leaflets, an
enlarged mitral annulus, abnormally long chordae or disordered papillary muscle contraction. Histology may demonstrate myxomatous degeneration of the mitral valve leaflets. It is more commonly seen in young women than in men or older women and it has a familial incidence. Its cause is unknown but it is associated with Marfan’s syndrome, thyrotoxicosis, rheumatic or ischaemic heart disease. It also occurs in association with atrial septal defect and as part of hypertrophic cardiomyopathy. Mild mitral valve prolapse is so common that it should be regarded as a normal variant.

Aortic stenosis

Aortic stenosis is a chronic progressive disease that produces obstruction to the left ventricular stroke volume leading to symptoms of chest pain, breathlessness, syncope and pre-syncope and fatigue.

Aortic valve stenosis includes calcific stenosis of a trileaflet aortic valve, stenosis of a congenitally bicuspid valve, and rheumatic aortic stenosis.

Calcific aortic valvular disease (CAVD) is the commonest cause of aortic stenosis and mainly occurs in the elderly. This is an inflammatory process involving macrophages and T lymphocytes with initially thickening of the subendothelium with adjacent fibrosis. The lesions contain lipoproteins which calcify, increasing leaflet stiffness and reducing systolic opening. This can occur in a tri or bileaflet aortic valve. Risk factors for CAVD include old age, male gender, elevated lipoprotein (a) and low-density lipoprotein (LDL), hypertension, diabetes and smoking.

Bicuspid aortic valve (BAV) (Fig. 14.78) is the commonest form of congenital heart disease occurring in 1–2% of live births and in many cases, is familial. Patients with CAVD of a bicuspid valve tend to present at an earlier age. BAV is associated with aortic coarctation, root dilatation, and potentially aortic dissection and patients should have regular follow-up echocardiography.

Rheumatic fever can produce progressive fusion, thickening and calcification of the aortic valve. In rheumatic heart disease the aortic valve is affected in about 30–40% of cases and there is usually associated mitral valve disease.

Other causes of valvular stenosis include chronic kidney disease, Paget’s disease of bone, previous radiation exposure, homozygous familial hypercholesterolaemia.

Valvar aortic stenosis should be distinguished from other causes of obstruction to left ventricular emptying (Fig. 14.79), which include:

- Supravalvular obstruction – a congenital fibrous diaphragm above the aortic valve often associated with mental retardation and hypercalcaemia (Williams’ syndrome)
- Hypertrophic cardiomyopathy – septal muscle hypertrophy obstructing left ventricular outflow
- Subvalvular aortic stenosis – a congenital condition in which a fibrous ridge or diaphragm is situated immediately below the aortic valve.

Pathophysiology

Obstructed left ventricular emptying leads to increased left ventricular pressure and compensatory left ventricular hypertrophy. In turn, this results in relative ischaemia of the left ventricular myocardium, and consequent angina, arrhythmias and left ventricular failure. The obstruction to left ventricular emptying is relatively more severe on exercise. Normally, exercise causes a many-fold increase in cardiac output, but when there is severe narrowing of the aortic valve orifice the cardiac output can hardly increase. Thus, the blood pressure falls, coronary ischaemia worsens, the myocardium fails and cardiac arrhythmias develop. Left ventricular systolic function is typically preserved in patients with aortic stenosis (cf. aortic regurgitation).

Symptoms

There are usually no symptoms until aortic stenosis is moderately severe (when the aortic orifice is reduced to one-third of its normal size). At this stage, exercise-induced syncope, angina and dyspnoea develop. When symptoms occur, the prognosis is poor – on average, death occurs within 2–3 years if there has been no surgical intervention.

Signs

See Clinical memo in Figure 14.80.

Pulse

The carotid pulse is of small volume and is slow-rising or plateau in nature (see this chapter).

Precordial palpation

The apex beat is not usually displaced because hypertrophy (as opposed to dilatation) does not produce noticeable cardiomegaly. However, the pulsation is sustained and obvious. A double impulse is sometimes felt because the fourth heart sound or atrial contraction (‘kick’) may be palpable. A systolic thrill may be felt in the aortic area.
Valvular heart disease

Electrocardiogram
The ECG shows left ventricular hypertrophy and left atrial delay. A left ventricular 'strain' pattern due to 'pressure overload' (depressed ST segments and T wave inversion in leads orientated towards the left ventricle, i.e. leads I, AVL, V5 and V6) is common when the disease is severe. Usually, sinus rhythm is present, but ventricular arrhythmias may be recorded.

Echocardiography
Echocardiography readily demonstrates the thickened, calcified and immobile aortic valve cusps, the presence of left ventricular hypertrophy, and can be used to determine the severity of aortic stenosis (Table 14.36, Fig. 14.81a,b). Transoesophageal echocardiography is rarely indicated.

Cardiac catheterization
Cardiac catheterization is rarely necessary since all of this information can be gained non-invasively with echocardiography and CMR. Coronary angiography is necessary before recommending surgery.

Cardiac magnetic resonance and cardiac CT
These techniques are indicated for assessing the thoracic aorta for the presence of aneurysm, dissection or coarctation but are rarely necessary.

Treatment
In patients with aortic stenosis, symptoms are a good index of severity and all symptomatic patients should have aortic valve replacement. Patients with a BAV and ascending aorta >50 mm or expanding at >5 mm/year should be considered

British Society of Echocardiography.

Figure 14.80 Features of aortic stenosis and aortic regurgitation. EC, ejection click; EDM, early diastolic murmur; MSM, mid-systolic murmur; S1, first heart sound. LSE, left sternal edge.

Auscultation
The most obvious auscultatory finding in aortic stenosis is an ejection systolic murmur that is usually ‘diamond-shaped’ (crescendo–decrescendo). The murmur is usually longer when the disease is more severe, as a longer ejection time is needed. The murmur is usually rough in quality and best heard in the aortic area. It radiates into the carotid arteries and also the precordium. The intensity of the murmur is not a good guide to the severity of the condition because it is lessened by a reduced cardiac output. In severe cases, the murmur may be inaudible.

Other findings include:
- Systolic ejection click, unless the valve has become immobile and calcified
- Soft or inaudible aortic second heart sound when the aortic valve becomes immobile
- Reversed splitting of the second heart sound (splitting on expiration) (see p. 679)
- Prominent fourth heart sound, which is caused by atrial contraction, is heard unless co-existing mitral stenosis prevents this.

Investigations
Chest X-ray
The chest X-ray usually reveals a relatively small heart with a prominent, dilated, ascending aorta. This occurs because turbulent blood flow above the stenosed aortic valve produces so-called ‘post-stenotic dilatation’. The aortic valve may be calcified. The CTR increases when heart failure occurs.
Percutaneous valve replacement

A novel treatment for patients unsuitable for surgical aortic valve replacement is transcatheter implantation with a balloon expandable stent valve. Valve implantation has been shown to be successful (86%) with a procedural mortality of 2% and 30-day mortality of 12%. Further larger and randomized studies with long-term follow-up are required.

Aortic regurgitation

Aortic regurgitation can occur in diseases affecting the aortic valve e.g. endocarditis and diseases affecting the aortic root, e.g. Marfan’s syndrome (Table 14.37).

Pathophysiology

Aortic regurgitation is reflux of blood from the aorta through the aortic valve into the left ventricle during diastole. If net cardiac output is to be maintained, the total volume of blood pumped into the aorta must increase, and consequently the left ventricular size must enlarge. Because of the aortic runoff during diastole, diastolic blood pressure falls and coronary perfusion is decreased. In addition, the larger left ventricular size is mechanically less efficient so that the demand for oxygen is greater and cardiac ischaemia develops.

Symptoms

In aortic regurgitation, significant symptoms occur late and do not develop until left ventricular failure occurs. As with mitral regurgitation, a common symptom is pounding of the heart because of the increased left ventricular size and its vigorous pulsation. Angina pectoris is a frequent complaint. Varying grades of dyspnoea occur depending on the extent of left ventricular dilatation and dysfunction. Arrhythmias are relatively uncommon.

Signs

See Clinical memo in Figure 14.80. The signs of aortic regurgitation are many and are due to the hyperdynamic circulation, reflux of blood into the left ventricle and the increased left ventricular size.

The pulse is bounding or collapsing (see p. 677). The following signs, which are rare, also indicate a hyperdynamic circulation:

- Quincke’s sign – capillary pulsation in the nail beds
- De Musset’s sign – head nodding with each heart beat
- Duroziez’s sign – a to-and-fro murmur heard when the femoral artery is auscultated with pressure applied distally (if found, it is a sign of severe aortic regurgitation)
- **Pistol shot femorals** – a sharp bang heard on auscultation over the femoral arteries in time with each heart beat.

The apex beat is displaced laterally and downwards and is forceful in quality. On auscultation, there is a high-pitched early diastolic murmur best heard at the left sternal edge in the fourth intercostal space with the patient leaning forward and the breath held in expiration. Because of the volume overload there is commonly an ejection systolic flow murmur. The regurgitant jet can impinge on the anterior mitral valve cusp, causing a mid-diastolic murmur (Austin Flint rumble).

**Investigations**

**Chest X-ray**
The chest X-ray features are those of left ventricular enlargement and possibly of dilatation of the ascending aorta. The ascending aortic wall may be calcified in syphilis, and the aortic valve calcified if valvular disease is responsible for the regurgitation.

**Electrocardiogram**
The ECG appearances are those of left ventricular hypertrophy due to ‘volume overload’ – tall R waves and deeply inverted T waves in the left-sided chest leads, and deep S waves in the right-sided leads. Normally, sinus rhythm is present.

**Echocardiogram**
The echocardiogram (Fig. 14.82) demonstrates vigorous cardiac contraction and a dilated left ventricle. The aortic root may also be enlarged. Diastolic fluttering of the mitral leaflets or septum occurs in severe aortic regurgitation (producing the Austin Flint rumble). The severity of aortic regurgitation is assessed with a combination of colour Doppler (extent of regurgitant jet, width of the vena contracta; see Fig. 14.82) and CW Doppler (diastolic flow reversal in the descending thoracic aorta, pressure half time). Transoesophageal echocardiography may provide additional information about the valves and aortic root.

**Cardiac catheterization**
Cardiac catheterization is required to assess for coronary artery disease in patients requiring surgery. During cardiac catheterization, injection of contrast medium into the aorta (aortography) will outline aortic valvular abnormalities and allow assessment of the degree of regurgitation.

**Cardiac magnetic resonance and cardiac CT**
These techniques may be indicated for assessing the thoracic aorta in cases of aortic dilatation or dissection. Cardiac MR can be used to quantify regurgitant volume.

**Treatment**
The underlying cause of aortic regurgitation (e.g. syphilitic aortitis or infective endocarditis) may require specific treatment. Patients with acute aortic regurgitation may require treatment with vasodilators and inotropes. ACE inhibitors are useful in patients with left ventricular dysfunction and beta-blockers may slow aortic dilatation in Marfan patients. Because symptoms do not develop until the myocardium fails and because the myocardium does not recover fully after surgery, operative valve replacement may be performed before significant symptoms occur.

Aortic surgery is indicated:
- in acute severe aortic regurgitation e.g. endocarditis
- in symptomatic (dyspnoea, NYHA class II-IV, angina) patients with chronic severe aortic regurgitation
- when asymptomatic with left ventricular ejection fraction is ≤50%
- when asymptomatic with left ventricular ejection fraction >50% but with a dilated left ventricle (end-diastolic dimension >70 mm or systolic dimension >50 mm)
- when undergoing CABG, surgery of the ascending aorta or other cardiac valve.

Both mechanical prostheses and tissue valves are used. Tissue valves are preferred in the elderly and when anticoagulants must be avoided, but are contraindicated in children and young adults because of the rapid calcification and degeneration of the valves.

Antibiotic prophylaxis against infective endocarditis (see p. 87) is not recommended.

**Tricuspid stenosis**
This uncommon valve lesion, which is seen much more often in women than in men, is usually due to rheumatic heart disease and is frequently associated with mitral and/or aortic valve disease. Tricuspid stenosis is also seen in the carcinoid syndrome.

**Pathophysiology**
Tricuspid valve stenosis results in a reduced cardiac output, which is restored towards normal when the right atrial pressure increases. The resulting systemic venous congestion produces hepatomegaly, ascites and dependent oedema.

**Symptoms**
Usually, patients with tricuspid stenosis complain of symptoms due to associated left-sided rheumatic valve lesions. The abdominal pain (due to hepatomegaly) and swelling (due to ascites), and peripheral oedema that occur are relatively severe when compared with the degree of dyspnoea.

**Signs**
If the patient remains in sinus rhythm, which is unusual, there is a prominent jugular venous a wave. This pre-systolic pulsation may also be felt over the liver. There is usually a rumbling mid-diastolic murmur, which is heard best at the lower left sternal edge and is louder on inspiration. It may be missed because of the murmur of co-existing mitral stenosis. A tricuspid opening snap may occasionally be heard.

Hepatomegaly, abdominal ascites and dependent oedema may be present.

**Investigations**
On the chest X-ray there may be a prominent right atrial bulge. On the ECG the enlarged right atrium is shown by
peaked, tall P waves (>3 mm) in lead II. The echocardiogram may show a thickened and immobile tricuspid valve, but this is not so clearly seen as an abnormal mitral valve.

**Treatment**

Medical management consists of diuretic therapy and salt restriction. Tricuspid valvotomy is occasionally possible, but tricuspid valve replacement is often necessary. Other valves usually also need replacement because tricuspid valve stenosis is rarely an isolated lesion.

**Tricuspid regurgitation** (Fig. 14.25)

Functional tricuspid regurgitation may occur whenever the right ventricle dilates, e.g. in cor pulmonale, myocardial infarction or pulmonary hypertension.

Organic tricuspid regurgitation may occur with rheumatic heart disease, infective endocarditis, carcinoid syndrome, Ebstein’s anomaly (a congenitally malpositioned tricuspid valve) and other congenital abnormalities of the atrioventricular valves.

**Symptoms and signs**

The valvular regurgitation gives rise to high right atrial and systemic venous pressure. Patients may complain of the symptoms of right heart failure (see this chapter).

Physical signs include a large jugular venous ‘c’ wave and a palpable liver that pulsates in systole. Usually a right ventricular impulse may be felt at the left sternal edge, and there is a blowing pansystolic murmur, best heard on inspiration at the lower left sternal edge. Atrial fibrillation is common. An echo shows dilatation of the right ventricle with thickening of the valve.

**Treatment**

Functional tricuspid regurgitation usually disappears with medical management. Severe organic tricuspid regurgitation may require operative repair of the tricuspid valve (annuloplasty or plication). Very occasionally, tricuspid valve replacement may be necessary. In drug addicts with infective endocarditis the tricuspid valve, surgical removal of the valve is recommended to eradicate the infection. This is usually well tolerated in the short term. The insertion of a prosthetic valve for this condition is sometimes necessary.

**Pulmonary stenosis**

This is a congenital lesion, but it may rarely result from rheumatic fever or from the carcinoid syndrome. Congenital pulmonary stenosis may be associated with an intact ventricular septum or with a ventricular septal defect (Fallot’s tetralogy).

Pulmonary stenosis may be valvar, subvalvar or supravalvar. Multiple congenital pulmonary arterial stenoses are usually due to infection with rubella during pregnancy.

**Symptoms and signs**

The obstruction to right ventricular emptying results in right ventricular hypertrophy, which in turn leads to right atrial hypertrophy. Severe pulmonary obstruction may be incompatible with life, but lesser degrees of obstruction give rise to fatigue, syncope and the symptoms of right heart failure. Mild pulmonary stenosis may be asymptomatic.

The physical signs are characterized by a harsh mid-systolic ejection murmur, best heard on inspiration, to the left of the sternum in the second intercostal space. This murmur is often associated with a thrill. The pulmonary closure sound is usually delayed and soft. There may be a pulmonary ejection sound if the obstruction is valvular. A right ventricular fourth sound and a prominent jugular venous wave are present when the stenosis is moderately severe. A right ventricular heave (sustained impulse) may be felt.

**Investigations**

The chest X-ray usually shows a prominent pulmonary artery owing to post-stenotic dilatation. On electrocardiography the ECG demonstrates both right atrial and right ventricular hypertrophy, although it may sometimes be normal even in severe pulmonary stenosis. A Doppler echocardiogram is the investigation of choice.

**Treatment**

Treatment of severe pulmonary stenosis requires pulmonary valvotomy (balloon valvotomy or direct surgery).

**Pulmonary regurgitation**

This is the most common acquired lesion of the pulmonary valve. It results from dilatation of the pulmonary valve ring, which occurs with pulmonary hypertension. It is characterized by a decrescendo diastolic murmur, beginning with the pulmonary component of the second sound that is difficult to distinguish from the murmur of aortic regurgitation. Pulmonary regurgitation usually causes no symptoms and treatment is rarely necessary.

**Prosthetic valves**

There is no ideal replacement for our own normally functioning, native heart valves. There are two options for valve prostheses: mechanical or tissue (bioprosthetic).

The valves consist of two basic components: an opening to allow blood to flow through and an occluding mechanism to regulate the flow. Mechanical prostheses rely on artificial concluders: a ball and cage (Starr–Edwards), tilting disc (Björk–Shiley) or double tilting disc (St Jude). Tissue prostheses are derived from human (homograft), or from porcine or bovine (xenograft) origin. A valve replacement from within the same patient (i.e. pulmonary to aortic valve position) is termed an autograft.

**Mechanical versus tissue valves**

Mechanical valves, being artificial structures, are more durable than their tissue counterparts, which tend to degenerate after 10 years. However, artificial structures are more thrombogenic. Mechanical valves require formal anticoagulation for the lifetime of the prosthesis. The target INR is determined by the type of valve inserted, the position, and whether the patient has additional risk factors for thromboembolism (mitral, tricuspid, pulmonary valve disease; previous thromboembolism; atrial fibrillation; left atrial diameter >50 mm; mitral stenosis; left ventricular ejection fraction <35%; hypercoagulable state) (see Ch. 8):

- Low thrombogenicity valve (Carbomedics (aortic position), Medtronic Hall, St Jude Medical (without silizone)): INR 2.5 without and 3.0 with additional risk factors.
- Medium thrombogenicity valve (Björk–Shiley, other bi-leaflet valves): INR 3.0 without and 3.5 with additional risk factors.
- Medium thrombogenicity valve (Lillehei–Kaster, Omnicore, Starr–Edwards): INR 3.5 without and 4.0 with additional risk factors.
Tissue valves only require anticoagulation for a limited postoperative period while the suture lines endothelialise (the European Society of Cardiology recommend 3 months with a target INR of 2.5 although some centres use low-dose aspirin 75–100 mg daily); it can then be discontinued unless another risk factor for thromboembolism (e.g. atrial fibrillation) persists. New anticoagulants (direct thrombin inhibitors) do not require monitoring.

On auscultation, tissue valve heart sounds are comparable to those of a native valve. Mechanical valve heart sounds are generally louder and both opening and closing sounds can be heard.

Complications

All prostheses carry a risk of infection. Prosthetic valve endocarditis is associated with significant morbidity and mortality; prevention is the cornerstone of management. Patient education about antibiotic prophylaxis is vital and this should be reinforced at clinic visits. Any procedure which results in a breach of the body’s innate defences (i.e. dental treatment, catheter insertion) increases the risk of exposing the prosthesis to a bacteremia. This must be borne in mind when managing a patient with a prosthetic heart valve and steps taken to minimize the risk involved. The prosthetic valve occluding mechanism can be interrupted by vegetations, but also by thrombosis and calcification, resulting in either stenosis or regurgitation. The prosthesis can become detached from the valve ring resulting in a para-prosthetic leak. Evidence of structural failure can be detected by simple auscultation, with echocardiography as the initial investigation of choice. Transthoracic echocardiography is non-invasive, but scattering of echoes by mechanical valves makes their assessment difficult. Transoesophageal echocardiography provides alternative views and higher image resolution, making it the investigation of choice when prosthetic valve endocarditis is suspected.

Interruption of anticoagulant therapy

For minor surgical procedures including dental extraction anticoagulation should not be interrupted although the INR should be reduced to a target of 2.0. Percutaneous arterial puncture is safe with an INR <2.0 although radial catheterization may be possible at higher INR levels. For major surgical procedures anticoagulation should be discontinued 5 days before the procedure and intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin commenced when the INR is below 2.0.

Pregnancy and prosthetic heart valves

The types of valve prosthesis in women of child-bearing age are:

- **Bioprosthetic valves** are preferable during pregnancy as they are less thrombogenic and do not require anticoagulation. However valve degradation in women of child-bearing age has been shown to be as high as 50% at 10 years, and 90% at 15 years and women with a bioprosthetic valve may require redo valve surgery.

- **Mechanical heart valves** have excellent durability but are thrombogenic and require life-long anticoagulation with warfarin. Pregnancy is a hypercoagulable state due to increased levels of fibrinogen, factors VII, VIII, X, decreased levels of protein S activity, venous hypertension and stasis.

Pregnancy in women with a mechanical heart valve is associated with increased maternal mortality (1–4%) due to valve thrombosis because safe anticoagulation in these patients is complex. Warfarin crosses the placenta and is associated with a 5–12% risk of embryopathy during the 1st trimester. Warfarin also has an anticoagulant effect in the fetus which may lead to spontaneous fetal intracranial haemorrhage. Many women will chose unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) as they do not cross the placenta and do not cause fetal embryopathy. However, UFH may not provide consistent therapeutic anticoagulation during pregnancy and there is a high incidence (25%) of valve thrombosis. LMWH provides a more consistent anticoagulant effect when given twice daily with dose adjustment to maintain anti-Xa levels of 0.8–1.2 U/mL 4 hours after administration.

**INFECTIVE ENDOCARDITIS**

Infective endocarditis is an endovascular infection of cardiovascular structures, including cardiac valves, atrial and ventricular endocardium, large intrathoracic vessels and intracardiac foreign bodies, e.g. prosthetic valves, pacemaker leads and surgical conduits. The annual incidence in the UK is 6–7/100,000, but it is more common in developing countries. Without treatment the mortality approaches 100% and even with treatment there is a significant morbidity and mortality.

Aetiology

Endocarditis is usually the consequence of two factors: the presence of organisms in the bloodstream and abnormal cardiac endothelium facilitating their adherence and growth. Bacteraemia may occur due to patient-specific reasons (poor dental hygiene, intravenous drug use, soft tissue infections) or be associated with diagnostic or therapeutic procedures (dental treatment, intravascular cannulae, cardiac surgery or permanent pacemakers). Although bacteraemia may occur there is no good evidence that it leads to infective endocarditis (p. 87).

Damaged endocardium promotes platelet and fibrin deposition which allows organisms to adhere and grow, leading to an infected vegetation. Valvular lesions may create non-laminar flow, and jet lesions from septal defects or a patent ductus arteriosus result in abnormal vascular endothelium. Aortic and mitral valves are most commonly involved in infective endocarditis apart from intravenous drug users in whom right-sided lesions are more common.

Organisms

Common organisms and the sources of infection are shown in Figure 14.83.

Rare causes

These include the HACEK group of organisms which tend towards a more insidious course (Box 14.2).

Culture negative endocarditis

This accounts for 5–10% of endocarditis cases. The usual cause is prior antibiotic therapy (good history taking is vital) but some cases are due to a variety of fastidious organisms that fail to grow in normal blood cultures. These include *Coxiella burnetti* (the cause of Q fever), *Chlamydia* species, *Bartonella* species (organisms that cause trench fever and cat scratch disease) and *Legionella*.

Clinical presentation

The clinical presentation of infective endocarditis is dependent on the organism and the presence of predisposing factors.
cardiac conditions. Infective endocarditis may occur as an acute, fulminating infection but also occurs as a chronic or subacute illness with low-grade fever and nonspecific symptoms. A high index of clinical suspicion is required to identify patients with infective endocarditis and certain criteria should alert the physician.

**High clinical suspicion:**
- New valve lesion (regurgitant) murmur
- Embolic event(s) of unknown origin

**Box 14.2 Modified Duke criteria for endocarditis**

**Major criteria**
- A positive blood culture for infective endocarditis, as defined by the recovery of a typical microorganism from two separate blood cultures in the absence of a primary focus (viridans streptococci, Abiotrophia species and Granulicatella species; Streptococcus bovis, HACEK group), or community-acquired *Staphylococcus aureus* or *Enterococcus* species
- A persistently positive blood cultures, defined as the recovery of a microorganism consistent with endocarditis from either blood samples obtained more than 12 h apart or all three or a majority of four or more separate blood samples, with the first and last obtained at least 1 h apart or
- A positive serological test for Q fever, with an immunofluorescence assay showing phase 1 IgG antibodies at a titre $>1:800$
- Echocardiographic evidence of endocardial involvement:
  - an oscillating intracardiac mass on the valve or supporting structures, in the path or regurgitant jets, or on implanted material in the absence of an alternative anatomical explanation; or

**Minor criteria**
- an abscess; or
- new partial dehiscence of prosthetic valve; or
- New valvular regurgitation.

**Early (poor prognosis):** occurring within 60 days of valve surgery and acquired in theatre or soon after on intensive care unit
Most common e.g. *Staph. aureus* and *Staph. epidermidis*
Poor outcome with MRSA (especially but not only hospital-acquired)

**Late: occurring more than 60 days after valve surgery and presumed to have been acquired in the community (haematologically spread)**
Caused by:
- *Strep. viridans* (50–70%)
- *Staph. aureus* (25%)

**Causes of infective endocarditis**
- aetiology and sources of infection.
- an oscillating intracardiac mass on the valve or supporting structures, in the path or regurgitant jets, or on implanted material in the absence of an alternative anatomical explanation; or

**Figure 14.83** Infective endocarditis — aetiology and sources of infection.
Echocardiography is an extremely useful tool in the treatment and monitoring of patients with infective endocarditis; to identify the organism to ensure appropriate antibiotic treatment; and to monitor the patient’s response to therapy. Investigations are required to confirm the diagnosis of infective endocarditis. The following should be considered:

- Positive blood cultures (with typical organism)
- Cutaneous (Osler, Janeway) or ophthalmic (Roth) manifestations
- Peripheral abscesses (renal, splenic, spine) of unknown origin
- Predisposition and recent diagnostic/therapeutic interventions known to result in significant bacteremia.

**Low clinical suspicion**

Fever plus none of the above.

**Diagnostic criteria**

The criteria for the clinical diagnosis of endocarditis have been established – the modified Duke criteria (Box 14.1).

**Investigations**

Investigations are required to confirm the diagnosis of infective endocarditis; to identify the organism to ensure appropriate therapy; and to monitor the patient’s response to therapy (Table 14.39). Echocardiography is an extremely useful tool if used appropriately. A negative echocardiogram does not exclude a diagnosis of endocarditis. It is not an appropriate screening test for patients with just a fever or an isolated positive blood culture, where there is a low pre-test probability of endocarditis.

**Treatment**

The location of the infection means that prolonged courses of antibiotics are usually required in the treatment of infective endocarditis. The combination of antibiotics may be synergistic in eradicating microbial infection and minimizing resistance. Blood cultures should be taken prior to empirical antibiotic therapy (but this should not delay therapy in unstable patients). Antibiotic treatment should continue for 4–6 weeks. Typical therapeutic regimens are shown in Table 14.40 but specific therapy should be sought from the local microbiology department according to the organism identified and current sensitivities. Serum levels of gentamicin and vancomycin need to be monitored to ensure adequate therapy and prevent toxicity.

- **Low clinical suspicion**
  - Fever plus none of the above.

| Table 14.39 Investigations and findings in endocarditis |
|--------------------------------------------------------|---------------|
| Blood cultures                                         | 3 sets from different venepuncture sites |
| Serological tests                                      | Consider in culture negative cases for Coxiella, Bartonella, Legionella, Chlamydia |
| Full blood count                                       | Reduced haemoglobin, increased white cells, increased or reduced platelets |
| Urea and electrolytes                                  | Increased urea and creatinine |
| Liver biochemistry                                      | Increased serum alkaline phosphatase |
| Inflammatory markers                                   | Increased erythrocyte sedimentation rate and C-reactive protein (CRP reduces in response to therapy and increases with relapse) |
| Urine                                                  | Proteinuria and haematuria |
| Electrocardiogram                                      | PR prolongation/heart block is associated with aortic root abscess |
| Chest X-ray                                            | Pulmonary oedema in left-sided disease, pulmonary emboli/abscess in right-sided disease |
| Transthoracic echocardiography                         | First-line non-invasive imaging test with sensitivity of 60–75%; demonstrates vegetations, valvular dysfunction, ventricular function, abscesses |
| Transoesophageal echocardiography (Fig. 16.15)         | Second-line invasive imaging test with greater sensitivity (>90%) and specificity; useful in suspected aortic root abscess and essential in prosthetic valve endocarditis |

**Persistent fever**

Most patients with infective endocarditis should respond within 48 hours of initiation of appropriate antibiotic therapy. This is evidenced by a resolution of fever, reduction in serum markers of infection and relief of systemic symptoms of infection. Failure of this to occur needs to be taken very seriously. The following should be considered:

- Perivalvular extension of infection and possible abscess formation
- Drug reaction (the fever should promptly resolve after drug withdrawal)
- Nosocomial infection (i.e. venous access site, urinary tract infection)
- Pulmonary embolism (secondary right-sided endocarditis or prolonged hospitalization).

In such cases, samples for culture should be taken from all possible sites and evidence sought for the above causes. Changing antibiotic dosage or regimen should be avoided unless there are positive cultures or a drug reaction is
CONGENITAL HEART DISEASE

A congenital cardiac malformation occurs in about 1% of live births. There is an overall male predominance, although some individual lesions (e.g. atrial septal defect and persistent ductus arteriosus) occur more commonly in females. As a result of improved medical and surgical management, more children with congenital cardiac disease are surviving into adolescence and adulthood. Thus, there is a need for an increased awareness among general physicians and cardiologists of the problems posed by these individuals.

Fetal circulation

(Fig. 14.84)

In the developing fetus, oxygenated blood and nutrients are supplied to the fetus via the placenta and the umbilical vein. Half of that blood is directed to the fetal ductus venosus and carried to the inferior vena cava (IVC), the other half enters the liver.

CONGENITAL HEART DISEASE

</tbody>
</table>

Note: 1. Monitor vancomycin and gentamicin levels, and adjust if necessary. 2. Choice of antibiotic for staphylococci depends on sensitivities. 3. Optimum choice of therapy needs close liaison with Microbiology/Infectious Diseases. All antibiotics given i.v. IVDA, intravenous drug abuse.

*aMRSA can affect valves.

**Table 14.40** Antibiotics in endocarditis (adapted from British Society for Antimicrobial Chemotherapy (BSAC) guidelines)

**FURTHER READING**

Blood moves from the IVC to the right atrium of the heart. In the fetus, there is an opening between the right and left atrium (the foramen ovale), and most of the blood (which is a mixture of oxygenated and de-oxygenated blood) flows from the right into the left atrium, bypassing pulmonary circulation. This blood goes into the left ventricle and is pumped through the aorta into the fetal body. Some of the blood flows from the aorta through the internal iliac arteries to the umbilical arteries and re-enters the placenta, where carbon dioxide and other waste products from the fetus are taken up and enter the woman’s circulation.

Some of the blood from the right atrium does not enter the left atrium, but enters the right ventricle and is pumped into the pulmonary artery. In the fetus, there is a connection between the pulmonary artery and the aorta, the ductus arteriosus, which directs most of this blood away from the lungs. With the first breath after delivery the vascular resistance in the pulmonary arteries falls and more blood moves from the right atrium to right ventricle and pulmonary arteries and oxygenated blood travels back to the left atrium through the pulmonary veins. The decrease in right atrial pressure and other increase in left atrial pressure results in closure of the foramen ovale.

The ductus arteriosus usually closes off within one or two days of birth completely separating the left and right system. The umbilical vein and the ductus venosus closes off within 2–5 days after birth, leaving behind the ligamentum teres and the ligamentum venosus of the liver, respectively.

Aetiology
The aetiology of congenital cardiac disease is often unknown, but recognized associations include:

- Maternal prenatal rubella infection (persistent ductus arteriosus, and pulmonary valvular and arterial stenosis)
- Maternal alcohol misuse (septal defects)
- Maternal drug treatment and radiation
- Genetic abnormalities (e.g. The familial form of atrial septal defect and congenital heart block)
- Chromosomal abnormalities (e.g. septal defects and mitral and tricuspid valve defects are associated with Down’s syndrome (trisomy 21) or coarctation of the aorta in Turner’s syndrome (45, XO)).

Classification
See Table 14.41.

Symptoms and signs
Congenital heart disease should be recognized as early as possible, as the response is usually better the earlier the treatment is initiated. Some symptoms, signs and clinical problems are common in congenital heart disease:

- **Central cyanosis** occurs because of right-to-left shunting of blood or because of complete mixing of systemic and pulmonary blood flow. In the latter case, e.g. Fallot’s tetralogy, the abnormality is described as cyanotic congenital heart disease.
- **Pulmonary hypertension** results from large left-to-right shunts. The persistently raised pulmonary blood leads to the development of increased pulmonary artery vascular resistance and consequent pulmonary hypertension. This is known as the Eisenmenger’s reaction (or the Eisenmenger’s complex when due specifically to a ventricular septal defect). The development of pulmonary hypertension significantly worsens the prognosis.
- **Clubbing of the fingers** occurs in congenital cardiac conditions associated with prolonged cyanosis.
- **Paradoxical embolism** of thrombus from the systemic veins to the systemic arterial system may occur when a communication exists between the right and left heart. There is therefore an increased risk of cerebrovascular emboli and also abscesses (as with endocarditis).
- **Polycythaemia** can develop secondary to chronic hypoxaemia, leading to a hyperviscosity syndrome and an increased thrombotic risk, e.g. strokes.
- **Growth retardation** is common in children with cyanotic heart disease.
- **Syncope** is common when severe right or left ventricular outflow tract obstruction is present. Exertional syncope, associated with deepening central cyanosis, may occur in Fallot’s tetralogy. Exercise increases resistance to pulmonary blood flow but reduces systemic vascular resistance. Thus, the right-to-left shunt increases and cerebral oxygenation falls.
- **Squatting** is the posture adopted by children with Fallot’s tetralogy. It results in obstruction of venous return of desaturated blood and an increase in the peripheral systemic vascular resistance. This leads to a reduced right-to-left shunt and improved cerebral oxygenation.

Presentation
Adolescents and adults with congenital heart disease present with specific common problems related to the long-standing structural nature of these conditions and any surgical treatment:

- Endocarditis (particularly in association with otherwise innocuous lesions such as small VSDs or bicuspid aortic valve that can give up to 10% lifetime risk)
- Progression of valvular lesions (calcification and stenosis of congenitally deformed valves, e.g. bicuspid aortic valve)
- Atrial and ventricular arrhythmias (often quite resistant to treatment)
- Sudden cardiac death
- Right heart failure (especially when surgical palliation results in the right ventricle providing the systemic supply)
- End-stage heart failure (rarely managed by heart or heart-lung transplantation).

Genetic counselling
These conditions necessitate active follow-up of adult patients. Pregnancy is normally safe except if pulmonary
Cardiovascular disease

Small restrictive VSDs (‘Maladie de Roger’) are often found incidentally as patients are asymptomatic. They are associated with a loud pan-systolic murmur. The majority close spontaneously by the age of 10 years.

Large (non-restrictive) VSDs result in significant LA and LV dilatation (due to LV volume overload). Large defects usually present with heart failure symptoms in childhood and eventually lead to pulmonary hypertension and Eisenmenger’s complex. As pressures equalize the murmur becomes softer.

Investigations and intervention

A small VSD produces no abnormal X-ray or ECG findings. In larger defects, the chest X-ray may demonstrate prominent pulmonary arteries owing to increased pulmonary blood flow but with pulmonary hypertension there may be ’pruned’ pulmonary arteries. Cardiomegaly occurs when a moderate or large VSD is present and the ECG may show both left and right ventricular hypertrophy. Echocardiography can assess the size and location of the VSD and its haemodynamic consequences. Interventional options are either surgical patch repair or device closure if it is an isolated muscular VSD. Indications for intervention include left atrial and ventricular enlargement with or without early LV dysfunction; reversible pulmonary hypertension (mild) where there is a residual left to right shunt and no significant desaturation with exercise; infective endocarditis. Patients with a restrictive VSD and patients after successful closure have an excellent long term outcome. Prophylaxis of endocarditis is discussed on page 87.

Table 14.2 lists the most common congenital lesions and their occurrence in first-degree relatives.

Genetic factors should be considered in all patients presenting with congenital heart disease. For example, parents with a child suffering from Fallot’s tetralogy stand a 4% chance of conceiving another child with the disease, and so fetal ultrasound screening of the mother during pregnancy is essential. Parents with congenital heart disease are also more likely to have affected offspring. Fathers have a 2% risk, while mothers have a higher risk (around 5%). Individual families can exhibit even higher risks of recurrence.

Ventricular septal defect (VSD) (Fig. 14.85)

VSD is the most common congenital cardiac malformation (1:500 live births). The haemodynamic consequences of this are dependent on the shunt size. Left ventricular pressure is higher than right and blood therefore moves from left to right and pulmonary blood flow increases. In large defects the large volumes of blood flow through the pulmonary vasculature leads to pulmonary hypertension and eventual Eisenmenger’s complex when right ventricular pressure becomes higher than left and as a result blood starts to shunt from right to left leading to cyanosis.

Atrial septal defect (ASD)

This condition is often first diagnosed in adulthood and represents one-third of congenital heart disease. It is twice to three times more common in women than in men. There are three main types of ASD (Fig. 14.86):

- **Sinus venosus defects** – located in the superior part of the septum near the SVC (superior sinus venosus defect) or the inferior part of the septum near the IVC (inferior sinus venosus defect) entry point.
- **Ostium secundum defects** (75%) – located in the mid-septum (fossa ovalis). This should not be confused with the patent foramen ovale (PFO), which is a normal

Harsh pansystolic murmur heard at the left sternal edge, accompanied by a systolic thrill ± left parasternal heave. May be signs of pulmonary hypertension

Pathophysiology

- Left-to-right shunt
- When the left ventricle contracts, it ejects some blood into the aorta and some across the ventricular septal defect into the right ventricle and pulmonary artery
- Small VSDs (‘maladie de Roger’): loud and sometimes long systolic murmur
- Moderate VSDs: loud ‘tearing’ pansystolic murmur
- Large VSDs: cause pulmonary hypertension and soft murmur
  Eisenmenger’s complex may result
Congenital heart disease

**Patent ductus arteriosus (PDA)**

This is a persistent communication between the proximal left pulmonary artery and the descending aorta resulting in a continuous left to right shunt (Fig. 14.89). Normally the ductus arteriosus closes within a few hours of birth in response to decreased pulmonary resistance however in some cases (particularly premature babies and in cases with maternal rubella) the ductus persists. Indometacin (a prostaglandin inhibitor) is given to stimulate duct closure. If the shunt is moderate to large it will result in left heart volume overload and in some cases pulmonary hypertension and Eisenmenger’s syndrome. The characteristic clinical signs are a bounding pulse and continuous ‘machinery murmur’ however as pulmonary hypertension develops in a large PDA the murmur becomes softer.

**Investigations and intervention**

The chest X-ray may demonstrate prominent pulmonary arteries with pulmonary plethora. Right bundle branch block and right axis deviation may be present on the ECG (because of dilatation of the right ventricle). Ostium primum defects may have left axis deviation on the ECG. Echocardiography may demonstrate hypertrophy and dilatation of the right heart and pulmonary arteries. Subcostal views with 2D and colour Doppler demonstrates the ASD (Fig. 14.87) and allow calculation of the left-right shunt (QP : QS ratio). CMR and CT are helpful to assess for anomalous pulmonary venous drainage which may accompany an ASD. Indications for intervention include: an ASD with significant left to right shunting resulting in right atrial/ventricular enlargement which should be closed irrespective of symptoms; thromboembolic events including certain patients with a patent foramen ovale. The options for intervention include device closure using a transcatheter clamshell device (Fig. 14.88) for most secundum ASDs (if suitable size) or surgical closure for all other ASD types.

**Investigations and intervention**

With a large shunt, the aorta and pulmonary arterial system may be prominent on chest X-ray. The ECG may demonstrate left atrial abnormality and left ventricular hypertrophy. The development of Eisenmenger reaction will produce right ventricular hypertrophy. Echocardiography may show a dilated left atrium and left ventricle with right heart changes occurring late. Colour Doppler imaging of the proximal pulmonary arteries can demonstrate the shunt, and echocardiography may also demonstrate pulmonary hypertension.

---

**Pathophysiology**

- Left-to-right shunt through the defect in the interatrial septum
- Dilatation of the pulmonary artery resulting from the shunt
- The murmur is produced by increased flow across pulmonary valve and an increased stroke volume

---

**Figure 14.86 Atrial septal defect:** pathophysiology and auscultatory findings.

Cardiovascular disease

arteries may demonstrate the shunt. Indications for intervention (usually with percutaneous devices) include left ventricular dilatation; mild–moderate pulmonary arterial hypertension (not Eisenmenger). Small defects may predispose to endarteritis and should be considered for device closure unless clinically silent.

**Figure 14.87** Ostium secundum atrial septal defect (arrows) in a young girl. (a) Shown by a 2-D echocardiogram subcostal four-chamber view. (b) Colour Doppler can demonstrate the left-to-right shunt. LA, left atrium; RA, right atrium.

**Figure 14.88** Angiographic appearance of a fully deployed ASD closure device. The device bridges the ASD and wedges against the surfaces of the right and left atrial septa, occluding flow. The metal object in frame is the distal end of a transoesophageal echocardiography probe. (Courtesy of Dr D Ward, St George’s, University of London.)

**Coarctation of the aorta**

A coarctation of the aorta is a narrowing of the aorta at or just distal to the insertion of the ductus arteriosus (distal to the origin of the left subclavian artery (Fig. 14.90). Rarely it can occur proximal to the left subclavian. It occurs twice as commonly in men as in women. It is also associated with Turner’s syndrome (p. 978). In 80% of cases, the aortic valve is bicuspid (and potentially stenotic or endocarditic). Other associations include patent ductus arteriosus, ventricular septal defect, mitral stenosis or regurgitation and circle of Willis aneurysms. Severe narrowing of the aorta encourages the formation of a collateral arterial circulation involving the periscapular and intercostal arteries. Decreased renal perfusion can lead to the development of systemic hypertension that persists even after surgical correction.

Coarctation of the aorta is often asymptomatic for many years. Headaches and nosebleeds (due to hypertension), and claudication and cold legs (due to poor blood flow in the lower limbs) may be present. Physical examination

---

**Heart sounds and murmurs**

- **Systole**
  - Left-to-right shunt
  - Some of the blood from the aorta crosses the ductus arteriosus and flows into the pulmonary artery
  - Murmur is produced by the turbulent aortic-to-pulmonary artery shunting in both systole and diastole
  - Dilatation of the pulmonary artery, left atrium and left ventricle
  - As pulmonary hypertension (Eisenmenger’s reaction) develops, the murmur becomes quieter, may be confined to systole or may even disappear causing central cyanosis

- **Diastole**
  - Continuous ‘machinery’ murmur best heard below the left clavicle in the first interspace or over the first rib.
  - A thrill can often be felt

**Pathophysiology**

- Left-to-right shunt
- Some of the blood from the aorta crosses the ductus arteriosus and flows into the pulmonary artery
- Murmur is produced by the turbulent aortic-to-pulmonary artery shunting in both systole and diastole
- Dilatation of the pulmonary artery, left atrium and left ventricle
- As pulmonary hypertension (Eisenmenger’s reaction) develops, the murmur becomes quieter, may be confined to systole or may even disappear causing central cyanosis

Cyanotic congenital heart disease

Fallot’s tetralogy

Tetralogy of Fallot (Fig. 14.92) consists of:
- A large malaligned VSD
- An overriding aorta
- Right ventricular outflow tract obstruction
- Right ventricular hypertrophy.

Symptoms depend on the degree of pulmonary stenosis. Often this is progressive in the first year of life and cyanosis develops due to increased right-sided pressures, resulting in a right to left shunt. Fallot’s spells are episodes of severe cyanosis noted in children due to spasm of the subpulmonary muscle – these can be relieved by increasing systemic resistance by postural manoeuvres, e.g. squatting. In babies with severe pulmonary stenosis systemic-to-pulmonary artery shunts (i.e. Blalock–Taussig – subclavian to pulmonary artery shunt) may be used initially to increase pulmonary blood flow in severe cases of pulmonary stenosis. The majority of adults with tetralogy of Fallot will have undergone complete repair which involves relief of the right ventricular outflow tract obstruction and closure of the VSD. The overall survival of those who have had operative repair is excellent. DiGeorge’s syndrome is found in 15% of those with tetralogy of Fallot.

Transposition of the great arteries

Complete transposition of the great arteries (TGA)

In complete transposition of the great arteries (TGA), the right atrium connects to the morphological right ventricle, which gives rise to the aorta and the left atrium connects to the morphological left ventricle, which gives rise to the pulmonary artery (Fig. 14.93). This is incompatible with life as blood circulates in two parallel circuits, i.e. deoxygenated blood from the systemic veins passes into the right heart and then via the aorta back to the systemic circulation. Oxygenated blood from the pulmonary veins passes through the left heart and back to the lungs. Babies with transposition are usually born cyanosed – if there is a significant ASD, VSD or PDA allowing a shunt (i.e. mixing of oxygenated and deoxygenated blood) the diagnosis might be delayed. In those without a shunt an atrial septostomy is performed. A Rashkind’s balloon is used to dilate the foramen ovale and is used to maintain saturations at 50–80% until a definitive procedure can be performed. The arterial switch procedure

Investigations and intervention

Chest X-ray may reveal a dilated aorta indented at the site of the coarctation. This is manifested by an aorta (seen in the upper right mediastinum) shaped like a “figure 3”. In adults, tortuous and dilated collateral intercostal arteries may erode the undersurfaces of the ribs ("rib notching"). ECG demonstrates left ventricular hypertrophy. Echocardiography sometimes shows the coarctation and other associated anomalies. CT and CMR (Fig. 14.91) scanning can accurately demonstrate the coarctation and quantify flow.

Intervention is required if there is a peak-peak gradient across the coarctation of >20 mmHg and/or proximal hypertension. In neonates coarctation is treated with surgical repair. In older children and adults, balloon dilatation and stenting is an option although many centres still prefer surgery. Balloon dilatation is preferred for recoarctation.

Figure 14.91 Severe aortic coarctation in an adult shown on cardiac magnetic resonance angiography.

Figure 14.90 Coarctation of the aorta: pathophysiology and auscultatory findings.
Cardiovascular disease

Figure 14.92 Fallot’s tetralogy: pathophysiology and auscultatory findings.

Pathophysiology

- Fallot’s tetralogy is characterized by a large ventricular septal defect, an aorta that overrides the left and right ventricles, right ventricular outflow tract obstruction, and right ventricular hypertrophy.
- With substantial obstruction of the right ventricular outflow tract, blood is shunted through the ventricular septal defect from right to left. Thus the patient is centrally cyanosed.

Heart sounds and murmurs

- Systolic ejection murmur often associated with a thrill in the second left interspace close to the sternum.
- Single second heart sound because the pulmonary component is too soft to be heard.

Figure 14.93 Transposition of great arteries.

is now performed in the first 2 weeks of life – the aorta is reconnected to the left ventricle and the pulmonary artery is connected to the right ventricle. The coronary arteries are re-implanted.

Currently, the majority of adult patients with transposition of the great arteries will have had an ‘atrial switch’ operation. The right ventricle remains the systemic ventricle in this situation. Although most of these patients do well for many years, life expectancy is clearly limited by eventual failure of the systemic right ventricle.

Congenitally corrected transposition of the great arteries (ccTGA)

In congenitally corrected transposition of the great arteries (ccTGA), systemic venous return to the right atrium enters a morphological left ventricle, which pumps into the pulmonary artery. Pulmonary venous blood returns to the left atrium and then via the morphological right ventricle to the aorta. The circulation is physiologically corrected but the systemic circulation is supported by a morphologic right ventricle. ccTGA is often associated with cardiac lesions; systemic (tricuspid) atrio-ventricular valve abnormalities with valve insufficiency; VSD; subpulmonary stenosis; complete heart block; Wolff–Parkinson–White syndrome; dextrocardia. Many patients with ccTGA live a normal life, although other patients require pacemaker insertion (the AV node is abnormal leading to heart block), surgery for a regurgitant tricuspid valve, or develop heart failure from the systemic (right ventricle).

MARFAN’S SYNDROME

Clinical features

Marfan’s syndrome (MFS) is one of the most common autosomal dominant inherited disorders of connective tissue, affecting the heart (aortic aneurysm and dissection, mitral valve prolapse), eye (dislocated lenses, retinal detachment) and skeleton (tall, thin body build with long arms, legs and fingers; scoliosis and pectus deformity) (Figs 14.94, 14.95; Table 14.43).

Clinically, two of three major systems must be affected, to avoid overdiagnosing the condition. Diagnosis may be
confirmed by studying family linkage to the causative gene, or by demonstrating a mutation in the Marfan’s syndrome gene (MFS1) for fibrillin (FBN-1) on chromosome 15q21. MFS affects approximately 1 in 5000 of the population worldwide and 25% of patients are affected as a result of a new mutation. This group includes many of the more severely affected patients, with high cardiovascular risk. Other known associations with early death due to aortic aneurysm and dissection are: family history of early cardiac involvement; family history of dissection with an aortic root diameter of >5 cm; male sex; and extreme physical characteristics, including markedly excessive stature and widespread striae. Histological examination of aortas often shows widespread medial degeneration, described as ‘cystic medial necrosis’.

**Cardiac investigations**
- **Chest X-ray** is often normal but may show signs of aortic aneurysm and unfolding, or of widened mediastinum. Pneumothorax affects 11% and scoliosis is present in 70% of patients.
- **ECG** may be misleadingly normal with an acute dissection. In conjunction with mitral valve prolapse, 40% of patients usually have arrhythmia, with premature ventricular and atrial arrhythmias.

**Echocardiography** shows mitral valve prolapse, and mitral regurgitation in the majority of patients. High-quality serial echocardiogram measurements of aortic root diameter in the sinuses of Valsalva, at 90° to the direction of flow are the basis for medical and surgical management (Fig. 14.95b).

**CT or CMR** can detect aortic dilatation and are useful in monitoring.

**Management**
- **Beta-blocker therapy** slows the rate of dilatation of the aortic root.
- **ACE receptor blockers**. In Marfan’s there is upregulation of TNF-β, which is specifically inhibited by ACE blockers. A small trial has shown no increase in aortic root diameter on this therapy.
- **Lifestyle alterations** are required because of ocular, cardiac or skeletal involvement. Sports that necessitate prolonged exertion at maximum cardiac output, such as cross-country running, are to be avoided. Sedentary occupations are usually best, as patients tend to suffer from easy fatigueability and hypermobile painful joints.
- **Monitoring** with yearly echocardiograms up to aortic root diameter of 4.5 cm, 6-monthly from 4.5 to 5 cm, and then referred directly to a surgeon who is experienced in aortic root replacement in Marfan’s syndrome for elective surgery.

Pregnancy is generally well tolerated if no serious cardiac problems are present, but is preferably avoided if the aortic root diameter is over 4 cm, with aortic regurgitation. Echocardiography should be performed every 6–8 weeks throughout pregnancy.
pregnancy and during the initial 6 months postpartum. Blood pressure should be regularly monitored and hypertension treated actively. Delivery should be by the least stressful method; ideally a vaginal delivery. Caesarean section should not be routinely performed. However, if the aortic root is over 4.5 cm, delivery at 39 weeks by induction or caesarean section should be considered. Beta-blocker therapy may be safely instituted or continued throughout pregnancy, to help prevent aortic dissection.

Medical and surgical management have increased the overall survival rate. On average, 13 years of life is added when surgical survival is compared to that reported in the natural history of MFS.

Genetic counselling
The condition is inherited in an autosomal dominant mode, with each child of one affected parent having a 50:50 chance of inheriting the condition. Males and females are equally often affected. In 25% of all cases, the condition arises as the result of a spontaneous mutation in gene 5 of one of the parents. Fibrillin-1 gene mutations can be identified in 80% of those affected, confirming diagnosis and aiding prognosis. The mutation can also be used to screen at-risk family members, including postnatal or prenatal offspring.

### PULMONARY HEART DISEASE

The normal mean pulmonary artery pressure (mPAP) at rest is 14 ± 3 mmHg with an upper limit of normal of 20 mmHg. The normal values for mean pulmonary artery pressure (mPAP), mean capillary wedge pressure (mPCWP) and cardiac output (CO) are 12 ± 2 mmHg, 6 ± 2 mmHg and 5 L/min, respectively. The fall in pressure across the lung circulation is known as the transpulmonary gradient and reflects the difference between mPAP and mPCWP. The normal transpulmonary gradient is 6 ± 2 mmHg.

The pulmonary vascular resistance (PVR) is calculated by the formula:

$$\frac{mPAP - mPCWP}{CO}$$

It is normally about 1.5 mmHg/L per min (1.5 Wood units). Approximately 60% of the body’s endothelial surface is in the lungs and the lungs normally offer a low resistance to blood flow. This is because the media of the precapillary pulmonary arterioles is thin as compared with their more muscular systemic counterparts that have to respond constantly to postural changes under the influence of gravity. The fact that the lung circulation normally offers a low resistance to flow explains the preferential passage of blood through the lungs in specific forms of congenital heart disease, which may eventually lead to remodelling of the lung circulation and pulmonary hypertension.

### Pulmonary hypertension

**Definition**

Pulmonary hypertension (PH) is defined as a mean pulmonary artery pressure (mPAP) of >25 mmHg at rest as measured on right heart catheterization. The clinical classification of PH is provided in Table 14.44. (PH can also complicate congenital heart disease as discussed in the ACHD section.)

**Pathophysiology**

The different groups are characterized by variable amounts of hypertrophy, proliferation and fibrotic changes in distal pulmonary arteries (pulmonary arterial hypertension PAH, pulmonary veno-occlusive disease PVOD, pulmonary hypertension PH due to left heart disease, PH due to lung disease and/or hypoxia). Pulmonary venous changes are seen in groups PVOD and PH due to left heart disease and the vascular bed may be destroyed in emphysematous or fibrotic areas seen in lung disease. In chronic thromboembolic pulmonary hypertension (CTEPH) organized thrombi are seen in the elastic pulmonary arteries. Patients with PH with unclear and/or multifactorial mechanisms have variable pathological findings.

Patients with progressive PH develop right ventricular hypertrophy, dilatation, failure and death.

Epidemiology of PAH
Pulmonary artery hypertension (PAH)
Data from a recent French registry of 674 patients with pulmonary artery hypertension (PAH) identified 39.2% with idiopathic pulmonary artery hypertension (IPAH), 3.9% familial (or heritable), 9.5% drugs and toxins (anorexigens), 15.3% connective tissue disorders (autoimmune rheumatic disease), 11.3% congenital heart disease, 10.4% portal hypertension and 6.2% HIV-associated. In familial or heritable PAH, mutations in the bone morphogenetic protein receptor 2 gene BMPR2 are detected in over 70% of cases; other mutations are seen in patients with hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu syndrome). Drugs and toxins known to cause PAH include aminorex, fenfluramine, dexfenfluramine, toxic rapeseed oil and benfluorex.

Diagnosis of PAH
Patients with PAH may present with symptoms of dyspnoea, fatigue, weakness, angina, syncope or abdominal distension. Clinical signs of PAH and right heart hypertrophy include a left parasternal heave, a loud P2 heart sound, a soft pansystolic murmur with tricuspid regurgitation or early diastolic murmur with pulmonary regurgitation. Right heart failure leads to jugular venous distension, ascites, peripheral oedema, and hepatomegaly. Clinical signs of associated diseases, e.g. systemic sclerosis, chronic liver disease, should be sought.

- **Chest X-ray** shows enlargement of the pulmonary arteries and the major branches, with marked tapering (pruning) of peripheral arteries. The lung fields are usually lucent and there may be right atrial and right ventricular enlargement.
- The **ECG** shows right ventricular hypertrophy and right atrial enlargement (P pulmonale). The **chest X-ray** may facilitate the diagnosis of PH due to left heart or chronic lung disease.
- **Echocardiography** (Fig. 14.96) with tricuspid regurgitation can be used for determination of pulmonary artery pressure (PAP) using the simplified Bernoulli equation (PAP = 4 × (tricuspid regurgitation velocity² + estimated right atrial pressure). Right atrial pressure can be assumed at 5–10 mmHg unless there is significant dilatation of the inferior vena cava with reduced respiratory variation. Mean PAP = 0.61 × PA systolic pressure + 2 mmHg (although the Bernoulli equation may not be accurate in cases of severe tricuspid regurgitation).
- **Cardiac magnetic resonance imaging** may be useful in ACHD and in assessing right ventricular function on serial assessment.
- **Routine blood tests** include full blood count, renal and liver function tests, thyroid function tests, serological assays for underlying connective tissue diseases, HIV and hepatitis.
- **Abdominal liver ultrasound** is useful to exclude liver cirrhosis and portal hypertension.
- **Right heart catheterization**. As part of the clinical assessment right heart catheterization (RHC) may be indicated to confirm the diagnosis (elevated PAP), to determine the pulmonary wedge pressure (PWP), to calculate the cardiac output, and to assess for pulmonary vascular resistance and reactivity. In PAH vasodilator challenge (inhaled nitric oxide, intravenous adenosine or epoprostenol) should be performed to identify patients who may benefit from vasodilator therapies. A responder is defined as a reduction in mean PAP of ≥10 mmHg to reach an absolute mean PAP of ≤40 mmHg with increased or unchanged cardiac output. These vasodilator challenges are not recommended in patients with other types of PH (types 2–5).

Treatment of PAH
- **Physical activity** – patients should be encouraged to remain physically active but avoid exertion that precipitates severe dyspnoea, chest pain or pre-syncope.
- **Pregnancy** – patients with PAH have a very high mortality rate during pregnancy (30–50%) and should be counselled against conception. Contraception may include barrier methods, progesterone-only pill, or the Mirena coil.
- **Travel** – during plane travel supplementary oxygen at 2 L/minute may be appropriate for patients with reduced functional class and with resting hypoxia of ≤8 kPa.
- **Vaccination** should be given for influenza and pneumococcal pneumonia.
- **Elective surgery** – epidural anaesthesia may be preferable to a general anaesthetic.
- **Oral anticoagulation** has evidence to support its use in patients with IPAH, heritable PAH and PAH due to anorexigens. The European target INR is 2.0–3.0.
- **Diuretics** – these are used in patients with right heart failure and fluid overload.
- **Digoxin** may be helpful in patients with tachyarrhythmias.
- **Calcium channel blockers** can be effective in high doses in selected patients with IPAH who demonstrate a response to a vasodilator challenge. A right heart catheter should be repeated in 3–4 months to assess response to therapy.
- **Prostanooids** – prostacyclin is a potent vasodilator that also inhibits platelet aggregation and cell proliferation. Synthetic prostacyclins are generally short-acting compounds requiring continuous intravenous or subcutaneous infusion or regular aerosol inhalation. They provide symptomatic relief and can improve exercise capacity and epoprostenol can improve survival in patients with IPAH and APAH.
- **Endothelin receptor antagonists** – endothelin-1 is a potent vasoconstrictor and mitogen that binds to endothelin A and B receptors in the pulmonary vasculature. Both dual antagonists (bosentan) and selective A receptor antagonists (sitaxsentan, ambrisentan) can improve symptoms, exercise capacity and haemodynamics in patients with IPAH.
- **Phosphodiesterase type 5 inhibitors** produce vasodilation in pulmonary vasculature and reduce cellular proliferation. Sildenafil and tadalafil have been demonstrated to provide symptomatic relief and improve exercise capacity in patients with IPAH.
- **Balloon atrial septostomy** may be considered as palliative therapy in severe cases of PH.
- **Cardiac transplantation** is used in patients with adverse prognosis although the 5-year survival following transplantation may be only 40–50%.

### Pulmonary hypertension

Left-sided heart disease (systolic and diastolic heart failure) and valvular heart disease is frequently associated with PH as is advanced chronic obstructive pulmonary disease (p. 814), pulmonary fibrosis and emphysema. Following acute pulmonary embolism 0.5–2.0 % of patients will develop CTEPH.

### Pulmonary embolism

Thrombus, usually formed in the systemic veins or rarely in the right heart (<10% of cases), may dislodge and embolize into the pulmonary arterial system. Post-mortem studies indicate that this is a very common condition (microemboli are found in up to 60% of autopsies) but it is not usually diagnosed this frequently in life. Of clinical pulmonary emboli, 10% are fatal.

Most clots which cause clinically relevant pulmonary emboli actually come from the pelvic and abdominal veins, but femoral deep venous thrombosis, and even occasionally axillary thrombosis, can be the origin of the clot. Clot forms as a result of a combination of sluggish blood flow, local injury or compression of the vein and a hypercoagulable state. Emboli can also occur from tumour, fat (long bone fractures), amniotic fluid and foreign material during i.v. drug use. Risk factors are shown in Table 8.26 and discussed on page 427.

After pulmonary embolism, lung tissue is ventilated but not perfused – producing an intrapulmonary dead space and resulting in impaired gas exchange. After some hours the non-perfused lung no longer produces surfactant. Alveolar collapse occurs and exacerbates hypoxaemia. The primary haemodynamic consequence of pulmonary embolism is a reduction in the cross-sectional area of the pulmonary arterial bed which results in an elevation of pulmonary arterial pressure and a reduction in cardiac output. The zone of lung that is no longer perfused by the pulmonary artery may infarct, but often does not do so because oxygen continues to be supplied by the bronchial circulation and the airways.

### Clinical features

Sudden onset of unexplained dyspnoea is the most common, and often the only symptom of pulmonary embolism. **Pleuritic chest pain** and **haemoptysis** are present only when infarction has occurred. Many pulmonary emboli occur silently, but there are three typical clinical presentations. A clinical deep venous thrombosis is not commonly observed, although detailed investigation of the lower limb and pelvic veins will reveal thrombosis in more than half of the cases.

### Small/medium pulmonary embolism

In this situation an embolus has impacted in a terminal pulmonary vessel. Symptoms are pleuritic chest pain and breathlessness. Haemoptysis occurs in 30%, often ≥3 days after the initial event. On examination, the patient may be tachypnoeic with a localized pleural rub and often coarse crackles over the area involved. An exudative pleural effusion (occasionally blood-stained) can develop. The patient may have a fever, and cardiovascular examination is normal.

### Massive pulmonary embolism

This is a much rarer condition where sudden collapse occurs because of an acute obstruction of the right ventricular outflow tract. The patient has severe central chest pain (cardiac ischaemia due to lack of coronary blood flow) and becomes shocked, pale and sweaty. Syncope may result if the cardiac output is transiently but dramatically reduced, and death may occur. On examination, the patient is tachypnoeic, has a tachycardia with hypotension and peripheral shutdown. The jugular venous pressure (JVP) is raised with a prominent ‘a’ wave. There is a right ventricular heave, a gallop rhythm and a widely split second heart sound. There are usually no abnormal chest signs.

### Multiple recurrent pulmonary emboli

This leads to increased breathlessness, often over weeks or months. It is accompanied by weakness, syncope on exertion and occasionally angina. The physical signs are due to the pulmonary hypertension that has developed from multiple occlusions of the pulmonary vasculature. On examination, there are signs of right ventricular overload with a right ventricular heave and loud pulmonary second sound.

### Investigations in pulmonary embolism

- **Chest X-ray** is often normal, but linear atelectasis or blunting of a costophrenic angle (due to a small effusion) is not uncommon. These features develop only after some time. A raised hemidiaphragm is present in some patients. More rarely, a wedge-shaped pulmonary infarct, the abrupt cut-off of a pulmonary artery or a translucency of an underperfused distal zone is seen. Previous infarcts may be seen as opaque linear scars.
- **ECG** is usually normal, except for sinus tachycardia, but sometimes atrial fibrillation or another tachyarrhythmia occurs. There may be evidence of right ventricular strain.
- **Blood tests.** Pulmonary infarction results in a polymorphonuclear leucocytosis, an elevated ESR and
Pulmonary heart disease

CT scans. Contrast-enhanced multidetector CT angiograms (CTA) (Fig. 14.98), have a sensitivity of 83% and specificity of 96%, with a positive predictive value of 92%. These values will increase with the use of 64-multislice scanners.

MR imaging gives similar results and is used if CT angiography is contraindicated.

Massive pulmonary emboli

Chest X-ray may show pulmonary oligaemia, sometimes with dilatation of the pulmonary artery in the hila. Often there are no changes.

ECG shows right atrial dilatation with tall peaked P waves in lead II. Right ventricular strain and dilatation give rise to right axis deviation, some degree of right bundle branch block, and T wave inversion in the right precordial leads (Fig. 14.99). The ‘classic’ ECG pattern with an S wave in lead I, and a Q wave and inverted T waves in lead III (S1, Q3, T3), is rare.

Blood gases show arterial hypoxaemia with a low arterial CO2 level, i.e. type I respiratory failure pattern.

Echocardiography shows a vigorously contracting left ventricle, and occasionally a dilated right ventricle and a clot in the right ventricular outflow tract.

Pulmonary angiography has now been replaced by CT and MR angiography.
Multiple recurrent pulmonary emboli
- **Chest X-ray** may be normal. Enlarged pulmonary arterioles with oligemic lung fields indicate advanced disease.
- **ECG** can be normal or show signs of pulmonary hypertension (Fig. 14.99).
- **Leg imaging** with ultrasound and venography may show thrombi.
- **V/Q** scan may show evidence of pulmonary infarcts.
- **Multidetector CT scans** can detect small emboli.

Further tests looking for exercise-induced hypoxaemia and catheter studies to estimate pulmonary artery pressures are sometimes required.

### Diagnosis

The symptoms and signs of small and medium-sized pulmonary emboli are often subtle and nonspecific, so the diagnosis is often delayed or even completely missed. Pulmonary embolism should be considered if patients present with symptoms of unexplained cough, chest pain, haemoptysis, new-onset atrial fibrillation (or other tachycardia), or signs of pulmonary hypertension if no other cause can be found. Patients that are haemodynamically stable should have their clinical probability of a pulmonary embolus determined with the Revised Geneva Score (Table 14.45).

- High clinical probability patients should proceed to multi-detector contrast-enhanced CT angiography (CTA) (see Fig. 14.98). A positive test confirms the diagnosis. A negative test but with an elevated D-dimer may require venous ultrasonography. (Patients with renal failure or contrast allergy can have ventilation/perfusion V/Q scanning).
- Low or intermediate clinical risk patients should have a D-dimer assay performed. A negative D-dimer rules out a pulmonary embolism. A positive D-dimer requires further investigation with CTA.

Patients who are haemodynamically unstable (shock, systolic blood pressure <90 mmHg, drop in pressure of ≥40 mmHg) may require urgent CTA or if critically ill with a high clinical probability, an echocardiogram should be performed – right ventricular dysfunction is highly suggestive of a pulmonary embolism – a normal right ventricle should suggest alternative diagnoses.

### Treatment

#### Acute management
- All patients should receive high-flow oxygen (60–100%) unless they have significant chronic lung disease. Patients with pulmonary infarcts require bed rest and analgesia.
- Patients should be anticoagulated initially with subcutaneous low-molecular-weight heparin or fondaparinux or intravenous unfractionated heparin followed by warfarin therapy.
- **Massive pulmonary emboli.** Intravenous fluids and even inotropic agents to improve the pumping of the right heart are sometimes required, and very ill patients will require care on the intensive therapy unit (see p. 885).
- **Fibrinolytic therapy** such as streptokinase (250,000 units by i.v. infusion over 30 min, followed by streptokinase 100,000 units i.v. hourly for up to 12–72 hours, according to manufacturer’s instructions) has been shown in controlled trials to clear pulmonary emboli more rapidly and to confer a survival benefit in massive PE. It should be used in unstable patients and in some stable patients with adverse features, e.g. right ventricular dysfunction.
- **Surgical embolectomy** is rarely necessary, but there may be no alternative when the haemodynamic circumstances are very severe.

#### Prevention of further emboli

Patients should be anticoagulated with vitamin K antagonists for a period of 3–6 months with a target INR of 2.0–3.0. Patients with cancer or pregnant women should be treated with long-term low-molecular-weight heparin. Occasionally, physical methods are required to prevent further emboli. This is usually because recurrent emboli occur despite adequate anticoagulation, but it is also indicated in high-risk patients in whom anticoagulation is absolutely contraindicated. The most common method by which pulmonary embolism is treated in this situation is by insertion of a filter in the inferior vena cava via the femoral vein to above the level of the renal veins.

Myocardial and endocardial disease

Myocarditis

Acute inflammation of the myocardium has many causes (Table 14.46). Establishment of a definitive aetiology with isolation of viruses or bacteria is difficult in routine clinical practice. In western societies, the commonest causes of infective myocarditis are Coxsackie or adenoviral infection. Myocarditis in association with HIV infection is seen at post-mortem in up to 20% of cases but causes clinical problems in less than 10% of cases. Chagas’ disease, due to Trypanosoma cruzi, which is endemic in South America, is one of the commonest causes of myocarditis worldwide. Additionally, toxins (including prescribed drugs), physical agents, hypersensitivity reactions and autoimmune conditions may also cause myocardial inflammation.

Pathology

In the acute phase, myocarditic hearts are flabby with focal haemorrhages; in chronic cases they are enlarged and hypertrophied. Histologically an inflammatory infiltrate is present – lymphocytes predominating in viral causes; polymorphonuclear cells in bacterial causes; eosinophils in allergic and hypersensitivity causes.

Clinical features

Myocarditis may be an acute or chronic process; its clinical presentations range from an asymptomatic state associated with limited and focal inflammation to fatigue, palpitations, chest pain, dyspnoea and fulminant congestive cardiac failure due to diffuse myocardial involvement. An episode of viral myocarditis, perhaps unrecognized and forgotten, may be the initial event that eventually culminates in an ‘idiopathic’ dilated cardiomyopathy. Physical examination includes soft heart sounds, a prominent third sound and often a tachycardia. A pericardial friction rub may be heard.

Investigations

- **Chest X-ray** may show some cardiac enlargement, depending on the stage and virulence of the disease.
- **ECG** demonstrates ST- and T-wave abnormalities and arrhythmias. Heart block may be seen with diphtheritic myocarditis, Lyme disease and Chagas’ disease (see below).
- **Cardiac enzymes** are elevated. However, since entero viral infection is common in the general population, the diagnosis depends on the demonstration of acutely rising titres.
- **Endomyocardial biopsy** may show acute inflammation but false negatives are common by conventional criteria. Biopsy is of limited value outside specialized units.
- **Viral RNA.** DNA can be measured from biopsy material using polymerase chain reaction (PCR). Specific diagnosis requires demonstration of active viral replication within myocardial tissue.

Myocardial and endocardial disease

The diagnosis is easily made by echocardiography because the tumour is demonstrated as a dense space-occupying lesion (Fig. 14.100). Surgical removal usually results in a complete cure.

Myxomas may also occur in the right atrium or in the ventricles. Other primary cardiac tumours include rhabdomyomas and sarcomas.

Myocardial disease

Myocardial disease that is not due to ischaemic, valvular or hypertensive heart disease, or a known infiltrative, metabolic/toxic or neuromuscular disorder may be caused by:

- An acute or chronic inflammatory pathology (myocarditis)
- Idiopathic myocardial disease (cardiomyopathy).

Figure 14.100 Atrial myxoma shown by a 2-D echocardiogram (long-axis view). The myxoma is an echo-dense mass obstructing the mitral valve orifice. It was removed surgically. LV, left ventricle; LA, left atrium.
Cardiovascular disease

**Hypertrophic cardiomyopathy (HCM)**

HCM includes a group of inherited conditions that produce hypertrophy of the myocardium in the absence of an alternate cause (e.g. aortic stenosis or hypertension). It is the most common cause of sudden cardiac death in young people and affects 1 in 500 of the population. The majority of cases are familial autosomal dominant, due to mutations in the genes encoding sarcomeric proteins (Fig. 14.101). The most common causes of HCM are mutations of the β-myosin heavy chain MYH7 and myosin-binding protein C MYBPC3. Other mutations include troponin T and I, regulatory and essential myosin light chains, titin, α-tropomyosin, α-actin, α-myosin heavy chain and muscle LIM protein (although over 400 mutations have been identified.) There are non-sarcomeric protein mutations in genes that control cardiac metabolism that result in glycogen storage diseases (Danon’s, Pompe’s and Fabry’s disease) that are indistinguishable from HCM.

**Giant cell myocarditis**

This is a severe form of myocarditis characterized by the presence of multinucleated giant cells within the myocardium. The cause is unknown but it may be associated with sarcoidosis, thymomas and autoimmune disease. It has a rapidly progressive course and a poor prognosis. Immunosuppression is recommended.

**Chagas’ disease**

Chagas’ disease is caused by the protozoan *Trypanosoma cruzi* and is endemic in South America where upwards of 20 million people are infected. Acutely, features of myocarditis are present with fever and congestive heart failure. Chronically, there is progression to a dilated cardiomyopathy with a propensity towards heart block and ventricular arrhythmias. Treatment is discussed on page 148. Amiodarone is helpful for the control of ventricular arrhythmias; heart failure is treated in the usual way (p. 719).

**Cardiomyopathy**

Cardiomyopathies are a group of diseases of the myocardium that affect the mechanical or electrical function of the heart. They are frequently genetic and may produce inappropriate ventricular hypertrophy or dilatation and can be primarily a cardiac disorder or part of a multisystem disease (Table 14.47). Nevertheless, there is considerable heterogeneity and overlap between the conditions (Fig. 14.10). Abnormal myocardial function produces systolic or diastolic heart failure; abnormal electrical conduction results in cardiac arrhythmias and sudden cardiac death.

Clinical categories of inherited cardiomyopathies and their genetic basis

**Mendelian genetic**
- Sarcomeric
- Mitochondrial
- LAMP2, GLA, AMPK

**Non-mendelian genetic**
- Restrictive cardiomyopathy
- Left ventricular non-compaction
- Arrhythmogenic right ventricular cardiomyopathy
- Genetic
  - Desmosome proteins
  - TMEM43

### Clinical features

HCM is characterized by variable myocardial hypertrophy frequently involving the interventricular septum and disorganization (‘disarray’) of cardiac myocytes and myofibrils. Some 25% of patients have dynamic left ventricular outflow tract obstruction due to the combined effects of hypertrophy, systolic anterior motion (SAM) of the anterior mitral valve leaflet and rapid ventricular ejection. The salient clinical and morphological features of the disease vary according to the underlying genetic mutation. For example, marked hypertrophy is common with β myosin heavy chain mutations whereas mutations in troponin T may be associated with mild hypertrophy but a high risk of sudden death. The hypertrophy may not manifest before completion of the adolescent growth spurt, making the diagnosis in children difficult. HCM due to myosin-binding protein may not manifest until the sixth decade of life or later.

### Symptoms

- Many are asymptomatic and are detected through family screening of an affected individual or following a routine ECG examination.
- Chest pain, dyspnoea, syncope or pre-syncope (typically with exertion), cardiac arrhythmias and sudden death are seen.
- Sudden death occurs at any age but the highest rates (up to 6% per annum) occur in adolescents or young adults. Risk factors for sudden death are discussed below.
- Dyspnoea occurs due to impaired relaxation of the heart muscle or the left ventricular outflow tract obstruction that occurs in some patients. The systolic cavity remains small until the late stages of disease when progressive dilatation may occur. If a patient develops atrial fibrillation there is often a rapid deterioration in clinical status due to the loss of atrial contraction and the tachycardia – resulting in elevated left atrial pressure and acute pulmonary oedema.

### Signs

- Double apical pulsation (forceful atrial contraction producing a fourth heart sound).
- Jerky carotid pulse because of rapid ejection and sudden obstruction to left ventricular outflow during systole.
- Ejection systolic murmur due to left ventricular outflow obstruction late in systole – it can be increased by manoeuvres that decrease afterload, e.g. standing or Valsalva, and decreased by manoeuvres that increase afterload and venous return, e.g. squatting.
- Pansystolic murmur due to mitral regurgitation (secondary to SAM).
- Fourth heart sound (if not in AF).

### Investigations

- **ECG** abnormalities of HCM include left ventricular hypertrophy (see Fig. 14.76), ST and T wave changes, and abnormal Q waves especially in the inferolateral leads.
- **Echocardiography** is usually diagnostic and in classical HCM there is asymmetric left ventricular hypertrophy (involving the septum more than the posterior wall), systolic anterior motion of the mitral valve, and a vigorously contracting ventricle (Fig. 14.102). However, any pattern of hypertrophy may be seen, including concentric and apical hypertrophy.
- **Cardiac MR** can detect both the hypertrophy but also abnormal myocardial fibrosis (Fig. 14.103).
- **Genetic analysis**, where available, may confirm the diagnosis and provide prognostic information for the patient and relatives.

### Treatment

The management of HCM includes treatment of symptoms and the prevention of sudden cardiac death in the patient and relatives.
Cardiovascular disease

Arrhythmogenic (right) ventricular cardiomyopathy (AVC)

AVC is an uncommon (1 in 5000 population) inherited condition that predominantly affects the right ventricle with fatty or fibro-fatty replacement of myocytes, leading to segmental or global dilatation (Fig. 14.104). Left ventricular involvement has been reported in up to 75% of cases. The fibro-fatty replacement leads to ventricular arrhythmia and risk of sudden death in its early stages, and right ventricular or biventricular failure in its later stages.

Autosomal dominant AVC has been mapped to eight chromosomal loci within mutations in four genes encoding for desmosomal proteins. These are the cardiac ryanodine receptor RyR2 (also responsible for familial catecholaminergic polymorphic ventricular tachycardia, CPVT), desmplakin, plakophilin-2 and mutations altering the regulatory sequences of the transforming growth factor-β gene.

There are two recessive forms: Naxos disease (associated with palmoplantar keratoderma and woolly hair) that is due to a mutation in junctional plakoglobin, and Carvajal’s syndrome, due to a mutation in desmoplakin.

Clinical features

Most patients are asymptomatic. Symptomatic ventricular arrhythmias, syncope or sudden death occur. Occasionally presentation is with symptoms and signs of right heart failure, although this is more common in the later stages of the disease. Some patients may be detected through family screening.
screening, although frequently the morphological appearance of the right ventricle is normal, despite significant cardiac arrhythmias.

**Investigations**

- **ECG** is usually normal but may demonstrate T wave inversion in the precordial leads related to the right ventricle (V1–V3). Small-amplitude potentials occurring at the end of the QRS complex (epsilon waves) may be present (Fig. 14.105) and incomplete or complete RBBB is sometimes seen. Signal averaged ECG may indicate the presence of late potentials, the delayed depolarization of individual muscle cells; 24-hour Holter monitoring may demonstrate frequent extrasystoles of right ventricular origin or runs of non-sustained ventricular tachycardia.

- **Echocardiography** is frequently normal but with more advanced cases may demonstrate right ventricular dilatation and aneurysm formation, and there may be left ventricular dilatation.

- **Cardiac MR** can more accurately assess the right ventricle and in some cases can demonstrate fibro-fatty infiltration (Fig. 14.106).

- **Genetic testing** may soon be the diagnostic ‘gold standard’.

Clinical diagnosis is made using Task Force Criteria that include structural abnormalities of the right ventricle and RVOT (dilatation and abnormal wall motion on echocardiography or MRI), fibro-fatty replacement of myocytes on tissue biopsy, repolarization and conduction abnormalities on ECG or signal averaged ECG, ventricular tachycardia or frequent ventricular extrasystoles on Holter monitor, family history of ARVC/D in a first- or second-degree relative or premature sudden death (<35 years) due to ARVC/D.

**Treatment**

Beta-blockers are first-line treatment for patients with non-life-threatening arrhythmias. Amiodarone or sotalol are used for symptomatic arrhythmias but for refractory or life-threatening arrhythmias an ICD is required. Occasionally cardiac transplantation is indicated either for intractable arrhythmia or cardiac failure.

**Dilated cardiomyopathy (DCM)**

DCM has a prevalence of 1 in 2500 and is characterized by dilatation of the ventricular chambers and systolic dysfunction with preserved wall thickness.

- **Familial DCM** is predominantly autosomal dominant and can be associated with over 20 abnormal loci and genes (Fig. 14.107). Many of these are genes encoding cytoskeletal or associated myocyte proteins (dystrophin in X-linked cardiomyopathy; actin, desmin, troponin T, beta myosin heavy chain, sarcoglycans, vinculin and lamin a/c in autosomal dominant DCM) (Fig. 14.108). Many of these have prominent associated features such as skeletal myopathy or conduction system disease and therefore differ from the majority of cases of DCM.

- **Sporadic DCM** can be caused by multiple conditions (Table 14.47):
  - Myocarditis – Coxsackie, adenoviruses, erythroviruses, HIV, bacteria, fungae, mycobacteria, parasitic (Chagas’s disease)
  - Toxins – alcohol, chemotherapy, metals (cobalt, lead, mercury, arsenic)
  - Autoimmune
  - Endocrine
  - Neuromuscular.

**FURTHER READING**

Cardiovascular disease

Clinical features
DCM can present with heart failure, cardiac arrhythmias, conduction defects, thromboembolism or sudden death. Increasingly, evaluation of relatives of DCM patients is allowing identification of early asymptomatic disease, prior to the onset of these complications. Clinical evaluation should include a family history and construction of a pedigree where appropriate.

Investigations
- **Chest X-ray** demonstrates generalized cardiac enlargement.
- **ECG** may demonstrate diffuse nonspecific ST segment and T wave changes. Sinus tachycardia, conduction abnormalities and arrhythmias (i.e. atrial fibrillation, ventricular premature contractions or ventricular tachycardia) are also seen.
- **Echocardiogram** reveals dilatation of the left and/or right ventricle with poor global contraction function (Fig. 14.109).
- **Cardiac MR** may demonstrate other aetiologies of left ventricular dysfunction (e.g. previous myocardial infarction) or demonstrate abnormal myocardial fibrosis (Fig. 14.110).
- **Coronary angiography** should be performed to exclude coronary artery disease in all individuals at risk (generally patients >40 years or younger if symptoms or risk factors are present).

Biopsy is generally not indicated outside specialist care.

Treatment
Treatment consists of the conventional management of heart failure with the option of cardiac resynchronization therapy and ICDs in patients with NYHA III/IV grading. Cardiac transplantation is appropriate for certain patients.

Left ventricular non-compaction (LVNC)
LVNC is associated with a sponge-like appearance of the left ventricle. The condition predominantly affects the apical portion of the left ventricle and may be associated with congenital heart abnormalities. The condition is diagnosed by echocardiography, cardiac MR or left ventricular angiography. The natural history of the condition is unresolved but includes congestive cardiac failure, thromboembolism, cardiac arrhythmias and sudden death. Familial and spontaneous cases have been described.

Conduction system disease
Lenegre’s disease (p. 701) is a progressive disease of the cardiac conduction system (His-Purkinje system) that causes broad QRS duration, long pauses and bradycardia which presents with syncope. Sick-sinus syndrome is phenotypically similar.

Ion channelopathies
Features of the ion channelopathies are long QT syndrome (LQTS) (p. 708), Brugada’s syndrome (p. 701), catecholaminergic polymorphic ventricular tachycardia (CPVT), short QT syndrome (SQTS) and idiopathic ventricular fibrillation (VF).

Primary restrictive non-hypertrophic cardiomyopathy
This is a rare condition in which there is normal or decreased volume of both ventricles with bi-atrial enlargement, normal wall thickness, normal cardiac valves and impaired ventricular filling with restrictive physiology but near normal systolic function. The restrictive physiology produces symptoms and signs of heart failure. Conditions associated with this form of cardiomyopathy include amyloidosis (commonest), sarcoidosis, Loeffler’s endocarditis and endomyocardial fibrosis; in the latter two conditions there is myocardial and endocardial fibrosis associated with eosinophilia. The idiopathic form of restrictive cardiomyopathy may be familial.

Clinical features
Patients with restrictive cardiomyopathy may present with dyspnoea, fatigue and embolic symptoms. On clinical examination there will be elevated jugular venous pressure with
diastolic collapse (Friedreich’s sign) and elevation of venous pressure with inspiration (Kussmaul’s sign), hepatic enlargement, ascites and dependent oedema. Third and fourth heart sounds may be present.

**Investigations**
- **Chest X-ray** may show pulmonary venous congestion. The cardiac silhouette can be normal or show cardiomegaly and/or atrial enlargement.
- **ECG** may demonstrate low-voltage QRS and ST segment and T wave abnormalities.
- **Echocardiography** shows symmetrical myocardial thickening and often a normal systolic ejection fraction but impaired ventricular filling. In amyloid patients the myocardium typically appears speckled with absent radial thickening as demonstrated by ‘tram-lines’ on M-mode echocardiography (Fig. 14.111).
- **Cardiac MR** may demonstrate abnormal myocardial fibrosis in amyloidosis or sarcoidosis.
- **Cardiac catheterization** and haemodynamic studies may help distinguish between restrictive cardiomyopathy and constrictive pericarditis, although volume loading may be required.
- **Endomyocardial biopsy** in contrast with other cardiomyopathies is often useful in this condition and may permit a specific diagnosis, such as amyloidosis, to be made.

**Treatment**
There is no specific treatment. Cardiac failure and embolic manifestations should be treated. Cardiac transplantation is necessary in some severe cases, especially the idiopathic variety. In primary amyloidosis combination therapy with melphalan plus prednisolone with or without colchicine may improve survival. However, patients with cardiac amyloidosis have a worse prognosis than those with other forms of the disease, and the disease often recurs after transplantation. Liver transplantation may be effective in familial amyloidosis (due to production of mutant pre-albumin) and may lead to reversal of the cardiac abnormalities.

**Acquired cardiomyopathies**

**Myocarditis** (see p. 767)

**Stress (Tako-tsubo/octopus pot/apical ballooning syndrome) cardiomyopathy**

Patients with this condition present acutely with chest pain and breathlessness associated with ECG changes and elevated cardiac biomarkers consistent with acute myocardial infarction. Diagnostic coronary angiography typically demonstrates unobstructed coronary arteries with characteristic akinesia of the mid-apical segments of the left ventricle on ventriculography or echocardiography with preserved basal function (Fig. 14.112). The pathophysiology of the condition is uncertain but may be due to transient catecholamine excess, coronary vasospasm, abnormalities of the coronary microcirculation and hypertrophy of the basal septum. The syndrome is more common in middle-old aged women. Severe cases may have cardiogenic shock and pulmonary oedema. Patients with a significant left ventricular gradient may respond to cautious beta-blockade. Complete recovery of function is normal within 4–6 weeks.

**Peripartum cardiomyopathy**

This rare condition affects women in the last trimester of pregnancy or within 5 months of delivery. It presents as a
dilated cardiomyopathy, is more common in obese, multiparous women over 30 years old and is associated with pre-eclampsia. Nearly half of patients will recover to normal function within 6 months but in some patients it can cause progressive heart failure and sudden death.

**Tachycardia cardiomyopathy**

Prolonged periods of supraventricular or ventricular tachycardia will lead to dilated cardiomyopathy. Cardioversion and ablation may be necessary to restore sinus rhythm and allow for recovery of cardiac function.

**PERICARDIAL DISEASE**

The pericardium acts as a protective covering for the heart. It consists of an outer fibrous pericardial sac and an inner serous pericardium that lines the heart and great vessels and its reflection the outer parietal pericardium that lines the fibrous sac. The normal amount of pericardial fluid is 20–49 mL that lubricates the surface of the heart. Presentations of pericardial disease include:

- Acute and relapsing pericarditis
- Pericardial effusion and cardiac tamponade
- Constrictive pericarditis.

**Acute pericarditis**

This refers to inflammation of the pericardium. Classically, fibrinous material is deposited into the pericardial space and pericardial effusion often occurs. Acute pericarditis has numerous aetiologies (Table 14.49) although in most cases a cause is not identified (idiopathic).

**Viral pericarditis.** The most common viral causes are Coxsackie B virus and echovirus. Viral pericarditis is usually painful but has a short time course and rarely long-term effects. Increasingly, HIV is implicated in the aetiology of pericarditis, both directly and via immunosuppression, which predisposes the subject to infective causes.

**Post-myocardial infarction pericarditis** occurs in about 20% of patients in the first few days following MI. It occurs more commonly with anterior MI and ST elevation MI with high serum cardiac enzymes, but its incidence is reduced to 5–6% with thrombolysis. It may be difficult to differentiate this pain from recurrent angina when it occurs early (day 1–2 post-infarct) but a good history of the pain and serial ECG monitoring is helpful. Pericarditis may also occur later on in the recovery phase after infarction. This usually occurs as a feature of Dressler’s syndrome, an autoimmune response to cardiac damage occurring 2–10 weeks’ post-infarct. Autoimmune reaction to myocardial damage is the main aetiology, and antimycocardial antibodies can often be found. Recurrences are common. Differential diagnosis includes a new myocardial infarction or unstable angina.

**Uraemic pericarditis** is due to irritation of the pericardium by accumulating toxins. It can occur in 6–10% of patients with advanced kidney disease if dialysis is delayed. It is an indication for urgent dialysis as it continues to be associated with significant morbidity and mortality.

**Bacterial pericarditis** may rarely occur with septicaemia or pneumonia, or it may stem from an early postoperative infection after thoracic surgery or trauma, or may complicate endocarditis. *Staphylococcus aureus* is a frequent cause of purulent pericarditis in HIV patients. This form of pericarditis, especially staphylococcal, is fulminant and often fatal.

**Other endemic infectious pericarditis** includes mycoplasmosis and Lyme pericarditis which are often effusive and require pericardial drainage. The diagnosis is based on serological tests of pericardial fluid and identification of organisms in pericardial or myocardial biopsies.

**Tuberculous pericarditis** usually presents with chronic low-grade fever, particularly in the evening, associated with features of acute pericarditis, dyspnoea, malaise, night sweats and weight loss. Pericardial aspiration is often required to make the diagnosis. Constrictive pericarditis is a frequent outcome. Treatment is as for pulmonary TB (p. 842) but prednisolone 60 mg daily for 2–6 weeks.

**Fungal pericarditis** is a common complication of endemic fungal infections, such as histoplasmosis and coccidioidomycosis but may be also caused by *Candida albicans*, especially in immunocompromised patients, drug addicts or after cardiac surgery.

**Malignant pericarditis.** Carcinoma of the bronchus, carcinoma of the breast and Hodgkin’s lymphoma are the most common causes of malignant pericarditis. Leukaemia and malignant melanoma are also associated with pericarditis. A substantial pericardial effusion is very typical and is due to the obstruction of the lymphatic drainage from the heart. The effusion is often haemorrhagic. Radiation and therapy for thoracic tumours may cause radiation injury to the pericardium resulting in serous or haemorrhagic pericardial effusion and pericardial fibrosis. Absence of neoplastic cells in the pericardial fluid in these conditions often helps diagnosis.

**Clinical features**

Pericardial inflammation produces sharp central chest pain exacerbated by movement, respiration and lying down. It is typically relieved by sitting forward. It may be referred to the neck or shoulders. The main differential diagnoses are angina and pleurisy. The classical clinical sign is a pericardial friction rub occurring in three phases corresponding to atrial systole, ventricular systole and ventricular diastole. It may also be heard as a biphasic ‘to and fro’ rub. The rub is heard best with the diaphragm of the stethoscope at the lower left chest pain.

| X. Post-traumatic pericarditis |

| XI. Familial and idiopathic pericarditis |
sternal edge at the end of expiration with the patient leaning forward. There is usually a fever, leucocytosis or lymphocytosis when pericarditis is due to viral or bacterial infection, rheumatic fever or myocardial infarction. Features of a pericardial effusion may also be present (p. 776). Large pericardial effusion can compress adjacent bronchi and lung tissue and may cause dyspnoea.

**Investigations**

ECG is diagnostic. There is widespread concave-upwards (saddle-shaped) ST elevation (Fig. 14.113), reciprocal ST depression in leads aVR and V₃, and PR segment depression. These changes evolve over time, with resolution of the ST elevation, T wave flattening/inversion and finally T wave normalization. The early ECG changes must be differentiated from the ST elevation found in myocardial infarction which is limited to the infarcted area, e.g. anterior or inferior. Sinus tachycardia may result from fever or haemodynamic embarrassment, and rhythm and conduction abnormalities may be present if myocardium is involved. Cardiac enzymes should be assayed as they may be elevated if there is associated myocarditis (see p. 767). Chest X-ray may demonstrate cardiomegaly (in cases with an effusion) which should be confirmed with echocardiography. CT and cardiac MR may be helpful for in cases with thickened (>4 mm) or inflamed (abnormal delayed enhancement) pericardium.

**Treatment**

If a cause is found, this should be treated. Bed rest and oral NSAIDs (high-dose aspirin indometacin or ibuprofen) are effective in most patients. Aspirin is the drug of choice for patients with a recent myocardial infarction. Colchicine is also effective in combination with conventional therapy, as demonstrated in the COPE trial. Corticosteroids should be reserved for patients with a known immune cause as their use is associated with an increased rate of recurrence.

**Recurrent or relapsing pericarditis**

About 20% of cases of acute pericarditis go on to develop idiopathic relapsing pericarditis which may be incessant (recurs within 6 weeks during weaning of NSAIDs) or intermittent (recurs >6 weeks after the initial presentation). The first-line treatment is again oral NSAIDs. The colchicine as first-choice therapy for recurrent pericarditis trial demonstrated that prolonged colchicine (for 6 months) was more effective than aspirin alone in reducing recurrence. In resistant cases, oral corticosteroids may be effective and in some patients pericardectomy may be appropriate.

**Pericardial effusion and cardiac tamponade**

A pericardial effusion is a collection of fluid within the potential space of the serous pericardial sac (Fig. 14.114), commonly accompanying an episode of acute pericarditis. When a large volume collects in this space, ventricular filling is compromised leading to embarrassment of the circulation. This is known as cardiac tamponade.

**Clinical features**

Symptoms of a pericardial effusion commonly reflect the underlying pericarditis. On examination:

- Heart sounds are soft and distant
- Apex beat is commonly obscured
- A friction rub may be evident due to pericarditis in the early stages, but this becomes quieter as fluid accumulates and pushes the layers of the pericardium apart
- Rarely, the effusion may compress the base of the left lung, producing an area of dullness to percussion below the angle of the left scapula (Ewart’s sign)

![Figure 14.113 ECGs associated with pericarditis. (a) Acute pericarditis. Note the raised ST segment, concave upwards (arrow). (b) Chronic phase of pericarditis associated with a pericardial effusion. Note the T wave flattening and inversion, and the alternation of the QRS amplitude (QRS alternans). (c) The same patient after evacuation of the pericardial fluid. Note that the QRS voltage has increased and the T waves have returned to normal.]

![Figure 14.114 Chest X-ray showing a pericardial effusion; the heart appears globular.]

**FURTHER READING**

As the effusion worsens, signs of cardiac tamponade may become evident:
- Raised jugular venous pressure with sharp rise and y descent (Friedreich’s sign)
- Kussmaul’s sign (rise in JVP/increased neck vein distension during inspiration)
- Pulsus paradoxus (an exaggeration in the normal variation in pulse pressure seen with inspiration such that there is drop in systolic blood pressure of ≥10 mmHg)
- Reduced cardiac output.

Investigations
- **ECG** reveals low-voltage QRS complexes (<0.5 mV in limb leads) with sinus tachycardia and there may be electric alternans (alteration of QRS amplitude or axis between beats).
- **Chest X-ray** (Fig. 14.114) shows large globular or pear-shaped heart with sharp outlines. Typically, the pulmonary veins are not distended.
- **Echocardiography** (Fig. 14.115) is the most useful technique for demonstrating the effusion and looking for evidence of tamponade – late diastolic collapse of the right atrium, early diastolic collapse of the right ventricle, ventricular septum displacement into the left ventricle during inspiration, diastolic flow reversal in the hepatic veins during expiration, dilated inferior vena cava with <50% reduction during inspiration.
- **Cardiac CT or MRI** should be considered if loculated pericardial effusions are suspected (post-cardiac surgery).
- **Pericardiocentesis** is the removal of pericardial fluid with aseptic technique under echocardiographic guidance. It is indicated when a tuberculous, malignant or purulent effusion is suspected.
- **Pericardial biopsy** may be needed if tuberculosis is suspected and pericardiocentesis is not diagnostic.

Other tests include looking for underlying causes, e.g. blood cultures, autoantibody screen.

**Treatment**
An underlying cause should be sought and treated if possible. Most pericardial effusions resolve spontaneously. However, when the effusion collects rapidly, tamponade may result. Pericardiocentesis is then indicated to relieve the pressure – a drain may be left in temporarily to allow sufficient release of fluid. Pericardial effusions may reaccumulate, most commonly due to malignancy (in the UK). This may require pericardial fenestration, i.e. creation of a window in the pericardium to allow the slow release of fluid into the surrounding tissues. This procedure may either be performed transcutaneously under local anaesthetic or using a conventional surgical approach.

**Constrictive pericarditis**
Certain causes of pericarditis such as tuberculosis, haemopericardium, bacterial infection and rheumatic heart disease result in the pericardium becoming thick, fibrous and calcified. This may also develop late after open heart surgery, and fibrosis also occurs with the use of dopamine agonists, e.g. cabergoline, pergolide. In many cases these pericardial changes do not cause any symptoms. If, however, the pericardium becomes so inelastic as to interfere with diastolic filling of the heart, constrictive pericarditis is said to have developed. As these changes are chronic, allowing the body time to compensate, this condition is not as immediately life-threatening as cardiac tamponade, in which the circulation is more acutely embarrassed.

Constrictive pericarditis should be distinguished from restrictive cardiomyopathy (see p. 772). The two conditions are very similar in their presentation, but the former is fully treatable, whereas most cases of the latter are not. In the later stages of constrictive pericarditis, the subepicardial layers of myocardium may undergo fibrosis, atrophy and calcification.

**Clinical features**
The symptoms and signs of constrictive pericarditis occur due to:
- reduced ventricular filling (similar to cardiac tamponade, i.e. Kussmaul’s sign, Friedreich’s sign, pulsus paradoxus)
- systemic venous congestion (ascites, dependent oedema, hepatomegaly and raised JVP)
- pulmonary venous congestion (dyspnoea, cough, orthopnoea, PND) less commonly
- reduced cardiac output (fatigue, hypotension, reflex tachycardia)
- rapid ventricular filling (‘pericardial knock’ heard in early diastole at the lower left sternal border)
- atrial dilatation (30% of cases have atrial fibrillation).

**Investigations**
- **Chest X-ray** shows a relatively small heart in view of the symptoms of heart failure. Pericardial calcification may be present in up to 50%. A lateral chest film may be useful in detecting calcification that is missed on an AP film. However, a calcified pericardium is not necessarily a constricted one.
- **ECG** reveals low-voltage QRS complexes with generalized T wave flattening or inversion.
- **Echocardiography** shows thickened calcified pericardium, and small ventricular cavities with
normal wall thickness. Doppler studies may be useful.

- **CT and CMR** are used to assess pericardial anatomy and thickness (≥4 mm) (see Fig. 14.28).
- **Endomyocardial biopsy** may be helpful in distinguishing constrictive pericarditis from restrictive cardiomyopathy in difficult cases.
- **Cardiac catheterization.** End-diastolic pressures in the left and right ventricles measured during this procedure are usually equal, owing to pericardial constriction.

Restrictive cardiomyopathy is a close mimic of constrictive pericarditis and all the above tests may not help to distinguish the two conditions.

**Treatment**
The treatment for chronic constrictive pericarditis is complete resection of the pericardium. This is a risky procedure with a high complication rate due to the presence of myocardial atrophy in many cases at the time of surgery. Thus early pericardiectomy is suggested in non-tuberculous cases, before severe constriction and myocardial atrophy have developed.

In cases of tuberculous constriction, the presence of pericardial calcification implies chronic disease. Current evidence tends to favour early pericardiectomy with antituberculous drug cover in these cases. If there is no calcification, a course of antituberculous therapy should be attempted first. If the patient’s haemodynamic state remains static or deteriorates after 4–6 weeks of therapy, pericardiectomy is recommended.

---

**SYSTEMIC HYPERTENSION**

**Definitions of hypertension**

Elevated arterial blood pressure is a major cause of premature vascular disease leading to cerebrovascular events, ischaemic heart disease and peripheral vascular disease. Blood pressure is a characteristic of each individual, like height and weight, with marked interindividual variation, and has a continuous (bell-shaped) distribution. The levels of blood pressure observed depend on the characteristics of the population studied – in particular, the age and ethnic background. Blood pressure in industrialized countries rises with age, certainly up to the seventh decade. This rise is more marked for systolic pressure and is more pronounced in men.

Hypertension is very common in the developed world. Blood pressure tends to run in families and children of hypertensive parents tend to have higher blood pressure than age-matched children of parents with normal blood pressure. This familial concordance of blood pressure may be explained, at least in part, by shared environmental influences. However, there still remains a large, still largely unidentified genetic component.

**Causes**
The majority (80–90%) of patients with hypertension have primary elevation of blood pressure, i.e. essential hypertension of unknown cause.

**Essential hypertension**

Essential hypertension has a multifactorial aetiology.

**Genetic factors**

Blood pressure tends to run in families and children of hypertensive parents tend to have higher blood pressure than age-matched children of parents with normal blood pressure. This familial concordance of blood pressure may be explained, at least in part, by shared environmental influences. However, there still remains a large, still largely unidentified genetic component.

**Fetal factors**

Low birth weight is associated with subsequent high blood pressure. This relationship may be due to fetal adaptation to intrauterine undernutrition with long-term changes in blood vessel structure or in the function of crucial hormonal systems.

**Environmental factors**

Among the several environmental factors that have been proposed, the following seem to be the most significant:

**Obesity.** Fat people have higher blood pressures than thin people. There is a risk, however, of overestimation if the blood pressure is measured with a small cuff. Adjust the bladder size to the arm circumference. Sleep disordered
breathing (see p. 818) often seen with obesity may be an additional risk factor.

**Alcohol intake.** Most studies have shown a close relationship between the consumption of alcohol and blood pressure level. However, subjects who consume small amounts of alcohol seem to have lower blood pressure level than those who consume no alcohol.

**Sodium intake.** A high sodium intake has been suggested to be a major determinant of blood pressure differences between and within populations around the world. Populations with higher sodium intakes have higher average blood pressures than those with lower sodium intake. Migration from a rural to an urban environment is associated with an increase in blood pressure that is in part related to the amount of salt in the diet. Studies of the restriction of salt intake have shown a beneficial effect on blood pressure in hypertensives. There is some evidence that a high potassium diet can protect against the effects of a high sodium intake.

**Stress.** While acute pain or stress can raise blood pressure, the relationship between chronic stress and blood pressure is uncertain.

**Humoral mechanisms**

The autonomic nervous system, as well as the renin-angiotensin, natriuretic peptide and kallikrein-kinin system, plays a role in the physiological regulation of short-term changes in blood pressure and has been implicated in the pathogenesis of essential hypertension. A low renin, salt-sensitive, essential hypertension in which patients have renal sodium and water retention has been described. However, there is no convincing evidence that the above systems are directly involved in the maintenance of hypertension.

**Insulin resistance**

An association between diabetes and hypertension has long been recognized and a syndrome has been described of hyperinsulinaemia, glucose intolerance, reduced levels of HDL cholesterol, hypertriglyceridaemia and central obesity (all of which are related to insulin resistance) in association with hypertension. This association (also called the ‘metabolic syndrome’, p. 218) is a major risk factor for cardiovascular disease.

**Secondary hypertension**

Secondary hypertension is where blood pressure elevation is the result of a specific and potentially treatable cause (Table 14.51).

**Pathophysiology**

The pathogenesis of essential hypertension remains unclear. In some young hypertensive patients, there is an early increase in cardiac output, in association with increased pulse rate and circulating catecholamines. This could result in changes in baroreceptor sensitivity, which would then operate at a higher blood pressure level.

In **established hypertension** there are:

- **Cardiac changes:**
  - **Resistance vessels** (the small arteries and arterioles) show structural changes in hypertension with an increase in wall thickness and a reduction in the vessel lumen diameter. It is an increased peripheral resistance that maintains the elevated blood pressure. The cardiac output is normal. There is also some evidence for rarefaction (decreased density) of these vessels. These mechanisms would result in an increased overall peripheral vascular resistance.

</table>

- **Large vessel changes occur:** there is thickening of the media, an increase in collagen and the secondary deposition of calcium. These changes result in a loss of arterial compliance, which in turn leads to a more pronounced arterial pressure wave.

- **Pulse wave velocity** is a measure of arterial stiffness and is inversely related to distensibility. With each systolic contraction a pulse wave travels down the arterial wall before the flow of blood. Thus, the more rigid the arterial wall, the faster the wave travels. It can be measured but is not in routine use. Atheroma develops in the large arteries owing to the interaction of these mechanical stresses and low growth factors (see p. 725). Endothelial dysfunction with alternations in agents such as nitric oxide and endothelins appear to be involved.

- **Left ventricular hypertrophy**, which results from increased peripheral vascular resistance and increased left ventricular load, is a significant prognostic indicator of future cardiovascular events.

- **Renal changes:** eventually, changes in the renal vasculature lead to a reduced renal perfusion, reduced glomerular filtration rate and, finally, a reduction in sodium and water excretion. The decreased renal perfusion may lead to activation of the renin-angiotensin system (renin converts angiotensinogen to angiotensin I, which is in turn converted to angiotensin II by angiotensin-converting enzyme) with increased secretion of aldosterone and further sodium and water retention.

- **Cerebral changes** in small vessel cause lacunae (small infarcts) and reversible neurological deficits which do not show abnormalities on imaging. This may lead to dementia and stroke.

**Complications**

Cerebrovascular disease and coronary artery disease are the most common causes of death, although hypertensive patients are also prone to renal failure and peripheral vascular disease (Fig. 14.116).

Hypertensions have a six-fold increase in stroke (both haemorrhagic and atherothrombotic). There is a three-fold increase in cardiac death (due either to coronary events or to cardiac failure). Furthermore, peripheral arterial disease is twice as common.

**Malignant hypertension**

Malignant or accelerated hypertension occurs when blood pressure rises rapidly and is considered with severe
Systemic hypertension

Hypertension (diastolic blood pressure >120 mmHg) (see p. 784). The characteristic histological change is fibrinoid necrosis of the vessel wall and, unless treated, it may lead to death from progressive renal failure, heart failure, aortic dissection or stroke. The changes in the renal circulation result in rapidly progressive renal failure, proteinuria and haematuria. There is also a high risk of cerebral oedema and haemorrhage with resultant hypertensive encephalopathy. In the retina there may be flame-shaped haemorrhages, cotton wool spots, hard exudates and papilloedema (Fig. 14.117). Without effective treatment there is a 1-year survival of <20%.

Assessment

Management should be considered in three stages: assessment, non-pharmacological treatment and drug treatment. During the assessment period, secondary causes of hypertension should be excluded, target-organ damage from the blood pressure should be evaluated and any concomitant conditions (e.g. dyslipidaemia or diabetes) that may add to the cardiovascular burden should be identified.

History

The patient with mild hypertension is usually asymptomatic. Attacks of sweating, headaches and palpitations point towards the diagnosis of phaeochromocytoma. Higher levels of blood pressure may be associated with headaches, epistaxis or nocturia. Breathlessness may be present owing to left ventricular hypertrophy or cardiac failure, while angina or symptoms of peripheral arterial vascular disease suggest the diagnosis of atheromatous renal artery stenosis. This is usually a local manifestation of more generalized atherosclerosis, and patients are often elderly with co-existent vascular disease (Fig. 14.118). Fibromuscular disease of the renal arteries encompasses a group of conditions in which fibrous or muscular proliferation results in morphologically simple or complex stenoses and tends to occur in younger patients (see Ch. 12). Malignant hypertension may present with severe headaches, visual disturbances, fits, transient loss of consciousness or symptoms of heart failure.

Examination

Elevated blood pressure is usually the only abnormal sign. Signs of an underlying cause should be sought, such as renal artery bruits in renovascular hypertension, or radiofemoral delay in coarctation of the aorta. The cardiac examination may also reveal features of left ventricular hypertrophy and a loud aortic second sound. If cardiac failure develops, there may be a sinus tachycardia and a third heart sound.
Cardiovascular disease

Fundoscopy is an essential part of the examination of any hypertensive patient (Fig. 14.117). The abnormalities are graded according to the Keith-Wagener classification:

- **Grade 1** – tortuosity of the retinal arteries with increased reflectiveness (silver wiring)
- **Grade 2** – grade 1 plus the appearance of arteriovenous nipping produced when thickened retinal arteries pass over the retinal veins
- **Grade 3** – grade 2 plus flame-shaped haemorrhages and soft (‘cotton wool’) exudates actually due to small infarcts
- **Grade 4** – grade 3 plus papilloedema (blurring of the margins of the optic disc)

Grades 3 and 4 are diagnostic of malignant hypertension.

**Ambulatory blood pressure monitoring**

Indirect automatic blood pressure measurements can be made over a 24-hour period using a measuring device worn by the patient. The clinical role of such devices remains uncertain, although they are used to confirm the diagnosis in those patients with ‘white-coat’ hypertension, i.e. blood pressure is completely normal at all stages except during a clinical consultation (Fig. 14.119a). These patients do not have any evidence of target-organ damage, and unnecessary treatment can be avoided. These devices may also be used to monitor the response of patients to drug treatment and, in particular, can be used to determine the adequacy of 24 hours control with once-daily medication (Fig. 14.119b,c).

Ambulatory blood pressure recordings seem to be better predictors of cardiovascular risk than clinic measurements. Analysis of the diurnal variation in blood pressure suggests that those hypertensives with loss of the usual nocturnal fall in blood pressure (‘non-dippers’) have a worse prognosis than those who retain this pattern.

**Investigations**

Routine investigation of the hypertensive patient should include:

- Urine stix test for protein and blood
- Fasting blood for lipids (total and HDL cholesterol) and glucose
- Serum urea, creatinine and electrolytes
- ECG.

If the urea or creatinine is elevated, more specific renal investigations are indicated – creatinine clearance, renal ultrasound (in case of polycystic kidney disease, or parenchymal renal artery disease) and a renal isotope scan or renal angiography if renovascular disease (either atheromatous or fibromuscular dysplasia) is suspected. A low serum potassium may indicate an endocrine disorder (either primary hyperaldosteronism or glucocorticoid excess), and aldosterone, cortisol and renin measurements must then be made, preferably prior to initiating pharmacological therapy. Clinical suspicion of phaeochromocytoma should be investigated further with measurement of urinary metanephrines and plasma or urinary catecholamines.
If the ECG shows evidence of coronary artery disease the coronary vascular status should be assessed. If left ventricular hypertrophy or aortic coarctation is suspected echocardiography (or MRI) should be undertaken.

**Treatment**

Unless the patient has severe or malignant hypertension, there should be a period of assessment with repeated blood pressure measurements, combined with advice and non-pharmacological measures prior to the initiation of drug therapy (Table 14.52). The British Hypertension Society provides guidance on when treatment should be commenced (Fig. 14.120).

**Target blood pressure**

- For most patients, a target of ~140 mmHg systolic blood pressure and ~85 mmHg diastolic blood pressure is recommended. For patients with diabetes, renal impairment or established cardiovascular disease a lower target of ~130/80 mmHg is recommended.
- When using ambulatory blood pressure readings, mean daytime pressures are preferred and this value would be expected to be approximately 10/5 mmHg lower than the clinic blood pressure equivalent for both thresholds and targets. Similar adjustments are recommended for averages of home blood pressure readings.

- The main determinant of outcome following treatment is the level of blood pressure reduction that is achieved rather than the specific drug used to lower blood pressure.
- Most hypertensive patients will require a combination of antihypertensive drugs to achieve the recommended targets.

**Figure 14.120 When to initiate treatment.** (From Williams B, Poulter RN, Brown MJ et al. British Hypertension Society guidelines for hypertension management 2004 (BHS-IV): summary. British Medical Journal 2004; 328:634–640, with permission from the BMJ Publishing Group.)
In most hypertensive patients therapy with statins and aspirin is added to reduce the overall cardiovascular risk burden. Glycaemic control should be optimized in diabetics (HbA1c <7%).

The decision to commence specific drug therapy should usually be made only after a careful period of assessment with lifestyle changes, of up to 6 months, with repeated measurements of blood pressure (Fig. 14.120). The aim of drug treatment to reduce the risk of complications of hypertension should be carefully explained to the patient and a plan for the patient’s treatment (drug dose titration, change of drug and combination of drugs) should be agreed with the patient. All of the drugs used to treat hypertension have side-effects and, since the benefits of drug treatment are not immediate, compliance may be a major problem.

Several classes of drugs are available to treat hypertension (Table 14.53). The norm are: (a) ACE inhibitors or angiotensin receptor antagonists; (b) beta-blockers; (c) calcium-channel blockers or (d) diuretics. It is recommended that drugs are chosen according to the scheme laid out in Figure 14.121.

The rationale for Step 1 in this scheme is that young Caucasians are more likely to have high renin hypertension, and older patients and black patients usually have low renin hypertension. If a drug within each pair is not tolerated, the alternative drug type can be used (e.g. if an ACE inhibitor is not tolerated, an angiotensin receptor antagonist). If a drug is not effective, a drug from the other group should be selected. Thus, if a calcium-channel blocker is not helpful, an ACE inhibitor/angiotensin receptor antagonist should be tried. Almost all patients will need more than one drug to effectively lower blood pressure.

Step 2 involves combining one drug from each group.

In Step 3 an ACE inhibitor (or angiotensin receptor antagonists) is combined with a calcium-channel blocker and diuretic. If triple therapy is not sufficient to achieve target blood pressure readings, an alpha-blocker, beta-blocker or spironolactone, or another agent may be used. It is not advisable to combine a diuretic with a beta-blocker since both aggravate diabetes.

Diuretics

Thiazide diuretics in low dosage are well-established agents which have been shown to reduce the risk of stroke in patients with hypertension. Chlortalidone is the drug of choice. However, they are ineffective in patients who have glomerular filtration rates below 30 ml/min. The majority of side-effects occur with higher doses but include increased serum cholesterol, impaired glucose tolerance, hyperuricaemia (which may precipitate gout) and hypokalaemia. Loop diuretics do have a hypotensive effect, but are not routinely used in the treatment of essential hypertension. Potassium-sparing diuretics are not effective agents when used alone, with the exception of spironolactone in the treatment of hypertension and hypokalaemia associated with primary hyperaldosteronism.

Beta-adrenoceptor blockers

Beta-blockers are no longer a preferred initial therapy for hypertension but they may be useful in younger people, particularly those with an intolerance or contraindication to ACE inhibitors and angiotensin-II receptor antagonists; women of child-bearing potential; or patients with evidence of increased sympathetic drive. If a second drug is required, add a calcium-channel blocker rather than a thiazide-type diuretic to reduce the patient’s risk of developing diabetes. Beta-blockers exert their effects by attenuating the effects of the sympathetic nervous and the renin-angiotensin systems. Atenolol has been shown to reduce brachial arterial pressure but not aortic pressure, which is more significant in causing strokes and heart attacks. The major side-effects of this class of agents are bradycardia, bronchospasm, cold extremities, fatigue, bad dreams and hallucinations. These agents are especially useful in the treatment of patients with hypertension and angina.

Angiotensin-converting enzyme (ACE) inhibitors

These drugs block the conversion of angiotensin I to angiotensin II, which is a potent vasoconstrictor. They also block the degradation of bradykinin, a potent vasodilator. There is evidence that black African patients respond less well to ACE inhibitors unless combined with diuretics. They are particularly useful in diabetics with nephropathy, where they have been shown to slow disease progression, and in those patients with symptomatic or asymptomatic left ventricular dysfunction, where they have been shown to improve survival.

Profound hypotension following the first dose is occasionally seen in sodium-depleted patients or in those on treatment with large doses of diuretics. Renal function should be monitored during therapy as deterioration may occur in patients with severe bilateral renovascular disease (in whom the production of angiotensin II is playing a major role in maintaining renal perfusion by causing effenter arteriolar constriction at the glomerulus). The most common side effect is a mild dry cough due to their effect on bradykinin.

**Angiotensin II receptor antagonists**

This group of agents selectively block the receptors for angiotensin II. They share many of the actions of ACE inhibitors but, since they do not have any effect on bradykinin, do not cause a cough. They are used for patients who cannot tolerate ACE inhibitors because of persistent cough.

**Calcium-channel blockers**

These agents effectively reduce blood pressure by causing arteriolar dilatation, and some also reduce the force of Angioneurotic oedema and renal dysfunction are encountered less with these drugs than with ACE inhibitors.

**Further Reading**

cardiac contraction. Like the beta-blockers, they are especially useful in patients with concomitant ischaemic heart disease. The major side-effects are particularly seen with the short-acting agents and include headache, sweating, swelling of the ankles, palpitations and flushing.

**Alpha-blockers**
These agents cause postsynaptic α₁-receptor blockade with resulting vasodilatation and blood pressure reduction. Earlier short-acting agents caused serious first-dose hypotension, but the newer longer-acting agents are far better tolerated.

**Renin inhibitors**
Aliskiren is the first orally active renin inhibitor which directly inhibits plasma renin activity: it reduces the negative feedback by which angiotensin II inhibits renin release. It has been used in combination with ACE inhibitors and angiotensin receptor blockers with a significant reduction in blood pressure. However, a recent FDA warning suggests avoiding these drugs in combination with aliskerin. Side-effects are few but hypokalaemia occurs.

**Other vasodilators**
These agents cause postsynaptic α₁-receptor blockade with resulting vasodilatation and blood pressure reduction. Earlier short-acting agents caused serious first-dose hypotension, but the newer longer-acting agents are far better tolerated.

**Management of severe or malignant hypertension**
Patients with severe hypertension (diastolic pressure >140 mmHg), malignant hypertension (grades 3 or 4 renalopa-thy), hypertensive encephalopathy or with severe hypertensive complications, such as cardiac failure, should be admitted to hospital for immediate initiation of treatment. However, it is unwise to reduce the blood pressure too rapidly, since this may lead to cerebral, renal, retinal or myocardial infarction, and the blood pressure response to therapy must be carefully monitored, preferably in a high-dependency unit. In most cases, the aim is to reduce the diastolic blood pressure to 100–110 mmHg over 24–48 hours. This is usually achieved with oral medication, e.g. amlodipine. The blood pressure can then be normalized over the next 2–3 days.

When rapid control of blood pressure is required (e.g. in an aortic dissection), the agent of choice is intravenous sodium nitroprusside. Alternatively, an infusion of labetalol can be used. The infusion dosage must be titrated against the blood pressure response.

**Management of hypertension in pregnancy**
There are three types of hypertension seen in pregnant women:

1. Chronic or pre-existing hypertension
2. Gestational hypertension
3. Pre-eclampsia and eclampsia.

During the normal pregnancy there is a reduction in blood pressure due to a fall in systemic vascular resistance which is maximal by weeks 22–24. Patients with pre-existing hypertension should discontinue ACE inhibitors and ARBs which are associated with abnormalities of the developing fetal renal system. The first-line therapy during pregnancy is methyldopa which has no adverse effects on the fetus although sedating side-effects may limit up-titration. Second-line agents include nifedipine and labetalol. The target blood pressure should be <150/100 mmHg.

Gestational hypertension is a blood pressure of >140/90 mmHg in the 2nd trimester in a previously normo-tensive woman. These patients should have twice-weekly BP measurements and urine tested for protein as there is an increased risk of developing pre-eclampsia. Patients with moderate hypertension (159–160/109–110 mmHg) should commence oral labetalol and have blood tests performed (electrolytes, blood count, liver function tests) and those with severe hypertension (>160/110 mmHg) should be admitted to hospital.

Pre-eclampsia is a multi-system disorder that occurs after 20 weeks’ gestation consisting of:

- Hypertension
- Oedema
- Proteinuria (>0.3 g/24 hours).

These patients should be admitted and treated for hypertension with regular BP measurements (4 times daily) and blood tests 2–3/week. Patients require close fetal monitoring due to the risks of placental insufficiency and intrauterine growth retardation. Patients who progress to eclampsia (convulsions) and/or HELLP (haemolysis, elevated liver enzymes, low platelet count) syndrome should be admitted to a critical care unit and may require intravenous hydralazine, labetalol, and magnesium sulphate (for convulsions) and prompt delivery.

**Prognosis**
The prognosis from hypertension depends on a number of features:

- Level of blood pressure
- Presence of target-organ changes (retinal, renal, cardiac or vascular)
- Co-existing risk factors for cardiovascular disease, such as hyperlipidaemia, diabetes, smoking, obesity, male sex
- Age at presentation.

Several studies have confirmed that the treatment of hypertension, even mild hypertension, will reduce the risk not only of stroke but of coronary artery disease as well.

### Peripheral Vascular Disease

**Peripheral arterial disease**
Peripheral vascular disease (PVD) is commonly caused by atherosclerosis and usually affects the aorto-iliac or infrain- guinal arteries. It is present in 7% of middle-aged men and 4.5% of middle-aged women, but these patients are more likely to die of myocardial infarction or stroke than lose their leg.

Limb ischaemia may be classified as chronic or acute.

**Chronic lower limb ischaemia**

**Symptoms**
Peripheral arterial disease can be described using the Fontaine classification:

- Stage I – asymptomatic
- Stage II – intermittent claudication
- Stage III – rest pain/nocturnal pain
- Stage IV – necrosis/gangrene.
Patients with **intermittent claudication** complain of exertional discomfort most commonly in the calf which is relieved by rest. Patients with aorto-iliac disease may experience pain in the buttock, hip or thigh and may notice erectile dysfunction. The ‘claudication-distance’ may be reproducible.

Patients with **rest pain** experience severe unremitting pain in the foot, which stops a patient from sleeping. It is partially relieved by dangling the foot over the edge of the bed or standing on a cold floor.

Patients with severe PVD or critical lower limb ischaemia may have ulceration or **necrosis** of the tissue (**gangrene**).

**Signs**
The lower limbs are cold with dry skin and lack of hair. Pulses may be diminished or absent. Ulceration may occur in association with dark discoloration of the toes or gangrene. The abdomen should be examined for a possible aneurysm.

**Risk factors**
Common risk factors are:
- Smoking
- Diabetes
- Hypercholesterolaemia
- Hypertension.

Premature atherosclerosis in patients aged <45 years may be associated with thrombophilia and hyper-homocysteinaemia.

**Differential diagnosis**
Symptoms may be confused with those of:
- Spinal canal claudication (but all pulses are present)
- Osteoarthritis hip/knee (knee pain often at rest)
- Peripheral neuropathy (associated with numbness and tingling)
- Popliteal artery entrapment (young patients who may have normal pulses)
- Venous claudication (bursting pain on walking with a previous history of a DVT)
- Fibromuscular dysplasia
- Buerger’s disease (young males, heavy smokers).

**Investigations**
An estimation of the anatomical level of disease may be possible with the examination of pulses. The severity of disease is indicated by **ankle/brachial pressure index** (ABPI). This is a measurement of the cuff pressure at which blood flow is detectable by Doppler in the posterior tibial or anterior tibial arteries compared to the brachial artery (ankle/brachial pressure). Intermittent claudication is associated with an ABPI of 0.5–0.9. Values of <0.5 are associated with critical limb ischaemia. The sensitivity of the test may be improved by a fall in ABPI after exercise. If the arteries are heavily calcified and incompressible, i.e. in renal or diabetic disease, the ABPI will be falsely elevated. In these patients toe pressure values are more sensitive. Diagnostic imaging includes:

- Digital subtraction angiography (DSA) – provides an arterial map (Fig. 14.122) but requires peripheral arterial cannulation and exposes the patient to ionised contrast and should be reserved for patients immediately prior to intervention.
- Duplex ultrasound using B-mode ultrasound and colour Doppler can provide an accurate anatomical map of the lower limbs with sensitivity of 87% and specificity of 94% compared to angiography although it is operator dependent.
- 3D-contrast enhanced magnetic resonance angiography provides excellent imaging of both legs with a single contrast injection without exposure to ionizing radiation. Sensitivity of 97% and specificity of 96% are reported.
- Computed tomography angiography is an effective alternative to MRA although extensive calcification may obscure stenoses. CTA requires ionising radiation and iodinated contrast media.

**Management**

**Medical**
All patients with peripheral vascular disease need aggressive risk factor management. Patients are encouraged to stop smoking and need smoking cessation advice. Patients with diabetes mellitus need regular chiropody care and diabetic management. Hypercholesterolaemia should be treated as this reduces disease progression. It has been shown by the Heart Protection Study that even the reduction of a normal cholesterol level reduces mortality from cardiovascular disease. Patients with peripheral arterial disease and a total cholesterol level above 3.5 mmol/L should be treated with statin therapy. Low-dose aspirin reduces the risk of myocardial infarction and stroke in patients with peripheral vascular disease. Patients should be encouraged to exercise and to avoid obesity.

**Pharmacological**
- **Cilostazol** is a phosphodiesterase III inhibitor that increases levels of cyclic AMP and produces vasodilation and reversibly inhibits platelet aggregation. At a dose of 100 mg twice daily it can increase walking distance in patients with short-distance claudication.
- **Naftidrofuryl** is a vasodilator agent than inhibits vascular and platelet 5-HT_2 receptors can reduce lactic acid levels. At a dose of 1–200 mg three times a day it may increase walking distance and improve quality of life.
Oxpentifyline, inositol nicotinate, and cinnarizine are not currently recommended for patients with claudication.

Surgical/radiological
Vascular intervention for stable claudication is not generally recommended except in patients with severe or disabling symptoms. Percutaneous transluminal angioplasty is the first option and is carried out via a catheter inserted into the femoral artery. The long-term patency rates decrease as the angioplasty becomes more distal. The long-term results of angioplasty appear to be similar to those of a continued exercise programme. Arterial stents may be deployed in recurrent iliac disease, and drug-eluting stents allowing long-term patency are being used, e.g. paclitaxel. Bypass procedures may be performed using Dacron, polytetrafluoroethylene (PTFE) or autologous veins. Bypasses to distal vessels have poorer long-term patencies. Prosthetic grafts have equal patencies in above-knee bypasses but are inferior to veins below the knee. In severe ischaemia with unreconstructable arterial disease an amputation may be necessary. An amputation may lead to loss of independence, with only 70% of below-knee and 30% of above-knee amputees achieving full mobility.

Acute lower limb ischaemia

Symptoms
Patients complain of the five Ps. They complain of: pain, that the leg looks white (pallor), paraesthesia, paralysis and that it feels perishingly cold. The pain is unbearable and normally requires opioids for relief.

Signs
The limb is cold with mottling or marbling of the skin. Pulses are diminished or absent. The sensation and movement of the leg are reduced in severe ischaemia. Patients may develop a compartment syndrome with pain in the calf on compression.

Causes
Acute limb ischaemia (ALI) may occur because of embolic or thrombotic disease. Embolic disease is commonly due to cardiac thrombus and cardiac arrhythmias. Rheumatic fever is now an uncommon cause and the frequency of cardiac embolic ALI is also on the decline. Emboli may also occur secondary to aneurysm thrombus or thrombus on atherosclerotic plaques. Emboli from atrial myxomas are rare.

Acute limb ischaemia is now often due to thrombotic disease. Acute thrombus usually forms on a chronic atherosclerotic stenosis in a patient who has previously reported symptoms of claudication. Thrombus may also form in normal vessels in patients who are hypercoagulable because of malignancy or thrombophilia defects. Prosthetic or venous grafts may also thrombose either de novo or secondary to a developing stenosis either in the graft or in the native vessels. Popliteal aneurysms may thrombose or embolize distally. Acute upper limb ischaemia may be caused by similar processes or occur secondary to external compression with a cervical rib/band.

Investigation and management
Investigations are similar to those described for chronic lower limb disease.

Medical
Management is dependent on the degree of ischaemia. Patients showing improvement may be treatable with heparin and appropriate treatment of the underlying cause. Patients with emboli following myocardial infarction or atrial fibrillation need long-term warfarin.

Surgical/radiological
Patients with mild to moderate ischaemic symptoms who have occluded a graft may need graft thrombolysis. Intraarterial thrombolysis may reveal an underlying stenosis within a graft or native vessel that could be treated with angioplasty. Patients with an embolus may benefit from its surgical removal (embolectomy). A bypass graft may be required after occlusion of a popliteal aneurysm or acute-on-chronic lower limb arterial disease. When an ischaemic limb is revascularized, the sudden improvement in blood flow can cause reperfusion injury with release of toxic metabolites into the circulation. In muscle compartments the consequent oedema may lead to a ‘compartment syndrome’, which requires fasciotomies (release of the fascia to prevent muscle damage). An amputation may be warranted in unreconstructable or severe ischaemia. In patients dying from other causes, acute limb ischaemia may occur and intervention may then be inappropriate.

Aneurysmal disease
Aneurysms are classified as true and false. An aneurysm is defined if there is a permanent dilatation of the artery to twice the normal diameter. In true aneurysms the arterial wall forms the wall of the aneurysm. The arteries most frequently involved are the abdominal aorta, iliac, popliteal, femoral artery and thoracic aorta (in decreasing frequency). In false aneurysms (pseudoaneurysms) the surrounding tissues form the wall of the aneurysm. False aneurysms can occur following femoral artery puncture. A haematoma is formed because of inadequate compression of the entry site and continued bleeding into the surrounding compressed soft tissue forms the wall of this aneurysm.

Abdominal aortic aneurysm
Abdominal aortic aneurysms (AAA) occur most commonly below the renal arteries (infrarenal). The incidence increases with age, being present in 5% of the population >60 years. They occur five times more frequently in men and in one in four male children of an affected individual. Aneurysms may occur secondary to atherosclerosis, infection (syphilis, Escherichia coli, Salmonella) and trauma, or may be genetic (Marfan’s syndrome, Ehlers–Danlos syndrome).

Symptoms
Most aneurysms are asymptomatic and are found on routine abdominal examination, plain X-ray or during urological investigations. Rapid expansion or rupture of an AAA may cause severe pain (epigastric pain radiating to the back). A ruptured AAA causes hypotension, tachycardia, profound anaemia and sudden death. The symptoms of rupture may mimic renal colic, diverticulitis and severe lower abdominal or testicular pain. Gradual erosion of the vertebral bodies may cause nonspecific back pain. The aneurysm may embolize distally. Inflammatory aneurysms can obstruct adjacent structures, e.g. ureter, duodenum and vena cava. Rarely patients with aneurysms can present with severe haematemesis secondary to an aortoduodenal fistula.

Signs
The aorta is retroperitoneal and in overweight patients there may be no overt signs. An aneurysm is suspected if a
pulsatile, expansile abdominal mass is felt. The presence of an AAA should alert a clinician to the possibility of popliteal aneurysms. Patients may present with ‘trash feet’, dusky discoloration of the digits secondary to embolism from the aortic thrombus.

**Investigations**

The UK NHS has introduced a screening programme for AAA using ultrasound for all men in their 65th year (http://aasa.screening.nhs.uk/public), although scanning at men and women at an earlier age may be appropriate in first-degree relatives of an affected individual. Patients diagnosed with an AAA may require further assessment with MRI or CT to assess the anatomical relationship to the renal and visceral vessels and for patients referred for intervention.

**Management**

Like any operation, the management of an asymptomatic aneurysm depends on the balance of operative risk and conservative management. The UK Small Aneurysm Trial showed that patients with infrarenal AAA did best with an operation if the aneurysm was:

- \[ \geq 5.5 \text{ cm diameter} \]
- expanding \( >1 \text{ cm/year} \)
- symptomatic.

**Medical**

Patients with aneurysmal disease need careful control of hypertension, to stop smoking and to have lipid-lowering medication. Patients with AAA <5.5 cm are followed up by regular ultrasound surveillance.

**Repair of abdominal aortic aneurysm**

Standard therapy is open surgical repair with insertion of a Dacron or Gore-Tex graft.

**Endovascular stent**

Endovascular stent insertion (via the femoral or iliac arteries) is a non-surgical approach to AAA repair. The endovascular Aneurysm Repair studies EVAR (stent vs open surgical repair) and EVAR 2 (stent vs medical therapy in patients unsuitable for open repair) investigated the role of endovascular stents in patients with AAA ≥5.5 cm on CT. In EVAR the 30-day mortality rate was 1.7% with stenting versus 4.7% with surgery \( (p=0.009) \) but the long-term mortality rate was similar in both groups at 4 years. In EVAR 2 the 30-day mortality rate with stenting was 9%. Long-term mortality rate was similar in both stent and medical therapy groups. A meta-analysis of three randomized control trials demonstrated a 30-day mortality rate of 2% for stent-graft repair versus 5% for open surgical repair; with reductions in ITU and in-hospital stay with stent-graft repair.

**Laparoscopic surgery**

An alternative to open-surgical repair or endovascular stenting is laparoscopic repair that is performed with hand-assisted laparoscopic surgery (HALS, requiring a midline mini-laparotomy) or by total laparoscopic surgery (TLS). In non-randomized controlled trials both methods were associated with reduced length of stay, although the operating times were longer.

**Prognosis**

After repair, patients with an AAA should return to normal activity within a few months.

**Thoraco-abdominal aneurysm (TAA)**

The ascending, arch or descending thoracic aorta may become aneurysmal. Ascending TAs occur most commonly in patients with Marfan’s syndrome or hypertension. Descending or arch TAs occur secondary to atherosclerosis and are now rarely due to syphilis.

**Symptoms**

Most aneurysms are asymptomatic and are found on routine chest X-ray or cardiological investigation. Rapid expansion may cause severe pain (chest pain radiating to the upper back) and rupture is associated with hypotension, tachycardia and death. Chest symptoms from expansion may include stridor (compressed bronchial tree), haemoptysis (aortobronchial fistula) and hoarseness (compression of the recurrent laryngeal nerve). Aorto-oesophageal fistula uncommonly causes haematemesis.

**Investigations**

- **CT or MRI scans** are used for assessment of a TAA.
- **Aortography** may be used to assess the position of the key branches in relation to the aneurysm.
- **Transoesophageal echocardiography** can be helpful by identifying an aortic dissection.

**Management**

If the aneurysm is >6 cm then operative repair or stenting may be appropriate, but these can be technically difficult and carry a high risk of mortality and paraplegia. EVAR is at present the procedure of choice for isolated descending thoracic aneurysms.

**Acute aortic syndromes**

Acute aortic syndromes include aortic dissection, intramural haematoma (IMH) and penetrating aortic ulcers. Aortic dissection usually begins with a tear in the intima. Blood penetrates the diseased medial layer and then cleaves the intimal laminal plain leading to dissection. IMH is considered a precursor of dissection in which there is rupture of the vasa vasorum in the aortic media with aortic wall infarction. IMH is typically in the descending thoracic aorta. Deep penetrating aortic plaques may lead to IMH, dissection or ulceration/perforation. Aortic dissection is predisposed in patients with autoimmune rheumatic disorders and Marfan’s and Ehlers-Danlos syndromes.

Aortic dissection can be classified according to the timing of diagnosis from the origin of symptoms: acute <2 weeks, subacute 2–8 weeks, chronic >8 weeks with mortality and extension decreasing with time. They can also be classified anatomically:

- **Type A**: involving the aortic arch and aortic valve proximal to the left subclavian artery origin. Includes De Bakey type I (extends to the abdominal aorta) and De Bakey type II (localized to ascending aorta)
- **Type B**: involving the descending thoracic aorta distal to the left subclavian artery origin. De Bakey type III (Fig. 14.123).

**Symptoms**

Most patients present with a sudden onset of severe and central chest pain often that radiates to the back and down the arms, mimicking myocardial infarction. The pain is often described as tearing in nature and may be migratory.

**Further Reading**

**Significant Websites**

Raynaud's phenomenon or Raynaud's disease

Raynaud's phenomenon consists of spasm of the digital arteries, usually precipitated by cold and relieved by heat. If there is no underlying cause, it is known as Raynaud's disease. This affects 5% of the population, mostly women. The disorder is usually bilateral with fingers affected more commonly than toes.

Symptoms
Vasoconstriction causes skin pallor followed by cyanosis due to sluggish blood flow, then redness secondary to hyperaemia. The duration of the attacks is variable but they can sometimes last for hours. Numbness, a burning sensation and severe pain occur as the fingers warm up. In chronic, severe disease tissue infarction and digital loss can occur.

Diagnosis
Primary Raynaud's disease needs to be differentiated from secondary treatable causes leading to Raynaud's phenomenon. These are the rheumatic autoimmune disorders such as systemic sclerosis. It can be associated with atherosclerosis or occupations that involve the use of vibrating tools. Ergot-containing drugs and beta-blockers, and smoking can aggravate symptoms.

Management
Patients should avoid cold provocation by wearing gloves and warm clothes, and stop smoking. Vasodilators can be prescribed but are often unacceptable as cerebral
vaso-dilatation causes severe headaches. Sympathectomy or prostacyclin infusion can be helpful in severe disease.

**Takayasu’s disease**

This is rare, except in Japan. It is known as the pulseless disease or aortic arch syndrome. It is of unknown aetiology and occurs in females. There is a vasculitis involving the aortic arch as well as other major arteries. There is also a systemic illness, with pain and tenderness over the affected arteries. Absent peripheral pulses and hypertension are common. Corticosteroids help the constitutional symptoms. Eventually heart failure and strokes may occur but most patients survive for at least 5 years. Treatment may require a surgical bypass to improve perfusion of the affected areas.

**Thromboangiitis obliterans (Buerger’s disease)**

This disease, involving the small vessels of the lower limbs, occurs in young men who smoke. It is thought by some workers to be indistinguishable from atheromatous disease. However, pathologically there is inflammation of the arteries and sometimes veins that may indicate a separate disease entity. Clinically, it presents with severe claudication and rest pain leading to gangrene. A thrombophlebitis is sometimes present. Treatment is as for all peripheral vascular disease, but patients must stop smoking.

**Cardiovascular syphilis**

This gives rise to:

- Uncomplicated aortitis
- Aortic aneurysms, usually in the ascending part
- Aortic valvulitis with regurgitation
- Stenosis of the coronary ostia.

The diagnosis is confirmed by serology. Treatment is with penicillin. Aneurysms and valvular disease are treated as necessary by the usual methods.

**Peripheral venous disease**

**Varicose veins**

Varicose veins are a common problem, sometimes giving rise to pain. They are treated by injection or surgery.

**Venous thrombosis**

Thrombosis can occur in any vein, but the veins of the leg and the pelvis are the most common sites.

**Superficial thrombophlebitis**

This commonly involves the saphenous veins and is often associated with varicosities. Occasionally the axillary vein is involved, usually as a result of trauma. There is local superficial inflammation of the vein wall, with secondary thrombosis.

The clinical picture is of a painful, tender, cord-like structure with associated redness and swelling.

The condition usually responds to symptomatic treatment with rest, elevation of the limb and analgesics (e.g. non-steroidal anti-inflammatory drugs). The Comparison of Arixtra in Lower Limb Superficial Vein Thrombosis with Placebo (CALISTO) trial demonstrated that a 45-day course of subcutaneous fondaparinux 2.5 mg o.d. compared with placebo significantly reduced the rate of thromboembolic events (pulmonary embolism and deep vein thrombosis) from 1.3% to 0.2% and limited the extension of superficial vein thrombosis to the saphenofemoral junction from 3.4% to 0.3% with no increased risk of bleeding.

**Deep vein thrombosis**

A thrombus forms in the vein, and any inflammation of the vein wall is secondary to this. Thrombosis commonly occurs after periods of immobilization, but it can occur in normal individuals for no obvious reasons. The precipitating factors are discussed on page 728.

A deep vein thrombosis in the legs occurs in 50% of patients after prostatectomy (without prophylactic heparin) or following a cerebral vascular event. In addition, 10% of patients with a myocardial infarct have a clinically detected deep vein thrombosis.

Thrombosis can occur in any vein of the leg or pelvis, but is particularly found in veins of the calf. It is often undetected; autopsy figures give an incidence of over 60% in hospitalized patients. Axillary vein thrombosis occasionally occurs, sometimes related to trauma, but usually for no obvious reason.

**Clinical features**

The individual may be asymptomatic, presenting with clinical features of pulmonary embolism (see p. 764).

A major presenting feature is pain in the calf, often with swelling, redness and engorged superficial veins. The affected calf is often warmer and there may be ankle oedema. Homans’ sign (pain in the calf on dorsiflexion of the foot) is often present, but it is not diagnostic and occurs with all lesions of the calf.

Thrombosis in the iliofemoral region can present with severe pain, but there are often few physical signs apart from occasional swelling of the thigh and/or ankle oedema.

Complete occlusion, particularly of a large vein, can lead to a cyanotic discoloration of the limb and severe oedema, which can very rarely lead to venous gangrene.

Pulmonary embolism can occur with any deep vein thrombosis but is more frequent from an iliofemoral thrombosis and is rare with thrombosis confined to veins below the knee. In 20–30% of patients, spread of thrombosis can occur proximally without clinical evidence, so careful monitoring of the leg, usually by ultrasound, is required.

**Investigations**

Clinical diagnosis is unreliable but combined with D-dimer level it has a sensitivity of 90%. Confirmation of an iliofemoral thrombosis can usually be made with B mode venous compression, ultrasonography or Doppler ultrasound with a sensitivity and specificity over 90%.

Below-knee thromboses can be detected reliably only by venography with non-invasive techniques, ultrasound, fibrinogen scanning and impedance plethysmography, having a sensitivity of only 70%. A venogram is performed by injecting a vein in the foot with contrast, which will detect virtually all thrombi that are present.

**Treatment**

The main aim of therapy is to prevent pulmonary embolism, and all patients with thrombi above the knee must be anticoagulated. Anticoagulation of below-knee thrombi is now recommended for 6 weeks, as 30% of patients will have an extension of the clot proximally. Bed rest is advised until the patient is fully anticoagulated. The patient should then be mobilized, with an elastic stocking giving graduated pressure over the leg.

**Low-molecular-weight heparins** (LMWH) (see p. 427) have replaced unfractionated heparin as they are more
effective, they do not require monitoring and there is less risk of bleeding. DVTs are being treated at home with low-molecular-weight heparin. Warfarin is started immediately and the heparin stopped when the INR is in the target range. The duration of warfarin treatment is debatable – 3 months is the period usually recommended, but 4 weeks is long enough if a definite risk factor (e.g. bed rest) has been present. Recurrent DVTs need permanent anticoagulants. The target INR should be 2.5. Anticoagulants do not lyse the thrombus that is already present. Unfractionated heparin should only be used if LMWH is unavailable.

**Thrombolytic therapy** (see p. 426) is occasionally used for patients with a large iliofemoral thrombosis.

**Prognosis**

Destruction of the deep vein valves produces a clinically painful, swollen limb that is made worse by standing and is accompanied by oedema and sometimes venous eczema. It occurs in approximately half of the patients with clinically symptomatic deep vein thrombosis, and it means that elastic support stockings are then required for life.

**Prevention**

An estimated 25 000 people in the UK die every year from a preventable hospital-acquired venous thromboembolism (VTE). In January 2010 the National Institute for Health and Clinical Excellence provided guidelines on the assessment and prevention of VTE in patients admitted to hospital:

- All patients should be assessed on admission to hospital (and again within 24 hours or when a change occurs in the patient’s clinical condition).
- Medical patients are at risk if they have reduced mobility for ≥3 days or if their mobility is reduced and they have ≥1 risk factor for VTE (Table 14.54).
- Surgical and trauma patients are at risk:
  - if they undergo a surgical procedure with a combined anaesthetic and surgery of >90 min (60 min if surgery on pelvis or lower limb)
  - if they are admitted with an acute inflammatory or intra-abdominal condition
  - if they have significantly reduced mobility
  - if they have ≥1 risk factor for VTE.

Patients at risk should be considered for pharmacological prophylaxis (fondaparinux or low-molecular-weight heparin or unfractionated heparin if renal impairment) unless they have a risk factor for bleeding (Table 14.55) that outweighs the benefits of VTE prophylaxis. Patients should also be encouraged to mobilize where possible and mechanical VTE (anti-thrombosis stockings (thigh or knee length), foot impulse devices, intermittent pneumatic compression devices (thigh or knee length) may be appropriate in certain patients. On discharge patients should be provided with advice on the signs and symptoms of VTE and if prescribed pharmacological or mechanical prophylaxis advice on their usage. (Anti-thrombin is now being used in orthopaedic surgery, see Chapter 8.)

INTRODUCTION
The main role of the respiratory system is to extract oxygen from the external environment and dispose of waste gases, principally carbon dioxide. This requires the lungs to function as efficient bellows, bringing in fresh air and delivering it to the alveoli, and expelling used air at an appropriate rate. Gas exchange is achieved by exposing thin-walled capillaries to the alveolar gas and matching ventilation to blood flow through the pulmonary capillary bed. In doing this, the lungs expose a large area of tissue, which can be damaged by dusts, gases and infective agents. Host defence is therefore a key priority for the lung and is achieved by a combination of structural and immunological defences.

STRUCTURE OF THE RESPIRATORY SYSTEM
The nose, pharynx and larynx
See Chapter 21 (p. 1052).

The trachea, bronchi and bronchioles
The trachea is 10–12 cm in length. It lies slightly to the right of the midline and divides at the carina into right and left main bronchi. The carina lies under the junction of the manubrium sterni and the second right costal cartilage. The right main bronchus is more vertical than the left and, hence, inhaled material is more likely to end up in the right lung.
The lungs

The lungs are separated into lobes by invaginations of the pleura, which are often incomplete. The right lung has three lobes, whereas the left lung has two. The positions of the oblique fissures and the right horizontal fissure are shown in Figure 15.4. The upper lobe lies mainly in front of the lower lobe and therefore physical signs on the right side in the front of the chest are due to lesions of the upper lobe or the middle lobe.

Each lobe is further subdivided into bronchopulmonary segments by fibrous septa that extend inwards from the pleural surface. Each segment receives its own segmental bronchus.

The bronchioles finally divide within the acinus into smaller respiratory bronchioles that have alveoli arising from the surface (Fig. 15.2). Each respiratory bronchiole supplies approximately 200 alveoli via alveolar ducts. The term ‘small airways’ refers to bronchioles of <2 mm; the average lung contains about 30,000 of these.

The alveoli

There are approximately 300 million alveoli in each lung. Their total surface area is 40–80 m². The epithelial lining consists mainly of type I pneumocytes (Fig. 15.3). These cells have an extremely thin layer of cytoplasm, which only offers a thin barrier to gas exchange. Type I cells are connected to each other by tight junctions that limit the movements of fluid in and out of the alveoli. Alveoli are not completely airtight – many have holes in the alveolar wall allowing communication between alveoli of adjoining lobules (pores of Kohn).

Type II pneumocytes are slightly more numerous than type I cells but cover less of the epithelial lining. They are found generally in the borders of the alveolus and contain distinctive lamellar vacuoles, which are the source of surfactant. Type I pneumocytes are derived from type II cells. Large alveolar macrophages are present within the alveoli and assist in defending the lung.

Figure 15.1 Cross-section of a cilia. Nine outer microtubular doublets and two central single microtubules are linked by spokes, nexin links and dynein arms.

Figure 15.2 Branches of a terminal bronchiole ending in the alveolar sacs.

cilia. Mucus, which contains macrophages, cell debris, inhaled particles and bacteria, is moved by the cilia towards the larynx at about 1.5 cm/min (the ‘mucociliary escalator’, see below).

The pleura

The pleura is a layer of connective tissue covered by a simple squamous epithelium. The visceral pleura covers the surface of the lung, lines the interlobar fissures, and is continuous at the hilum with the parietal pleura, which lines the inside of the hemithorax. At the hilum the visceral pleura continues alongside the branching bronchial tree for some distance before reflecting back to join the parietal pleura. In health, the pleurae are in apposition apart from a small quantity of lubricating fluid.

The diaphragm

The diaphragm is covered by parietal pleura above and peritoneum below. Its muscle fibres arise from the lower ribs and insert into the central tendon. Motor and sensory nerve fibres go separately to each half of the diaphragm via the phrenic nerves. Fifty per cent of the muscle fibres are of the slow-twitch type with a low glycolytic capacity; they are relatively resistant to fatigue.

Pulmonary vasculature and lymphatics

The lung has a dual blood supply, receiving deoxygenated blood from the right ventricle via the pulmonary artery and oxygenated blood via the bronchial circulation.
The pulmonary artery divides to accompany the bronchi. The arterioles accompanying the respiratory bronchioles are thin-walled and contain little smooth muscle. The pulmonary venules drain laterally to the periphery of the lobules, pass centrally in the interlobular and intersegmental septa, and eventually join to form the four main pulmonary veins.

The bronchial circulation arises from the descending aorta. These bronchial arteries supply tissues down to the level of the respiratory bronchiole. The bronchial veins drain into the pulmonary vein, forming part of the normal physiological shunt.

Nerve supply to the lung
The innervation of the lung remains incompletely understood. Parasympathetic and sympathetic fibres (from the vagus and sympathetic chain respectively) accompany the pulmonary arteries and the airways. Airway smooth muscle is innervated by vagal afferents, postganglionic muscarinic vagal efferents and vagally derived non-adrenergic non-cholinergic (NANC) fibres which use a range of neurotransmitters including substance P, neurokinins A and B, calcitonin gene-related peptide, vasoactive intestinal polypeptide and various adenosine and guanine phosphates. Three muscarinic receptor subtypes have been identified: M1 receptors on parasympathetic ganglia, a smaller number of M2 receptors on muscarinic nerve terminals, and M3 receptors on airway smooth muscle. The parietal pleura is innervated from intercostal and phrenic nerves but the visceral pleura has no innervation.

Breathing
Lung ventilation can be considered in two parts:
- The mechanical process of inspiration and expiration
- The control of respiration to a level appropriate for metabolic needs.

Mechanical process
The lungs have an inherent elastic property that causes them to tend to collapse away from the thoracic wall, generating a negative pressure within the pleural space. The strength of this retractive force relates to the volume of the lung: at higher lung volumes the lung is stretched more, and a greater negative intrapleural pressure is generated. Lung compliance is a measure of the relationship between this retractive force and lung volume. At the end of a quiet expiration, the retractive force exerted by the lungs is balanced by the tendency of the thoracic wall to spring outwards. At this point, respiratory muscles are resting. The volume of air remaining in the lung after a quiet expiration is called the functional residual capacity (FRC).

Inspiration from FRC is an active process: a negative intrapleural pressure is created by descent of the diaphragm and movement of the ribs upwards and outwards through contraction of the intercostal muscles. During tidal breathing in healthy individuals, inspiration is almost entirely due to contraction of the diaphragm. More vigorous inspiration requires the use of accessory muscles of ventilation (sternomastoid and scalene muscles). Respiratory muscles are similar to other skeletal muscles but are less prone to

The nose
The major functions of nasal breathing are:
- To heat and moisten the air
- To remove particulate matter.
Ventilation is controlled by a combination of neurogenic and chemical factors (Fig. 15.5).

Breathlessness on physical exertion is normal and not considered a symptom unless the level of exertion is very light, such as when walking slowly. Surveys of healthy western populations reveal that over 20% of the general population report themselves as breathless on relatively minor exertion. Although breathlessness is a very common symptom, the sensory and neural mechanisms underlying it remain obscure. The sensation of breathlessness is derived from at least three sources:

- Changes in lung volume. These are sensed by receptors in thoracic wall muscles signalling changes in their length.
- Tension developed by contracting muscles. This is sensed by Golgi tendon organs.
- Central perception of the sense of effort.

The control of respiration

Coordinated respiratory movements result from rhythmical discharges arising in an anatomically ill-defined group of interconnected neurones in the reticular substance of the brainstem, known as the respiratory centre. Motor discharges from the respiratory centre travel via the phrenic and intercostal nerves to the respiratory musculature.

In healthy individuals, the main driver for respiration is the arterial pH, which is closely related to the partial pressure of carbon dioxide in arterial blood. Oxygen levels in arterial blood are usually above the level which triggers respiratory drive. In a typical normal adult at rest:

- The pulmonary blood flow of 5 L/min carries 11 mmol/min (250 mL/min) of oxygen from the lungs to the tissues.
- Ventilation at about 6 L/min carries 9 mmol/min (200 mL/min) of carbon dioxide out of the body.
- The normal pressure of oxygen in arterial blood ($P_{aO2}$) is between 11 and 13 kPa.
- The normal pressure of carbon dioxide in arterial blood ($P_{aCO2}$) is 4.8–6.0 kPa.

Ventilation is controlled by a combination of neurogenic and chemical factors (Fig. 15.5).

Breathlessness on physical exertion is normal and not considered a symptom unless the level of exertion is very light, such as when walking slowly. Surveys of healthy western populations reveal that over 20% of the general population report themselves as breathless on relatively minor exertion. Although breathlessness is a very common symptom, the sensory and neural mechanisms underlying it remain obscure. The sensation of breathlessness is derived from at least three sources:

- Changes in lung volume. These are sensed by receptors in thoracic wall muscles signalling changes in their length.
- Tension developed by contracting muscles. This is sensed by Golgi tendon organs.
- Central perception of the sense of effort.

The airways of the lungs

From the trachea to the periphery, the airways decrease in size but increase in number. Overall, the cross-sectional area available for airflow increases as the total number of airways increases. The airflow rate is greatest in the trachea and slows progressively towards the periphery (since the velocity of airflow depends on the cross-sectional area). In the terminal airways, gas flow occurs solely by diffusion. The resistance to airflow is very low (0.1–0.2 kPa/L in a normal tracheobronchial tree), steadily increasing from the small to the large airways.

Airways expand as the lung volume increases. At full inspiration (total lung capacity, TLC) they are 30–40% larger in
calibre than at full expiration (residual volume, RV). In chronic obstructive pulmonary disease (COPD), the small airways are narrowed but this can be partially compensated by breathing closer to TLC.

**Control of airway tone**

Bronchomotor tone is maintained by vagal efferent nerves and can be reduced by atropine or β-adrenoceptor agonists. Adrenoceptors on the surface of bronchial muscles respond to circulating catecholamines – there is no direct sympathetic innervation. Airway tone shows a circadian rhythm, which is greatest at 04.00 and lowest in the mid-afternoon. Tone can be increased transiently by inhaled stimuli acting on epithelial nerve endings, which trigger reflex bronchoconstriction via the vagus. These stimuli include cigarette smoke, solvents, inert dust and cold air. Airway responsiveness to these stimuli increases following respiratory tract infections even in healthy subjects. In asthma, the airways are very irritable and as the circadian rhythm remains the same, asthmatic symptoms are usually worse in the early morning.

**Airflow**

Movement of air through the airways results from a difference between atmospheric pressure and the pressure in the alveoli; alveolar pressure is negative in inspiration and positive in expiration. During quiet breathing, the pleural pressure is negative throughout the breathing cycle. With vigorous expiratory efforts (e.g. cough), the pleural pressure becomes positive (up to 10 kPa). This compresses the central airways, but the smaller airways do not close off because the driving pressure for expiratory flow (alveolar pressure) is also increased.

Alveolar pressure (P_{ALV}) is equal to the pleural pressure (P_{PL}) plus the elastic recoil pressure (P_{EL}) of the lung.

When there is no airflow (i.e. during a pause in breathing), the tendency of the lungs to collapse (the positive recoil pressure) is exactly balanced by an equivalent negative pleural pressure.

As air flows from the alveoli towards the mouth there is a gradual drop of pressure owing to flow resistance (Fig. 15.6a).

In forced expiration, as mentioned above, the driving pressure raises both the alveolar pressure and the intrapleural pressure. Between the alveolus and the mouth, there is a point (C in Fig. 15.6b) where the airway pressure equals the intrapleural pressure, and the airway collapses. However, this collapse is temporary, as the transient occlusion of the airway results in an increase in pressure behind it (i.e. upstream) and this raises the intra-airway pressure so that the airways open and flow is restored. The airways thus tend to vibrate at this point of ‘dynamic collapse’.

As lung volume decreases during expiration, the elastic recoil pressure of the lungs decreases and the ‘collapse point’ moves upstream (i.e. towards the smaller airways – see Fig. 15.6c). Where there is pathological loss of recoil pressure (as in chronic obstructive pulmonary disease, COPD), the ‘collapse point’ is located even further upstream and causes expiratory flow limitation. The measurement of the forced expiratory volume in 1 second (FEV₁) is a useful clinical index of this phenomenon. To compensate, patients with COPD often ‘purse their lips’ in order to increase airway pressure so that their peripheral airways do not collapse. During inspiration, the intrapleural pressure is always less than the intraluminal pressure within the intrathoracic airways, so increasing effort does not limit airflow. Inspiratory flow is limited only by the power of the inspiratory muscles.

**Flow-volume loops**

The relationship between maximal flow rates and lung volume is demonstrated by the maximal flow-volume (MFV) loop (Fig. 15.7a).

In subjects with healthy lungs, maximal flow rates are rarely achieved even during vigorous exercise. However, in patients with severe COPD, limitation of expiratory flow occurs even during tidal breathing at rest (Fig. 15.7b). To increase ventilation these patients have to breathe at higher lung volumes and allow more time for expiration, both of which reduce the tendency for airway collapse. To compensate they increase flow rates during inspiration, where there is relatively less flow limitation.

The volume that can be forced in from the residual volume in 1 second (FIV₁) will always be greater than that which can be forced out from TLC in 1 second (FEV₁). Thus, the ratio of FEV₁ to FIV₁ is below 1. The only exception to this occurs when there is significant obstruction to the airways outside the thorax, such as tracheal tumour or retrosternal goitre. Expiratory airway narrowing is prevented by tracheal resistance and expiratory airflow becomes more effort-dependent. During forced inspiration this same resistance causes such negative intraluminal pressure that the trachea is compressed by the surrounding atmospheric pressure. Inspiratory flow thus becomes less effort-dependent, and the ratio of FEV₁ to FIV₁ exceeds 1. This phenomenon, and the characteristic
Ventilation and perfusion relationships

For optimum gas exchange there must be a match between ventilation of the alveoli (V̇ₐ) and their perfusion (Q̇). However, in reality there is variation in the (V̇ₐ/Q̇) ratio in both normal and diseased lungs (Fig. 15.8). In the normal lung both ventilation and perfusion are greater at the bases than at the apices, but the gradient for perfusion is steeper, so the net effect is that ventilation exceeds perfusion towards the apices, while perfusion exceeds ventilation at the bases. Other causes of (V̇ₐ/Q̇) mismatch include direct shunting of deoxygenated blood through the lung without passing through alveoli (e.g. the bronchial circulation) and areas of lung that receive no blood (e.g. anatomical deadspace, bullae and areas of underperfusion during acceleration and deceleration, e.g. in aircraft and high performance cars).

An increased physiological shunt results in arterial hypoxaemia since it is not possible to compensate for some of the

Alveolar stability

Pulmonary alveoli are essentially hollow spheres. Surface tension acting at the curved internal surface tends to cause the sphere to decrease in size. The surface tension within the alveoli would make the lungs extremely difficult to distend were it not for the presence of surfactant, an insoluble lipoprotein largely consisting of dipalmitoyl lecithin, which forms
a thin monomolecular layer at the air-fluid interface. Surfactant is secreted by type II pneumocytes within the alveolus and reduces surface tension so that alveoli remain stable.

Fluid surfaces covered with surfactant exhibit a phenomenon known as hysteresis; that is, the surface-tension-lowering effect of the surfactant can be improved by a transient increase in the size of the surface area of the alveoli. During quiet breathing, small areas of the lung undergo collapse, but it is possible to re-expand these rapidly by a deep breath; hence the importance of sighs or deep breaths as a feature of normal breathing. Failure of this mechanism, e.g. in patients with fractured ribs – gives rise to patchy basal lung collapse. Surfactant levels may be reduced in a number of diseases that cause damage to the lung (e.g. pneumonia). Lack of surfactant plays a central role in the respiratory distress syndrome of the newborn. Severe reduction in perfusion of the lung impairs surfactant activity and this may explain the characteristic areas of collapse associated with pulmonary embolism.

DEFENCE MECHANISMS OF THE RESPIRATORY TRACT

Pulmonary disease often results from a failure of the normal host defence mechanisms of the healthy lung (Fig. 15.9). These can be divided into physical, physiological, humoral and cellular mechanisms.

Physical and physiological mechanisms

Humidification

This prevents dehydration of the epithelium.

Particle removal

Over 90% of particles greater than 10 μm diameter are removed in the nostril or nasopharynx. This includes most pollen grains, which are typically >20 μm in diameter. Particles between 5 and 10 μm become impacted at the carina. Particles smaller than 1 μm tend to remain airborne, thus the particles capable of reaching the deep lung are those in the 1–5 μm range.

Particle expulsion

This is effected by coughing, sneezing or gagging.

Respiratory tract secretions (Fig. 15.9)

The mucus of the respiratory tract is a gelatinous substance consisting of water and highly glycosylated proteins (mucins). The mucus forms a thick gel that is relatively impermeable to water and floats on a liquid or sol layer found around the cilia of the epithelial cells. The gel layer is secreted from goblet cells and mucus glands as distinct globules that coalesce increasingly in the central airways to form a more or less continuous mucus blanket. In addition to the mucins, the gel contains various antimicrobial molecules (lysozyme, defensins), specific antibodies (IgA) and cytokines, which are secreted by cells in airways and get incorporated into the mucus gel. Bacteria, viruses and other particles get trapped in the mucus and are either inactivated or simply expelled before they can do any damage. Under normal conditions the tips of the cilia engage with the undersurface of the gel phase and by coordinated movement they push the mucus blanket upwards and outwards to the pharynx where it is either swallowed or coughed up. While it only takes 30–60 minutes for mucus to be cleared from the large bronchi, it can be several days before mucus is cleared from respiratory bronchioles. One of the major long-term effects of cigarette smoking is a reduction in mucociliary transport. This contributes to recurrent infection and prolongs contact with carcinogenic material. Air pollutants, local and general anaesthetics and products of bacterial and viral infection also reduce mucociliary clearance.

Congenital defects in mucociliary transport lead to recurrent infections and eventually to bronchiectasis. For example, in the ‘immotile cilia’ syndrome there is an absence of the dynein arms in the cilia themselves, while in cystic fibrosis there is ciliary dyskinesia and abnormally thick mucus.

Humoral and cellular mechanisms

Nonspecific soluble factors

- α-Antitrypsin (α,-antiprotease, see p. 341) in lung secretions is derived from plasma. It inhibits chymotrypsin and trypsin and neutralizes proteases including neutrophil elastase.
- Antioxidant defences include enzymes such as superoxide dismutase and low-molecular-weight antioxidant molecules (ascorbate, urate) in the epithelial lining fluid. In addition, lung cells are protected by an extensive range of intracellular defences, especially members of the glutathione S-transferase (GST) superfamily.
- Lysozyme is an enzyme found in granulocytes that has bactericidal properties.
- Lactoferrin is synthesized from epithelial cells and neutrophil granulocytes and has bactericidal properties.
- Interferons are produced by most cells in response to viral infection and are potent modulators of lymphocyte function.
- Complement in secretions is also derived from plasma. In association with antibodies, it plays a major role in cytotoxicity.

- Surfactant protein A (SPA) is one of four species of surfactant proteins which opsonizes bacteria/particles, enhancing phagocytosis by macrophages.
Defensins are bactericidal peptides present in the azurophil granules of neutrophils. Dimeric secretory IgA targets specific antigens (p. 262).

Innate and adaptive immunity
These mechanisms act as a defence against microbes, inorganic substances, e.g. asbestos, particulate matter, such as dust, and other antigens. They act by aiding opsonization so that macrophages can better ingest foreign material.

With infection, neutrophils migrate out of pulmonary capillaries into the air spaces and phagocytose and kill microbes with, for example, antimicrobial proteins (lactoferrin), degradative enzymes (elastase) and oxidant radicals. In addition, neutrophil extracellular traps (NET) ensnare and kill extracellular bacteria. Neutrophils also generate a variety of mediators, e.g. TNF-α, IL-1 and chemokines which activate dendritic cells and B cells and produce the T-cell-activating cytokine IL-12. The latter enhances neutrophil-mediated defence during pneumonia. Dendritic cells are antigen presenting cells and are key to the adaptive immune response (p. 58).

Microbes are detected by host cells by pattern recognition receptors, e.g. toll-like receptors. These act via NF-κB transcription factors in the epithelial cells to produce adhesion molecules, chemokines and colony stimulating factors to initiate inflammation. Inflammation is necessary for innate immunity and host defence but can lead to lung damage: there is a fine line between defence and injury.

SYMPTOMS

Runny, blocked nose and sneezing
Nasal symptoms (see also p. 691) are extremely common and both common colds and allergic rhinitis cause ‘runny nose’ (rhinorrhea), nasal blockage and attacks of sneezing. In allergic rhinitis, symptoms may be intermittent, following contact with pollens or animal danders, or persistent, especially when house-dust mite is the allergen. Colds are frequent during the winter but if the symptoms persist for weeks the patient probably has perennial rhinitis rather than persistent viral infection.

Nasal secretions are usually thin and runny in allergic rhinitis but thicker and discoloured with viral infections. Nose bleeds and blood-stained nasal discharge are common and rarely indicate serious pathology. However, a blood-stained nasal discharge associated with nasal obstruction and pain may be the presenting feature of a nasal tumour (p. 1051). Nasal polyps typically present with nasal blockage and loss of smell.

Cough
Cough (see also p. 822) is the commonest symptom of lower respiratory tract disease. It is caused by mechanical or chemical stimulation of cough receptors in the epithelium of the pharynx, larynx, trachea, bronchi and diaphragm. Afferent receptors go to the cough centre in the medulla where efferent signals are generated to the expiratory musculature. Smokers often have a morning cough with a little sputum. A productive cough is the cardinal feature of chronic bronchitis, while dry coughing, particularly at night, can be a symptom of asthma. Cough also occurs in asthmatics after mild exertion or following forced expiration. Cough can also occur for psychological reasons without any definable pathology.

A worsening cough is the most common presenting symptom of lung cancer. The normal explosive character of the cough is lost when a vocal cord is paralysed, usually as a result of lung cancer infiltrating the left recurrent laryngeal nerve – sometimes termed a bovine cough. Cough can be accompanied by stridor in whooping cough or if there is laryngeal or tracheal obstruction.

Sputum
Approximately 100 mL of mucus is produced daily in a healthy, non-smoking individual. This flows gradually up the airways, through the larynx, and is then swallowed. Excess mucus is expectorated as sputum. Cigarette smoking is the commonest cause of excess mucus production.

Mucoid sputum is clear and white but can contain black specks resulting from the inhalation of carbon. Yellow or green sputum is due to the presence of cellular material, including bronchial epithelial cells, or neutrophil or eosinophil granulocytes. Yellow sputum is not necessarily due to infection, as eosinophils in the sputum, as seen in asthma, can give the same appearance. The production of large quantities of yellow or green sputum is characteristic of bronchiectasis. Haemoptysis (blood-stained sputum) varies from small streaks of blood to massive bleeding.

The commonest cause of mild haemoptysis is acute infection, particularly in exacerbations of chronic obstructive pulmonary disease (COPD) but it should not be attributed to this without investigation.

Other common causes are pulmonary infarction, bronchial carcinoma and tuberculosis.

In lobar pneumonia, the sputum is usually rusty in appearance rather than frankly blood-stained.

Pink, frothy sputum is seen in pulmonary oedema.

In bronchiectasis, the blood is often mixed with purulent sputum.

Massive haemoptyses (>200 mL of blood in 24 hours) are usually due to bronchiectasis or tuberculosis.

Uncommon causes of haemoptyses are idiopathic pulmonary haemosiderosis, Goodpasture’s syndrome, microscopic polyangiitis, trauma, blood disorders and benign tumours.

Haemoptysis should always be investigated. Although a diagnosis can often be made from a chest X-ray, a normal chest X-ray does not exclude disease. However, if the chest X-ray is normal, CT scanning and bronchoscopy are only diagnostic in about 5% of patients with haemoptysis.

Firm plugs of sputum may be coughed up by patients suffering from an exacerbation of allergic bronchopulmonary aspergillosis. Sometimes such sputum looks like casts of inflamed bronchi.

Breathlessness
Dyspnoea is a sense of awareness of increased respiratory effort that is unpleasant and that is recognized by the patient as being inappropriate. Patients often complain of tightness in the chest; this must be differentiated from angina.

Breathlessness should be assessed in relation to the patient’s lifestyle. For example, a moderate degree of breathlessness will be totally disabling if the patient has to climb many flights of stairs to reach home.

Orthopnoea (see p. 675) is breathlessness on lying down. While it is classically linked to heart failure, it is partly due to the weight of the abdominal contents pushing the diaphragm up into the thorax. Such patients may also become breathless on bending over.

Tachypnoea and hyperpnoea are, respectively, an increased rate of breathing and an increased level of...
ventilation. These may be appropriate responses (e.g. during exercise).

**Hyperventilation** is inappropriate overbreathing. This may occur at rest or on exertion and results in a lowering of the alveolar and arterial $PO_2$ (see p. 1178).

**Paroxysmal nocturnal dyspnoea** (see p. 798) is acute episodes of breathlessness at night, typically due to heart failure.

**Wheezing**

Wheezing is a common complaint and results from airflow limitation due to any cause. The symptom of wheezing is not diagnostic of asthma; other causes include vocal chord dysfunction, bronchiolitis and chronic obstructive pulmonary disease (COPD). Conversely, wheeze may be absent in the early stages of asthma.

**Chest pain**

The most common type of chest pain reported in respiratory disease is a localized sharp pain, often termed pleuritic. It is made worse by deep breathing or coughing and the patient can usually localize it. Localized anterior chest pain with tenderness of a costochondral junction is caused by costochondritis. Shoulder tip pain suggests irritation of the diaphragmatic pleura, while central chest pain radiating to the neck and arms is likely to be cardiac. Retrosternal soreness is associated with tracheitis, while malignant invasion of the chest wall causes a constant, severe, dull pain.

### Examination of the respiratory system

**The nose** (see p. 1051)

**The chest**

Examination of the chest

**Inspection**

Assess mental alertness, cyanosis, breathlessness at rest, use of accessory muscles, any deformity or scars on the chest and movement on both sides. CO₂ intoxication causes coarse tremor or flap of the outstretched hands. Prominent veins on the chest may imply obstruction of the superior vena cava.

**Cyanosis** (see p. 676) is a dusky colour of the skin and mucous membranes, due to the presence of more than 50 g/L of desaturated haemoglobin. When due to central causes, cyanosis is visible on the tongue (especially the underside) and lips. Patients with central cyanosis will also be cyanosed peripherally. Peripheral cyanosis without central cyanosis is caused by a reduced peripheral circulation and is noted on the fingernails and skin of the extremities with associated coolness of the skin.

**Finger clubbing** is present when the normal angle between the base of the nail and the nail fold is lost. The base of the nail is fluctuant owing to increased vascularity, and there is an increased curvature of the nail in all directions, with expansion of the end of the digit. Some causes of finger clubbing are given in Table 15.1. Clubbing is not a feature of uncomplicated COPD.

**Palpation and percussion**

Check the position of the trachea and apex beat. Examine the supraclavicular fossa for enlarged lymph nodes. The distance between the sternal notch and the cricoid cartilage (three to four finger breadths in full expiration) is reduced in patients with severe airflow limitation. Check chest expansion. A tape measure is used if precise or serial measurements are needed, e.g. in ankylosing spondylitis. Local discomfort over the sternochondral joints suggests costochondritis. In rib fractures, compression of the chest laterally and anteroposteriorly produces localized pain. On percussion, liver dullness is usually detected anteriorly at the level of the sixth rib. Liver and cardiac dullness disappear when lungs are over-inflated (Table 15.2).

**Auscultation**

Ask the patient to take deep breaths through the mouth. Inspiration should be more prolonged than expiration. Normal breath sounds are caused by turbulent flow in the larynx and sound harsher anteriorly over the upper lobes (particularly on the right). Healthy lungs filter out most of the high-frequency component, and the resulting sounds are called vesicular.

If the lung is consolidated or collapsed, the high-frequency hissing components of breath are not attenuated, and can be heard as ‘bronchial breathing’. Similar sounds may be heard over areas of localized fibrosis or bronchiectasis. Bronchial breathing is accompanied by whispering pectoriloquy (whispered, high-pitched sounds can be heard distinctly through a stethoscope).

**Added sounds**

**Wheeze.** Wheeze results from vibrations in the collapsible part of the airways when apposition occurs as a result of the flow-limiting mechanisms. Wheeze is usually heard during expiration and is commonly but not invariably present in asthma and in chronic obstructive pulmonary disease. In acute severe asthma wheeze may not be heard, as airflow may be insufficient to generate the sound. Wheezes may be monophonic (single large airway obstruction) or polyphonic (narrowing of many small airways). An end-inspiratory wheeze or ‘squeak’ may be heard in obliterative bronchiolitis.

**Crackles.** These brief crackling sounds are probably produced by opening of previously closed bronchioles – early inspiratory crackles are associated with diffuse airflow limitation, while late inspiratory crackles are characteristically heard in pulmonary oedema, lung fibrosis and bronchiectasis.

**Pleural rub.** A creaking or groaning sound that is usually well localized. It indicates inflammation and roughening of
Respiratory disease

Chest X-ray. Conversely, asthma or chronic bronchitis may be associated with a normal chest X-ray. Always try to get previous films for comparison.

Chest X-ray
When viewing films consider:

- **Centring of the film.** The distance between each clavicular head and the spinal processes should be equal
- **Penetration** (check film is not too dark)
- **View.** Routine films are taken postero-anterior (PA), i.e. the film is placed in front of the patient with the X-ray source behind. Anteroposterior (AP) films are taken only in very ill patients who are unable to stand up or be taken to the radiology department; the cardiac outline appears bigger and the scapulae cannot be moved out of the way. Lateral chest X-rays were often performed in the past to localize pathology, but CT scans have replaced these.

- Look at:
  - The shape and bony structure of the chest wall
  - Whether the trachea is central
  - Whether the diaphragm is elevated or flat
  - The shape, size and position of the heart
  - The shape and size of the hilar shadows
  - The size and shape of any lung abnormalities and vascular shadowing.

X-ray abnormalities

**Collapse and consolidation**
Simple pneumonia is easy to recognize (see Fig. 15.33) but look carefully for any evidence of collapse (Fig. 15.10, Table 15.3). Loss of volume or crowding of the ribs are the best indicators of lobar collapse. The lung lobes collapse in

Additional bedside tests
Since so many patients with respiratory disease have airflow limitation, airflow should be routinely measured using a peak flow meter or spirometer. This is a much more useful assessment of airflow limitation than any physical sign.

---

the pleural surfaces, which normally glide silently over one another.

**Vocal resonance.** Healthy lung attenuates high-frequency notes, as compared to the lower-pitched components of speech. Consolidated lung has the reverse effect, transmitting high frequencies well; the spoken word then takes on a bleating quality. Whispered (and therefore high-pitched) speech can be clearly heard over consolidated areas, as compared to healthy lung. Low-frequency sounds such as ‘ninety-nine’ are well transmitted across healthy lung to produce vibration that can be felt over the chest wall. Consolidated lung transmits these low-frequency noises less well, and pleural fluid severely dampens or obliterates the vibrations altogether. Tactile vocal fremitus is the palpation of this vibration, usually by placing the edge of the hand on the chest wall. For all practical purposes this duplicates the assessment of vocal resonance and is not routinely performed as part of the chest examination.

**Cardiovascular system examination** (p. 676) gives additional information about the lungs.

---

**INVESTIGATION OF RESPIRATORY DISEASE**

**Imaging**
Radiology is essential in investigating most chest symptoms. Some diseases such as tuberculosis or lung cancer may be undetectable on clinical examination but are obvious on the chest X-ray. Conversely, asthma or chronic bronchitis may be associated with a normal chest X-ray. Always try to get previous films for comparison.

---

800
characteristic directions. The lower lobes collapse downwards and towards the mediastinum, the left upper lobe collapses forwards and towards the anterior chest wall, while the right upper lobe collapses upwards and inwards, forming the appearance of an arch over the remaining lung. The right middle lobe collapses anteriorly and inward, obscuring the right heart border. If a whole lung collapses, the mediastinum will shift towards the side of the collapse. Uncomplicated consolidation does not cause mediastinal shift or loss of lung volume, so any of these features should raise the suspicion of an endobronchial obstruction.

**Pleural effusion**

Pleural effusions (see Fig. 15.45) need to be larger than 500 mL to cause much more than blunting of the costophrenic angle. On an erect film they produce a characteristic shadow with a curved upper edge rising into the axilla. If very large, the whole of one hemithorax may be opaque, with mediastinal shift away from the effusion.

**Fibrosis**

Localized fibrosis causes streaky shadowing, and the accompanying loss of lung volume causes mediastinal structures to move to the same side. More generalized fibrosis can lead to a honeycomb appearance (see p. 849), seen as diffuse shadows containing multiple circular translucencies a few millimetres in diameter.

**Round shadows**

Lung cancer is the commonest cause of large round shadows but many other causes are recognized (Table 15.4).

**Miliary mottling**

This term, derived from the Latin for millet, describes numerous minute opacities, 1–3 mm in size. The commonest causes are tuberculosis, pneumoconiosis, sarcoidosis, idiopathic pulmonary fibrosis and pulmonary oedema (see Fig. 14.15), although pulmonary oedema is usually perihilar and accompanied by larger, fluffy shadows. Pulmonary microlithiasis is a rare but striking cause of miliary mottling.

### Computed tomography

CT provides excellent images of the lungs and mediastinal structures (Fig. 15.11). Narrow slice, high-resolution CT scans show the lung parenchyma well, while thicker slice staging CT scans are used for diagnosis of malignant disease. Mediastinal structures are shown more clearly after injecting intravenous contrast medium.

CT is essential in staging bronchial carcinoma by demonstrating tumour size, nodal involvement, metastases and invasion of mediastinum, pleura or chest wall. CT-guided needle biopsy allows samples to be obtained from peripheral masses. Staging scans should assess liver and adrenals, which are common sites for metastatic disease.

**High-resolution CT** (HRCT) scanning samples lung parenchyma with 1–2 mm thickness scans at 10–20 mm intervals and are used to assess diffuse inflammatory and infective parenchymal processes. It is valuable in:

- Evaluating diffuse disease of the lung parenchyma, including sarcoidosis, hypersensitivity pneumonitis, occupational lung disease, and any other form of interstitial pulmonary fibrosis.
- Diagnosis of bronchiectasis. HRCT has a sensitivity and specificity >90%.
- Distinguishing emphysema from diffuse parenchymal lung disease or pulmonary vascular disease as a cause of a low gas transfer factor with otherwise normal lung function.
- Suspected opportunistic lung infection in immunocompromised patients
- Diagnosis of lymphangitis carcinomatosa.

**Multi-slice CT** scanners can produce detailed images in two or three dimensions in any plane. This detail is particularly useful for the detection of pulmonary emboli. Pulmonary nodules and airway disease are more easily defined and the technique makes HRCT less necessary.

### Magnetic resonance imaging

MRI is less valuable than CT in assessing the lung parenchyma. In the mediastinum, MRI with ECG-gating allows...
accurate imaging of the heart and aortic aneurysms, and MRI has been used in staging lung cancer, for assessing tumour invasion in the mediastinum, chest wall and at the lung apex, because it produces good images in the sagittal and coronal planes. Vascular structures can be clearly differentiated as flowing blood produces a signal void on MRI.

**Positron emission tomography (PET)**

Tumours take up labelled fluorodeoxyglucose (FDG), which emits positrons that can be imaged and helps to differentiate benign from malignant tumours. In bronchial carcinoma, PET scanning combined with CT is now the investigation of choice for assessing lymph nodes and metastatic disease.

**Scintigraphic imaging**

Isotopic lung scans were used widely for the detection of pulmonary emboli but are now performed less often owing to widespread use of D-dimer measurements and CT pulmonary angiography.

**Perfusion scan**

Macro-aggregated human albumin labelled with technetium-99m (Tc) is injected intravenously. The particles impact in pulmonary capillaries, where they remain for a few hours. A gamma camera is then used to detect the deposition of the particles. The resultant pattern indicates the distribution of pulmonary blood flow; cold areas occur where there is defective blood flow (e.g. in pulmonary emboli).

**Ventilation–perfusion scan**

Xenon-133 gas is inhaled and its distribution is detected at the same time as the perfusion scan. Areas affected by pulmonary embolism will have reduced perfusion relative to ventilation (see Chapter 14). Other lung diseases (e.g. asthma or pneumonia) impair both ventilation and perfusion. Unfortunately, a pulmonary embolus can affect the lung substance (e.g. atelectasis) leading to reduced ventilation. Nevertheless, this is a better technique than perfusion scan alone.

**Ultrasound (USS)**

Ultrasound is useful for diagnosing and aspirating small pleural effusions, and for the safe placement of intercostal drains. Ultrasound guided biopsy is used for lung masses that abut the pleura, but ultrasound is not useful for lung parenchymal disease as ultrasound energy is scattered by air. Endobronchial ultrasound is helpful.

**Respiratory function tests** (Table 15.5)

In clinical practice, airflow limitation can be assessed by relatively simple tests that have good intra-subject repeatability. Results must be compared with predicted values for healthy subjects as normal ranges vary with sex, age and height. Moreover, there is considerable variation between healthy individuals of the same size and age; the standard deviation for the peak expiratory flow rate is approximately 50 L/min, and for the FEV; it is approximately 0.4 L. Repeated measurements of lung function are useful for assessing the progression of disease in individual patients.

**Tests of ventilatory function**

These tests are used mainly to assess the degree of airflow limitation during expiration.

**Spirometry**

The patient takes a maximum inspiration followed by a forced expiration (for as long as possible) into the spirometer. The spirometer measures the one second forced expiratory volume (FEV₁) and the total volume of exhaled gas (forced vital capacity, FVC). Both FEV₁ and FVC are related to height, age and sex (Fig. 15.12).

In airflow limitation, the FEV₁ is reduced as a percentage of FVC. In normal health the FEV₁/FVC ratio is around 75%. With increasing airflow limitation FEV₁ falls proportionately more than FVC, so the FEV₁/FVC ratio is reduced. With restrictive lung disease FEV₁ and FVC are reduced proportionately and the FEV₁/FVC ratio remains normal or may even increase because of enhanced elastic recoil.

In chronic airflow limitation (particularly in COPD and asthma) the total lung capacity (TLC) is usually increased, yet there is nearly always some reduction in the FVC. This is due to collapse of small airways causing obstruction to airflow before the normal residual volume (RV) is reached. This trapping of air within the lung is a characteristic feature of these diseases.

**Peak expiratory flow rate (PEFR)**

This is an extremely simple and cheap test. Subjects take a full inspiration to total lung capacity and then blow out forcefully into the peak flow meter (Fig. 15.13). The best of three attempts is recorded.

Although reproducible, PEFR is mainly dependent on the flow rate in larger airways and it may be falsely reassuring in patients with moderate airflow limitation. PEFR is mainly used to diagnose asthma, and to monitor exacerbations of asthma and response to treatment. Regular measurements of peak flow rates on waking, during the afternoon, and before going to bed demonstrate the wide diurnal variations in airflow limitation that characterize asthma and allow objective assessment of response to treatment (Fig. 15.14).

**Other ventilatory function tests**

Measurement of airways resistance in a body box (plethysmograph) is more sensitive but the equipment is expensive...
Respiratory disease

and the necessary manoeuvres are too exhausting for many patients with chronic airflow limitation.

Flow-volume loops
Plotting flow rates against expired volume (flow-volume loops, see Fig. 15.7) shows the site of airflow limitation within the lung. At the start of expiration from TLC, maximum resistance is from the large airways, and this affects the flow rate for the first 25% of the curve. As air is exhaled, lung volume reduces and the flow rate becomes dependent on the resistance of smaller airways. In chronic obstructive pulmonary disease (COPD), where the disease mainly affects the smaller airways, expiratory flow rates at 50% or 25% of the vital capacity are disproportionately reduced when compared with flow rates at larger lung volumes. Flow-volume loops will also show obstruction of large airways, e.g. tracheal narrowing due to tumour or retrosternal goitre.

Lung volumes
The subdivisions of lung volume are shown in Figure 15.15. Tidal volume and vital capacity can be measured using a simple spirometer, but alternative techniques are needed to measure TLC and RV. TLC is measured by inhaling air containing a known concentration of helium and measuring its dilution in the exhaled air. RV can be calculated by subtracting the vital capacity from the TLC.

TLC measurements using this technique are inaccurate if there are large cystic spaces in the lung, because helium cannot diffuse into them. Under these circumstances the thoracic gas volume can be measured more accurately using a body plethysmograph. The difference between measurements made by these two methods shows the extent of non-communicating air space within the lungs.

Transfer factor
To measure the efficiency of gas transfer across the alveolar-capillary membrane carbon monoxide is used as a surrogate, since its diffusion rate is similar to oxygen. A low concentration of carbon monoxide is inhaled and the rate of absorption calculated. In normal lungs the transfer factor accurately reflects the diffusing capacity of the lungs for oxygen and depends on the thickness of the alveolar-capillary membrane. In lung disease the diffusing capacity ($D_{CO}$) is also affected by the ventilation–perfusion relationship. To control for differences in lung volume, the uptake of carbon monoxide is expressed relative to lung volume as a transfer coefficient ($K_{CO}$).

Gas transfer is reduced in patients with severe degrees of emphysema and fibrosis, but also in heart failure and
anaemia. Although relatively nonspecific, gas transfer is particularly useful in the detection and monitoring of diseases affecting the lung parenchyma (e.g. idiopathic pulmonary fibrosis, sarcoidosis, asbestosis).

**Measurement of blood gases**
This technique is described on page 891.

Measurement of the partial pressures of oxygen and carbon dioxide in arterial blood is essential in managing respiratory failure and severe asthma, when repeated measurements are often the best guide to therapy.

Peripheral oxygen saturation (S\textsubscript{O}2) can be continuously measured using an oximeter with either ear or finger probes. Pulse oximetry has become an essential part of routine monitoring of patients in hospital and clinics. It is also useful in exercise testing and reduces the need to measure arterial blood gases.

**Exhaled nitric oxide**
Nitric oxide is produced by the bronchial epithelium and increases in asthma and other forms of airway inflammation. Measuring exhaled NO can guide therapy in asthma that is difficult to control.

**Haematological and biochemical tests**
It is useful to measure:

- Haemoglobin, to detect anaemia or polycythaemia
- Packed cell volume (secondary polycythaemia occurs with chronic hypoxia)
- Routine biochemistry (often disturbed in carcinoma and infection)
- D-dimer to detect intravascular coagulation. A negative test makes pulmonary embolism very unlikely.

Other blood investigations sometimes required include α\textsubscript{1}-antitrypsin levels, *Aspergillus* antibodies, viral and mycoplasma serology, autoantibody profiles and specific IgE measurements.

**Sputum**

Sputum should be inspected for colour:

- Yellowish-green indicates inflammation (infection or allergy)
- Blood suggests neoplasm or pulmonary infarct (see haemoptysis, p. 798).

Microbiological studies (e.g. Gram-stain and culture) are rarely helpful in upper respiratory tract infections or in acute or chronic bronchitis. They are of value in:

- Pneumonia
- Tuberculosis
- Unusual clinical problems
- *Aspergillus* lung disease.

**Sputum cytology**

This is useful in the diagnosis of bronchial carcinoma and asthma. Its advantages are speed, cheapness and its non-invasive nature.

However, not everyone can produce sputum and a reliable cytologist is needed. Sputum can be induced by inhalation of nebulized hypertonic saline (5%). Better samples can be obtained by bronchoscopy and bronchial washings (see p. 797).

**Exercise tests**

The predominant symptom in respiratory medicine is breathlessness. The degree of disability produced by breathlessness can be assessed by asking the patient to walk for 6 minutes along a measured track. This has been shown to be a reproducible and useful test once the patient has undergone an initial training walk to overcome the learning effect. Additional information can be obtained by using pulse oximetry during exercise to assess desaturation.

More sophisticated cardiopulmonary exercise tests are useful in investigating unexplained breathlessness. Measurement of uptake of oxygen (VO\textsubscript{2}), work performed, heart rate and blood pressure together with serial ECGs allows the following:

- The early detection of lung disease
- The detection of myocardial ischaemia
- The distinction between lung and heart disease
- Assessment of fitness
- Assessment of inappropriate hyperventilation on exertion fitness.

**Pleural aspiration**

Diagnostic aspiration is necessary for all but very small effusions. Nowadays this is usually done under ultrasound guidance, using full aseptic precautions. A needle attached to a 20 mL syringe is inserted under local anaesthesia through an intercostal space towards the top of an area of dullness. Fluid is withdrawn and the presence of any blood is noted. Samples are sent for protein estimation, lactate dehydrogenase (LDH), cytology and bacteriological examination, including culture and Ziehl-Neelsen/auramine stain for tuberculosis. Large amounts of fluid can be aspirated through a large-bore needle to help relieve extreme breathlessness.

**Pleural biopsy**

Pleural biopsy used to be performed at the bedside, but is now generally done under direct vision using video-assisted thoracoscopy.

**Intercostal drainage**

This is carried out when large effusions are present, producing severe breathlessness, or for drainage of an empyema (see Practical Box 15.1). Drains should be inserted with ultrasound guidance. Pleurodesis is performed for recurrent/malignant effusion.

**Mediastinoscopy and scalene node biopsy**

Mediastinoscopy is used in the diagnosis of mediastinal masses and in staging nodal disease in carcinoma of the bronchus. An incision is made just above the sternum and a mediastinoscope inserted by blunt dissection.

**Fibreoptic bronchoscopy**

See Practical Box 15.2 and Fig. 15.16.

Under local anaesthesia and sedation, the central airways can be visualized down to subsegmental level and biopsies taken for histology. More distal lesions may be sampled by washing or blind brushing. Diffuse inflammatory and infective lung processes may be sampled by bronchoalveolar lavage and transbronchial biopsy. The yield is best in sarcoidosis, lymphangitis carcinomatosa and hypersensitivity pneumonitis. Other fibrotic lung diseases usually yield nondiagnostic samples so it may be more relevant to proceed directly to open or thoracoscopic lung biopsy. Endoscopic...
Respiratory disease

Practical Box 15.1

**Intercostal drainage**

- Explain to the patient the nature of the procedure.
- Get written consent.
- Identify the site for aspiration (using ultrasound in most cases).
- Carefully sterilize the skin over the aspiration site.
- Anaesthetize the skin, muscle and pleura with 2% lidocaine.
- Make a small incision, and insert an 8–12 French gauge drain, using the Seldinger technique. A needle is used to enter the pleural space, and then withdrawn over a guide wire over which the catheter is then inserted. (A larger calibre catheter is needed for drainage of empyema, or a 28 French gauge Angyle catheter.)
- Attach to a three-way tap and 50 mL syringe and aspirate up to 1000 mL. Stop aspiration if the patient becomes uncomfortable – shock may ensue if too much fluid is withdrawn too quickly.
- If the drain is to stay in, secure to skin with suture and sterile dressing.
- Attach the drain to an underwater seal drainage bottle and allow fluid to drain. Clamp the drain and release periodically, especially if patient becomes uncomfortable (usually up to 1000 mL at a time before clamping for a few hours).
- Perform chest X-ray to check position of drain.

For **pleurodesis**

Tetracycline 500 mg or bleomycin 15 units in 30–50 mL sodium chloride 0.9% solution is instilled into the pleural cavity to achieve pleurodesis in recurrent/malignant effusion.

Practical Box 15.2

**Fibreoptic bronchoscopy**

This enables the direct visualization of the bronchial tree as far as the subsegmental bronchi under a local anaesthetic. Informed written consent should be obtained after explaining the nature of the procedure.

**Indications**

- Lesions requiring biopsy seen on chest X-ray
- Haemoptysis
- Stridor
- Positive sputum cytology for malignant cells with no chest X-ray abnormality
- Collection of bronchial secretions for bacteriology, especially tuberculosis
- Recurrent bronchial secretions for bacteria, (to obtain a transbronchial biopsy)
- Investigation of collapsed lobes or segments and aspiration of mucus plugs.

**Disadvantages**

- All patients require sedation to tolerate the procedure.
- Minor and transient cardiac dysrhythmias occur in up to 40% of patients on passage of the bronchoscope through the larynx. Monitoring is required.
- Oxygen supplementation is required in patients with PaO₂ below 8 kPa.
- Fibreoptic bronchoscopy should be performed with care in the very sick, and transbronchial biopsies avoided in ventilated patients owing to the increased risk of pneumothorax.
- Massive bleeding may occur after biopsy of vascular lesions or carcinoid tumours. Rigid bronchoscopy may be required to allow adequate access to the bleeding point for haemostasis.

**SMOKING AND AIR POLLUTION**

**Smoking**

**Prevalence**

Cigarette smoking is declining in the western world. In 1974 in the UK, 51% of men and 41% of women smoked cigarettes – nearly half the adult population. Now 22% of men and 21% of women aged 16 years and over smoke. The highest rates are in women aged 20–24, 31% of whom smoke, and men aged 25–34, 30% of whom smoke. The highest rates of cigarette consumption per capita are in Greece, Russia and parts of Eastern Europe. In global terms the USA ranks 39th and the UK is now down to 65th, close to the rates in Sweden and Malaysia. Smoking continues to increase in many developing countries, particularly among women.

**Toxic effects**

Cigarette smoke contains polycyclic aromatic hydrocarbons and nitrosamines, which are potent carcinogens and mutagens in animals. It causes release of enzymes from neutrophil granulocytes and macrophages that are capable of destroying elastin and leading to lung damage. Pulmonary epithelial permeability increases even in symptomless cigarette smokers, and correlates with the concentration of carboxyhaemoglobin in blood. This altered permeability may allow easier access for carcinogens.

**Video-assisted thoracoscopic (VATS) lung biopsy**

This technique has largely replaced open thoracotomy when a lung biopsy is required (p. 850).

**Skin-prick tests**

Allergen solutions are placed on the skin (usually the volar surface of the forearm) and the epidermis is broken using a 1 mm tipped lancet. A separate lancet should be used for each allergen. If the patient is sensitive to the allergen a wheal develops. The wheal diameter is measured after 10 minutes. A wheal of at least 3 mm diameter is regarded as positive provided that the control test is negative. The results should always be interpreted in the light of the history. Skin tests are not affected by bronchodilators or corticosteroids but antihistamines should be discontinued at least 48 hours before testing.

bronchoscopic ultrasound enables direct sampling of lymph nodes for diagnostic staging of lung cancer.
Stopping smoking

If the entire population could be persuaded to stop smoking, the effect on healthcare use would be enormous. National campaigns, bans on advertising and a substantial increase in the cost of cigarettes are the best ways of achieving this at the population level. Smoking bans in the workplace, pubs and public spaces have also helped. Meanwhile, active encouragement to stop smoking remains a useful approach for individuals. Smokers who want to stop should have access to smoking cessation clinics to provide behavioural support. Nicotine replacement therapy (NRT) and bupropion are effective aids to smoking cessation in those smoking >10 cigarettes/day. Both should only be used in smokers who commit to a target stop date, and the initial prescription should be for 2 weeks beyond the target stop date. NRT is the preferred choice; there is no evidence that combined therapy offers any advantage. Therapy should be changed after 3 months if abstinence is not achieved.

Varenicline is an oral partial agonist on the α4β2 subtype of the nicotinic acetylcholine receptor. It stimulates the nicotine receptor and reduces withdrawal symptoms and also the craving for cigarettes. A 12-week course increases the chance of stopping smoking four times; its main side-effects are nausea and sometimes severe depression. Cytisine, which has high affinity for the same receptor, also aids smoking cessation.

Air pollution and epidemiology

Atmospheric air pollution, due to the burning of coal for energy and heat, has been a feature of urban living in developed countries for at least two centuries. It consists of black smoke and sulphur dioxide (SO2). Air pollution of this type peaked in the 1950s in the UK, until legislation led to restrictions on coal burning. Such pollution remains common in some parts of Eastern Europe and Russia and is increasing in newly industrialized countries (especially India and China). The combustion of hydrocarbon fuels in motor vehicles has led to new forms of air pollution, consisting of primary pollutants such as nitrogen oxides (NO and NO2), diesel particulates, polyaromatic hydrocarbons and ozone, a secondary pollutant generated by photochemical reactions in the atmosphere (ozone levels are highest in sunny, rural areas). Levels of NO2 can be high in poorly ventilated kitchens and living rooms where gas is used for cooking and fires.

**Particulate matter** consists of coarse particles (10–2.5 μm in aerodynamic diameter), produced by construction work and farming, and fine particles (<2.5 μm) generated from burning fossil fuels. Fine particulates (PM2.5) remain airborne for long periods and are carried into rural areas. Several respiratory and cardiac problems are exacerbated by these very small particles.

The WHO global air-quality guidelines suggest 24 hour values of <25 μg/m³ for PM10 for the short term and 10 μg/m³ in the long term. In Europe, 70% of the particulates present in urban air result from the combustion of diesel fuel, providing a background concentration of 3–5 μg/m³. The WHO estimates that air pollution causes 800 000 premature deaths worldwide every year.

Deaths from respiratory and cardiovascular disease occur mainly in older populations; air pollution mainly causes bronchitis in children. Pollution from motor vehicles has been linked to increased hospital admissions, reduced lung function in children and younger adults and an increase in lung cancer (polyaromatic hydrocarbons).

The dangers

Cigarette smoking is addictive and harmful to health (Table 15.6). People usually start smoking in adolescence for psychosocial reasons and, once they smoke regularly, the pharmacological properties of nicotine encourage persistence, by their effect on the smoker’s mood. Very few cigarette smokers (<2%) can limit themselves to occasional or intermittent smoking.

Significant dose-response relationships exist between cigarette consumption, airway inflammation (Table 15.7) and lung cancer mortality. Sputum production and airflow limitation increase with daily cigarette consumption, and effort tolerance decreases. Smoking 20 cigarettes daily for 20 years increases the lifetime risk of lung cancer by about 10 times compared to a lifelong non-smoker. Smoking and asbestos exposure are synergistic risk factors for lung cancer, with a combined risk of about 90 times that of unexposed non-smokers.

Cigarette smokers who change to cigars or pipe-smoking can reduce their risk of lung cancer. However, pipe and cigar smokers remain at greater risk of lung cancer than lifelong non-smokers or former smokers.

Environmental tobacco smoke (‘passive smoking’) has been shown to increase the frequency and severity of asthma attacks in children and may also increase the incidence of asthma. It is also associated with a small but definite increase in lung cancer. Worldwide, second hand smoke was estimated to affect 40% of children, 33% of non-smoking males and 35% of non-smoking females in 2004. This caused a 1% worldwide mortality and 0.7% of the total worldwide burden of disease in DALYs (disability-adjusted life years).

---

**FURTHER READING**

Although it has been proposed that air pollution may cause asthma and other allergic diseases, there is no current evidence for this (Table 15.8). However, air pollution does adversely affect lung development in teenage children, while both NO₂ and ozone enhance the nasal and lung airway responses to inhaled allergen in people with established allergic disease.

Management

When air quality is poor, asthmatics are advised to avoid exercising outdoors and to increase their anti-inflammatory medication (i.e. inhaled corticosteroids).

Short- and long-term measures are required to reduce air pollution, particularly diesel particulate which are (predicted to increase as more diesel engines are used). Such measures include increased motor engine efficiency, catalytic converters, diesel particulate traps and decreased reliance on cars and trucks.

**DISEASES OF THE UPPER RESPIRATORY TRACT**

**The common cold (acute coryza)**

This highly infectious illness causes a mild systemic upset and prominent nasal symptoms. It is due to infection by a wide range of respiratory viruses, of which the rhinoviruses are the most common. Other common cold viruses include coronaviruses and adenoviruses. Infectivity from close personal contact (nasal mucus on hands) or droplets is high in the early stages of the infection, and spread is facilitated by overcrowding and poor ventilation. There are at least 100 different antigenic strains of rhinovirus, making it difficult for the immune system to confer protection. On average, individuals suffer two to three colds per year, but the incidence lessens with age, presumably as a result of accumulating immunity to different virus strains. The incubation period varies from 12 hours to 5 days.

The clinical features are tiredness, slight pyrexia, malaise and a sore nose and pharynx. Sneezing and profuse, watery nasal discharge are followed by thick mucopurulent secretions which may persist for up to a week. Secondary bacterial infection occurs only in a minority of cases.

**Sinusitis** (see p. 1052)

**Rhinitis**

Rhinitis is defined clinically as sneezing attacks, nasal discharge or blockage occurring for more than an hour on most days:

- For a limited period of the year (seasonal or intermittent rhinitis)
- Throughout the whole year (perennial or persistent rhinitis).

**Seasonal rhinitis**

This is the commonest allergic disorder. It is often called ‘hayfever’ but as this implies that only grass pollen is responsible, it is better described as seasonal (or intermittent) allergic rhinitis. Worldwide prevalence rates vary from 2% to 20%. Prevalence is maximal in the 2nd decade, and up to 30% of UK teenagers and young adults are affected each June and July.

Nasal irritation, sneezing and watery rhinorrhoea are the most troublesome symptoms, but many also suffer from itching of the eyes and soft palate and occasionally even itching of the ears because of the common innervation of the pharyngeal mucosa and the ear. In addition, approximately 20% suffer from seasonal wheezing. The common seasonal allergens are shown in Figure 15.17. Since pollination of plants that give rise to high pollen counts varies from country to country, seasonal rhinoconjunctivitis and accompanying wheeze may occur at different times of year in different regions.

**Perennial rhinitis**

Patients with perennial rhinitis rarely have symptoms that affect the eyes or throat. Half have symptoms predominantly of sneezing and watery rhinorrhoea, whilst the other half complain mostly of nasal blockage. The patient may lose the sense of smell and taste. Sinusitis occurs in about 50% of cases, due to mucosal swelling that obstructs drainage from the sinuses. Perennial rhinitis is most frequent in the 2nd and 3rd decades, decreasing with age, and can be divided into four main types.

**Perennial allergic rhinitis**

The commonest cause is allergy to the faecal particles of the house-dust mite *Dermatophagoides pteronyssinus* or...
Diseases of the upper respiratory tract

Fig. 15.18

Common allergens causing allergic rhinitis and asthma. The house-dust mite, faeces of house-dust mites, pollen grains, domestic pets and moulds. Percentages are those of positive skin-prick tests to these allergens in patients with allergic rhinitis.

D. farinae; these are under 0.5 mm in size, invisible to the naked eye (Fig. 15.18), and found in dust throughout the house, particularly in older, damp dwellings. Mites live off desquamated human skin scales and the highest concentrations (4000 mites/g of surface dust) are found in human bedding. Their faecal particles are approximately 20 μm in diameter (Fig. 15.18), and impact in the nose rather than the lungs, unless the patient breathes through their mouth.

The next most common allergens come from domestic pets (especially cats) and are proteins derived from urine or saliva spread over the surface of the animal as well as skin protein. Allergy to urinary protein from small mammals is a major cause of morbidity among laboratory workers.

Industrial dust, vapours and fumes cause occupationally related perennial rhinitis more often than asthma.

The presence of perennial rhinitis makes the nose more reactive to non-specific stimuli such as cigarette smoke, washing powders, household detergents, strong perfumes and traffic fumes. Although patients often think they are allergic to these stimuli, these are irritant responses and do not involve antibodies.

**Perennial non-allergic rhinitis with eosinophilia**

No extrinsic allergic cause can be identified, either from the history or on skin testing, but eosinophilic granulocytes are present in nasal secretions. Most of these patients are intolerant of aspirin/NSAIDs.

**Vasomotor rhinitis**

These patients with perennial rhinitis have no demonstrable allergy or nasal eosinophilia. Watery secretions and nasal congestion are triggered by, for example, cold air, smoke, perfume, newsprint, possibly because of an imbalance of the autonomic nerves controlling the erectile tissue (sinusoids) in the nasal mucosa.

**Nasal polyps**

These are round, smooth, soft, semi-translucent, pale or yellow, glistening structures attached to the sinus mucosa by a relatively narrow stalk or pedicle, occurring in patients with allergic or vasomotor rhinitis. The mechanism(s) of their formation is not known. They contain mast cells, eosinophils and mononuclear cells in large numbers and cause nasal obstruction, loss of smell and taste, and mouth breathing, but rarely sneezing, since the mucosa of the polyp is largely denervated.

**Pathogenesis**

Sneezing, increased secretion and changes in mucosal blood flow are mediated both by efferent nerve fibres and by released mediators (see p. 827). Mucus production results largely from parasympathetic stimulation. Blood vessels are under both sympathetic and parasympathetic control. Sympathetic fibres maintain tonic contraction of blood vessels, keeping the sinusoids of the nose partially constricted with good nasal patency. Stimulation of the parasympathetic system dilates these blood vessels. This stimulation varies spontaneously in a cyclical fashion so that air intake alternates slowly over several hours from one nostril to the other. The erectile cavernous nasal sinusoids can be influenced by emotion, which, in turn, can affect nasal patency.

B cells produce IgE antibody against the allergen. IgE binds to mast cells via high affinity cell surface receptors, causing degranulation and release of histamine, proteases (tryptase, chymase), prostaglandins (PGDs), cysteinyl leukotrienes (LTC4, LTD4, LTE4), and cytokines. This causes the acute symptoms of sneezing, itch, rhinorrhoea and nasal congestion. Sneezing results from stimulation of afferent nerve endings (mostly via histamine) and begins within minutes of the allergen entering the nose. This is followed by nasal exudation and secretion and eventually nasal blockage peaking 15–20 minutes after contact with the allergen. These latter symptoms are driven by increased epithelial permeability, mostly due to histamine.

Additionally, allergens are also presented to T cells via antigen presenting cells (dendritic cells). This causes a release of IL-4 and IL-13 which further stimulate the B cells and also IL-5, IL-9 and GM-CSF, switching from a Th1 to a Th2 response to activate and recruit eosinophils, basophils, neutrophils and T lymphocytes. These cause chronic swelling
and irritation, leading to nasal obstruction, hyper-reactivity
and anosmia.

Investigations and diagnosis
The allergic factors causing rhinitis can usually be identified
from the history. Skin-prick testing is used to support the
history. A positive test does not necessarily mean that the
particular allergen producing the wheal causes the respira-
tory disease. However, if there is a compatible clinical history,
a causative role is likely. Allergen-specific IgE antibodies can
be measured in blood but such tests are much more expen-
tsive than skin tests and should only be used in patients who
cannot be skin tested for some reason (e.g. dermatogra-
phism, active eczema or inability to stop antihistamines for 3
days before skin tests).

Treatment
Allergen avoidance
Removal of a household pet or total enclosure of industrial
processes releasing sensitizing agents can lead to cure of
rhinitis and, indeed, asthma.

Pollen avoidance is impossible. Contact may be dimin-
ished by wearing sunglasses, driving with the car windows
shut, avoiding walks in the countryside (particularly in the late
afternoon when the number of pollen grains is highest at
ground level), and keeping the bedroom window shut at
night. These measures are rarely sufficient in themselves to
control symptoms. Exposure to pollen is generally lower in
coastal regions, where sea breezes keep pollen grains inland.

The house-dust mite infests most areas of the house, but
particularly the bedroom. Mite allergen exposure can be
reduced by enclosing bedding in fabric specifically designed
to prevent the passage of mite allergen, while allowing
water vapour through. This is both comfortable and reduces
symptoms. Acaricides are less effective and cannot be
recommended. Increased room ventilation and reduced
soft furnishings including carpets, curtains and soft toys are
all helpful in reducing the mite load. However, a meta-analysis
has questioned the value of house-dust mite control meas-
ures in asthma (p. 829).

H<sub>1</sub> antihistamines
Antihistamines remain the most common therapy for rhinitis,
and many can be purchased directly over the counter in
the UK. They are particularly effective against sneezing and
itching of the eyes and palate, but are less effective against
rhinorrhoea and have little influence on nasal blockage. First-
generation antihistamines (chlorphenamine, hydroxyzine)
cause sedation and loss of concentration in all patients
(including those who are not aware of the problem) and
should no longer be used. Second-generation drugs such as
loratadine (10 mg once daily), desloratadine (5 mg daily),
cetirizine (10 mg daily), and fexofenadine (120 mg daily) are
at least as potent and they do not cause sedation.

Decongestants
Drugs with sympathomimetic activity (α-adrenergic agents)
are widely used to treat nasal obstruction. They may be taken
orally or more commonly as nasal drops or sprays (e.g. eph-
ephrine nasal drops). Xylometazoline and oxymetazoline are
widely used because they have a prolonged action and
tachyphylaxis does not develop. Secondary nasal hyperae-
mia can occur some hours later as a rebound effect and
rhinitis medicamentosa can develop if patients take increas-
ing quantities of decongestant to overcome this phenome-
non. Although local decongestants are an effective treatment
for vasomotor rhinitis, patients must be warned about
rebound nasal obstruction and should use the drugs care-
fully. Usually, such preparations should be prescribed for
only a limited period to open the nasal airways and allow
better access for other local therapy, such as topical
corticosteroids.

Anti-inflammatory drugs
Sodium cromoglycate and nedocromil sodium act by block-
ing an intracellular chloride channel and influence mast cell
eosinophil activation and nerve function. Topical sodium
cromoglycate and nedocromil sodium can be very effective
in allergic conjunctivitis but are of limited value in allergic
rhinitis.

Corticosteroids
The most effective treatment for rhinitis is a topical corticos-
teroid preparation (e.g. beclometasone, fluticasone propion-
ate, fluticasone furoate or mometasone furoate spray).
Topical steroids should be started before the beginning of
seasonal symptoms. The combination of a topical corticos-
teroid with a non-sedating antihistamine taken regularly is
particularly effective. Patients should be carefully instructed
in how to use the nasal steroid device to achieve optimal
drug deposition. In selected cases, an α-adrenergic agonist
may help to decongest the nose prior to taking the topical
corticosteroid. Patients often worry about possible side-
effects: nasal steroids can cause epistaxis, but the amount
used is insufficient to cause systemic effects.

If other therapy has failed, seasonal and perennial rhinitis
respond readily to a short course (max. 2 weeks) of treatment
with oral prednisolone 5–10 mg daily. Nasal polyps may
respond to oral corticosteroids and their recurrence may be
prevented by continuous use of topical corticosteroids.

Leukotriene antagonists
In patients who do not respond to antihistamines or topical
steroids, a leukotriene antagonist (e.g. montelukast 10 mg
daily in the evening) may be helpful, especially in those with
a history of NSAID sensitivity or concomitant asthma.

Immunotherapy
This is used for patients with seasonal allergic rhinitis who
have not responded to the above. Both oral and injectable
vaccines are available (p. 69). Other forms of desensitizing
vaccines are under development.

Pharyngitis
The most common viruses causing pharyngitis are adenovi-
ruses, of which there are about 32 serotypes. Endemic ade-
virus infection causes the common sore throat, in which the
oropharynx and soft palate are reddened and the tonsils
are inflamed and swollen. Within 1–2 days the tonsillar lymph
dnodes enlarge. Occasionally, localized epidemics due to
adenovirus serotype 8 occur, particularly in schools during
summer, with episodes of fever, conjunctivitis, pharyngitis
and lymphadenitis of the neck glands. The disease is self-
limiting and only requires symptomatic treatment without
antibiotics.

Over several decades, the proportion of sore throats due
to bacterial infections, e.g. haemolytic streptococcus, has
fallen. Many different pathogens have been implicated in
pharyngitis but most do not require specific treatment. Per-
sistent and severe tonsillitis should be treated with phe-
noxyethylpenicillin 500 mg four times a day or cefaclor
250 mg three times daily. Amoxicillin and ampicillin should
be avoided if there is a possibility of infectious mononucleosis (p. 100).

**Acute laryngotracheobronchitis**

*Acute laryngitis* is an occasional but striking complication of upper respiratory tract infections, particularly those caused by parainfluenza viruses and measles. The condition is most severe in children under the age of 3 years. Inflammatory oedema extends to the vocal cords and the epiglottis, causing narrowing of the airway; there may be associated *tracheitis* or *tracheobronchitis*. The voice becomes hoarse, with a barking cough (croup) and there is audible stridor. Progressive airways obstruction may occur, with recession of the soft tissue of the neck and abdomen during inspiration and, in severe cases, central cyanosis. Steam inhalations are not helpful. Nebulized adrenaline (epinephrine) gives short-term relief. Oral or i.m. corticosteroids (e.g. dexamethasone) should be given with oxygen and adequate fluids. If steroids are used, endotracheal intubation is rarely necessary. Rarely, a tracheostomy is required.

**Acute epiglottitis**

*H. influenzae* type b (Hib) can cause life-threatening infection of the epiglottis, usually in children under 5 years of age. The child becomes extremely ill with a high fever, and severe airway obstruction may rapidly occur. This is a life-threatening emergency and requires urgent endotracheal intubation and intravenous antibiotics (e.g. ceftazidime 25–150 mg/kg). Chloramphenicol (50–100 mg/kg) can also be used. The epiglottis, which is red and swollen, should not be inspected until facilities to maintain the airways are available.

Other manifestations of Hib infection are meningitis, septic arthritis and osteomyelitis. A highly effective vaccine is now available, which is given to infants at 2, 3 and 4 months, with their primary immunizations against diphtheria, tetanus and pertussis (DTP). This programme has reduced death rates from Hib infections virtually to zero in many countries.

**Influenza** (see also p. 108)

The influenza virus belongs to the orthomyxovirus group and exists in two main forms, A and B. Influenza B is associated with localized outbreaks of mild disease, whereas influenza A causes worldwide pandemics (see p. 108).

**Clinical features**

The incubation period of influenza is usually 1–3 days. The illness starts abruptly with a fever, shivering and generalized aching in the limbs. This is associated with severe headache, soreness of the throat and a dry cough that can persist for several weeks. Diarrhoea occurs in 70% of cases of H5N1. Influenza infection can be followed by a prolonged period of debility and depression that may take weeks or months to clear.

**Complications**

Secondary bacterial infection is common following influenza virus infection, particularly with *Strep. pneumoniae* and *H. influenzae*. Secondary pneumonia caused by *Staph. aureus* is rarer, but more serious, and carries a mortality of up to 20%. Post-infectious encephalomyelitis is rare after influenza infection.

**Diagnosis and treatment**

Laboratory diagnosis is not usually necessary, but a definitive diagnosis can be established by demonstrating a four-fold increase in complement-fixing antibody or the haemagglutinin antibody measured at onset and after 1–2 weeks or by demonstrating the virus in throat or nasal secretions.

**Treatment** is by bed rest and paracetamol, with antibiotics to prevent secondary infection in those with chronic bronchitis, cardiac or renal disease.

Neuraminidase inhibitors help to shorten the duration of symptoms in patients with influenza, if given within 48 h of the first symptom. The cost-benefit of zanamivir and oseltamivir remains unproven but these are currently recommended in the UK for patients with suspected influenza over the age of 65 and ‘at-risk’ adults, as part of a strategy to reduce admissions to hospital when influenza is circulating in the community.

**Prophylaxis**

Protection by influenza vaccines is only effective in about 70% of people and only lasts for about a year. Influenza vaccine should not be given to individuals who are allergic to egg protein as some are manufactured in chick embryos. New vaccines have to be prepared to cover each change in viral antigenicity and are therefore in limited supply at the start of an epidemic. Nevertheless, routine vaccination is recommended for all individuals over 65 years of age and also for younger people with chronic heart disease, chronic lung disease (including asthma), chronic kidney disease, diabetes mellitus and those who are immunosuppressed. During pandemics, key hospital and health service personnel should also be vaccinated.

**Inhalation of foreign bodies**

Children inhale foreign bodies, e.g. peanuts, more commonly than do adults. In adults, inhalation may occur after excess alcohol or under general anaesthesia (loose teeth or dentures).

When the foreign body is large it may impact in the trachea. The person chokes and then becomes silent; death ensues unless the material is quickly removed (see Emergency Box 15.1).

More often, impaction occurs in the right main bronchus and produces:

- Choking
- Persistent monophonic wheeze
- Persistent suppurative pneumonia
- Lung abscess (common).

**Emergency Box 15.1**

**Treatment of inhaled foreign bodies (Heimlich manoeuvre)**

**Emergency**

The Heimlich manoeuvre is used to expel the obstructing object:

1. Stand behind the patient.
2. Encircle your arms around the upper part of the abdomen just below the patient’s rib cage.
3. Give a sharp, forceful squeeze, forcing the diaphragm sharply into the thorax. This should expel sufficient air from the lungs to force the foreign body out of the trachea.

**Non-emergency**

Rigid bronchoscopy should be performed.
DISEASES OF THE LOWER RESPIRATORY TRACT

Lower respiratory tract infection accounts for approximately 10% of the worldwide burden of morbidity and mortality. Some 75% of all antibiotic usage is for these diseases, despite the fact that they are mainly due to viruses.

Acute bronchitis

Acute bronchitis in previously healthy subjects is often viral. Bacterial infection with Strep. pneumoniae or H. influenzae is a common sequel to viral infections, and is more likely to occur in cigarette smokers or people with chronic obstructive pulmonary disease (COPD).

The illness begins with an irritating, non-productive cough, together with discomfort behind the sternum. There may be associated chest tightness, wheezing and shortness of breath. Later the cough becomes productive, with yellow or green sputum. There is a mild fever and a neutrophil leucocytosis; wheeze with occasional crackles can be heard on auscultation. In otherwise healthy adults the disease improves spontaneously in 4–8 days without the patient becoming seriously ill.

Antibiotics are often given (e.g. amoxicillin 250 mg three times daily), but it is not known whether this hastens recovery in otherwise healthy individuals.

Chronic obstructive pulmonary disease (COPD)

COPD is predicted to become the third most common cause of death and fifth most common cause of disability worldwide by 2020.

The term COPD was introduced to bring together a variety of clinical syndromes associated with airflow obstruction and destruction of the lung parenchyma. The older terms ‘chronic obstructive Airways disease’ and ‘chronic obstructive lung disease’ are synonymous with COPD. Prior to 1979, patients with COPD were often classified by symptoms (chronic bronchitis, chronic asthma), by pathological changes (emphysema) or by physiological correlates (pink puffers, blue bloaters). Recognition that these entities overlapped and often co-existed led to introduction of the term COPD.

COPD is associated with a number of co-morbidities, e.g. ischaemic heart disease, hypertension, diabetes, heart failure and cancer, suggesting that it may be part of a generalized systemic inflammatory process.

Definition of COPD

COPD has been described as ‘a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases’.

Epidemiology and aetiology

COPD is caused by long-term exposure to toxic particles and gases. In developed countries, cigarette smoking accounts for over 90% of cases. In developing countries other factors, such as the inhalation of smoke from biomass fuels used in heating and cooking in poorly ventilated areas, are also implicated. However, only 10–20% of heavy smokers develop COPD, indicating individual susceptibility. The development of COPD is proportional to the number of cigarettes smoked per day; the risk of death from COPD in patients smoking 30 cigarettes daily is 20 times that of a non-smoker. Autopsy studies have shown substantial numbers of centri-acinar emphysematous spaces in the lungs of 50% of British smokers over the age of 60 years independent of whether significant respiratory disease was diagnosed before death.

Climate and air pollution are lesser causes of COPD, but mortality from COPD increases dramatically during periods of heavy atmospheric pollution (p. 341). Urbanization, social class and occupation may also play a part in aetiology, but these effects are difficult to separate from that of smoking. Some animal studies suggest that diet could be a risk factor for COPD, but this has not been proven in humans.

The socioeconomic burden of COPD is considerable. In the UK, COPD causes approximately 18 million lost working days annually for men and 2.1 million lost working days for women, accounting for approximately 7% of all days of absence from work due to sickness. Nevertheless, the number of COPD admissions to UK hospitals has been falling steadily over the last 30 years.

Pathophysiology

The most consistent pathological finding in COPD is increased numbers of mucus-secreting goblet cells in the bronchial mucosa, especially in the larger bronchi (Fig. 15.19). In more advanced cases, the bronchi become overtly inflated and pus is seen in the lumen.

Microscopically, there is infiltration of the walls of the bronchi and bronchioles with acute and chronic inflammatory cells; lymphoid follicles may develop in severe disease. In contrast to asthma, the lymphocytic infiltrate is predominantly CD8. The epithelial layer may become ulcerated and, with time, squamous epithelium replaces the columnar cells. The inflammation is followed by scarring and thickening of the walls which narrows the small airways (Fig. 15.20).

The small airways are particularly affected early in the disease, initially without the development of any significant breathlessness. This initial inflammation of the small airways is reversible and accounts for the improvement in airway function if smoking is stopped early. In later stages the inflammation continues, even if smoking is stopped.

Further progression of the airways disease leads to progressive squamous cell metaplasia, and fibrosis of the
to depend on hypoxaemia to drive their ventilation. Such patients appear less breathless and because of renal hypoxia they start to retain fluid and increase erythrocyte production (leading eventually to polycythaemia). In consequence they become bloated, plethoric and cyanosed, the typical appearance of the ‘blue bloater’. Attempts to abolish hypoxaemia by administering oxygen can make the situation much worse by decreasing respiratory drive in these patients who depend on hypoxia to drive their ventilation.

The classic Fletcher and Peto studies (Fig. 15.21) show that there is a loss of 50 mL per year in FEV₁ in patients with COPD compared with 20 mL per year in healthy people. A recent study has shown a 40 mL loss per year but only in 38% of the patients studied. Biomarkers to indicate the rate of decline have been unhelpful although CC16 (Clare cell secretory protein 16) was shown to be a reasonable indicator in a study.

In summary, three mechanisms have been suggested for this limitation of airflow in small airways (<2 mm in diameter).

- Loss of elasticity and alveolar attachments of airways due to emphysema. This reduces the elastic recoil and the airways collapse during expiration.
- Inflammation and scarring cause the small airways to narrow.
- Mucus secretion, which blocks the airways.

Each of these narrows the small airways and causes air trapping leading to hyperinflation of the lungs. \( V_a / Q \) mismatch, increased work of breathing and breathlessness.

**Pathogenesis**

**Cigarette smoking**

Bronchoalveolar lavage and biopsies of the airways of smokers show increased numbers of neutrophil granulocytes. These granulocytes can release elastases and proteases, which may help to produce emphysema. It has been suggested that there is an imbalance between protease and antiprotease activity causes the damage. \( \alpha \)-Antitrypsin is a major serum antiprotease which can be inactivated by cigarette smoke (see below).

Mucous gland hypertrophy in the larger airways is thought to be a direct response to persistent irritation resulting from the inhalation of cigarette smoke. The smoke has an adverse effect on surfactant, favouring overdistension of the lungs.

**Infections**

Patients with COPD cope badly with respiratory infections, which are often the precipitating cause of acute exacerbations of the disease. However, it is less clear whether
infection is responsible for the progressive airflow limitation that characterizes disabling COPD. Prompt use of antibiotics and routine vaccinations against influenza and pneumococci are appropriate.

### α1-Antitrypsin deficiency

α1-Antitrypsin (see also p. 341) is a protease inhibitor which is produced in the liver, secreted into the blood and diffuses into the lung. Here it inhibits proteolytic enzymes such as neutrophil elastase, which are capable of destroying alveolar wall connective tissue.

More than 75 alleles of the α1-antitrypsin gene have been described. The three main phenotypes are MM (normal), MZ (heterozygous deficiency) and ZZ (homozygous deficiency). About 1 child in 5000 in Britain is born with the homozygous deficiency, but not all develop chest disease. Those who do develop breathlessness under the age of 40 years have radiographic evidence of basal emphysema and are usually, but not always, cigarette smokers. Hereditary deficiency of α1-antitrypsin accounts for about 2% of emphysema cases. A small minority develop liver disease (see p. 341).

### Clinical features

#### Symptoms

The characteristic symptoms of COPD are productive cough with white or clear sputum, wheeze and breathlessness, usually following many years of a smoker’s cough. Colds seem to ‘settle on the chest’ and frequent infective exacerbations occur, with purulent sputum. Symptoms can be worsened by cold, foggy weather and atmospheric pollution. With advanced disease, breathlessness is severe even after mild exercise such as getting dressed. Apart from the pulmonary features, there are systemic effects including hypertension, osteoporosis, depression, weight loss and reduced muscle mass with general weakness.

#### Signs

In mild COPD, there may be no signs or just quiet wheezes throughout the chest. In severe disease, the patient is tachypnoeic, with prolonged expiration. The accessory muscles of respiration are used and there may be intercostal indrawing on inspiration and pursing of the lips on expiration (see p. 792). Chest expansion is poor, the lungs are hyperinflated, and there is loss of the normal cardiac and liver dullness.

Patients who remain responsive to CO2 are usually breathless and rarely cyanosed. Heart failure and oedema are rare features except as terminal events. In contrast, patients who become insensitive to CO2 are often oedematous and cyanosed but not particularly breathless. Those with hypercapnia may have peripheral vasodilatation, a bounding pulse, and when the Pco2 is above about 10 kPa, a coarse flapping tremor of the outstretched hands. Severe hypercapnia causes confusion and progressive drowsiness. Papilloedema may be present but this is neither specific nor sensitive as a diagnostic feature.

### Respiratory failure

The later stages of COPD are characterized by the development of respiratory failure. For practical purposes this is said to occur when there is either a Pao2 <8 kPa (56 mmHg) or a Paco2 >7 kPa (55 mmHg).

Chronic alveolar hypoxia and hypercapnia leads to constriction of the pulmonary arterioles and pulmonary hypertension. Cardiac output is normal or increased but salt and fluid retention occurs as a result of renal hypoxia.

### Pulmonary hypertension (cor pulmonale)

Patients with advanced COPD may develop cor pulmonale, which is defined as symptoms and signs of fluid overload secondary to lung disease. The fluid retention and peripheral oedema is due to failure of excretion of sodium and water by the hypoxic kidney rather than heart failure. It is characterized by pulmonary hypertension and right ventricular hypertrophy. On examination, the patient is centrally cyanosed (owing to the lung disease) and later becomes more breathless and develops ankle oedema. Initially there may be a prominent parasternal heave, due to right ventricular hypertrophy, and a loud pulmonary second sound. In very severe pulmonary hypertension, the pulmonary valve becomes incompetent. With severe fluid overload, tricuspid incompetence may develop with a greatly elevated jugular venous pressure (JVP), ascites and upper abdominal discomfort due to liver swelling.

### Diagnosis

This is usually clinical (Table 15.9) and based on a history of breathlessness and sputum production in a chronic smoker. In the absence of a history of cigarette smoking asthma is a more likely explanation unless there is a family history suggesting α1-antitrypsin deficiency.

No individual clinical feature is diagnostic. The patient may have signs of hyperinflation and typical pursed lip respiration. There may be signs of overinflation of the lungs (e.g. loss of liver dullness on percussion), but this also occurs in other diseases such as asthma. Conversely, centri-acinar emphysema may be present without signs of overinflation. The chest may become ‘barrel-shaped’ but this can also result from osteoporosis of the spine in older men without emphysema.

### Investigations

- **Lung function tests** show evidence of airflow limitation (see Figs 15.7 and 15.12). The FEV1/FVC ratio is reduced and the PEFR is low. In many patients the

| Table 15.9 Classification of severity of Airflow limitation in COPD (2011) |
|-------------------------|------------------|------------------|
| **Gold stage** | **FEV1/FVC** | **% Predicted** |
| 1. Mild | <70% | ≥80% |
| 2. Moderate | <70% | <80% |
| 3. Severe | <70% | <50% |
| 4. Very severe | <70% | <30% |

airflow limitation is partly reversible (usually a change in FEV1, of <15%), and it can be difficult to distinguish between COPD and asthma. Lung volumes may be normal or increased; carbon monoxide gas transfer factor is low when significant emphysema is present.

- **Chest X-ray** is often normal, even when the disease is advanced. The classic features are overinflation of the lungs with low, flattened diaphragms, and sometimes the presence of large bullae. Blood vessels may be ‘pruned’ with large proximal vessels and relatively little blood visible in the peripheral lung fields.

- **High-resolution CT scans** are useful, particularly when the plain chest X-ray is normal.

- **Haemoglobin level and PCV** can be elevated as a result of persistent hypoxaemia (secondary polycythaemia, see p. 404).

- **Blood gases** are often normal at rest, but patients desaturate on exercise. In more advanced cases there is resting hypoxaemia and there may also be hypercapnia.

- **Sputum examination** is not useful in ordinary cases. Strep. pneumoniae and H. influenzae are the only common organisms to produce acute exacerbations. Occasionally, Moraxella catarrhalis may cause infective exacerbations.

- **Electrocardiogram** is often normal. In advanced pulmonary hypotension the P wave is tall (P’ pulmonale) and there may be right bundle branch block and pulmonary hypotension the P wave is tall (P’ pulmonale) and there may be right bundle branch block and pulmonary hypertension (see p. 764).

- **Echo-cardiogram** is useful to assess cardiac function where there is disproportionate dyspnoea.

- **α1-Antitrypsin** levels and genotype are worth measuring in premature disease or lifelong non-smokers.

**Management**

See Figure 15.22 for management strategies.

### Smoking cessation

The single most useful measure is to persuade the patient to stop smoking. Even in advanced disease this may slow down the rate of deterioration and prolong the time before disability and death occur (see Fig. 15.22). Smoke from burning biomass fuels in poorly ventilated homes should also be reduced or get to non-smoking facilities if possible.

### Drug therapy

This is used both for the short-term management of exacerbations and for the long-term relief of symptoms. Many of the drugs used are similar to those used in asthma (see p. 829).

#### Bronchodilators

**β-Adrenergic agonists.** Many patients with mild COPD feel less breathless after inhaling a β-adrenergic agonist such as salbutamol (200 μg every 4–6 hours). In more severe airway limitation (moderate and severe COPD), a long-acting β2 agonist should be used, e.g. formoterol 12 μg powder inhaled twice daily or salmeterol 50 μg twice daily. Indacaterol 150–300 μg daily is also effective.

**Antimuscarinic drugs.** More prolonged and greater bronchodilatation is achieved with antimuscarinic agents: tiotropium (long-acting) (18 μg daily, ipratropium (40 μg four times daily) or oxitropium (200 μg twice daily). Tiotropium improves function and quality of life but does not affect the decline in FEV1. Compound bronchodilators, a selective β2 agonist and an antimuscarinic agent, are used. If patients find inhalers difficult to use, spacer devices improve delivery. Objective evidence of improvement in peak flow rate or FEV1 may be small and decisions to continue or stop therapy are based mainly on the patient’s reported symptoms.

**Theophyllines.** Long-acting preparations of theophylline are of little benefit in COPD.
Phosphodiesterase type 4 inhibitors
Roflumilast is an inhibitor with anti-inflammatory properties. It is used as an adjunct to bronchodilators for the maintenance treatment of COPD patients.

Corticosteroids
In symptomatic patients with moderate/severe COPD, a trial of corticosteroids is always indicated, since a proportion of patients have a large, unsuspected, reversible element to their disease and airway function may improve considerably. Prednisolone 30 mg daily should be given for 2 weeks, with measurements of lung function before and after the treatment period. If there is objective evidence of a substantial degree of improvement in airflow limitation (FEV₁ increase >15%), prednisolone should be discontinued and replaced by inhaled corticosteroids (beclometasone 40 μg twice daily in the first instance, adjusted according to response). The long-term value of regular inhaled corticosteroids in all patients with COPD has not been proven.

Combination of a corticosteroid with a long-acting β₂ agonist may protect against lung function decline but does not improve overall mortality. High-dose inhaled steroids are not advised as they cause increased rates of respiratory infection.

Antibiotics
Prompt antibiotic treatment shortens exacerbations and should always be given in acute episodes as it may prevent hospital admission and further lung damage. Patients can be given antibiotics to keep at home to start as soon as their sputum turns yellow or green. Although amoxicillin-resistant H. influenzae is increasing worldwide (occurring in about 20% of isolates from sputum) it is not a serious clinical problem. Resistance to cefaclor (500 mg 8-hourly) or cefixime (400 mg once daily) is significantly less frequent; co-amoxiclav is a useful alternative.

Long-term treatment with antibiotics remains controversial. They were once thought to be of no value, but eradication of infection and keeping the lower respiratory tract free of bacteria may help to prevent deterioration in lung function.

Antimucolytic agents
These reduce sputum viscosity and can reduce the number of acute exacerbations. A 4-week trial of carbocysteine 2,25 g daily can be tried.

Diuretic therapy (see p. 644)
This is necessary for all oedematous patients. Daily weights should be recorded during acute inpatient episodes.

Oxygen therapy
Two controlled trials (chiefly in males) have shown improved survival with the continuous administration of oxygen at 2 L/min via nasal prongs to achieve an oxygen saturation of greater than 90% for large proportions of the day and night. Survival curves from these two studies are shown in Figure 15.23.

Only 30% of those not receiving long-term oxygen therapy survived for more than 5 years. A fall in pulmonary artery pressure was achieved if oxygen was given for 15 hours daily, but substantial improvement in mortality was only achieved by the administration of oxygen for 19 hours daily. These results suggest that long-term continuous domiciliary oxygen therapy will benefit patients who have:
- $P_{aO_2}$ of <7.3 kPa (55 mmHg) when breathing air.
- Measurements should be taken on two occasions at least 3 weeks apart after appropriate bronchodilator therapy (Box 15.1).

$P_{aO_2}$ 7.3–8 kPa with secondary polycythaemia, nocturnal hypoxaemia, peripheral oedema or evidence of pulmonary hypertension.
- Carboxyhaemoglobin of <3% (i.e. patients who have stopped smoking).

Domiciliary oxygen is best provided by using an oxygen concentrator, which is considerably cheaper than using oxygen cylinders.

Nocturnal hypoxia
COPD patients with severe arterial hypoxaemia may experience profound nocturnal hypoxaemia which may drop the $P_{aO_2}$ as low as 2.5 kPa (19 mmHg), particularly during the rapid eye movement (REM) phase of sleep.

Because patients with COPD are already hypoxic, the fall in $P_{aO_2}$ produces a much larger fall in oxygen saturation.
(owing to the shape of the oxygen-haemoglobin dissociation curve) and desaturation of up to 50% occurs. The mechanism is alveolar hypoventilation due to:

- Inhibition of intercostal and accessory muscles in REM sleep
- Shallow breathing in REM sleep, which reduces ventilation, particularly in severe COPD
- An increase in upper airway resistance because of a reduction in muscle tone.

These nocturnal hypoxaemic episodes are associated with a further rise in pulmonary arterial pressure owing to vasoconstriction. Most deaths in patients with COPD occur at night, possibly from cardiac arrhythmias due to hypoxaemia. Secondary polycythaemia may be exacerbated by the severe nocturnal hypoxaemia.

Each episode of desaturation is usually terminated by arousal from sleep, so the amount of normal sleep is reduced and patients suffer from daytime sleepiness.

**Treatment.** Patients with arterial hypoxaemia should not be given sleeping tablets, as these will further depress respiratory drive. Treatment is with nocturnal administration of oxygen and ventilatory support.

Non-invasive positive-pressure ventilation can be administered with a tightly fitting nasal mask and bilevel positive airway pressure (BiPAP) – inspiratory to provide inspiratory assistance and expiratory to prevent alveolar closure, each adjusted independently. This improves ventilation during sleep and allows respiratory muscles to rest at night. BiPAP helps prevent hypoxaemic damage at night in COPD but it does not improve daytime respiratory function, respiratory muscle strength, exercise tolerance or breathlessness.

**Pulmonary rehabilitation**

Exercise training can modestly increase exercise capacity with a diminished sense of breathlessness and improved general wellbeing. Regular training periods can be instituted at home; climbing stairs or walking fixed distances can be combined with regular clinic visits for encouragement. Breathing exercises are probably of less value. Quality-of-life can be improved by a multidisciplinary approach involving physiotherapy, exercise and education, although this does not alter life expectancy or the rate of decline in lung function; stopping smoking is still the most useful thing patients can do to help themselves. Nutritional advice, psychological, social and behavioural interventions are also helpful.

**Additional measures**

- **Vaccines.** Patients with COPD should receive a single dose of the polyvalent pneumococcal polysaccharide vaccine and yearly influenza vaccinations.

  - **α1-Antitrypsin replacement.** Weekly or monthly infusions of α1-antitrypsin have been recommended for patients with serum levels below 310 mg/L and abnormal lung function. Whether this modifies the long-term progression of the disease remains to be determined.

- **Heart failure** should be treated (p. 718).

- **Secondary polycythaemia** requires venesection if the PCV is >55%.

- **Pulmonary hypertension** can be partially relieved by the use of oral β-adrenergic agonists such as salbutamol (4 mg three times daily), but the long-term value is unknown.

- The **sensation of breathlessness** can be reduced by either promethazine 125 mg daily or dihydrocodeine 1 mg/kg by mouth. Although opiates are the most effective treatment for intractable breathlessness they depress ventilation and carry the risk of increasing respiratory failure.

- **Antileukotriene agents** have been tried but are rarely effective (p. 831).

- **Air travel.** Commercial aircraft are pressurized to the equivalent of 2000–2400 m altitude. In healthy people, this causes $P_{O_2}$ to fall from 13.5 to 10 kPa, causing a trivial 3% drop in oxygen saturation, but patients with moderate COPD may desaturate significantly. The desaturation associated with air travel can be simulated by breathing 15% oxygen at sea level. Patients whose saturation drops below 85% within 15 minutes should be advised to contact their airline to request supplemental oxygen during flight.

- **Surgery.** Some patients have large emphysematous bullae which reduce lung capacity. Surgical bullectomy can enable adjacent areas of collapsed lung to re-expand and start functioning again. In addition, carefully selected patients with severe COPD (FEV1 < 1 L) have been treated with lung volume reduction surgery. This increases elastic recoil, which reduces the expiratory collapse of the airway and decreases expiratory airflow limitation. It also enables the diaphragm to work at a better mechanical advantage. Initial studies suggested that ventilation was improved and patients felt less breathless, although mortality was unchanged. However, a controlled trial in severe emphysema found increased mortality and no improvement in the patients’ condition. Single lung transplantation (see p. 822) is used for end-stage emphysema, with 3-year survival rates of 75%. The principal benefit is improved quality of life but it does not extend survival.

**Acute respiratory failure in COPD**

- **Oxygen therapy.** COPD is by far the commonest cause of respiratory failure (Fig. 15.24). In managing respiratory failure the main goal is to improve the $P_{O_2}$ by continuous oxygen therapy. In type II respiratory failure the $P_{CO_2}$ is elevated and the patient is dependent on hypoxic drive. In this setting, giving additional oxygen will nearly always cause a further rise in $P_{CO_2}$. Small increases in $P_{CO_2}$ can be tolerated but the pH should not be allowed to fall below 7.25; if it does, increased ventilation must be achieved either by artificial ventilation or by using a respiratory stimulant. In COPD exacerbations, a fixed-percentage mask (Venturi mask; Fig. 15.25) is used to deliver controlled concentrations of oxygen. Initially, 24% oxygen is given, and the concentration of inspired oxygen can be gradually increased provided the $P_{CO_2}$ does not rise unacceptably.

- **Removal of retained secretions.** Patients should be encouraged to cough up secretions. Physiotherapy is helpful. If this fails, secretions can be aspirated by bronchoscopy or via an endotracheal tube.

- **Respiratory support** (see p. 895). Non-invasive ventilatory techniques can be very helpful in avoiding the need for endotracheal intubation. The best current technique uses tight-fitting facial masks to deliver bilevel positive airway pressure ventilatory support (BiPAP). Assisted ventilation with an endotracheal tube is occasionally used for patients with COPD with severe respiratory failure but only when there is a clear
Respiratory disease

Yellow/green sputum

Bronchodilators

Intercostal drainage

CXR, chest X-ray.

Corticosteroids, antibiotics and bronchodilators should be administered in the acute phase of respiratory failure but decisions on long-term use should wait until the patient has recovered (see above).

Prognosis of COPD

Predictors of a poor prognosis are increasing age and worsening airflow limitation, i.e. decreasing FEV₁. A predictive index (BODE: Body mass index, degree of airflow obstruction, dyspnoea and exercise capacity) is shown in Box 15.2.

A patient with a BODE index of 0–2 has a 4-year mortality rate of 10%, compared with an 80% rate in one with a BODE index of 7–10.

Obstructive sleep apnoea

OSA affects 1–2% of the population and occurs most often in overweight middle-aged men. It can occur in children, particularly those with enlarged tonsils. The major symptoms and their frequency are listed in Table 15.10.

During sleep, activity of the respiratory muscles is reduced, especially during REM sleep when the diaphragm is virtually the only active muscle. Apnoeas occur when the airway at the back of the throat is sucked closed when breathing in during sleep.

When awake, this tendency is overcome by the action of opening muscles of the upper airway, the genioglossus and palatal muscles, but these become hypotonic (Fig. 15.26). Partial narrowing results in snoring, complete occlusion causes apnoea and critical narrowing causes hypopnoeas. Apnoea leads to hypoxia and increasingly strenuous respiratory efforts until the patient overcomes the resistance. The combination of the central hypoxic stimulation and the effort to overcome obstruction wakes the patient from sleep. These awakenings are so brief that the patient remains unaware of them but may be woken hundreds of times per night leading to sleep deprivation, especially a reduction in REM sleep, with consequent daytime sleepiness.

Figure 15.25 ‘Fixed-performance’ device for administration of oxygen to spontaneously breathing patients (Venturi mask). Oxygen is delivered through the injector of the Venturi mask at a given flow rate. A fixed amount of air is entrapped and the inspired oxygen can be predicted accurately. Masks are available to deliver 24%, 28% and 35% oxygen.

Precipitating factor and the overall prognosis is reasonable. Assessing the likelihood of reversibility in an acute setting can present a difficult ethical problem.

Respiratory stimulants. Respiratory stimulants such as doxapram were widely used in the past, but have fallen out of favour due to improvements in non-invasive ventilation.

Corticosteroids, antibiotics and bronchodilators should be administered in the acute phase of respiratory failure but decisions on long-term use should wait until the patient has recovered (see above).

Prognosis of COPD

Predictors of a poor prognosis are increasing age and worsening airflow limitation, i.e. decreasing FEV₁. A predictive index (BODE: Body mass index, degree of airflow Obstruction, Dyspnoea and Exercise capacity) is shown in Box 15.2.

A patient with a BODE index of 0–2 has a 4-year mortality rate of 10%, compared with an 80% rate in one with a BODE index of 7–10.

Obstructive sleep apnoea

OSA affects 1–2% of the population and occurs most often in overweight middle-aged men. It can occur in children, particularly those with enlarged tonsils. The major symptoms and their frequency are listed in Table 15.10. During sleep, activity of the respiratory muscles is reduced, especially during REM sleep when the diaphragm is virtually the only active muscle. Apnoeas occur when the airway at the back of the throat is sucked closed when breathing in during sleep.

When awake, this tendency is overcome by the action of opening muscles of the upper airway, the genioglossus and palatal muscles, but these become hypotonic (Fig. 15.26). Partial narrowing results in snoring, complete occlusion causes apnoea and critical narrowing causes hypopnoeas. Apnoea leads to hypoxia and increasingly strenuous respiratory efforts until the patient overcomes the resistance. The combination of the central hypoxic stimulation and the effort to overcome obstruction wakes the patient from sleep. These awakenings are so brief that the patient remains unaware of them but may be woken hundreds of times per night leading to sleep deprivation, especially a reduction in REM sleep, with consequent daytime sleepiness.
Figure 15.26 Section through head, showing pressure changes (in kPa) in (a) the normal situation and (b) obstructive sleep apnoea. There is a pressure drop during inspiration as air is sucked through the turbinates. In patients with obstructive sleep apnoea this is sufficient to collapse the pharynx, obstructing inspiration.

and impaired intellectual performance. Contributory factors are obesity, narrow pharyngeal opening and co-existent COPD. Correctable factors occur in about one-third of cases and include:

- **Encroachment on pharynx** – obesity, acromegaly, enlarged tonsils
- **Nasal obstruction** – nasal deformities, rhinitis, polyps, adenoids
- **Respiratory depressant drugs** – alcohol, sedatives, strong analgesics.

**Diagnosis**

Relatives often provide a good history of the snore-silence-snore cycle. The Epworth Sleepiness Scale (Table 15.11) helps discriminate OSA from simple snoring. The diagnosis is supported by overnight pulse oximetry performed at home. Characteristically, oxygen saturation falls in a cyclical manner giving a sawtooth appearance to the tracing. If oximetry is negative or equivocal, inpatient assessment with oximetry and video-recording is indicated, preferably in a room specifically adapted for sleep studies. Full polysomnographic studies are rarely needed for clinical diagnosis but are useful in research labs. These involve oximetry, direct measurements of thoracic and abdominal movement to assess breathing, and electro-encephalography to record patterns of sleep and arousal. Some centres also measure oronasal airflow.

The diagnosis of sleep apnoea/hypopnoea is confirmed if there are more than 10–15 apnoeas or hypopnoeas in any 1 hour of sleep. There is, however, overlap with central sleep apnoea (see p. 1069).

**Management**

Management consists of correction of treatable factors (see above) with, if necessary, nasal continuous positive airway pressure (CPAP) delivered by a nasal mask during sleep. Such systems raise the pressure in the pharynx by about 1 kPa, keeping the walls apart. Nasal CPAP improves symptoms, quality of life, daytime alertness and survival. However, up to 50% of OSA patients cannot tolerate CPAP. Modafinil (a CNS stimulant) is a useful short-term alternative.

**Bronchiectasis**

This term describes abnormal and permanently dilated airways. Bronchial walls become inflamed, thickened and irreversibly damaged. The mucociliary transport mechanism is impaired and frequent bacterial infections ensue. Clinically, the disease is characterized by productive cough with large amounts of discoloured sputum, and dilated, thickened bronchi, detected on CT.

**Aetiology**

Cystic fibrosis is the most common cause in developed countries. For other causes see Table 15.12.

**Clinical features**

Patients with mild bronchiectasis only produce yellow or green sputum after an infection. Localized areas of the lung may be particularly affected, in which case sputum production will vary with position. As the condition worsens, patients suffer persistent halitosis, recurrent febrile episodes with malaise, and episodes of pneumonia. Clubbing occurs, and coarse crackles can be heard over the infected areas, usually the lung bases. When the condition is severe there is continuous production of foul-smelling, thick, khaki-coloured sputum. Haemoptysis can occur either as blood-stained sputum or as a massive haemorrhage. Breathlessness may result from airflow limitation.

**Investigations**

- **Chest X-ray** may show dilated bronchi with thickened bronchial walls and sometimes multiple cysts containing fluid, but can be normal.
- **High-resolution CT scanning** (see p. 791) reveals thickened, dilated bronchi and cysts at the end of the bronchioles (Fig. 15.27). Characteristically the airways are larger than their associated blood vessels.
- **Sputum** examination and culture are essential for adequate treatment. The major pathogens are Staph. aureus, Pseudomonas aeruginosa, H. influenzae and anaerobes. Other pathogens include Strep.
class levels but fail to respond to respiratory pathogens. Responses to Hib and pneumococcal vaccines may be impaired.

- **Sweat electrolytes** – if cystic fibrosis is suspected (see p. 821).
- **Mucociliary clearance** (nasal clearance of saccharin). A 1 mm cube of saccharin is placed on the inferior turbinate and the time to taste measured (normally <30 minutes).

### Treatment

#### Postural drainage

Postural drainage is valuable. Patients must be trained by physiotherapists to tip themselves so that the affected lobe(s) are uppermost at least three times daily for 10–20 minutes. Most patients find that lying over the side of the bed with head and thorax down is effective.

#### Antibiotics

Experience from the treatment of cystic fibrosis suggests that bronchopulmonary infections need to be eradicated if progression of the disease is to be halted. In mild cases, intermittent chemotherapy with cefaclor 500 mg three times daily or ciprofloxacin 500 mg twice daily may be sufficient. Flucloxacin 500 mg 6-hourly is needed if *Staph. aureus* is isolated.

If the sputum remains yellow or green despite regular physiotherapy and intermittent chemotherapy, or if lung function deteriorates despite treatment with bronchodilators, it is likely that there is infection with *Pseudomonas aeruginosa*. Treatment requires parenteral or aerosol chemotherapy at regular 3-month intervals. Ceftazidime 2 g intravenously 8-hourly or by inhalation (1 g twice daily) has been shown to be effective. Ciprofloxacin 750 mg twice daily orally may work in the short term, but resistance can develop rapidly. High sputum levels of some antibiotics, e.g. colistin or tobramycin, can be achieved by inhalation.

**Treatment** for aspergillus is described on page 852 and MAI on page 192.

#### Bronchodilators

Bronchodilators are useful in patients with demonstrable airflow limitation.

#### Anti-inflammatory agents

Inhaled or oral steroids can decrease the rate of progression.

#### Surgery

Unfortunately, it is rare for bronchiectasis to be sufficiently localized for resection to be practical. Lung or heart-lung transplantation is sometimes required.

#### Complications

The incidence of complications has fallen with antibiotic therapy. Pneumonia, pneumothorax, empyema and metastatic cerebral abscess can occur. Severe, life-threatening haemoptysis can also occur, particularly in patients with cystic fibrosis. Massive haemoptysis originates from the high-pressure systemic bronchial arteries and has a mortality of 25%. Other causes of massive haemoptysis are pulmonary tuberculosis (most common), aspergillosis, lung abscess and primary and secondary malignant tumours.

**Treatment** of the haemoptysis consists of bed rest and antibiotics, when most stop bleeding. Blood transfusion is given if required. Urgent fiberoptic bronchoscopy is needed to look for and remove an obstructing foreign body, granuloma or tumour.

occasionally necessary to detect the source of bleeding. If the haemoptysis does not settle rapidly, the treatment of choice is bronchial artery embolization. Surgical resection may be required if embolization fails.

**Prognosis**

The advent of effective antibiotic therapy has greatly improved the prognosis. Ultimately, most patients with severe bronchiectasis will develop respiratory failure or cor pulmonale, but those with mild disease have normal life expectancy. Of the pathogens that cause infective episodes, the most difficult to eradicate are *Pseudomonas aeruginosa*, *Aspergillus fumigatus* and MAI.

**Cystic fibrosis**

In cystic fibrosis (CF) there is an alteration in the viscosity and tenacity of mucus produced at epithelial surfaces. The classical form of the syndrome includes bronchopulmonary infection and pancreatic insufficiency, with a high sweat sodium and chloride concentration. It is an autosomal recessive inherited disorder with a carrier frequency in Caucasians of 1 in 22 (see p. 43). There is a gene mutation on the long arm of chromosome 7 in the region of 7q31.2. The commonest abnormality is a specific deletion at position 508 in the amino acid sequence \([\Delta F508]\) – which results in a defect in a transmembrane regulator protein (see p. 44). This is the cystic fibrosis transmembrane conductance regulator (CFTR), which is a critical chloride channel (Fig. 15.28). The mutation alters the secondary and tertiary structure of the protein, leading to a failure of opening of the chloride channel in response to elevated cyclic AMP in epithelial cells. This results in decreased excretion of chloride into the airway lumen and an increased reabsorption of sodium into the epithelial cells. With less excretion of salt there is less excretion of water and increased viscosity and tenacity of airway secretions. A possible reason for the high salt content of sweat is that there is a CFTR-independent mechanism of chloride secretion in the sweat gland with an impaired reabsorption of sodium chloride in the distal end of the duct.

Many genetic variants are known. The frequency of \([\Delta F508]\) mutation in CF is 70% in the USA and UK, under 50% in southern Europe and 30% in Ashkenazi families. A further mutation G551D-CFTR reaches the cell surface but fails to open VX-770 allows it to open momentarily (see p. 811)

**Clinical features**

**Respiratory effects**

Although the lungs of babies born with CF are structurally normal at birth, frequent respiratory infections soon develop and are often the presenting feature. CF is the commonest cause of recurrent bronchopulmonary infection in childhood, and is a major cause in early adult life. Sinusitis is almost universal and nasal polyps are common. Breathlessness and haemoptysis occur in the later stages as airflow limitation and bronchiectasis develop. Spontaneous pneumothorax may occur. Respiratory failure and cor pulmonale eventually develop.

**Gastrointestinal effects**

About 85% of patients have symptomatic steatorrhoea owing to pancreatic dysfunction (see p. 366). Children may be born with meconium ileus owing to the viscid consistency of meconium in CF; later in life they may develop the meconium ileus equivalent syndrome, a form of small intestinal obstruction unique to CF. Cholesterol gallstones occur with increased frequency. Cirrhosis develops in about 5% of older patients and there are increased incidences of peptic ulceration and gastrointestinal malignancy.

**Nutritional effects**

Many patients suffer from malnutrition due to a combination of malabsorption and maldigestion. Poor nutrition is associated with increased risk of pulmonary sepsis.

**Other features**

Puberty and skeletal maturity are delayed in most CF patients. Males are almost always infertile owing to failure of development of the vas deferens and epididymis. Females are able to conceive, but often develop secondary amenorrhoea as the disease progresses. Arthropathy and diabetes mellitus occur in 11% of adults with CF.

**Diagnosis**

The diagnosis of CF in older children and adults is based on the clinical history and:
- a family history of the disease
- a high sweat sodium concentration over 60 mmol/L

**Figure 15.28 Cystic fibrosis.** Abnormalities and possible therapies (see text). CFTR, cystic fibrosis transmembrane conductance regulator. Ph\(^{ΔF508}\)* phenylalanine deletion in \(Δ F508\). G551D, glycine replaced by aspartate.
sweat analysis is essential, but the test is still difficult to
interpret in adults)
- blood DNA analysis of gene defect
- radiology showing features seen in bronchiectasis (see
  p. 819)
- absent vas deferens and epididymis
- blood immunoreactive trypsin levels – these are not
  useful diagnostically but may be useful in screening.

Treatment
CF patients should be managed by multidisciplinary special-
ized teams. The overall care involves education to improve
their quality of life, good nutrition and the prompt treatment
of exacerbations to avoid hospitalization.
- General care should include stopping smoking,
vaccination with influenza and pneumococcal vaccines
and pulmonary rehabilitation (p. 817).
- Oxygen therapy should be given as necessary (Box
  15.1).
- Antibiotic treatment for respiratory infections is as
  described under bronchiectasis on page 820.
- Seventy per cent of adults with CF have Pseudomonas
  infection in their sputum. Nebulized anti-pseudomonal
  antibiotic therapy improves lung function and decreases
  the risk of infective exacerbations and hospitalization.
- Drug therapy: β₂ agonists (p. 830) and inhaled
corticosteroids (p. 831) may provide symptomatic relief
but have no effect on long-term survival.
- Airway clearance. Inhalation of recombinant DNAse
  (dornase alfa 2.5 mg daily) has been shown to improve
FEV₁ by 20% in some patients. Hyper tonic saline
by inhalation (in concentrations of up to 7%) gives
short-term benefit. Amlodire, which inhibits sodium
transport, has been used but no overall benefit has been
shown in meta-analysis. Acetylcysteine has been shown
in vitro to liquefy CF sputum by cleaving disulfide bonds
in mucus glycoproteins but clinical studies have been
disappointing.
- Non-invasive ventilation (p. 895) improves symptoms
in chronic respiratory failure but there is no evidence of
a survival benefit. It acts as a bridge to lung
transplantation (p. 822).
- Treatment for pancreatic insufficiency (p. 366) and
  malnutrition (p. 203).
- Human experimental studies have been conducted on
  the delivery to the epithelium of the normal CFTR gene
using, as a vector, a replication-deficient adenovirus
containing normal human CFTR complementary DNA
which is trophic for epithelial cells. Gentamicin can
suppress premature termination codons, and nasal
administration has been shown to correct the
physiological abnormality. These studies are in their
early stages.
- Targeted genetic therapy – see page 44.

Prognosis and screening
Almost all CF patients develop progressive respiratory failure
but the prognosis has improved considerably over the years.
Some 90% of children now survive into their teens and the
median survival for those born after 1990 is estimated at 40
years. A major problem is sputum infection with Burkholderia
cepacia which is associated with accelerated disease and
rapid death. Multiple antibiotic resistance is common and
spread occurs from person to person. Strategies to limit
transmission include rigid segregation of both inpatients and
outpatients and advice to CF sufferers not to socialize together.
Sadly, groups formed for mutual support and education have
had to be dissolved, leading to considerable distress.
Genetic screening is available for the 20 commonest muta-
tions and this identifies 85–95% of carriers. Screening for the
carer state should be offered to persons or couples with a
family history of CF, together with counselling (see p. 43).

Chronic cough (see p. 798)
Pathological coughing results from two mechanisms:
- Stimulation of sensory nerves in the epithelium by
  secretions, foreign bodies, cigarette smoke and tumours
- Sensitization of the cough reflex with abnormal increase
  in the sensitivity of the cough receptors
Sensitization of the cough reflex can be demonstrated by
inhalation of capsaicin or saline solution and presents clini-
cally as a persistent tickling sensation in the throat with
paroxysms of coughing induced by changes in air tempera-
ture, aerosol sprays, perfumes and cigarette smoke. It is
found in association with viral infections, oesophageal reflux,
post-nasal drip, cough-variant asthma, and in 15% of
patients taking angiotensin-converting enzyme (ACE)
Inhibitors. The association with ACE inhibitors implicates neu-
ropetidesth, prostaglandins E₂ and F₂ and bradykinin as
causes of the cough. In some patients no cause can be found
(idiopathic cough). In the absence of chest X-ray abnormali-
ties, possible investigations include:
- ENT examination (p. 1051) and sinus CT for post-nasal
drip
- Lung function tests and histamine bronchial provocation
testing (p. 829) for cough-variant asthma
- Ambulatory oesophageal pH monitoring and manometry
  for oesophageal reflux
- Fibroptic bronchoscopy for inhaled foreign body or
  tumour
- ECG, echocardiography and exercise testing and
  impedance for cardiac causes
- Hyperventilation testing
- Psychiatric appraisal.
Symptomatic management of unexplained cough can be
difficult. Morphine depresses the sensitized cough reflex but
its unwanted effects limit its long-term use. Dihydrocodeine
linctus may help some patients. Demulcent preparations
and cough sweets only provide temporary relief. Patients
who cough while taking ACE inhibitors should switch to an
angiotensin-II receptor antagonist, e.g. losartan (see p. 719),
which does not block bradykinin breakdown.

Lung and heart-lung transplantation
Indications and donor selection
The main diseases treated by transplantation are:
- Pulmonary fibrosis
- Primary pulmonary hypertension
- Cystic fibrosis
- Bronchiectasis
- Emphysema – particularly α₁-antitrypsin inhibitor
deficiency
- Eisenmenger’s syndrome.
Patients selected for transplantation are usually under
60 years with a life expectancy of less than 18 months, no
underlying cancer and no serious systemic disease.
Donor organs are taken from donors under 40 years, with good cardiac and lung function, and chest measurements slightly smaller than those of the recipient. Matching for ABO blood group is essential, but rhesus blood group compatibility is not essential. Since donor material is limited, single lung transplantation is preferred to double lung or heart-lung transplantation and can be successfully undertaken in pulmonary fibrosis, pulmonary hypertension and emphysema. Bilateral lung transplantation is required in infective conditions to prevent spillover of bacteria from the diseased lung to a single lung transplant. Eisenmenger’s syndrome requires heart-lung transplant.

Complications and their treatment
- **Early post-transplant pulmonary oedema** requires diuretics and ventilatory support.
- **Infections**, particularly within first 3 months:
  - Bacterial pneumonia – antibiotics
  - Cytomegalovirus – ganciclovir
  - Herpes simplex – aciclovir.
  - P. jiroveci – prophylactic co-trimoxazole.
- **Immunosuppression** is with ciclosporin (inhaled formulation has shown benefit) or tacrolimus, azathioprine or mycophenolate mofetil and prednisolone.
- **Rejection**:
  - Early (first few weeks) – high-dose i.v. corticosteroids
  - Late (after 3 months) – high-dose i.v. corticosteroids are sometimes effective in obliterative bronchiolitis. Post-transplant lymphoproliferative disease may respond to rituximab, an anti-B-cell monoclonal antibody.

Prognosis
Several studies show a major improvement in overall quality of life. One year survival rates have improved with a yearly mortality rate of about 10%. Death is mainly due to bronchitis. Actual survival varies with the original diagnosis but the median survival is approximately four years.

**ASTHMA**

Asthma is a common chronic inflammatory condition of the airways whose cause is incompletely understood. Symptoms include wheeze, chest tightness, cough and shortness of breath, often worse at night. Asthma commonly starts in childhood between the ages of 3 and 5 years and may either worsen or improve during adolescence. Classically asthma has three characteristics:

- **Airflow limitation** which is usually reversible spontaneously or with treatment
- **Airway hyperresponsiveness** to a wide range of stimuli (see below)
- **Bronchial inflammation** with T lymphocytes, mast cells, eosinophils with associated plasma exudation, oedema, smooth muscle hypertrophy, matrix deposition, mucus plugging and epithelial damage.

In chronic asthma, inflammation may be accompanied by irreversible airflow limitation as a result of airway wall remodelling that may involve large and small airways and mucus impaction.

Prevalence
In many countries, the prevalence of asthma is increasing. This increase is particularly marked in children and young adults where this disease may affect up to 15% of the population. There is also geographical variation, with asthma being commoner in more developed countries. Some of the highest rates are in the UK, New Zealand and Australia, with much lower rates in Far Eastern countries such as China and Malaysia, Africa and Central and Eastern Europe. Long-term follow-up in developing countries suggests that asthma may become more frequent as individuals adopt a more ‘westernized’ lifestyle, but the environmental factors accounting for this remain unknown. Studies of occupational asthma suggest that a large proportion of the workforce (15–20%) may become asthmatic if exposed to potent sensitizers. Worldwide, approximately 300 million people have asthma and this is expected to rise to 400 million by 2025.

Classification
Asthma is a complex disorder of the conducting airways that was often classified into extrinsic and intrinsic asthma but there is considerable overlap.

- **Extrinsic asthma** occurs most frequently in atopic individuals: i.e. those with positive skin-prick reactions to common inhalant allergens such as dust mite, animal danders, pollens and fungi; 90% of children and 70% of adults with persistent asthma have positive skin-prick tests to inhalant allergens. Childhood asthma is often accompanied by eczema (atopic dermatitis) (see p. 1206). Sensitization to chemicals or biological products in the workplace is a frequently overlooked cause of late-onset asthma in adults.

- **Intrinsic asthma** often starts in middle age. Nevertheless, many patients with adult-onset asthma show positive allergen skin tests and on close questioning some of these will give a history of childhood respiratory symptoms suggesting they have extrinsic asthma.

Non-atopic individuals may develop asthma in middle age from extrinsic causes such as sensitization to occupational agents such as toluene diisocyanate, intolerance to non-steroidal anti-inflammatory drugs such as aspirin or because they were given β-adrenoceptor-blocking agents for concurrent hypertension or angina that block the protective effect of endogenous adrenergic agonists. Extrinsic causes must be considered in all cases of asthma and, where possible, avoided.

**Aetiology and pathogenesis**
The two major factors involved in the development of asthma and many other stimuli that can precipitate attacks are shown in Figure 15.29.

**Atopy and allergy**
The term ‘atopy’ was coined in the early twentieth century to describe a group of disorders, including asthma and hay-fever, which appeared:

- to run in families
- to have characteristic wealing skin reactions to common allergens in the environment
- to have circulating allergen-specific antibodies (later shown to be IgE).

Allergen-specific IgE is present in 30–40% of the UK population, and there is a link between serum IgE levels and both the prevalence of asthma and airway hyperresponsiveness. Genetic and environmental factors affect serum IgE levels.

**Genetic**
There is no single gene for asthma, but several genes, in combination with environmental factors, appear to influence the development of asthma.

Figure 15.29 Causes and triggers of asthma. RSV, respiratory syncytial virus; NSAIDs, non-steroidal anti-inflammatory drugs.

- Genes controlling the production of the cytokines IL-3, IL-4, IL-5, IL-9, IL-13 and GM-CSF – which in turn affect mast and eosinophil cell development and longevity as well as IgE production – are present in a cluster on chromosome 5q31-33 (the IL-4 gene cluster).
- Polymorphic variation in proteins along the IL-4/IL-13 signalling pathway is strongly associated with allergy and asthma.
- Novel asthma genes identified by positional cloning from whole genome scans are the PHF11 locus on chromosome 17q21. This feature of asthma and can be demonstrated by asking patients to inhale gradually increasing concentrations of histamine or methacholine (bronchial provocation tests). This induces transient airflow limitation in susceptible individuals (approximately 20% of the population); the severity of BHR can be graded according to the provocation dose (PD) or concentration (PC) of the agonist that produces a 20% fall in forced expiratory volume in one second (FEV1). BHR can also be assessed by exercise testing or inhalation of cold dry air, mannitol or hypertonic saline. These are indirect tests that release endogenous mediators such as histamine, prostaglandins and leukotrienes which then cause bronchoconstriction. Indirect measures of BHR correlate more closely with symptoms and diurnal peak expiratory flow rate (PEFR) variation than PC20 histamine or methacholine: both are useful in diagnosing asthma if there is doubt and in guiding controller treatment.
- Some patients also react to methacholine but at higher doses, e.g. those with:
  - attacks of asthma only on extreme exertion, e.g. winter sports enthusiasts
  - wheezing or prolonged periods of coughing following a viral infection
  - seasonal wheeze during the pollen season
  - allergic rhinitis, but not complaining of lower respiratory symptoms until specifically questioned
  - and some subjects with no respiratory symptoms.

Increased responsiveness of the airways of the lung (airway hyperresponsiveness)

Bronchial hyperresponsiveness (BHR) is a characteristic feature of asthma and can be demonstrated by asking patients to inhale gradually increasing concentrations of histamine or methacholine (bronchial provocation tests). This induces transient airflow limitation in susceptible individuals (approximately 20% of the population); the severity of BHR can be graded according to the provocation dose (PD) or concentration (PC) of the agonist that produces a 20% fall in FEV1 (PD20 FEV1 or PC20 FEV1). Patients with clinical symptoms of asthma respond to very low doses of methacholine, i.e. they have a low PD20 FEV1. BHR can also be assessed by exercise testing or inhalation of cold dry air, mannitol or hypertonic saline. These are indirect tests that release endogenous mediators such as histamine, prostaglandins and leukotrienes which then cause bronchoconstriction. Indirect measures of BHR correlate more closely with symptoms and diurnal peak expiratory flow rate (PEFR) variation than PC20 histamine or methacholine: both are useful in diagnosing asthma if there is doubt and in guiding controller treatment.

- Environmental factors
  Early childhood exposure to allergens and maternal smoking has a major influence on IgE production. Much current interest focuses on the role of intestinal bacteria and childhood infections in shaping the immune system in early life. It has been suggested that growing up in a relatively ‘clean’ environment may allow the immune system to avoid developing allergic responses. Components of bacteria (e.g. lipopolysaccharide endotoxin, immunostimulatory CpG DNA sequences, flagellin), viruses (e.g. SS- and DS-RNA) and fungi (e.g. chiton, a cell wall component) stimulate various toll-like receptors (TLRs) expressed on immune and epithelial cells to direct the immune and inflammatory response away from the allergic (Th2) towards protective (Th1 and Treg) pathways. Th1 immunity is associated with antimicrobial protective immunity whereas regulatory T cells are strongly implicated in tolerance to allergens. Thus early life exposure to inhaled and ingested products of microorganisms, as occurs in livestock farming communities and developing countries, may reduce the subsequent risk of a child becoming allergic and/or developing asthma.

- Precipitating factors
  Occupational sensitizers (Table 15.13)
  Over 250 materials encountered at the workplace can cause occupational asthma, which accounts for about 15% of all...
Asthma cases. These are recognized occupational diseases in the UK, and patients in insurable employment are eligible for statutory compensation provided they apply within 10 years of leaving the occupation in which the asthma developed.

Asthma can be due to:

- Low molecular weight compounds, e.g. reactive chemicals such as isocyanates and acid anhydrides that bond chemically to epithelial cells to activate them as well as provide haptenes recognized by T cells.
- High molecular weight compounds, e.g. flour, organic dusts and other large protein molecules involving specific IgE antibodies.

The risk of developing some forms of occupational asthma increases in smokers. The proportion of employees developing occupational asthma depends primarily upon the level of exposure. Proper enclosure of industrial processes or appropriate ventilation greatly reduces the risk. Atopic individuals develop occupational asthma more rapidly when exposed to agents causing the development of specific IgE antibody. Non-atopic individuals can also develop asthma when exposed to such agents, but after a longer period of exposure.

**Nonspecific factors**

The characteristic feature of BHR in asthma means that, as well as reacting to specific antigens, the airways will also respond to a wide variety of nonspecific direct and indirect stimuli.

**Cold air and exercise**

Most asthmatics wheeze after prolonged exercise or inhaling cold dry air. Typically, the attack does not occur while exercising but afterwards. Exercise-induced wheeze is driven by release of histamine, prostaglandins (PGs) and leukotrienes (LTs) from mast cells as well as stimulation of neural reflexes when the epithelial lining fluid of the bronchi becomes hyperosmolar owing to drying and cooling during exercise. The phenomenon can be shown by exercise, cold air and hypertonic (e.g. saline or mannitol) provocation tests.

**Atmospheric pollution and irritant dusts, vapours and fumes**

Many patients with asthma experience worsening of symptoms on contact with tobacco smoke, car exhaust fumes, solvents, strong perfumes or high concentrations of dust in the atmosphere. Major epidemics have been recorded when large amounts of allergens are released into the air, e.g. soybean dust in Barcelona. Asthma exacerbations increase during summer and winter air pollution episodes associated with climatic temperature inversions. Epidemics of asthma have occurred in the presence of high concentrations of ozone, particulates and NO₂ in the summer and particulates, NOₓ and SO₂ in the winter.

**Diet**

Increased intakes of fresh fruit and vegetables have been shown to be protective, possibly owing to the increased intake of antioxidants or other protective molecules such as flavonoids. Genetic variation in antioxidant enzymes is associated with more severe asthma.

**Emotion**

It is well known that emotional factors may influence asthma both acutely and chronically, but there is no evidence that patients with the disease are any more psychologically disturbed than their non-asthmatic peers. An asthma attack is a frightening experience, especially when of sudden and unexpected onset. Patients at special risk of life-threatening attacks are understandably anxious.

**Drugs**

**Non-steroid anti-inflammatory drugs (NSAIDs).** NSAIDs, particularly aspirin and propionic acid derivatives, e.g. indometacin and ibuprofen, are implicated in triggering asthma in approximately 5% of patients. NSAID intolerance is especially prevalent in those with both nasal polyps and asthma and is not infrequently associated with rhinitis and flushing on drug exposure. NSAIDs inhibit arachidonic acid metabolism via the cyclo-oxygenase (COX) pathway, preventing the synthesis of certain prostaglandins. In aspirin-intolerant asthma there is reduced production of PGE₂ which, in a sub-proportion of genetically susceptible subjects, precipitated by COX-2 inhibitors, indicating that it is blockade of the COX-1 isoenzyme that is linked to impaired PGE₂ production.

**Beta-blockers.** The airways have a direct parasympathetic innervation that tends to produce bronchoconstriction. There is no direct sympathetic innervation of the smooth muscle of the bronchi, and antagonism of parasympathetically induced bronchoconstriction is critically dependent upon circulating epinephrine (adrenaline) acting through β₁-receptors on the surface of smooth muscle cells. Inhibition of this effect by β₁-adrenoceptor-blocking drugs such as propranolol leads to bronchoconstriction and airflow limitation, but only in asthmatic subjects. Selective β₂-adrenergic-blocking drugs such as atenolol may still induce attacks of asthma; ideally alternative drugs should be used to treat hypertension or angina in asthmatic patients.

**Allergen-induced asthma**

The experimental inhalation of allergen by atopic asthmatic individuals leads to the development of different types of reaction, as illustrated in Figure 15.31. Much of our knowledge of asthma mechanisms comes from studies of allergen inhalation, but it must always be remembered this is only a model of the disease.

**Immediate asthma (early reaction).** Airflow limitation begins within minutes of contact with the allergen, reaches its maximum in 15–20 minutes and subsides by 1 hour.

**Dual and late-phase reactions.** Following an immediate reaction many asthmatics develop a more prolonged and sustained attack of airflow limitation that responds less well to inhalation of bronchodilator drugs such as salbutamol. Isolated late-phase reactions with no preceding immediate response can occur after the inhalation of some occupational sensitizers such as isocyanates. BHR increases during and for several weeks after the exposure, which may explain persisting symptoms after allergen exposure.

**Pathogenesis**

The pathogenesis of asthma is complex and not fully understood. It involves a number of cells, mediators, nerves and vascular leakage that can be activated by several different mechanisms, including exposure to allergens (Fig. 15.32). The varying clinical severity and chronicity of asthma is dependent on an interplay between airway inflammation and airway wall remodelling. The inflammatory component is driven by Th2-type T lymphocytes which facilitate IgE synthesis through production of IL-4 and eosinophilic inflammation through IL-5 (Fig. 15.32). However, as the disease becomes more severe and chronic and loses its sensitivity to corticosteroids, there is greater evidence of a Th1 response with release of mediators such as TNF-α and associated tissue damage, mucous metaplasia and aberrant epithelial and mesenchymal repair.

**Figure 15.30 Arachidonic acid metabolism and the effect of drugs.** The sites of action of NSAIDs (e.g. aspirin, ibuprofen) are shown. The enzyme cyclo-oxygenase occurs in three isoforms, COX-1 (constitutive), COX-2 (inducible) and COX-3 (in brain). PG, prostaglandin; BLT, B leukotriene receptor; CysLT, cysteiny1 leukotriene receptor.

**Figure 15.31 Different types of asthmatic reactions following challenge with allergen.** M, midnight; N, noon.
Inflammation

Several key cells are involved in the inflammatory response that characterizes all types of asthma.

**Mast cells** (see also p. 53). These are increased in the epithelium, smooth muscle and mucous glands in asthma and release powerful preformed and newly generated mediators that act on smooth muscle, small blood vessels, mucus-secreting cells and sensory nerves, such as histamine, tryptase, PGD$_2$, and cysteinyl leukotrienes, which cause the immediate asthmatic reaction. Mast cells are inhibited by sodium cromoglycate and $\beta_2$ agonists, which may partly explain their ability to prevent acute bronchoconstriction triggered by indirect challenges. Mast cells also release an array of cytokines, chemokines and growth factors that contribute to the late asthmatic response and more chronic aspects of asthma.

**Eosinophils.** These are found in large numbers in the bronchial wall and secretions of asthmatics. They are attracted to the airways by the eosinophilopoietic cytokines IL-3, IL-5 and GM-CSF as well as by chemokines which act on type 3 C-C chemokine receptors (CCR-3) (i.e. eotaxin, RANTES, MCP-1, MCP-3 and MCP-4). These mediators also prime eosinophils for enhanced mediator secretion. When activated, eosinophils release LTC$_4$, and basic proteins such as major basic protein (MBP), eosinophil cationic protein (ECP) and eosinophil peroxidase (EPX) that are toxic to epithelial cells. Both the number and activation of eosinophils are rapidly decreased by corticosteroids. Sputum eosinophilia is of diagnostic help as well as providing a biomarker of response to therapy.

**Dendritic cells and lymphocytes.** These cells are abundant in the mucous membranes of the airways and the alveoli. Dendritic cells have a role in the initial uptake and presentation of allergens to lymphocytes. T helper lymphocytes (CD$^+$) show evidence of activation (Fig. 15.32) and the release of their cytokines plays a key part in the migration and activation of mast cells (IL-3, IL-4, IL-9 and IL-13) and eosinophils (IL-3, IL-5, GM-CSF). In addition, production of IL-4 and IL-13 helps maintain the proallergic Th2 phenotype, favouring switching of antibody production by B lymphocytes to IgE. In mild/moderate asthma there is selective upregulation of Th2 T cells with reduced evidence of the Th1 phenotype (producing gamma-interferon, TNF-$\alpha$ and IL-2), although Th1 cells are more prominent in more severe disease. This polarization is mediated by dendritic cells and involves a combination of antigen presentation, co-stimulation and exposure to polarizing cytokines. The activity of both macrophages and lymphocytes is influenced by corticosteroids but not $\beta_2$-adrenoceptor agonists.
Remodelling

A characteristic feature of chronic asthma is an alteration of structure and functions of the formed elements of the airways. Together, these structural changes interact with inflammatory cells and mediators to cause the characteristic features of the disease. Deposition of matrix proteins, swelling and cellular infiltration expand the submucosae beneath the epithelium so that for a given degree of smooth muscle shortening there is excess airway narrowing. Swelling outside the smooth muscle layer spreads the retractive forces exerted by the surrounding alveoli over a greater surface area so that the airways close more easily. Several factors contribute to these changes.

The epithelium. In asthma the epithelium of the conducting airways is stressed and damaged with loss of ciliated columnar cells. Metaplasia occurs with a resultant increase in the number and activity of mucus-secreting goblet cells. The epithelium is a major source of mediators, cytokines and growth factors that enhance inflammation and promote tissue remodelling (Fig. 15.32). Damage and activation of the epithelium make it more vulnerable to infection by common respiratory viruses (e.g. rhinovirus, coronavirus) and to the effects of air pollutants. Increased production of nitric oxide (NO), due to the increased expression of inducible NO synthase, is a feature of epithelial damage and activation. Measurement of exhaled NO is proving useful as a non-invasive test of continuing inflammation (p. 829).

Epithelial basement membrane. A pathognomonic feature of asthma is the deposition of repair collagens (types I, III and V) and proteoglycans in the lamina reticularis beneath the basement membrane. This, along with the deposition of other matrix proteins such as laminin, tenasin and fibronectin, causes the appearance of a thickened basement membrane observed by light microscopy in asthma. This collagen deposition reflects activation of an underlying sheath of fibroblasts that transform into contractile myofibroblasts which also have increased capacity to secrete matrix. Aberrant signalling between the epithelium and underlying myofibroblasts is thought to be the principal cause of airway wall remodelling, since the cells are prolific producers of a range of tissue growth factors such as epidermal growth factor (EGF), transforming growth factor (TGF)-α and β, connective tissue-derived growth factor (CTGF), platelet-derived growth factor (PDGF), endothelin (ET), insulin-like growth factors (IGF), nerve growth factors and vascular endothelial growth factors (Fig. 15.32). The same interaction between epithelium and mesenchymal tissues is central to branching morphogenesis in the developing fetal lung. It has been suggested that these mechanisms are reactivated in asthma, but instead of causing airway growth and branching, they lead to thickening of the airway wall (remodelling, Fig. 15.32). Increased deposition of collagens, proteoglycans and matrix proteins creates a microenvironment which encourages ongoing inflammation since these molecules also possess cell-signalling functions, which aid cell movement, prolong inflammatory cell survival and prime them for mediator secretion.

Smooth muscle. Another prominent feature of asthma is hyperplasia of the helical bands of airway smooth muscle. In addition to increasing in amount, the smooth muscle alters in function so it contracts more easily and stays contracted because of a change in actin–myosin cross-link cycling. These changes allow asthmatic airways to contract too much and too easily at the least provocation. Asthmatic smooth muscle also secretes a wide range of cytokines, chemokines and growth factors that help sustain the chronic inflammatory response. The asthma gene ADAM33 has been implicated in driving increased airway smooth muscle and other features of remodelling through increased availability of growth factors.

Nerves. Neural reflexes, both central and peripheral, contribute to the irritability of asthmatic airways. Central reflexes involve stimulation of nerve endings in the epithelium and submucosa with transmission of impulses via the spinal cord and brain back down to the airways where release of acetylcholine from nerve endings stimulates M3 receptors on smooth muscle causing contraction. Local neural reflexes involve antidromic neurotransmission and the release of a variety of neuropeptides. Some of these are smooth muscle contractants (substance P, neuropeptide A), some are vasoconstrictors (e.g. calcitonin gene-related peptide, CGRP) and some vasodilators (e.g. neuropeptide Y, vasoactive intestinal polypeptide). A polymorphism of the neuropeptide S receptor (GPR 154) is associated with asthma susceptibility. Bradykinin generated by tissue and serum proteolytic enzymes (including mast cell tryptase and tissue kallikrein) is also a potent stimulus of local neural reflexes involving (nonmyelinated) nerve fibres.

Clinical features

The principal symptoms of asthma are wheezing attacks and episodic shortness of breath. Symptoms are usually worst during the night, especially in uncontrolled disease. Cough is a frequent symptom that sometimes predominates, especially in children in whom nocturnal cough can be a presenting feature. Attacks vary greatly in frequency and duration. Some patients only have one or two attacks a year that last for a few hours, while others have attacks lasting for weeks. Some patients have chronic persistent symptoms, on top of which there are fluctuations. Attacks may be precipitated by a wide range of triggers (Fig. 15.29). Asthma is a major cause of impaired quality of life with impact on work and recreational, as well as physical activities, and emotions.

Investigations

There is no single satisfactory diagnostic test for all patients with asthma.

Lung function tests

Peak expiratory flow rate (PEFR) measurements on waking, prior to taking a bronchodilator and before bed after a bronchodilator, are particularly useful in demonstrating the variable airflow limitation that characterizes the disease (Fig. 15.14). The diurnal variation in PEFR is a good measure of asthma activity and is of help in the longer-term assessment of the patient’s disease and its response to treatment.

Spirometry is useful, especially in assessing reversibility. Asthma can be diagnosed by demonstrating a greater than 15% improvement in FEV1 or PEFR following the inhalation of a bronchodilator. However, there may be less reversibility when asthma is in remission or in severe chronic asthma when little reversibility can be demonstrated or if the patient is already being treated with long-acting bronchodilators.

The carbon monoxide (CO) transfer test is normal in asthma.

Exercise tests

These have been widely used in the diagnosis of asthma in children. Ideally, the child should run for 6 minutes on a treadmill at a workload sufficient to increase the heart rate above 160 beats per minute. Alternative methods use cold air challenge, isocapnic hyperventilation (forced...
overbreathing with artificially maintained $P_aCO_2$ or aerosol challenge with hypertonic solutions. A negative test does not automatically rule out asthma.

**Histamine or methacholine bronchial provocation test** (see p. 824)

This test indicates the presence of airway hyperresponsive-ness, a feature found in most asthmatics, and can be particularly useful in investigating those patients whose main symptom is cough. The test should not be performed on individuals who have poor lung function (FEV1 <1.5 L) or a history of ‘brittle’ asthma. In children, controlled exercise testing as a measure of BHR is often easier to perform.

**Trial of corticosteroids**

All patients who present with severe airflow limitation should undergo a formal trial of corticosteroids. Prednisolone 30 mg orally should be given daily for 2 weeks with lung function measured before and immediately after the course. A substantial improvement in FEV1 (>15%) confirms the presence of a reversible element and indicates that the administration of inhaled steroids will prove beneficial to the patient. If the trial is for ≤2 weeks, the oral corticosteroid can be withdrawn without tailing off the dose, and should be replaced by inhaled corticosteroids in those who have responded.

**Exhaled nitric oxide (NO)**

A measure of airway inflammation and an index of corticosteroid response; used in children to assess the efficacy of corticosteroids.

**Blood and sputum tests**

Patients with asthma sometimes have increased numbers of eosinophils in peripheral blood (>0.4×10^9/L) but sputum eosinophils is a more specific diagnostic finding.

**Chest X-ray**

There are no diagnostic features of asthma on the chest X-ray, although overinflation is characteristic during an acute episode or in chronic severe disease. A chest X-ray may be helpful in excluding a pneumothorax, which can occur as a complication, or in detecting the pulmonary infiltrates associated with allergic bronchopulmonary aspergillosis.

**Skin tests**

Skin-prick tests (SPT) should be performed in all cases of asthma to help identify allergic trigger factors. Allergen-specific IgE can be measured in serum if SPT facilities are not available, if the patient is taking antihistamines or no suitable allergen extracts are available.

**Allergen provocation tests**

Allergen inhalation challenge is a useful research tool, and is required when investigating of patients with suspected occupational asthma, but not in ordinary asthma.

**Management**

The aims of treatment are to:

- Abolish symptoms
- Restore normal or best possible lung function
- Reduce the risk of severe attacks
- Enable normal growth to occur in children
- Minimize absence from school or employment.

This involves:

- Patient and family education about asthma
- Patient and family participation in treatment

- Avoidance of identified causes where possible
- Use of the lowest effective doses of convenient medications to minimize short-term and long-term side-effects.

Many asthmatics join self-help groups whose aim in order to improve their understanding of the disease and to foster self-confidence and fitness.

**Control of extrinsic factors**

Measures must be taken to avoid causative allergens such as pets, moulds and certain foodstuffs (see allergic rhinitis), particularly in childhood. Avoidance of house-dust mite is very difficult. There is little evidence for the effectiveness of current physical or chemical measures to control house-dust mite levels. The use of covers for bedding and changes to living accommodation has no beneficial effect on outcomes. Active and passive smoking should be avoided, as should beta-blockers in either tablet or eye drop form. Individuals intolerant to aspirin should avoid NSAIDs, although they may tolerate COX-2 inhibitors. Other agents (e.g. preservatives and colouring materials such as tartrazine) should be avoided if shown to be a causative factor. About one-third of individuals sensitized to occupational agents may be cured if they are kept permanently away from exposure. The remaining two-thirds will continue to have symptoms, and in half of these the symptoms may be as severe as when exposed to materials at work, especially if they were symptomatic for a long time before the diagnosis was made.

This emphasizes that:

- The rapid identification of extrinsic causes of asthma and their removal is necessary wherever possible (e.g. occupational agents, family pets).
- Once extrinsic asthma is initiated, it may become self-perpetuating, possibly by non-immune mechanisms.

**Drug treatment**

The mainstay of asthma therapy is the use of therapeutic agents delivered as aerosols or powders directly into the lungs (see Practical Box 15.3). The advantages of this method
of administration are that drugs are delivered direct to the airways and first-pass metabolism in the liver is avoided; thus lower doses are necessary and systemic unwanted effects are minimized.

Both national and international guidelines have been published on the stepwise treatment of asthma (Box 15.3), based on three principles:

- **Asthma self-management with regular asthma monitoring using PEF meters and individual treatment plans that are discussed with each patient and written down.**

- The appreciation that asthma is an inflammatory disease and that anti-inflammatory (controller) therapy should be started even in mild cases.

- Use of short-acting inhaled bronchodilators (e.g. salbutamol and terbutaline) only to relieve breakthrough symptoms. Increased use of bronchodilator treatment to relieve increasing symptoms is an indication of deteriorating disease.

A list of drugs used in asthma is shown in Box 15.4. These are given in a stepwise fashion as indicated in Box 15.3.

Once asthma is brought under control, for at least 2–3 months, the drug regimen should be reassessed in order to reduce the dosage of inhaled steroids.

### β₂-Adrenoceptor agonists

The most widely used bronchodilator preparations contain β₂-adrenoceptor agonists that are selective for the respiratory tract and do not stimulate the β₁, adrenoceptors of the myocardium. These drugs are potent bronchodilators because they relax the bronchial smooth muscle. They are very effective in relieving symptoms but do little for the underlying airways inflammation. Their usage is as follows:

- **Mildest asthmatics with intermittent attacks.** Only these people should rely on bronchodilator treatment alone. Short-acting β agonists (SABAs) such as salbutamol (100 μg), (called albuterol in the USA), or terbutaline (250 μg) should be prescribed as ‘two puffs as required’. Some patients use nebulizers at home for self-administration of salbutamol or terbutaline. Such treatment is effective, but patients should not rely on repeated home administration of nebulized β₂-adrenoceptor agonists for worsening asthma, and should seek medical advice urgently if their condition does not improve. Excessive use of SABAs was linked to two epidemics of asthma mortality in the 1960s and 1980s.

- **SABAs** can be taken at any step, as and when required from **step 1 to step 5** (see above).
Poorly controlled asthmatics on standard doses of inhaled steroids. These patients require salmeterol or formoterol, which are highly selective and potent long-acting β₂-adrenoceptor agonists (LABAs) effective by inhalation for up to 12 hours, thereby reducing the need for administration to once or twice daily. LABAs improve symptoms and lung function and reduce exacerbations in patients. They should never be used alone but always in combination with an inhaled corticosteroid. Increasingly, these drugs are administered as fixed-dose combinations with corticosteroids (salmeterol/fluticasone and formoterol/budesonide) in the same inhaler (step 3).

To help those who cannot coordinate activation of the aerosol and inhalation, several breath-activated or dry powder devices have been developed.

Antimuscarinic bronchodilators
Muscarinic receptors are found in the respiratory tract; large airways contain mainly M₂ receptors whereas the peripheral lung tissue contains M₁ and M₃ receptors (see p. 793). Non-selective muscarinic antagonists – ipratropium bromide (20–40 μg three or four times daily) or oxtropium bromide (200 μg twice daily) – by aerosol inhalation can be useful during asthma exacerbations, but they are less useful in stable asthma.

Anti-inflammatory drugs
Sodium cromoglycate and nedocromil sodium prevent activation of many inflammatory cells, particularly mast cells, eosinophils and epithelial cells, but not lymphocytes, by blocking a specific chloride channel which in turn prevents calcium influx. These drugs are effective in patients with milder asthma (step 2) but have fallen out of favour in recent years.

Inhaled corticosteroids
All patients who have regular persistent symptoms (even mild symptoms) need regular treatment with inhaled corticosteroids delivered in a stepwise fashion (from step 2 upwards) or as a high dose followed by a reduction to maintenance levels. Beclomethasone dipropionate (BDP) is the most widely used inhaled steroid and is available in doses of 50, 100, 200 and 250 μg per puff. Other inhaled steroids include budesonide, fluticasone, mometasone and triamcinolone.

Much of the inhaled dose does not reach the lung but is either swallowed or exhaled. Deposition in the lung varies between 10% and 25% depending on inhaler technique and the technical characteristics of the aerosol device. Drug which is deposited in the airways reaches the systemic circulation, thereby reducing systemic effects, are also used (e.g. ciclesonide 80 μg daily).

Asthmatic patients who smoke are less responsive to inhaled corticosteroids due to induction of a range of genes and proteins in their respiratory epithelium. Assistance with smoking cessation should be offered, and additional therapy, e.g. with leukotriene receptor antagonists or theophylline, is required.

A functional GLCCI1 variant is associated with a decreased response to inhaled corticosteroids.

Many patients with anything more than mild/moderate asthma benefit from combination LABA/corticosteroid therapy and there is some evidence that the two drugs interact therapeutically.

Oral corticosteroids and steroid-sparing agents
Oral corticosteroids are needed for individuals not controlled on inhaled corticosteroids (step 5). The dose should be kept as low as possible to minimize side-effects. The effect of short-term treatment with prednisolone 30 mg daily is shown in Figure 15.14 (p. 804). Some patients require continuing treatment with oral corticosteroids. Several studies suggest that treatment with low doses of methotrexate (15 mg weekly) can significantly reduce the dose of prednisolone needed to control the disease in some patients, and ciclosporin also improves lung function in some steroid-dependent asthmatics. Several other steroid-sparing strategies including ciclosporin and immunoglobulin have also been tried, but with varying success.

Cysteinyl leukotriene receptor antagonists (LTRAs)
This class of anti-asthma therapy targets one of the principal asthma mediators by inhibiting the cysteinyl LT₁ receptor. A second receptor (cyst LT₂) has been identified on inflammatory cells. Montelukast, pranlukast (only available in South East Asia) and zafirlukast are given orally and are effective in a subpopulation of patients. However, it is not possible to predict which individuals will benefit: a 4-week trial of LTRA therapy is recommended before a decision is made to continue or stop.LTRAs should be tried in any patient who is not controlled on low to medium doses of inhaled steroids (step 2). Their action is additive to that of long-acting β₂ agonists. LTRAs are particularly useful in patients with aspirin-intolerant asthma, in those patients requiring high-dose inhaled or oral corticosteroids and in asthmatic smokers. Because these drugs are orally active they are helpful in asthma combined with rhinitis and in young children with asthma and/or virus-associated wheezing.

Monoclonal antibodies
Omalizumab, a recombinant humanized monoclonal antibody directed against IgE, chelates free IgE and downregulate the number and activity of mast cells and basophils. It is given subcutaneously every 2–4 weeks, depending on total serum IgE level and body weight. Although expensive, it is cost-effective in patients with frequent exacerbations
Emergency Box 15.2

Treatment of severe asthma

At home
1. The patient is reassessed. Tachycardia, a high respiratory rate and inability to speak in sentences indicate a severe attack.
2. If the PEFR is <150 L/min (in adults), an ambulance should be called. (All doctors should carry peak flow meters.)
3. Nebulized salbutamol 5 mg or terbutaline 10 mg is administered.
4. Hydrocortisone sodium succinate 200 mg i.v. is given.
5. Oxygen 40–60% is given if available.
6. Prednisolone 60 mg is given orally.

At hospital
1. The patient is reassessed.
2. Oxygen 40–60% is given.
3. The PEFR is measured using a low-reading peak flow meter, as an ordinary meter measures only from 60 L/min upwards.
4. Nebulized salbutamol 5 mg or terbutaline 10 mg is repeated and administered 4-hourly.
5. Add nebulized ipratropium bromide 0.5 mg to nebulized salbutamol/terbutaline.
6. Hydrocortisone 200 mg i.v. is given 4-hourly for 24 hours.
7. Prednisolone is continued at 60 mg orally daily for 2 weeks.
8. Arterial blood gases are measured; if the $P_aO_2$ is <7 kPa, ventilation may be required.
9. A chest X-ray is performed to exclude pneumothorax.
10. One of the following intravenous infusions is given if no improvement is seen:
   - Salbutamol 3–20 μg/min, or
   - Terbutaline 1.5–5.0 μg/min, or
   - Magnesium sulphate 1.2–2 g over 20 min.
11. No improvement – urgent; transfer to ITU.

Treatment (Emergency Box 15.2) consists of nebulized short-acting bronchodilators; nebulized antimuscarinics (e.g. ipratropium bromide) are also helpful. A chest X-ray is useful to exclude pneumothorax and other causes of dyspnoea. Intravenous hydrocortisone is useful, and in very severe cases, β₂-adrenoceptor agonists and/or magnesium sulphate are also given intravenously. Oral prednisolone (40–60 mg daily) should be given orally. Ventilation is required for patients who deteriorate despite this initial regimen.

Depending on progress, patients may go home after receiving nebulized therapy. More severe cases should be kept in hospital for 2–5 days with regular monitoring of oxygen saturation and peak flow rates. Downstream assessment of patients admitted with asthma should address trigger factors and aim to reduce the risk of readmission. Bronchial thermoplasty is a novel approach for moderate to severe persistent asthma. This bronchoscopic procedure reduces the mass of airway smooth muscle, reducing bronchoconstriction, and is being evaluated.

Management of catastrophic sudden severe asthma (brittle asthma)

A small minority of patients with asthma suffer sudden life-threatening attacks despite being well controlled between attacks. These attacks may occur within hours or even minutes, and can cause sudden death. Such patients require a carefully worked out management plan agreed by patient, primary care physician, hospital emergency services and the respiratory physician, which may include:

Acute severe asthma

The term acute severe asthma is used to mean an exacerbation of asthma that has not been controlled by the use of standard medication.

Patients with acute severe asthma typically have:
- the inability to complete a sentence in one breath
- a respiratory rate of ≥25 breaths/min
- Tachycardia ≥110 beats/min (pulsus paradoxus is not useful as it is only present in 45% of cases)
- PEFR <50% of predicted normal or best.

Features of life-threatening attacks are:
- A silent chest, cyanosis or feeble respiratory effort
- Exhaustion, confusion or coma
- Bradycardia or hypotension
- PEFR <30% of predicted normal or best (approximately 150 L/min in adults).

Arterial blood gases should always be measured in asthmatic patients requiring admission to hospital, with particular attention paid to the $P_aCO_2$. Pulse oximetry is useful in monitoring oxygen saturation during the admission and can reduce the need for repeated arterial puncture. Features suggesting very severe life-threatening attacks are:
- a high $P_aCO_2$ >6 kPa
- severe hypoxaemia $P_aO_2$ <8 kPa despite treatment with oxygen
- a low and falling arterial pH.

Asthma attack

Although these may occur spontaneously, asthma exacerbations are most commonly caused by lack of treatment adherence, respiratory virus infections associated with the common cold, and exposure to allergen or triggering drug, e.g. an NSAID. Whenever possible, patients should have a written personalized plan that they can implement in anticipation of or at the start of an exacerbation that includes the early use of a short course of oral corticosteroids. If the PEFR is >150 L/min, patients may improve dramatically on nebulized therapy and may not require hospital admission. Their regular treatment should be increased, to include treatment for 2 weeks with 30–60 mg of prednisolone followed by substitution by an inhaled corticosteroid preparation. Short courses of oral prednisolone can be stopped abruptly without tailing down the dose.

Antibiotics

Although wheezing frequently occurs in infective exacerbations of COPD, there is little evidence that antibiotics are helpful in managing patients with asthma. During acute exacerbations, yellow or green sputum containing eosinophils and bronchial epithelial cells may be coughed up. This is normally due to viral rather than bacterial infection and antibiotics are not required. Occasionally, mycoplasma and Chlamydia infections can cause chronic relapsing asthma and macrolide antimicrobials may be helpful if a bacterial diagnosis has been established by culture or serology.

Respiratory disease

Emergency Box 15.2

requiring hospital admission. Proof-of-concept trials have shown that anti-TNF therapy (infliximab or etanercept) may be helpful in severe corticosteroid-refractory asthma. There is still a need to examine other biological agents as potential new controller therapies for the 5–10% of patients with severe disease, who account for a high proportion of the health costs of asthma.

Lebrikizumab, a monoclonal antibody to IL-3, showed improvement in lung function in one recent study.

Emergency Box 15.2

The term acute severe asthma is used to mean an exacerbation of asthma that has not been controlled by the use of standard medication.

Pneumonia

Pneumonia is usually classified by the setting in which the person has contracted their infection, e.g.
- In the community setting or community-acquired pneumonia (CAP) by a person with no underlying immunosuppression or malignancy
- In a hospital or other institution such as a nursing home – hospital-acquired pneumonia (HAP)
- In a patient whose immune system is compromised, through either genetic defect, immunosuppressive medication, or acquired immunodeficiency such as HIV infection.

Community-acquired pneumonia (CAP)
Community-acquired pneumonia occurs across all ages, but is commoner at the extremes of age. There has been an increase in rates of hospital admission due to community-acquired pneumonia over the last 10 years, reflecting changes in clinical practice and an ageing population, rather than a true increase in incidence.
