Introduction: Developing The International Encyclopedia of Geography

The International Encyclopedia of Geography: People, the Earth, Environment, and Technology represents one of the most ambitious and far-reaching publication projects in the recent history of the fields of geography and GIScience. This 15-volume work is published in both hard copy and online. Annual online updates and prospective extensions to supplemental material and resources will enhance the value of the Encyclopedia to the researcher, educator, and user alike.

This six-year project, initiated by the American Association of Geographers (AAG) and Wiley Blackwell in 2010, has engaged geographers, GIScientists, and geographic societies around the globe. Its editors and authors reflect the interdisciplinary and international nature of geography’s scholarly and research activities. The sheer scale of this undertaking, in terms of the Encyclopedia’s depth and breadth of coverage and its international scope, has not, to our knowledge, been attempted before in the contemporary discipline of geography.

Geography today is a rapidly growing, dynamic, and highly relevant field, frequently leading the way in providing groundbreaking research and meaningful applications to address our world’s major societal problems and global challenges. Building on its traditional strengths of interdisciplinarity and integrative science, infused today by vibrant critical theory and revolutionary new geographic technologies, geography increasingly occupies a central place in the university and in society more broadly. Geographical theories, concepts, methods, tools, and applications now permeate environmental science, the social sciences, the health sciences, international studies, and the humanities, generating productive new research collaborations and extending knowledge frontiers.

The scope and range of The International Encyclopedia of Geography enables a much fuller discussion of the multiple subdisciplines and perspectives of modern geography than is typically the case in such endeavors, and it permits the engagement of ideas and topics from other closely aligned fields. The format of an encyclopedia, with the alphabetical sequencing of topics across the full sweep of the discipline, generates its own insightful juxtapositions and interactions among geographical topics, and illustrates how geography’s subfields inform and enrich one another. In-depth entries of up to 10,000 words allow key topics and concepts in geography and GIScience to be analyzed and presented in ways that recognize their inherent complexity.

The goal and the significant challenge of this publication project was to create the most comprehensive and authoritative in-print and online resource available for geography, while incorporating international perspectives and encompassing the discipline as a whole, broadly and synergistically defined to include:

- human geography,
- physical geography,
- geographic information science and technologies,
- economic geography and regional development,
- nature–society interactions.

It is our hope that this reference work will become the first and foremost destination for all
INTRODUCTION: DEVELOPING THE INTERNATIONAL ENCYCLOPEDIA OF GEOGRAPHY

those needing scholarly, authoritative information about these fields for decades to come. A valuable resource for educators and students at all levels, the Encyclopedia provides an enormous body of new content and analysis for teaching geography and the geosciences, environmental studies, and the social sciences and humanities fields in schools and universities. It also will be an indispensable resource for governmental ministries and planning agencies, and for private-sector firms and society at large now benefiting from the explosive growth of new geographic technologies and geospatial information.

The International Encyclopedia of Geography is designed to address a worldwide audience, which will have a comprehensive, accurate, and regularly updated account of the field at its fingertips. The entries are designed to be accessible at the advanced undergraduate and graduate level, but will also appeal to researchers and top scholars in the field. They provide accessible introductions to basic concepts as well as sophisticated coverage of complex or contentious areas.

What also distinguishes this project from other encyclopedias is that it is truly international, and it has the institutional support of the AAG and other major geographical associations from around the world. This institutional support will ensure that the Encyclopedia will be updated on an ongoing basis and, as such, has the potential to continue as the authoritative reference work in the fields of geography and GIScience for decades to come.

Where appropriate, the Encyclopedia also incorporates perspectives and input from across the full spectrum of interdisciplinary research—from science, the social sciences, and the humanities—to bear on the topics it explains and explores. Throughout, the editors also have encouraged co-authorship by collaborative teams of human and physical geographers, or teaming with GIScientists or social theorists to provide comprehensive coverage of cross-cutting and cutting-edge topics.

In sum, our goal has been to provide a serious, comprehensive, in-depth, peer-reviewed analysis of these fields for an interdisciplinary audience of scholars, graduate students, undergraduates, professionals, and other interested researchers as well as the general public. Our ongoing plan is to regularly update and maintain The International Encyclopedia of Geography as the world’s leading reference resource for the field, one that genuinely engages the needs of the international academic and professional research communities.

Structure and process of the project

The International Encyclopedia of Geography contains approximately 4 000 000 words, and 8000 printed and bound pages in 15 volumes, including an index. Over 1000 illustrations, graphs, charts, and color photographs are included. An international editorial team was responsible for ensuring that the entries are relevant, accurate, and consistent and, in so doing, ensuring that the Encyclopedia as a whole, and each of the entries, is of high quality. At least three peer reviewers assessed each entry to check that it conforms to well-established standards of scholarly publication and fairly and adequately presents the state of the field for the subject matter.

We selected an experienced and distinguished general editorial team, which helped inform the overall project and guide the way in developing a taxonomy of topical entries that knits together the research in the major fields of geography. The core editorial team consists of myself as Editor-in-Chief and five outstanding General Editors—Noel Castree (Human–Nature Interactions), Michael F. Goodchild (GIScience and Technology), Audrey Kobayashi (Human Geography), Weidong Liu (Economic Geography, Economics, and Development), and Catherine Hall (Geography and Development).
and Regional Development), and Richard A. Marston (Physical Geography)—all of whom have broad networks of contacts in their areas of expertise, as well as editorial experience with leading journals and other publications. Our core editorial team worked closely with 34 Section Editors, each a leading subject-matter expert representing a relevant subfield. Each Section Editor reviewed and edited approximately 30 entries each.

The online version of the Encyclopedia includes advanced search functions and extensive cross-linkage to related entries and to online supporting information. Considerable care was taken in creating the taxonomy of entries and in the choice of contributors commissioned, to provide state-of-the-art analyses and discussion written in an accessible style, in keeping with the aims of a definitive reference work. In addition to the entries themselves, the Encyclopedia includes a thematic lexicon by subject, an index, and an appendix of geographical associations worldwide.

The International Encyclopedia of Geography is published in conjunction with Wiley Blackwell, with whom the AAG worked closely during all editorial and production phases of the project. Distribution of the Encyclopedia will be worldwide and explicitly reflects the international scope of the work.

Using the encyclopedia

The structure and layout of the publication is designed to enhance its value as a reference work and an educational resource.

- In the online encyclopedia, abstracts and a list of key words provide a quick reference to the content.
- Search functions enable easy location of specific topics and also enhance browsing of related topics and resources.
- The entries are substantive and most are long enough (i.e., as long as regular journal articles) to be self-contained position statements on a topic, thus being suitable for students to be given on a reading list as an article to read.
- In the print encyclopedia, entries are presented alphabetically rather than grouped by narrower geographic subdisciplines, to encourage a grasp by the reader of the interactive nature of discipline and its subfields. The SEE ALSO listing at the end of each entry provides suggestions for other closely related entries in the encyclopedia.
- A list of References documents the text of each of the entries and alerts the reader to articles that expand on specific aspects of the entry. References are readily available following each individual entry so they can be consulted immediately, rather than having to refer to a distant master list of references elsewhere. Many entries also include a Further reading list that provides focused suggestions for readers who wish to explore a topic further.
- A clear example illustrating how students or others should cite an entry from the Encyclopedia is provided on page iv.
- Unlike most other encyclopedias, each entry of The International Encyclopedia of Geography has been peer-reviewed to enhance the quality and accuracy of the content, and to ensure that citations of the Encyclopedia’s entries by students and researchers are far more authoritative and reliable than is often the case in a world of increasingly unscreened and questionable Internet sources.
- The online encyclopedia allows for enhanced searching and discoverability. Users can search by key word or phrase across the full
INTRODUCTION: DEVELOPING THE INTERNATIONAL ENCYCLOPEDIA OF GEOGRAPHY

text of this resource, or browse alphabetically or by topic to explore the breadth of coverage. Users can export citations, click through reference links, and bookmark content to share on social networks.

Building international collaboration and community

The International Encyclopedia of Geography has been not only a project, but also a process. It has involved reaching out to, listening to, and working with thousands of geographers, editors, authors, educators, and reviewers around the world. Significantly, one of my reasons for undertaking this daunting project was the opportunity to build international collaboration around a major project for geography’s future. As former AAG President Ken Foote pointed out in 2010, The International Encyclopedia of Geography not only “will be an influential work for years to come but also represents an important community-building project within the discipline, both nationally and internationally.”

As such, we have sought to engage leading members of the international geography and GIScience communities as participants, authors, and editors. I am pleased to report that this first edition of the Encyclopedia includes contributions by distinguished editors and authors from 45 different countries. We also made a special effort to involve younger editors and contributors who are working at the cutting edges of new directions in geography and GIScience, including those who can address the evolving nature and diversity of our discipline, ranging from new trends in critical theory to our revolutionary and rapidly changing new geographic technologies.

Continuous updating of the Encyclopedia will provide further ongoing opportunities for broad participation by all geography and GIScience communities in this landmark project. As we move forward with regular updates of key entries in the Encyclopedia, we encourage your suggestions on candidates for editorial roles and new authors for the project, and also indications of your own interest in being considered as a contributing author or editor. Special informational and discussion sessions will be scheduled during AAG Annual Meetings in the years ahead for those who wish to learn more about The International Encyclopedia of Geography. Thank you in advance for your ideas and suggestions, and I look forward to working together with you on this most engaging project in the future.

Acknowledgments

The International Encyclopedia of Geography is the work of many talented individuals. I would like to express special appreciation for the opportunity to work with the highly distinguished and talented General Editors and Section Editors, who are listed on the Editorial Board page. A total of 1070 authors contributed 1032 entries to the Encyclopedia. To each: thank you for your time, knowledge, care, and effort.

A very special and heartfelt thank you goes to Jennifer Cassidento, the freelance project manager working with both the AAG and Wiley, without whom an encyclopedia of this scale and complexity would have been impossible to produce in the time frame allotted to us. Jennifer was with the project from beginning to end, and her efficiency, productivity, and commitment was extraordinary.

I also would like to acknowledge the editors at Wiley Blackwell, who contributed patience and good advice throughout this project. Justin Vaughan, who first approached me regarding the Encyclopedia project, has provided continuous support and encouragement throughout the
full publication process. Others at Wiley who helped at different times with editorial aspects of the *Encyclopedia* include Tiffany Mok, Lucy Wheeler, Kerry Powell, Clive Lawson, Layla Harden, Lisa Sharp, and Tanya McMullin. Barbara Duke, who led the production aspects of the project, Nik Prowse, the freelance project manager who led the copy-editing, proofreading, and indexing processes, copy-editors Giles Flitney, Jacqueline Harvey, Alta Bridges, and Kevin Dunn, proofreaders Mary Malin, Paul Sensecall, Felicity Watts, Graeme Leonard, David Adams, Jane Hammett, and Harriet Stewart-Jones, and indexers Michelle Baker, Marian Preston, James Helling, and Milla Hills in association with Indexing Specialists (UK) Ltd also contributed in essential ways, as did marketing staff Amanda Banner, Louise Morgan, and Patrick Wright.

Last but not least I would also like to acknowledge talented AAG staff members Jenny Lunn, Miranda Lecea, Joy Adams, Michelle Ledoux, Teri Martin, and Rebecca Pendergast, who provided valuable support to the project at various stages of its development. Michael Solem, Candida Mannonzzi, and Jan Monk also worked closely with Ken Foote to research and compile the appendix of international geography associations, a valuable addition to the *Encyclopedia*.

In closing, I am deeply grateful for the efforts of all those who have participated in creating this remarkable *International Encyclopedia of Geography*, which I hope will play a role in contributing to greater understanding of our world and, perhaps even more importantly, to greater understanding in our world.

Douglas Richardson
Editor-in-Chief

Accessibility, employment

Qing Shen
University of Washington, USA

Accessibility — more specifically, spatial accessibility — refers to the ease with which an individual or organization can reach spatially distributed opportunities, or, similarly, the potential for an individual or organization to interact with spatially distributed activities. It is a function of the locations of opportunities (activities) and opportunity seekers (activity participants), as well as the transportation and communication connections between them. This concept is frequently linked to employment because accessibility to economic opportunities, commonly known as employment accessibility or job accessibility, is especially important for the wellbeing of working-age individuals and for the productivity and livability of cities. Employment accessibility has significant efficiency, equity, and sustainability implications.

This entry first discusses the conceptualization and measurement of employment accessibility, focusing primarily on several operational accessibility measures that are commonly applied to urban planning and policy analysis. It then illustrates the usefulness of these employment accessibility measures for understanding the spatial structure of metropolitan labor markets and for examining the employment outcomes of urban residents, especially the poor.

Conceptualization and measurement of employment accessibility

Half a century ago, Hansen (1959) defined accessibility as the potential for interaction with spatially distributed activities. He operationalized this concept as a measurement of the spatial distribution of activities about a location, adjusted for the ability and desire of people or organizations in the location to overcome the spatial separation. Formally, the accessibility at location $i$ to a particular type of activity in location $j$ is directly proportional to the size of activity in location $j$ and inversely proportional to some function of the distance between these two locations; the total accessibility is the summation of the accessibility to activity in each of the individual locations around location $i$. Hansen’s conceptualization can be generally expressed by the following simple mathematical formula:

$$A_i = \sum_j O_j f(c_{ij})$$

where $A_i$ is the accessibility for people or organizations in location $i$; $O_j$ is the size of activity in location $j$; and $f(c_{ij})$ is an impedance function capturing the effect of $c_{ij}$, the cost of spatial separation between locations $i$ and $j$. For a metropolitan region with $N$ locations, $i, j = 1, 2, \ldots, N$.

Equation 1 has been widely adopted by researchers in geography, urban planning, and other related fields. While seemingly simple, application of this general formula actually
Accessibility involves many decisions, and some can be complicated. What should be considered as relevant activities or opportunities, and hence included in the variable $O_j$? What should be used to measure $c_{ij}$, the cost of spatial separation? Should it be distance, travel time, or travel cost? What if people choose different transportation modes to reach the opportunities? Moreover, how should the impedance function $f(c_{ij})$ be specified? Should it be a power function, exponential function, or some other mathematical form? Answers to some of these questions are dependent on the application context. For example, if the researcher is interested in comparing residential locations in terms of accessibility to grocery stores, $O_j$ will be the number or total size of grocery stores in location $j$. And if the residents rely on different transportation modes that have substantially different speeds, accessibility will be more appropriately measured for each mode separately, and $c_{ij}$ will probably be most effectively represented by the travel time between locations $i$ and $j$ for each mode. The selection of an appropriate impedance function is made largely on an empirical basis; the exponential function is the most frequent choice, but other reasonable mathematical forms usually lead to broadly consistent results.

Different application contexts may not just require different specifications of the components of equation 1; they may necessitate differently formulated accessibility measures. In light of several categories of application, including evaluation of the transportation and land-use system, modeling travel behavior, modeling urban development, and characterizing urban spatial structure, Morris, Dumble, and Wigan (1979) reviewed a wide range of accessibility measures. These various measures were results of many researchers’ attempts to link accessibility with application contexts and behavioral theories. Given the critical importance of economic opportunities in people’s lives and in cities’ formation and growth, a large portion of the literature on spatial accessibility has focused on employment accessibility. The approach to conceptualizing and measuring employment accessibility is to treat it as accessibility to a particular type of activities or opportunities. Following this approach, employment accessibility can be measured by adopting an appropriate accessibility measure and specifying the activity in location $j$ ($O_j$) as the size of employment, or number of job opportunities, in location $j$, with any necessary adjustment of parameter values in the impedance function. For example, equation 1 is frequently applied to the measurement of employment accessibility, typically with $O_j$ measured by employment in each location and $f(c_{ij})$ computed using data on commuting flows and times.

Employment accessibility measured by equation 1 is effective and appropriate for many applications. For example, it can be used to compare alternative locations in terms of urban development potentials because higher employment accessibility values computed using equation 1 show greater location advantages in interacting with economic activities within a city or region. Measuring employment accessibility this way is also generally useful for evaluating a transportation and land-use system by finding out whether jobs are located within reasonable proximity, or connected by effective transportation, to workers’ homes. This simple measure of employment accessibility can even help compare cities in terms of the size and diversity of a labor pool that each draws, which provides a basis for assessing the subsequent agglomeration economies that each creates.

However, equation 1 is not suitable for the measurement of employment accessibility in some other contexts. Most notably, it is not an appropriate measure of job seekers’ potential for

Given the critical importance of economic opportunities in people’s lives and in cities’ formation and growth, a large portion of the literature on spatial accessibility has focused on employment accessibility. The approach to conceptualizing and measuring employment accessibility is to treat it as accessibility to a particular type of activities or opportunities. Following this approach, employment accessibility can be measured by adopting an appropriate accessibility measure and specifying the activity in location $j$ ($O_j$) as the size of employment, or number of job opportunities, in location $j$, with any necessary adjustment of parameter values in the impedance function. For example, equation 1 is frequently applied to the measurement of employment accessibility, typically with $O_j$ measured by employment in each location and $f(c_{ij})$ computed using data on commuting flows and times.

Employment accessibility measured by equation 1 is effective and appropriate for many applications. For example, it can be used to compare alternative locations in terms of urban development potentials because higher employment accessibility values computed using equation 1 show greater location advantages in interacting with economic activities within a city or region. Measuring employment accessibility this way is also generally useful for evaluating a transportation and land-use system by finding out whether jobs are located within reasonable proximity, or connected by effective transportation, to workers’ homes. This simple measure of employment accessibility can even help compare cities in terms of the size and diversity of a labor pool that each draws, which provides a basis for assessing the subsequent agglomeration economies that each creates.

However, equation 1 is not suitable for the measurement of employment accessibility in some other contexts. Most notably, it is not an appropriate measure of job seekers’ potential for
(or ease of) reaching job opportunities. This is because equation 1 does not consider the spatial distribution of job seekers, and therefore implicitly and incorrectly assumes that the demand for the available employment opportunities is uniformly distributed across the space (Shen 1998). For opportunities that are rival goods, such as jobs — each of which is for only one worker at any moment in time — competition should be an important consideration when measuring accessibility. So long as the spatial distribution of relevant job seekers is not uniform, equation 1 generates an inaccurate or even misleading result of employment accessibility.

Because job opportunities exist in locations with various levels of demand potential, accessibility to each set of job opportunities is determined partly by the demand potential for the particular location. Shen (1998) proposed the following formula to measure the accessibility to any type of opportunities that are rival goods, and used it to compute the employment accessibility:

\[
A_i = \sum_j \frac{O_j f(\epsilon_{ij})}{\sum_k P_k f(\epsilon_{kj})}
\]  

(2)

where \(O_j\) is the number of job opportunities in location \(j\); \(P_k\) is the number of job seekers in location \(k\); and \(f(\epsilon_{ij})\) is an impedance function capturing the effect of \(\epsilon_{ij}\), the cost of spatial separation between locations \(k\) and \(j\). For a metropolitan region with \(N\) locations, \(k = 1, 2, \ldots, N\). Other notations are the same as in equation 1.

Recognizing that different opportunity seekers may depend on different transportation modes for search and travel, yet compete for the same opportunities, Shen (1998) extended equation 2 into an employment measure for a multimodal context. For job seekers who live in location \(i\) and commute by mode \(v\), employment accessibility is computed as follows:

\[
A_i^v = \sum_j \sum_k \frac{O_j f(\epsilon_{ij}^v)}{\sum_{m} P_{km}^v f(\epsilon_{kj}^m)}
\]  

(3)

where \(P_{km}^v\) is the number of job seekers living in location \(k\) and commuting by mode \(m\); and \(f(\epsilon_{ij}^v)\) and \(f(\epsilon_{kj}^m)\) are impedance functions capturing the effect of spatial separations between, respectively, locations \(i\) and \(j\) for mode \(v\) and locations \(k\) and \(j\) for mode \(m\). For a transportation system with \(M\) modes, \(v, m = 1, 2, \ldots, M\). Other notations are the same as in equation 2.

Equation 3 enables researchers to directly compare accessibility among opportunity seekers, such as job seekers, who are differentiated by transportation modes and by residential locations. Sometimes, it is also useful to examine the average level of accessibility for all opportunity seekers who live in the same location (say, a residential neighborhood). In the context of employment accessibility, this can be accomplished by computing the weighted average value for all the subgroups of job seekers commuting by different modes:

\[
A_i^G = \sum_v \left( \frac{P_i^v}{P_i} \right) A_i^v
\]  

(4)

where \(A_i^G\) is a general measure of employment accessibility for \(P_i\), all job seekers living in location \(i\); \(P_i^v\) is the number of job seekers in location \(i\) who commute by mode \(v\) and hence, enjoy accessibility \(A_i^v\). For a transportation system with \(M\) modes, \(v = 1, 2, \ldots, M\).

Shen (1998) showed that equations 2, 3, and 4 share an important property: the expected value of measured accessibility values equals the ratio of the total number of opportunities to the total number of people seeking the opportunities. This property provides a useful benchmark for assessing the resulting accessibility values, as
Advances in information and communications technologies (ICT), especially the rapid growth and wide applications of the Internet over the past two decades, have created new spatial paths and barriers that profoundly affect people’s access to economic opportunities and social services. For example, recent American Community Survey data indicate that “work at home” has the highest growth rate among all commuting modes, implying the growing importance of ICT in employment accessibility (AASHTO 2013). This has presented a major challenge to the traditional accessibility concepts and measures, which focus exclusively on the physical space. Research efforts have been made to incorporate cyberspace into the measurement of accessibility. For example, Shen (1999) extended conventional accessibility measures by conceptualizing the total accessibility from location $i$ as the sum of three components:

$$ A_i = A_i^p + A_i^c + A_i^h $$

(5)

where $A_i^p$ is accessibility to opportunities in the physical space that require transportation for access; $A_i^c$ is accessibility to opportunities in cyberspace that require ICT for access; and $A_i^h$ is accessibility to opportunities in the hybrid space that can be accessed through either transportation or ICT.

By classifying job opportunities accordingly into the three categories, and job seekers into two groups based on whether they have the ability to reach opportunities in cyberspace, equation 5 can be specified for each group of job seekers. $A_i^c$ and $A_i^h$ can be quantified because people’s activities in cyberspace (e.g., telecommuting) are embedded in their activities in the physical space that involve time and monetary costs.

Conceptualizing and measuring employment accessibility in the age of advanced ICT is still at the exploratory stage, and there is much exciting research to be done. Additionally, innovations in transportation continue to pose new questions regarding employment accessibility. For example, future development and deployment of automated vehicles may lead to some significant changes in how we measure accessibility, probably with an increased emphasis on the effects of monetary cost and intermodal coordination.

**Employment accessibility, spatial barriers, and employment outcomes**

Accessibility measures represented by equations 1, 2, and 3 have been widely applied to urban economics, geography, planning, and other related fields. Several applications of employment accessibility measures to research on the nature and impacts of spatial barriers to employment in American metropolitan areas, briefly described below, illustrate the usefulness of these measures.

Unemployment and poverty has been an important research area for urban economists, geographers, planners, and sociologists, among others. The high-level concentration of unemployed adults—who are disproportionately African Americans—in poor neighborhoods in central cities of the United States, along with industrial restructuring and employment decentralization that have been taking place for the last five decades, has drawn many scholars’ attention to the spatial dimension of this problem. A widely shared view, commonly referred to as the “spatial mismatch hypothesis,” is that the structural and spatial transformations of urban labor markets, combined with racial discrimination in housing markets, have caused the isolation of low-skilled minorities...
ACCESSIBILITY, EMPLOYMENT

in poor central city neighborhoods which are disconnected from suburban job opportunities (Gobillon, Selod, and Zenou 2007). Many proponents of the “spatial mismatch hypothesis” believe that central cities have become a geographically disadvantaged residential location for low-skilled job seekers because relevant job opportunities for them are mostly in suburban locations, and that an effective approach to solving the problem of urban unemployment is to relocate the poor to the suburbs.

To examine spatial barriers to low-skilled job seekers’ labor participation in American cities, Shen (1998) applied the accessibility measures expressed by equations 3 and 4 to an empirical study of the Boston metropolitan area. He showed that for job seekers who travel by a given transportation mode, those living in central city neighborhoods still have relatively higher employment accessibility than those living in the suburbs. He also showed, however, that travel mode is far more important than residential location in determining employment accessibility. For job seekers who can travel by car, most residential neighborhoods allow them to have good accessibility to jobs, but for those who depend on public transportation, only a few residential neighborhoods – all located in the central city – give them good employment accessibility. For the great majority of poor central city neighborhoods, the limited location advantage is far from sufficient to offset the comparative disadvantage of public transportation on which a high percentage of their residents depend. In other words, many poor central city minorities are indeed spatially disadvantaged, but the reason for this is their relatively low transportation mobility resulting from dependence on the slower travel mode (public transit), not their residential location being too far from job opportunities.

The more recently published study by Grengs (2010) tells a similar story, but it is particularly compelling because the case is the Detroit metropolitan region where the central city has suffered the most from structural and spatial transformations of the urban economy. His results indicate clearly that even though the areas of high employment accessibility in Detroit are more decentralized and dispersed than in other metropolitan regions, the central city remains a place of relatively good accessibility – better than most of the rest of the region. In addition, public transportation is shown to be such a severely inferior substitute for owning a car in Detroit that nearly every location offers better employment accessibility by auto than the location with the best employment accessibility by public transit.

Part of the explanation for central cities’ location advantage in reaching job opportunities is that they are typically the median location of such opportunities. In addition, for transit-dependent job seekers, central cities are better served by public transportation. Yet another reason, which is perhaps the most important one, is that all types of employment opportunities are still relatively concentrated in central city areas despite decades of industrial restructuring and employment decentralization. In a typical American metropolitan region, job openings are created predominantly by turnovers from pre-existing employment; new jobs typically account for only a minor portion of job openings at a given time. Even low-end jobs are still somewhat more concentrated in central city areas than low-skilled adults seeking these jobs.

Many researchers have taken another step to examine the effects of employment accessibility on employment outcomes. Most such research efforts focused on employment status, commuting distance, or cost as the outcome measure. Studies of the relationship between
employment accessibility and commuting distance or cost have obtained highly consistent results indicating that higher accessibility generally shortens commuting and reduces its cost. However, findings on the effect of employment accessibility on residents’ employment status have been mixed. While some researchers found that higher accessibility tended to be associated with higher probability of being employed, other researchers found only a weak or no relationship between these two variables.

Hu and Giuliano (2015) used the Los Angeles metropolitan area as the case study area to examine the effects of employment accessibility on the labor market outcomes of poor job seekers. Their results show that accessibility does not explain unequal employment status of the poor. On the other hand, their results indicate a significant association between accessibility and poor job seekers’ commute distance.

These studies challenge the traditional conceptualization of spatial mismatch. They indicate clearly the critical importance of transportation, rather than residential location, in determining a low-skilled job seeker’s spatial advantage or disadvantage within a metropolitan labor market. However, their findings also suggest that spatial accessibility only plays a rather limited role in job seekers’ employment status. These new perspectives point to the need to redirect public policies from encouraging housing dispersal to improving transportation mobility — perhaps by enabling more job seekers to use cars — and to develop new strategies for tackling other major barriers to employment. Indeed, Teitz and Chapple (1998) provided a wide variety of theoretical explanations for concentrated poverty in American cities, which point to economic, racial, and cultural, as well as spatial, factors as possible key causes. A critical future step toward developing effective strategies is to gain a deeper understanding of how the various spatial and nonspatial factors individually and interactively influence the employment outcomes of urban residents, especially those living in poor neighborhoods.

**References**

Accessibility is a deep-seated concept in spatial planning and transportation geography as it is the main product of transportation systems and has gained wide acceptance as a policy target. The concept of accessibility helps to explain the interrelationships between human activity, land use, and transportation system. Apart from its explanatory power, accessibility also plays an important role in the ex-ante and ex-post appraisal of land-use and transport infrastructure plans. At an aggregate level, accessibility is a key driver of regional development generating positive externalities for social cohesion, environmental sustainability, and economic growth.

Notwithstanding the currency and widespread use of the notion in transport planning and research, there is still no consensus about its exact definition. Definitions include “the potential of opportunities for interaction” (Hansen 1959), “the inherent characteristic (or advantage) of a place with respect to overcoming some form of spatially operating source of friction” (Ingram 1971), “the ease with which any land-use activity can be reached from a location using a particular transport system” (Dalvi and Martin 1976), and “the freedom of individuals to decide whether or not to participate in different activities” (Burns 1979). While diverging definitions abound, a common denominator is that accessibility is associated with the potential to reach spatially dispersed activities. Conceptually, this potential has been approached from the perspective of either locations or persons. The former attributes accessibility to a location representing how well this location is connected to other locations, while the latter attributes accessibility to a person indicating how well that person can reach a set of alternative destinations.

The variety of perspectives and meanings assigned to accessibility has prompted a host of different accessibility measures, with a tendency towards increased complexity. Location-based accessibility measures usually have three elements in common: (i) a reference origin (e.g., home location or zonal centroid), (ii) the quality and/or magnitude of activities at destinations (e.g., number of jobs in a zone), and (iii) a cost of physical separation between the origin and the destinations (e.g., travel time). An early yet still intensively employed mathematical expression of location-based accessibility has been formulated by Walter G. Hansen (1959) in his seminal paper “How Accessibility Shapes Land Use.” Hansen’s formulation is inspired by the notion of population potential in social physics and assumes accessibility at a certain location to be directly proportional to the size of opportunity at some other location, and inversely proportional with the distance, travel time, or composite travel cost between them. In a general form, the total accessibility $A_i$ of zone $i$ to all other zones $j$ can be expressed as:

$$A_i = \sum_j a_j f(c_{ij})$$

where $a_j$ denotes the size of opportunity at zone $j$, $c_{ij}$ represents the travel impedance between zones $i$ and $j$, and $f$ is a function reflecting
the dampening effect of distance, time, or transport costs on travel. Since the dimensions of the quantities in this equation are generally incompatible, the resulting accessibility values are often interpreted in purely relative terms by normalizing the values over a particular range. The impedance function $f$ can take different forms, with the inverse power $(c_{ij}^{-\alpha})$ and negative exponential function $(e^{-\beta c_{ij}})$ being most frequently employed. Ideally, decay parameters $\alpha$ and $\beta$ should be estimated on the basis of observed travel behavior and differentiated by mode, trip purpose, and socio-economic attributes. In practice, they are often borrowed from locally calibrated trip generation models.

Another related and commonly applied accessibility measure is a cumulative opportunity measure, also referred to as an isochrone measure, contour measure, proximity count, or container index. This measure counts the number of opportunities (e.g., jobs, hospital beds, shops) that can be reached within a predetermined cut-off distance or time. In most studies, this fixed cutoff value is not empirically substantiated but simply equated to an arbitrary threshold value that delimits catchment areas that are deemed reasonable in the application context at hand. This type of measure can be seen as a special case of gravity measure where $a_j$ denotes the number of opportunities at zone $j$ and the shape of the impedance function $f$ is rectangular; that is, it takes the value of 1 if the zone is within the predetermined threshold, and 0 otherwise. Cumulative opportunity measures have the advantage of being more intuitive and communicable than the cost-discounted values of gravity measures, making them appealing for planners and decision-makers. In contrast to gravity measures, cumulative opportunity counts do not need to be normalized since they can be directly interpreted in comparable and absolute units.

Despite their popularity in empirical work and policy, the above measures have been criticized for at least three reasons. First, zonal location-based accessibility measures are liable to aggregation problems such as the modifiable areal unit problem, meaning that accessibility values depend on the arbitrary configuration and scale of a zoning system. They also suffer from ecological errors since they attribute the same level of accessibility to all persons residing in the same zone, although these persons may dispose of different mobility resources and therefore perceive the set of destination alternatives differently. In addition, zonal measures are insensitive to local variations in accessibility resulting from intra-zonal improvements to the transport system. Second, location-based measures adopt a single reference location (i.e., origin zone or location) as the origin of travel, thereby ignoring the effects of trip-chaining behavior and the interdependence between activities. Third, place-based measures ignore temporal fluctuations in accessibility resulting from congestion, temporal availability (e.g., opening hours) of urban opportunities, and the fact that individual time budgets to travel to and participate in discretionary activities vary substantially throughout the day, between days, and across individuals.

In order to address the above limitations, more sophisticated person-based measures with a stronger behavioral basis have been developed. Two groups of person-based measures can be distinguished: utility-based measures and space–time measures. Utility-based measures are derived from discrete choice theory and assume that a decision-maker $p$ assigns a utility to each destination $j$ in a choice set $J_p$ and then chooses the alternative that maximizes his/her utility. Under the assumption of a logit decision process, the accessibility of individual $p$ to choice set $J_p$
can be expressed as a logsum, being the denominator of a multinomial logit model (Ben-akiva and Lerman 1979):

\[ A_p = \frac{1}{\lambda} \ln \sum_{j \in J_p} e^{-\lambda u_{pj}} + K \]  

where \( \lambda \) is a travel cost sensitivity parameter and \( K \) is a constant of integration which is sometimes set equal to zero, implying that no accessibility is derived if the measured utility \( u_{pj} \) equals zero. Constant \( K \) can also be canceled out of the equation by taking the difference between the accessibility benefits of two choice situations (e.g., before and after the introduction of policy). Note that accessibility expressed by a logsum measure is now person-specific rather than attached to a location or zone. Despite its theoretical appeal, the application of the logsum measure is not standard practice in land-use and transport project appraisals.

In order to measure accessibility at the individual level, researchers have also relied on the space–time approach. While this approach goes back to space–time studies of the 1960s and 1970s (Hägerstrand 1970), it was particularly during the last two decades that significant inroads were made in terms of operationalization. This is in part due to advances in geographical information systems (GIS) and the increased availability of data on individual activity-travel behavior. Space–time measures are based on the time-geographic construct of the space–time prism, which is the set of possible paths through space and time that a person can follow, given a set of space–time constraints resulting from mandatory commitments and limited mobility resources. The spatial footprint of the prism, the potential path area, gathers all locations where discretionary activities can be performed. Its size or the opportunities contained within it represent a direct measure of individual accessibility. While measures based on the potential path area enable the comparison of accessibility among different social groups, the requirement of individual-level data and the computational burden associated with their implementation hampers their practical use. Only a few insightful illustrations of the approach with real-world data have surfaced to date (e.g., Kwan and Weber 2008; Neutens et al. 2010). Space–time approaches have been integrated with utility-based approaches in the late 1970s and early 1980s through the work of Beckmann, Golob, and Zahavi (1983) on travel probability fields, and through the space–time utility function proposed by Burns (1979) and its subsequent modifications (Ettema and Timmermans 2007; Miller 1999).

ACCESSIBILITY, IN TRANSPORTATION PLANNING

Actor-network theory

Beth J. Greenhough
*University of Oxford, UK*

Actor-network theory (ANT) is an approach to research developed within the interdisciplinary field of science and technology studies (STS). ANT is shaped by the conviction that the world as we encounter it is not some pre-given, natural entity. Instead, reality is constantly in the process of being socially and materially reconstructed through the relations and associations formed between human and nonhuman actors. ANT is noted for both its refusal of hierarchies (for these assume that the order of things is given rather than socially and materially contingent) and for its recognition of the role of nonhuman agency, incorporating everything from living beings to technological devices in its analysis of how particular assemblages of agents – actor-networks – are produced and reproduced. The term assemblage is one increasingly being used within geography to stress how the phenomena we study are not discrete social or material entities, but often hybrid collections of diverse human and nonhuman, organic and inorganic, natural and technological elements. Consider, for example, genetically modified foods, which are organic and nonhuman in form but dependent on human expertise and technology and inorganic fertilizers for their production and reproduction, and which, given their controversial status, cannot be understood outside of their social as well as material context.

Origins of ANT

ANT was developed in the mid-1980s at the Centre de Sociologie de l’Innovation of the École Nationale Supérieure des Mines de Paris, by STS scholars Bruno Latour and Michel Callon, and the visiting British sociologist John Law. Latour, Callon, and Law were critical of science’s claims to objectivity – its claims to offer a “view from no-where” – and countered this by stressing the ways in which scientific knowledge is socially constructed, shaped by the social and environmental contexts of its production. However, where earlier work in social studies of science had focused on the analysis of scientific discourse and controversies, Latour and his colleagues brought a new ethnographic approach to studying the production of scientific knowledge. In their landmark publication, *Laboratory Life*, Latour and his colleague Steve Woolgar (1979) sought to demonstrate how scientific facts are both socially and materially constructed, highlighting the role of nonhuman (technologies, materials, organisms, machines, experimental subjects) as well as human actors in producing and verifying scientific knowledge. They sought a middle ground between the strong social constructivism of their predecessors (who insisted the world is shaped by relationships between human social actors, or in other words it is about who you
**ACTOR-NETWORK THEORY**

know and who knows you) and the ontological imperatives of scientific analysis to engage with the substance of the “real” world (the conviction that the world is made up of material elements with pre-given physical properties that can be uncovered through rigorous, objective scientific analysis). Scientific views of the world, Latour and Woolgar argued, were not pre-given facts but careful achievements produced by the assemblage of a diverse range of human and nonhuman actors into networks of relations. This detailed analysis of the actor-networks necessary to produce scientific facts evolved into a broader approach – ANT – asserting the inseparability of natural and social worlds and that phenomena, knowledge, objects and agents are co-constituted through the relations between them. The world is not preformed but emerges as humans and nonhumans interact with each other.

### Key aspects of ANT

ANT consists of four key elements. Firstly, ANT challenges the division of the world into structure and agency and other associated dualisms (nature-society, human-physical, global-local), instead offering “an encouragement to think relationally, in terms of associations rather than separations” (Castree 2002, 118). It criticizes the tendency within existing social theories to analytically prioritize (assign explanatory power to) one side of these dualisms over the other. One of the benefits of ANT is that it resists asymmetry whereby one side of the binary (e.g., nature) becomes subsumed as something explained through the other (e.g., society/social constructions). So, whereas early cultural geography studied landscape as something designed and brought into being by human actors, ANT would stress the role of nonhuman actors in co-constructing that landscape.

Consequently, despite the name, the proponents of actor-network theory (ANT) have always been keen to stress that ANT is not a theory, at least not in the sense that it offers a meta-level explanation for phenomena. Instead they suggest ANT should be thought of as a method or approach to understanding how the world comes to be. Secondly, therefore, ANT is a constructivist approach. In contrast to other approaches that seek to understand essential differences between their objects of study, ANT seeks explanations that work or are useful. Rather than choosing explanations based on the conviction that they are the one true explanation, ANT’s explanations are, therefore, contingent upon the social (and ANT’s understanding of who counts as a social actor is heterogeneous, see below) and environmental contexts from which they emerge.

Thirdly, ANT understands the phenomena with which it engages not as pre-given but as always in the process of being performed. Furthermore, phenomena must be performed constantly or they risk falling apart. This precarity means that pre-given explanations or theories are of little use. Bruno Latour argues that if we wish to understand the work which goes into pulling together and sustaining particular networks, then we need to study the different actors (both human and nonhuman) involved, producing detailed descriptions of how they sustain themselves. Explanation is only possible once the actor-network is fully mapped out; the material and the semiotic (conceptual) must be thought together. Importantly, this includes a reflexive acknowledgment of the researcher’s role in shaping the actor-networks they study: researchers intervene in and shape the world through the process of studying it.

Fourthly, ANT questions the assumption that agency is located within individual (usually human) actors, capable of intent. For ANT,
agency is a property of a diverse range of both human and nonhuman actants, or more accurately a property of the associations (networks) formed between them. ANT is critical of understandings which assume that the power to effect or resist change is an exclusively human property, one located within or against social actors and systems (e.g., capitalism or patriarchy). It is not surprising perhaps that this arose from a theory with roots in STS. One of the key insights from exploring the production of scientific knowledge ethnographically (as opposed to say through an analysis of official publications and papers) is a recognition of the notorious recalcitrance of nonhuman agency to comply with experimental protocols. Through experimental failures we are made conscious of the capacity of nonhuman agency to resist what humans conceive of as their ability to (re)order the natural world. Successful networks are often hidden from sight and many actor-networks only become visible when they fall apart.

ANT in geography

Whatmore and Thorne (2000) suggest that within geography ANT had two key contributions to make. First it provided a way (a metaphor and a method) for holding onto the situatedness of practices and subjects in the face of a stretched-out, distributed, globalized world. John Law suggests ANT should be thought of topologically, replacing Euclidian space and its insistence on seeing the world as a series of discrete objects with a more relational and fluid, networked sense of space. From this topological perspective, phenomena can only be located and understood by virtue of their connections or relations to other elements in the network. Rather than exploring local-global distinctions (topography), the ANT approach would be to focus instead on the connections and intermediaries between, flattening out hierarchical understandings of space and scale. One of the impacts of globalization is to make things seem as though they are both everywhere and nowhere. We all know what Coca-Cola is, but we would be hard pressed to tell you where it is. Actor-network theory brings to the analysis of this kind of phenomenon a sense that to be both universally (known) or everywhere while coming from no-where is not a given, but a hard-won achievement, not unlike the production of scientific knowledge, one that requires a complex chain of actors and networks. ANT would ask how exactly does Coca-Cola achieve this seemingly ubiquitous brand presence and would trace out the humans and nonhumans involved. There are analogies here with analyses of production chains and commodity networks. What distinguishes ANT though, is a recognition of the fragility of these networks and the emphasis placed not just on nonhuman components (as in a commodity chain) but on nonhuman agency.

Attention to nonhuman agency constitutes a second key contribution made by ANT to geographical scholarship. Perhaps unsurprisingly, therefore, ANT has particularly appealed to geographers working on nature-society relations, and ANT has been used to bring new posthumanist perspectives on the presence of nonhuman agency in the fabric of social life. Posthumanist approaches arose from the need to critique the ways in which human geography focused on human agency as if it could be detached and dissociated from nonhuman agency, and as if the social world could be understood through a focus on human needs, emotions and responses alone. Nonhuman agency remained the concern of the natural sciences and physical geography. The result
was an asymmetrical tendency within human and physical geography to attribute explanatory power to social and natural phenomena respectively, an approach Whatmore (2002) describes as deadening geography to the world and its liveliness, as though human society is formed and functions in ways that are ignorant of and unaffected by the actions and responses of nonhuman agents. In contrast, ANT insists nature and society are co-constituted. For example, Whatmore and Thorne (2000) draw on ANT in the development of their understanding of spatial formations of wildlife exchange, and the multiple ways in which elephants are reconfigured as they are caught up in social networks as zoo exhibits, database entries, and charismatic cover photos for conservation projects. Hinchliffe (2001) equally drew attention to co-fabrication of human and nonhuman worlds in his study of the late 1980s/early 1990s British Bovine Spongiform Encephalopathy (BSE) crisis, but did so in order to critique political tendencies to seek bureaucratic and technical quick fixes to complex biosocial problems. In drawing attention to complex interweaving and interdependency of human and nonhuman lives, this work stresses the impossibility of producing useful and functioning explanations of phenomena, such as wildlife conservation and zootonic disease, while insisting on a separation between natural and social worlds.

Other work contrasts the insights of ANT with Marxist approaches to understanding the role played by capitalism in the (re)production of nature-society relations. In an edited collection entitled Remaking Reality, Bruce Braun and Noel Castree contrasted a Marxist emphasis on how nature is transformed through capitalist imperatives with insights from poststructuralism and ANT (Castree and Braun 1998). They show how Marx’s emphasis on the ways in which the world is shaped by macroscale social and economic structures (such as capitalism) might be combined with an attention to how the capitalist imperative to generate profit and surplus value is dependent on, facilitated by, and might also be resisted by assemblages of both human and nonhuman actors brought together – for example in the process of developing, producing, and consuming genetically modified crops. Maria Kaika and Erik Swyngedouw (2000) combined ANT with more traditional political ecology approaches to explore how nature (in the form of water) is accommodated within and resists the urban fabric. Humans remain unaware how dependent they are on underground water supply networks until those networks fail, until the pipe bursts or the waterborne bacteria infect a human host. Beth Greenhough (2006) drew on Callon’s ANT-inspired engagement with commodity fetishism to explore the processes of decontextualization, dissociation, and detachment necessary to facilitate the extraction and circulation of human bioinformation and biosamples (medical records and DNA) as “bodily commodities” for the life science industries. She described how human society seemingly needs to be able to distance itself from its bodily-derivatives before it is comfortable with them being commodified and used in scientific research. Arguably because human society (and humanist social science approaches) gives so little agency to nonhuman materials and objects, we are rendered very uncomfortable by the idea that a large part of our human selves is a collection of organic and inorganic, social, and technical parts. In each of these cases ANT becomes a resource for emphasizing capitalist social relations and processes (e.g., commodification) as geographically contingent and precarious achievements. It shows that at any point both the human and nonhuman elements might resist their enrolment or exercise their
agency in ways that go against the imperative to make profits.

**Critiques of ANT**

Perhaps surprisingly, some of the strongest critiques of ANT come from within ANT itself. John Law and colleagues in their reflections in the edited collection *Actor Network Theory and After* (Law and Hassard 1999), lamented the widespread and, importantly, often uncritical adoption of ANT to the point where they note, somewhat ironically, that the network topology has in itself become naturalized. Or to put it another way, practitioners of ANT have become so accustomed to the idea that everything is defined relationally they fail to interrogate this assumption through a critical unpacking of the precise nature of the particular relations which shape the phenomenon under investigation. It is not enough, Law and his colleagues cautioned, to say things are complicated and relative. Instead we must always also ask how things are continually in the process of becoming complicated, the labor it takes to hold them stable, and the potential that at any point these relations may fall apart. This later work includes a much keener sense of the absences and exclusions within particular actor-networks, as in the process of assemblage some things are brought together in ways highly visible to human senses, others are present but hard to sense and others are excluded entirely. In *Actor Network Theory and After*, Michel Callon stresses the importance of enrolment; the process by which actants (human and nonhuman agents) become incorporated within particular networks of relations. Enrolment is not all inclusive, Callon suggests, and in contrast to structuralism’s insistence on an underlying (socioeconomic) imperative (the idea that everything is ordered by some underlying structure or goal, e.g., capitalism’s aim to generate profit or surplus), not all enrolments are intentional or seemingly beneficial for human interests. Again, for example, think about the spread of viruses or the contamination of water supplies.

Outside the field of actor-network theory, critiques have largely focused on the assertion that ANT offers little ground for building political critique and collective resistance. It has been argued that some networks are much more powerful than others, and ANT has been accused of an almost nihilistic relativism that refuses to acknowledge the ongoing influence of structural forces such as capitalism in shaping social inequality. In response, proponents of ANT criticize Marxist and other structuralist approaches for being insufficiently radical in their preoccupation with the impact of human-defined economic structures on largely human concerns. They argue that interests of the nonhumans in, for example, the impact of deforestation on Amazonian ecologies, become subsumed under a concern for how this affects (usually) marginalized and disempowered human populations within these communities. Latour’s more politically orientated later work therefore emphasizes the need to bring the nonhuman into political debates, challenging the tendency to rely on scientific analysis to represent its interests.

Castree (2002) seeks a middle ground between what he refers to as the “false antithesis” of Marxism and ANT, suggesting that we might equally conceptualize capitalism or other explanatory social systems as particularly enduring actor-networks, which, while unique, share many characteristics and compositional elements, including a focus on extracting surplus value. This way, we can acknowledge that capitalist imperatives play a role in the way actor-networks are assembled, sustained and reproduced. Furthermore, thinking of the seemingly dominant macrostructures of capitalism as precarious
assemblages opens up the possibility that they could be re-made along radically different lines, a possibility Annemarie Mol in *Actor Network Theory and After* refers to as “ontological politics” (Mol 1999).

**ANT futures**

ANT is often linked to the broader turn towards poststructuralism, an approach which criticizes structuralism’s emphasis on large-scale social structures (e.g., patriarchy) as the dominant forces shaping how the world comes to be. Since its inception ANT has been adopted across a wide range of fields, including health studies, sociology, anthropology, feminist studies, and economics as well as geography. However, by the late 1990s Latour and his colleagues were becoming increasingly frustrated by the overuse of the term and felt it had lost its critical edge. The above mentioned volume *Actor-Network Theory and After* made an attempt to re-orientate ANT towards competing, multiple, and discordant elements within the network, acknowledging how drawing things together also involves taking them apart. There was also an effort to pay greater attention to the fleeting and multiple nature of many actor-networks.

Within contemporary geography ANT is perhaps best recognized through its impact on three emerging trends. First, ANT is viewed as one of the reference points for the rise of assemblage-thinking within geography (Anderson and McFarlane 2011), sharing with these approaches an insistence on the relational and performative constitution of phenomena. Second, in its attention to performance and the nonhuman, it forms a key influence on Non-Representational Theory. This is an approach that emphasizes aspects of the world which are hard to capture through processes of representation, such as mood and sensation. Third, its attention to nonhuman agency and refusal of the separation between nature and society inform what Whatmore (2006) refers to as “materialist returns” within cultural geography, specifically concerned with the development of more-than-human geographical approaches to tackling key political environmental challenges such as climate change. It is arguably through these influences (or associations), rather than any rigorous adoption of ANT’s methodologies, that ANT continues to shape geographical thought and practice, a fittingly modest legacy for a theory which consistently resists its status as such.

Agent-based modeling

Dawn C. Parker and Derek T. Robinson
University of Waterloo, Canada

Agent-based models: definition and context

A definition of agent-based models of geographic systems

Agent-based modeling (ABM) is a computational simulation methodology that represents key system actors as agents who make individualized, decentralized decisions. Agent-based models represent characteristics of real-world actors, items, and processes as virtual agents, objects, and algorithms, most often in computer code. These actors can include, but are not limited to, gas particles, animals, plants, people, or more complex social entities such as households or institutions. When applied in a geographic context, ABMs also generally include a spatially explicit landscape over which agents interact. Thus ABMs can situate agents within a geographic context, concurrently representing spatial aspects of actors, their decisions, and their interactions. This enables the modeling of both direct and indirect spatial interactions, which are often central to the research questions investigated by ABMs of geographical systems.

Identifying the community of ABM users

ABM is increasingly used throughout the social, natural, and information sciences. ABM has been applied in the domain of ecology, where it has been referred to as individual-based modeling (IBM) since the 1970s. Many geographical applications represent coupled human and natural systems (CHANS). In other disciplines ABM is often used to generate solutions to specific problems. For example, in computer science, software agents are designed to accomplish a specific task (e.g., harvest data from the World Wide Web), and in operations research, n-polynomial optimization problems are solved using agents. In many other cases ABM is used for pedagogical purposes (e.g., to illustrate theory or teach computer programming).

How ABMs develop decision models

Often modelers combine theoretical frames from several traditional disciplines to develop agent decision-making, action and reaction, or interaction rules among agents and between agents and their environment. In some research and applications, agent rules, attributes, and behaviors are empirically informed from social surveys, behavioral economics experiments, ethnographic fieldwork, ecological fieldwork, spatial analysis, and other data collection and analysis methods. Often these empirical efforts strive to (i) objectively identify groups of agents within a specific agent type (e.g., profit-driven, risk-averse, or hobbyist farmers), (ii) calibrate agent attributes and population numbers, and (iii) provide empirical patterns for validating model structure and output.

ABMs as representations of complex systems

Since it is not necessary to define and solve a mathematical equilibrium or optimum for
ABMs, as required by many other modeling methods, there is a high degree of flexibility that allows researchers to construct ABMs that represent a wide range of processes and feedbacks. Therefore, ABMs are ideal tools to represent and explore complex systems. While multiple definitions of complex systems are in play, commonly recognized components include: heterogeneity and interaction among agents and their environment, learning and adaptation, aggregation (i.e., emergence), path dependence, and nonlinear dynamics. Many of these components cannot be practically or wholly represented using mathematical (e.g., ordinary differential equations) or statistical (e.g., logistic regression) models.

Modelers incorporating the concepts of complex systems into ABMs are able to make both theoretical and applied advances by constructing a range of models that extend from simple toy models (e.g., flocking behavior in birds) that lack data but offer a proof of existence to high-fidelity models that enable the simulation of real-world physics and processes (e.g., a flight simulator). Thus, ABM is used both as a tool for exploration and to make substantive gains in domain-specific and broader scientific knowledge. In the real world, many phenomena cannot be methodically explored due to lack of data variation, especially given that the real world provides only a single historical trajectory reflecting particular circumstances. In such circumstances, ABMs can be used as “computational laboratories,” to explore such phenomena “in silico.”

One strong appeal for complex systems modelers using an ABM approach is to demonstrate that the individual actions and interactions of agents can aggregate to create macroscopic patterns of interest at the system or landscape level, which can include measures of spatial pattern and connectivity or equilibrium (i.e., emergence). If, through the validation process, these emergent outcomes are found to be consistent with a sufficient number of real-world data series and/or patterns, the models are said to offer a supportable candidate explanation for its hypothetical causal mechanisms. Again, although an equilibrium may emerge in the ABM, its conditions are not imposed on the model a priori. In addition to the standard notion of equilibrium, ABMs are also used to represent nonequilibrium situations including threshold effects, punctuated equilibrium, quasi-equilibrium, and out-of-equilibrium dynamics.

Elements of ABM

Landscape

An agent-based model of a geographic system generally begins with a representation of the spatial environment over which modeled agents interact. Typically, the data models used to represent the landscape correspond to raster and vector models used in traditional geographic information systems. The majority of spatially explicit ABMs use a raster-based representation of the landscape. This may be due to the ease with which data can be assimilated during model construction, accessed by agents within the model, and compared to remotely sensed data during model evaluation, among other reasons. Vector-based applications are increasingly used but face challenges when the subdivision of a polygon or other topological process requires representation. Other representations of space have also been used (e.g., triangular irregular networks, hexagon tessellations, networks). In all cases, the landscape units (e.g., cell or polygon) can store attribute information that facilitates linkages between stationary or mobile agents and neighborhood stimuli. In land-change models, for example, agents can modify the land use of landscape units, and these units in turn may be used to drive other modeled social or
environmental processes or inform the decisions of other agents.

Collection of agents

The second element of an ABM is a defined collection of agents. While many formal “agent” definitions are seen in the literature, an agent is generally a goal-oriented entity, possessing a model of cognition that links goals and behavior, that is capable of sensing and responding to changes in its environment through autonomous action. Agents are generally characterized by both internal resources (including attributes representing knowledge, experience, behavioral parameters, and decision strategies) and external resources, such as assets or position within a social network.

Each agent possesses a decision model – a set of rules that link information about his or her environment, resources, and estimated payoffs to a decision regarding possible actions. In an ABM, decisions often depend on the state of the agent’s attributes and the physical environment. They may also depend on the state of the agent’s social environment. Specifically, decisions in ABMs are often linked to and influenced by the prior decisions of other agents. A wide variety of models are used to represent decision-making in ABMs, including rule-based and classifier systems, regression and neural network models, and optimization routines such as mathematical programs or genetic algorithms. There is no consensus on the most appropriate way of representing agent decision-making in an ABM, and current decisions are based on the complexity of the actors represented, the skill and domain specialization of the modeler(s) or project team, and the data and time available.

Interaction

The third key element of ABMs is a set of rules governing interaction among agents and between agents and their environment. Rules governing agent–agent interactions may involve a distance parameter that defines the vision of the agent. For example, the implementation of a predator–prey model requires both the predator and the prey to have defined a maximum distance for which they may observe other agents in the landscape. In other cases, interactions may be based on the evolution of a social network, a change in household dynamics based on its life cycle, or observation of the behaviors of spatial neighbors (adjacent or farther away). The result of these interactions can be a change in the flow of information, interdependencies between and impacts of agent actions, and the sequencing of model events.

Event sequencing within an ABM plays an important role. In ABMs, event-sequencing mechanisms can generally be characterized as predetermined and event-driven. Predetermined event-sequencing rules are set by the modeler, and generally operate similarly over model runs. Such rules can be used to simulate synchronous behavior, where each model agent has an opportunity to make a decision, taking the last previous action of all other agents as a starting point. Rules can also be asynchronous, where, for example, each agent has a fixed probability of being active in any time period. In asynchronous implementations of agent behaviors, model results can be dependent on the order in which agents act. To alleviate this modeling artifact, most ABM platforms provide a shuffle routine that rearranges the order of agents within the population that takes actions. Event-driven rules, in contrast, dictate action when a state variable in the system – for a single agent, another agent, or the system as a whole – reaches a certain threshold. For example, a farm may be sold when the owner retires, or a family may seek a larger residence when they have children.

ABMs are also generally constructed with mechanisms to track and record information
about model states and flows. Such information can be stored in many formats—GIS layers, text files, formal databases, and others. Software and libraries designed for building agent-based models often have such capabilities built in.

When ABMs are applied to models of geographic systems

Spatially explicit ABMs have been used by researchers in a variety of different disciplines to gain insight into space-dependent problems (e.g., geography, economics, planning, political science, ecology, anthropology). Examples of spatial applications include: evaluating the effects of different types of policies on the patterns of urban development and their subsequent ecological impacts; estimating conflict and improving route scheduling for tourists in national parks; quantifying changes in crop yields due to demographic and life cycle changes in farming households; comparing social and environmental factors affecting the extinction of communities; quantifying human responses to emergencies and assessing alternative designs to affect evacuation patterns; and defining territorial boundaries for nations within states. A large suite of recent applications are presented in Heppenstall et al. (2012).

In each of these domains of study, spatially explicit ABMs can be better designed and understood by conceptualizing the sources of spatial, temporal, and behavioral complexity in the system of study and captured in the ABM. The majority of geographic applications include one or more sources of spatial complexity. While not comprehensive, spatial complexity can be broken down into three areas: spatial autocorrelation, zonal spatial relationships, and network relationships.

- **Spatial autocorrelation**, at a general level, follows Tobler’s first law of Geography: “All things are related, but nearby things are more related than distant things.” Spatial autocorrelation refers to cases in which a spatial state is either more or less likely when in proximity to a similar spatial state. In human systems, spatial autocorrelation can occur for many reasons, including imitative behavior, diffusion processes, synergies between compatible activities, spatial competition, and negative spatial spillovers. It implies a causal spatial relationship between locations.

- **Zonal spatial relationships** occur when locations share a common characteristic or state variable value, for a noncausal reason—for example, similar levels of accessibility, political or zoning designation, soil type, climate, or topography. Often different zonal relationships are non-nested (for example, political and watershed boundaries), creating measurement and modeling challenges.

- **Spatial networks** define spatial relationships between entities that are constrained by an existing structure in the landscape (e.g., roads, pipelines, forest corridors). Unlike measurements that are based on Euclidean distance (i.e., what is commonly referred to as “as the crow flies”), spatial networks provide a realistic account of distance and include impedances that can slow the travel of processes through the network. Networks can be physical, such as transportation or hydrologic networks, or social, such as communication, relationships, and trade and commerce networks. Concepts and algorithms from network analysis are commonly applied in ABMs.

Temporal complexity shares many of the same characteristics as spatial complexity, but instead of quantifying the behavior of a process across space,
it is concerned with quantifying the process over time. Temporal autocorrelation measurements are used to quantify the dependency of future measurements of a phenomenon based on past measurements. Geographical systems are often characterized by important temporal growth and decay processes. These processes can be social, such as population growth and decline, social trends, and growth of financial investments. They can also be biophysical, such as soil degradation, carbon sequestration, and erosion. Such processes lead to temporal autocorrelation, where a given time period’s state depends on that of the last time period.

When combined with spatial autocorrelation and its various drivers, processes will affect state variables across both time and space, such as species colonization and fire spread. Such processes are often modeled using cellular automaton models, which are implicitly contained in many ABMs. Further, Hagerstrand’s time geography approach is increasingly applied to monitoring individual and group behaviors in agent-based models and provides one of many geovisualization techniques to evaluate agent behavior in an ABM.

Behavioral complexity in spatially explicit ABMs refers to the degree of complexity incorporated in representing how agents make decisions as well as the complexity of social and institutional structures represented in the model. With regard to decision-making, a range of approaches are used that span from simple heuristic “if-then-else” algorithms, to utility equations, and learning and adaptation algorithms (e.g., genetic programming). While often omitted from ABMs of geographical systems, forward-looking behavior by humans and other animals plays an important role in decision-making. Examples include food and seed storage, crop rotation, strategic behavior, such as preemptive colonization, and financial investments. To account for such behavior, models must build in expectations of the future and possible responses in order to develop models of learning and adaptation.

Behavioral actors in models are often characterized by heterogeneity and interdependencies. Not only are different types of actors present in most systems, even within a type, actors may differ in their goals, expectations, strategies, and motivations, as well as their internal and external resources. Actors are also interconnected in social, economic, and ecological networks. Collections of actors may also have their own rules of behavior.

The representations of the spatial, temporal, and behavioral complexity of a study system in an ABM are each characterized by a notion of scale, and complex processes for each can operate at multiple scales. Spatial scale is characterized by spatial resolution (e.g., minimum mapping unit) and spatial extent (i.e., total area represented), temporal scale by temporal resolution (i.e., length of the smallest unit of time represented, also known as the time step) and temporal extent (duration of time represented), and behavioral scale by the minimal decision-making actors and collectives of such actors.

Processes can be characterized by feedbacks across scales in each case – for example in a spatial system, between neighborhoods and a city, in a temporal system, between fast processes such as weather events and slower processes such as climate change, and in a behavioral system, by interactions between family members and a household. Cross-scale processes can operate both from the bottom up and from the top down, with feedbacks between scales.

The collective result of these forms and sources of complexity is that systems generally modeled using ABM are highly path dependent. A small change in an initial condition or stochastic seed at a given point in time may move the system to
AGENT-BASED MODELING

a qualitatively different outcome. Modelers need to be aware of this sensitivity, testing models using a wide variety of initial conditions and/or stochastic seeds to trace out distributions of outcome variables that may emerge from the modeled system.

Model development: elements and process

While the development of ABMs often proceeds iteratively, ideally based on scientific and stakeholder feedback, the following template provides a framework that can be usefully applied to the development of most ABMs of geographical systems.

First, the purpose of modeling should be identified. While many researchers find that the process of model construction can be useful to codify existing knowledge and gain consensus as to an appropriate representation of the real-world system, ideally model design should be framed by the clearly defined research questions of what the model is for and what questions its output can be used to answer.

Next, researchers typically identify the real-world spatial, temporal, and behavioral processes they strive to represent. ABMs are structural models, which embed hypotheses about process-based relationships and causal mechanisms. The process of identifying these relationships and mechanisms in the applied problem is critically important. Often, it can be very useful to create simple system diagrams, noting the scale of operation of each process and identifying key causal linkages via arrows and feedback loops. Having done this, researchers can identify what factors and processes they might reasonably assume are exogenous (determined from outside the model — information you have before you run the ABM) and endogenous (determined as part of the model run — information you did not have before you ran the model). It is important within this process to try to distill the model elements to the minimal possible level of complexity that you can practically model. While the first question to ask is, “How can we characterize the complexity of the real-world system?” the second is, “How little complexity can we get away with modeling?”

Having undertaken this process of identifying real-world structures and mechanisms, if building an empirically supported model, the team should identify the ideal spatial, temporal, and behavioral representation (both structure and resolution) for model parameterization, calibration, and assessment data. As with any empirical undertaking, this phase is generally followed by a practical assessment of the data that might actually be available for model construction. This is generally followed by a second round of model structuring during which the modelers simplify the model plan and goals. Empiricizing ABMs can be particularly challenging, as they require data about both actors and the actors’ environment, in contrast to some geographic models that rely on spatial data alone, or social science models that use only actor data. The fine-scale, disaggregated nature of ABMs creates further challenges.

Having made high-level decisions regarding what processes to model and what data to use, modelers must turn their attention to detailed decisions regarding model design, model rules, and system architecture. While no standard texts or templates have been available historically, experienced researchers are beginning to offer texts to guide learning and model development (see below for readings). Decisions regarding software implementation must be made. In spite of community consensus that such tools could be useful, to date few standard software packages and model libraries are available. However, two sets
of software libraries are commonly used: RePast and Netlogo. Further, the Community Modeling Library hosted by the CoMSES (Computational Modeling in the Social and Ecological Sciences) Network provides code examples of previously implemented models (http://www.openabm.org/models). Journals are also providing links to model code archives with increasing frequency. Along with a push towards code sharing, many scholars have emphasized the need for standard model documentation protocols and metadata. Various approaches have been taken to the problem. Along these lines, research groups should set forth protocols for documenting, archiving, and sharing their model data and code, with access rights within and external to the research group carefully defined before modeling begins. Often such agreement might be dictated and/or constrained by institutional and access agreements. Such points should be considered when choosing data and software options.

The value of ABMs

ABMs offer many advantages. While often seen first and foremost as models, ABMs offer value by encouraging discussion and learning in a number of ways. First, even before an ABM is coded, the design phase can act as a medium for discussion and can formalize a range of assumptions and knowledge about a study system. This process continues as assumptions are formalized in computer code. This modeling process often acts as a bridge across disciplines, facilitating communication and project developments on large interdisciplinary research teams. Second, the ABM offers a proof of concept and a pedagogical framework to demonstrate the effects of different processes in isolation or in combination. Third, because ABMs are built with a focus on representing process, behavior, and interaction, they often cause data to be analyzed and interrogated in new ways. They may also highlight new types of data that have not been collected but are necessary to understand a question being answered.

Beyond their pedagogical and conceptual contributions, ABMs are valued for their ability to provide evidence to support general and overarching advances to our scientific understanding of a broad range of human and natural systems. For example, Schelling’s segregation model demonstrates that society may segregate from households having only a small preference for neighbors that are like them (e.g., 25%). New models have represented sheepdog behavior with only two agent rules and offer approaches for corralling crowds. Others have shown that simple behaviors can solve complex problems (e.g., ant-agents searching for food and leaving pheromones can solve n-polynomial optimization problems). These are but few of the many hundreds, if not thousands, of systems to which ABM are (or could be) applied.

Limitations and challenges

In spite of the successful applications described above, the development, analysis, and communication of ABMs present challenges. These challenges are widely recognized by the modeling community, and incremental and steady progress is being made to address them.

On the model development side, standard and easy-to-use software libraries, such as those available for statistical analysis, are not yet generally available for ABMs. This creates a barrier to entry to the field, as generally some programming abilities are needed to construct and modify an ABM. However, increasing availability of software packages such as Netlogo and introductory texts create a fairly accessible entry point to programming and modeling. Even for the proficient
nombre, there is a lack of standardized libraries and modeling algorithms available. In
spite of a recognition that it may not be the most efficient use of resources at a community
level, most projects start from scratch to build their own models, rather than reusing existing
model components. Thus, model comparison, evaluation, and replication are hindered.

Due to their fine-scale design, ABMs can be computationally demanding. This can create
a particular challenge in terms of scalability, especially in cases where the ABM is intended
to provide an input into a higher-scale process model. For example, an ABM may be used to
model a local economy, with the input designed to feed into a regional model. One option to
address this challenge is to explore methods to fit metamodels, or aggregate functions that rep-
resent model behavior, to the output of ABMs, then use the metafunction as an input to the
higher scale model. For example, ABMs have been developed that replicate the smooth, regular
system dynamics seen in analytical epidemiological models and predator–prey models. Further,
conceptualizing the event-sequencing methods and the modes of interaction among actors and
processes acting across and between spatial and temporal scales remains an ongoing challenge.

As mentioned above, empirical ABMs can have high data demands, especially when they com-
bine spatial and actor level data. Both cost and confidentiality concerns can be barriers to data
access. The need to separate data used for model development from that used for validation creates
further data demands. As ABMs become more empirically informed, they have become more
site specific and have rarely been applied across multiple case-study sites, limiting their ability to
demonstrate broad scientific achievements.

Once a model is constructed and verified, model analysis can be challenging due to the
complexity of model design. While fairly simply

protocols have been developed for interpretation of alternative modeling methods, such as comparative statics and dynamics for analytical equilibrium models, and interpretation of estimated coefficients for regression models, standardized methods for understanding relationships between the exogenous and endogenous elements of ABMs are not yet developed. Given the purposeful pursuit of nonlinearity and complexity in ABM, it can be especially challenging to map, interpret, and understand model behavior over the entire potential parameter space of the model. From a scientific perspective, this leads some to question the validity of the sim-
ulation modeling effort, as the global behavior of models is not well understood. A corollary
to this challenge is that it can be challenging to communicate complex model mechanisms
and interpret outcomes for nonacademic audiences, such as local stakeholders, planners,
politicians, and policymakers. Participatory or companion modeling methods, in which models
are co-designed and analyzed, can potentially address this challenge.

At the end of 2008, during the world financial crisis, the CEO of IBM proposed a vision called Smart Planet (http://www.ibm.com/smarterplanet/us/en/), indicating a major direction for the application of information. In addition, the proliferation of the Internet of Things has contributed to the formation of a “central nervous system” across the world, connecting all people and things using the Internet. Currently, populated by numerous sensing devices and more than one billion users, the Internet has aggregated a vast amount of data. Although users are frequently overwhelmed by the multiplicity of information available, they lack access to the information and knowledge required for decision-making. This is a paradoxical situation widely prevalent in workplaces. IBM holds that a solution to this dilemma lies in integrating intelligence and knowledge into the ocean of data to render all data locatable, allowing all information and analytical tools that decision-makers need to be made available efficiently with the assistance of intelligent agents.

How can intelligence and knowledge be obtained? Currently, the information science community has developed theories and instruments of ontology development to enable the systematic organization of human intelligence and knowledge (Hadzic, Chang, and Wongthongtham 2009). Ontology enables easy sharing of intelligence and knowledge, and assists in rapidly locating information and data. Ontology also enables the accumulation of research results and assists researchers in identifying worthwhile research topics. However, ontology alone is insufficient; intelligent-agent-related technologies are required to combine ontology with intelligent agents to maximize benefits.

If ontology is analogous to the human brain, intelligence agents are analogous to the hands and feet. Ontology supplies the intelligence and knowledge required in the decision-making process, while intelligent agents provide the driving force to solve problems.

Intelligent spatial decision-support systems (ISDSSs) are a critical research direction in geographic information science and are desired for use in governmental and corporate decision-making. In this entry, developmental trends in spatial decision-support systems, and the development of ontologies and intelligent-agent-related technologies, are addressed. A framework for ISDSS development is also proposed.

Developmental trends in spatial decision-support systems

Spatial decision-support systems are a major item of development in geographic information science (Armstrong and Densham 1990; Sikder and Gangopadhyay 2002; Sengupta and
AGENTS, ONTOLOGY-BASED DECISION-SUPPORT SYSTEMS

Bennett 2003; Sugumaran and Sugumaran 2003; Sugumaran and DeGroote 2011). As a result of the upsurge in broadband networking in recent years, geographic information system (GIS) databases have been used to provide web services, and spatial decision-support systems have been integrated into the Internet. In addition to geographic databases, model bases and knowledge bases are required in spatial decision-support systems. Evolving cloud computing technology may provide an environment for information computing that enables complex model computing. Therefore, the establishment of model bases and knowledge bases is a key concern in current development of ISDSSs. Good results in information science have been achieved by constructing knowledge bases using ontology, and continued efforts are being made to develop large-scale knowledge bases and model bases (Sugumaran and DeGroote 2011).

The development of ontology and Semantic Web technology

Advances in geographic information science and technology gave rise to the development of GIS, software, and web services (Goodchild et al. 2005). However, most geographic information has been developed by different research institutes or government organizations with different software and data formats, resulting in sizable difficulties when integrating these GIS, especially in regard to data formats, coordinate systems, or semantic differences. In recent years, the Open Geospatial Consortium (OGC) has been committed to publishing geographic information in standardized web services such as web mapping services (WMS) (OGC 2006b), web feature services (WFS) (OGC 2005), and web coverage services (WCS) (OGC 2003). The disparity in data formats can be resolved by standardizing service-oriented architecture (SOA) web services. The European Petroleum Survey Group (EPSG) (www.epsg.org) is committed to recording a standardized coordinate system format as a reference for coordinate conversion. However, semantic integration of data cannot be achieved by standardized web services.

The semantics of data refers to the meanings or concepts underlying data. In information communication, text and graphics are used to convey meanings or concepts, in part or in entirety. In different cultural contexts, different words are used to express the same meaning or concept. As a result, geographic information generated in different contexts typically leads to semantic problems in data integration. Therefore, the effective integration of semantic issues with respect to geographic information has been one of the most popular research topics in the field of geographic information in recent years (Egenhofer 2002; Kuhn 2003).

“Semantic Web” is a term coined by Tim Berners-Lee, the inventor of the Internet (Berners-Lee 2000). The Semantic Web uses the XML format to record information and describes the semantic relationship between documents; it enables computers to understand the semantics underlying information and automatically derive and query semantic meanings associated with that information. By denoting semantic information and the relationships between linked information, a web of knowledge semantics is formed on the Internet, which is known as a Semantic Web. The application of the Semantic Web to the geospatial field has resulted in the formation of geospatial Semantic Webs (Egenhofer 2002; Fonseca and Sheth 2002; Kolas, Hebeler, and Dean 2005) and the semantic reference system (Kuhn 2003).

Egenhofer (2002) defined the geospatial Semantic Web as “a web that retrieves, analyzes,
and links geographic information semantics to achieve geospatial semantic interoperability,” and meets the following requirements.

1. The creation of spatial and temporal ontologies: ontology is an explicit specification of a conceptualization (Gruber 1993) that can be understood and derived by computers. This conceptualization includes the concept definition, the relationship between this concept and others (e.g., a hierarchical relationship), and related vocabulary derived from this concept. Ontology can be perceived as an electronic dictionary that not only maintains records of terms’ definitions, but also includes all concepts and knowledge in the field. It describes and records in detail “definitions of concepts,” “relationships between concepts,” and “related vocabulary contained in the relevant concept.” Thus, the convertibility of geospatial semantics is achieved by creating spatial and temporal knowledge ontologies, in which detailed descriptions of various concepts are provided.

2. The explicit presentation of semantics: concepts recorded in ontologies can be quickly and clearly comprehended and derived by computers or humans.

3. Searchable spatial statements: spatial statements can be queried in the ontology, and whether the results of queries satisfy the query statements can be evaluated.

Research on geospatial Semantic Web applications in recent years can be broadly classified into the following categories: (i) research concerned with achieving interchangeability of geographic semantics (Bishr 1998; Harvey et al. 1999; Egenhofer 2002; Fonseca and Sheth 2002; Kuhn 2003; Lemmens et al. 2006); (ii) research concerned with investigating geospatial ontologies to establish definitions of and relationships between various concepts, and constructing geospatial ontologies (Egenhofer and Mark 1995; Mark et al. 1999; Smith and Mark 2003); (iii) research concerned with strengthening geospatial semantic retrieval and searching, such as in the project “A spatially aware search engine for information retrieval on the internet” (SPIRIT) (Purves et al. 2007); (iv) research concerned with the application of a spatial data infrastructure (SDI) to locate appropriate GIS web services, including web services incorporating GIS data and analysis methods (Bernard et al. 2003; Lutz and Kolas 2007); and (v) research concerned with the application of geospatial ontologies that are (semi-)automatically combined with GIS web services (Di et al. 2006; Lemmens et al. 2006; Yue et al. 2007).

The development of intelligent agent technology

Agent technology is an area in information science that has rapidly developed in recent years. Agent technology enables information systems to dynamically exchange and share information through agents, and accomplish tasks and goals in collaboration. Agents are characterized by autonomy, sociability, reactivity, and proactiveness, and can actively assist users by locating useful information on the Internet to complete the tasks assigned. However, without the assistance of ontologies, the effectiveness of agents is severely limited. After the integration of agent technology with ontology technologies, agents gained access to domain knowledge and became intelligent agents (Hadzic, Chang, and Wongthongtham 2009). To fully leverage its effectiveness, an ISDSS must incorporate GIS, ontology, and agent technologies.
Framework for intelligent spatial decision-support systems

The application of geospatial Semantic Webs or ontologies to improve or solve problems pertaining to geospatial semantics regarding spatial decision-support systems has not been adequately explored in the aforementioned studies. Traditionally, spatial decision-support systems operate in stand-alone mode, in which all GIS data and analysis to be used are pretreated (including GIS file formats and semantics) and saved in a stand-alone version; although current GIS web services like WMS and WFS can be applied in spatial decision-support systems, solving the GIS file format problem, geospatial semantic interchangeability is critical because of the varying semantics used by different web services. In addition, different spatial decision-support systems established on the basis of different topics may use the same GIS data and analytic methods repeatedly. Repeated use of the same GIS data and analysis may result in imperceptibly increased costs.

Therefore, proposed here is the use of a geospatial Semantic Web and geospatial ontology to improve the spatial decision-support system (Jung, Sun, and Yuan 2013; Jung et al. 2013). Detailed information about the intelligent spatial decision support system (ISDSS) framework can be found elsewhere (Jung et al. 2013). The objectives were as follows.

1. To propose a knowledge-oriented structure based on geospatial semantics, and solve geospatial semantic problems using geospatial ontologies.
2. To improve spatial decision-support systems. Based on GIS web services, geospatial ontology automatically locates and infers reasonable web services in response to various decision-making problems. Assembling is performed to generate preliminary results, which are subsequently provided to decision-makers as a reference for further evaluation. This resolves the problem of repeatedly using the same GIS data and analysis methods.

Figure 1 depicts an ontology-based information structure that consists of four components: a portal, a geospatial ontology, SDI, and web services.

Portal

The portal serves as an interface for human–computer interaction between decision-makers and the framework, and provides a web map service and registration platform for decision-makers and system developers to input spatial decision questions, including questions regarding spatial relationships and spatial scope. Any problems raised by the decision-maker are transferred from the portal to the ontology for derivation. After the appropriate web services are located, assembling and execution are performed to generate preliminary results, which are finally presented in the portal to provide decision-makers with references for further evaluation. Service providers may register on the portal to make their services available to policymakers.

Geospatial ontologies

Geospatial ontologies are the core of the structure and are responsible for receiving question inputs from decision-makers, subsequently deriving appropriate solutions and GIS web services. Geospatial ontologies that are created by experts who differ in their knowledge of geospatial domains are expandable and can be connected to each other, enabling the sharing of concepts between different ontologies.
With reference to Kolas, Hebeler, and Dean (2005), the following geospatial ontologies were constructed.

1. **Geospatial geometry ontology**: basic geometric geospatial ontologies are constructed based on the definition of the OGC simple feature specification (OGC 2006a). This includes geometric properties like points, lines, and polygons (Figure 2).

2. **Geospatial web services ontology**: common definitions and hierarchical structures for GIS web services are provided, such as WMS, WFS, and WSDL (web service definition language) services (Figure 3).

3. **Geospatial analysis ontology**: because of the present lack of a complete, unified classification system for GIS analysis, the classification system of the ArcToolbox featured in the ArcGIS 9.3 software was referenced to construct the ontology of geospatial analysis methods. The input, output, precondition, and results (IOPR) of each GIS analysis method are completely recorded in the ontology (Figure 4).

4. **Domain ontology**: domain ontology is a domain knowledge classification structure developed by experts in the field. The global Earth observation system of systems (GEOSS) addresses nine areas, including...
disasters, health, energy, climate change, ecosystems, agriculture, biodiversity, water resources, and meteorology. The content of the domain ontology is gradually built up through collaborative efforts by experts in the field mediated with GEOSS (www.ogcnetwork.net).

5 Task ontology: Timpf (2001) emphasizes that task ontology is as crucial as domain ontology. Task ontologies focus on various tasks in a given area and provide detailed descriptions of various concepts and relationships associated with that task, thereby simplifying and organizing large-scale domain knowledge. In task ontologies using this structure, each task represents a different spatial decision problem; the concepts required for solving the task and the relationships between these concepts are defined in detail. Based on GIS analytic methods, the concepts and their relationships provide a conceptual workflow.

As shown in Figure 5, when the user selects Task A, the task ontology may derive three analytical methods (i.e., Function1, Function2, and Function3), which are connected in series by hasNext relationships. For example, the Function1 hasNext Function2, and Function2 hasNext Function3.

Spatial data infrastructure (SDI)

Knowledge derived by geospatial ontology is conceptual and is not directly connected to actual web services. For example, the three functions derived in Figure 5 belong to a conceptual workflow, where conditions satisfied by each function must have been predefined in the ontology, although not directly connected to the web service. Thus, the derived functions and their associated conditions must be mapped to appropriate web services by searching within the existing SDI. During the construction of the SDI, geospatial web services are provided by the
Figure 3  Geospatial web services ontology.

Figure 4  Geospatial analysis ontology.
data provider, and the web services are registered to the portal.

**Service chain mediator**

After the appropriate web services are located, the conceptual workflow is located within the task ontology through the assistance of the service chain mediator using agent technology. Following assembling and execution, the preliminary results are transferred back to the portal, providing a reference for further evaluation by decision-makers.

The information framework presented here employs ontology technology to effectively integrate various geographic information services offered by government, academia, and private firms. The government is responsible for providing data services across the databases of SDI, academic institutes are to provide data analysis and simulation model services, and private firms are to provide various application services to government agencies and the general public. This enables complex environmental problems faced by decision-makers to be solved through joint efforts.

**Conclusion and recommendations**

The development of a “Smart Planet” is currently a major task faced by the GIS community. Proposed here is a framework for an ISDSS that may be used to accelerate the implementation of the Smart Planet initiative. In addition to developing geographic databases, an ISDSS also requires the development of knowledge bases and model bases. In the next phase, building a knowledge database and model bases is critical. Adopting the framework introduced here, ISDSSs can be constructed to comprehensively improve the quality and efficiency of the government’s policies.

AGENTS, ONTOLOGY-BASED DECISION-SUPPORT SYSTEMS

Aging

Christine Milligan
Lancaster University, UK

At a population level, aging refers to a shift in the age distribution over time towards older ages. The increased number and proportion of older people is measured on the basis of increased life expectancy at birth and declining birth rates coupled with migration.

The definition of old age against which population statistics are measured can vary. In many high-income countries retirement age (generally still taken to be 65 years of age) is the baseline against which population aging is calculated. However, at a global level life expectancy rates vary significantly; furthermore, the concept of retirement as a baseline for calculation may have little meaning (for example, in low-income countries). As a consequence, population aging may be measured on the basis of 60 years and over (see for example the World Health Organization).

Measuring aging on the basis of those aged over 60 or 65 years covers a wide age range. As a consequence, distinctions are often made between the “young old” (those aged under 75 years), the “mid-old” (those aged 75–84) and the “oldest old” (those aged 85 years and over). The terms “third age” and “fourth age” are also commonly referred to in the literature. Retirement is usually seen to mark the beginnings of the third age. There is less agreement on what marks the beginnings of the “fourth age” but most often it is used to refer to those aged 85 and over; in most high-income countries this demarcates the stage when most individuals have lived beyond average life expectancy. While these figures and terms are somewhat arbitrary, the distinctions are useful for research and policy as the oldest old are most likely to experience the highest population levels of disability arising from chronic disease that requires long-term care and support.

As perhaps the major demographic challenge of the twenty-first century, population aging will have profound consequences and implications for all places and all aspects of human life. While, on the one hand, global aging represents a triumph of human achievement in the medical, social, and economic spheres, on the other, it presents challenges to existing systems and institutions at all spatial scales that will affect nearly all aspects of society. In the social sphere, population aging will impact public services, health, care and wellbeing, family composition and living arrangements, housing, and migration. In the economic sphere, it will impact on economic growth, savings, investment and consumption, labor markets, pensions, taxation, and intergenerational transfers. In the political arena, it will influence voting patterns and representation.

The historical and ongoing shift in the aging of the population makes it important to understand how these social and economic implications are being played out in different places for different groups of people. The sheer breadth of issues affecting, and affected by, this demographic shift has led to the study of aging being addressed across a wide range of social science and health-care disciplines – traditionally through the multidisciplinary study of (social and critical) gerontology.

Those working in this field have done so from a variety of perspectives and at a range of spatial
AGING

scales stretching from the global to the local and individual.

The spatial demography of aging

Globally, the population is undergoing a significant transformation that is unprecedented in human history. The current bulge in the middle-aged demographic, together with ongoing improvements in life expectancy, means that the population of older people is projected to rise significantly, increasing from 530.5 million in 2010 to 1.5 billion in 2050. These projections point to a much older world, and a future in which approximately one in six of the global population is expected to be 65+ by 2050. This situation will double the current proportion of those aged over 65 years. Population aging is not just a feature of high-income countries; however, considerable variations do exist between regions, countries, and even within countries. Population geographers have been concerned to examine these patterns, their causes, and the implications of this spatial unevenness, and more recently to understand the why and where of spatial trends on aging.

At a regional level, Europe and North America have the highest proportion of their populations in the 65+ age group and the lowest proportion of those aged under 19 years, whilst Africa and South America exhibit the reverse population patterns. Some variation does occur within these regions, but overall the figures point to Europe as the “hotspot” of global aging, although Japan too figures highly. Population projections, however, suggest that by 2050, six of the top 20 countries/regions with the highest proportion of those aged 65+ will be Asian, including Singapore, Japan, Hong Kong, South Korea, Taiwan, and Macau. African countries will continue to have the lowest proportion of those aged 65+. It is important to recognize that these estimates are based on the proportion of the population and not actual population numbers. So while countries such as China, India, the United States, India, and Brazil may have lower proportions of older people in their populations, the actual numbers of those aged 65+ in these countries will far exceed those of European countries. As McCracken and Phillips (2005) point out, while currently these countries account for 59% of those aged over 65 years, by 2050 this figure is projected to rise to 80%.

Currently, the oldest old constitute 7% of the global population over 65 years of age. This percentage is not evenly distributed, with more developed countries having approximately 10% of the over 65s in this age group and less developed countries having around 5%. In many countries the oldest old are the fastest growing proportion of the population. This trend is most striking in Japan where it is estimated that by 2030 nearly 24% of the population will be over 85 years of age. Globally, the National Institutes of Health in the United States have estimated that between 2005 and 2030 this age group will have increased by 151%.

As life expectancy increases, causes of death will shift from infectious and parasitic diseases to chronic and noncommunicable diseases such as heart disease, cancers, and diabetes. This situation has led to debates about whether we can expect to see a compression of morbidity, where medical advance means that the young old are likely to live relatively healthy and active lives, delaying the onset of multiple health problems and disability to old old age. Others, however, maintain we will see an expansion of morbidity with an increase in the prevalence of chronic illness and disability across the total of our older populations as life expectancy increases.

The demographic transition model (DTM) is one approach that has frequently been drawn
upon to explain global patterns of aging. First formulated in the 1940s by Frank Notestein and refined over time, the model describes temporal shifts in birth rates and death rates and links the resultant changes in the population profile to transformations in socioeconomic conditions across four stages of shifting birth and death rates:

- **high stationary**: high birth and high death rates due to high infant mortality, poor medical knowledge, famine, war, and epidemics;
- **early expanding**: population growth as birth rates remain high but death rates decline significantly due to improved sanitation and access to clean water, better nutrition, and increased medical knowledge;
- **late expanding**: population growth slows due to declining birth rates resulting from shifts in attitudes to birth control and family planning and the gradual stabilization of death rates at a low rate due to continued improvements in medical technologies and nutrition;
- **low stationary**: low and stable birth and death rates due to: continued family planning and later marriages, the improved status of women; a shift in the main causes of death from disease and epidemics to chronic diseases of affluence such as heart disease, cancers.

A further stage has also been added to the model, based upon recent shifts in some (mostly European) countries that are now experiencing both an aging population and population decline as death rates remain stable but birth rates fall below replacement rates. Some argue that this disequilibrium will be balanced by controlled in-migration. Drawing on evidence from Europe and the United States, Coleman (2006) cautions that if this continues, increased rates of in-migration will eventually lead to a displacement of the original population, both by age profile and ethnic composition, leading to a radical and permanent alteration of the national population in which the original population would hold a minority position.

The DTM was modeled on relatively slow shifts over time in European countries. In many newly developing countries the shift through the stages of the model has occurred much more quickly due to their ability to take advantage of current public health knowledge and advanced medical and other technologies.

This model is not without its critics, who cite evidence of reversals in the aging of populations in countries such as Russia, Botswana, Zambia, and Zimbabwe where life expectancy at birth has fallen below 60 years of age. In Russia this fall has been attributed to social and political upheaval and economic collapse in the post-USSR period. In the African countries it has been largely attributed to war, famine, and the HIV/AIDS pandemic. These examples illustrate that the transition is not one of inevitable progression and improvement but can be subject to reversals. Using the example of Europe, the region with the world’s oldest population structure, it is also clear that cultural and political factors – such as governments’ approaches to migration, health care, and welfare – are also at play. These issues will be particularly significant for newly developing countries where the pace of population aging may make it difficult for them to adjust their economic, health, and social care systems to cope.

Despite contestation about the DTM, as a model it has proven remarkably resilient as a means of explaining observed spatial unevenness in population aging, though it is less useful as a model for explaining observed spatial variability within countries (see Population growth).
Environment and geographical gerontology

Cutting across both disciplinary and subject contexts there is consensus within aging research that understanding the environment and the individual’s location within it is a crucial factor in understanding the aging process. Both environmental and geographical gerontologists place emphasis on the importance of understanding the ordinary everyday contexts that older people inhabit (Scheidt and Schwarz 2013). This situation is not new; rather, a sustained body of research around older people’s relationships with their social and physical environments stretches back at least 40 years to the early work of M. Powell Lawton, Stephen Golant, Graham Rowles, and others. Golant, for example, looked at future housing options across a range of different scales from segregated housing projects for older people to retirement villages – developments that have sparked ongoing debates about the “ghettoization” of old age versus the development of supported and protected living environments.

Many of these early geographical and environmental gerontologists adopted behavioral and humanistic approaches to understand the ways in which older people’s environmental experiences differed from those of younger populations. Lawton and Nahemow’s (1973) model of “environmental press” is seen as a major contribution to understanding person–environment transactions in later life; here, optimal environmental fit is seen to occur when an older person’s abilities and capacities are consistent with the demands and opportunities within that person’s environment. If the demands of the environment exceed those of the person and their abilities (for example as an older person’s health or mobility declines), a person–environment misfit occurs, triggering the need for support to enable the older person to age in place successfully.

Aging in place continues to be a key theme in environmental and geographical gerontology. This involves understanding older people’s experiences of, and engagement with, domestic and community environments, the characteristics of these environments, and how they influence an older person’s quality of life, health, and mental wellbeing. A particular concern has been to unpack the continually changing relationalities between older people and their sociophysical environments and how these act to shape the human experience and processes of aging. The assumption here is that as people age, their physical and/or cognitive abilities change or decline, resulting in shifting – and often more vulnerable – relationships with the environments they inhabit. Rowles’s seminal work “Prisoners of Space” set a marker for this field of enquiry. His detailed ethnographic account of the lived experience of older people’s lives painted a rich and detailed narrative of the ever-decreasing lifeworlds that people inhabit as they age.

The work of early geographical and environmental gerontologists has stimulated a deeper engagement with older people’s social and physical experiences of, relationship with, and exclusion from, the communities they inhabit. This scholarship has mainly focused on issues of access and mobility within these communities and on what facilitates and excludes – stretching from design and infrastructure to social and structural ageism and inclusion. This work is exemplified by the emergence of a body of conceptual, empirical, and policy-oriented work around the development of age-friendly environments. Recognizing the potential challenges of our aging societies, for example, the World Health Organization has set up a global network of age-friendly cities and communities. These are designed to foster...
worldwide mutual learning about how to create inclusive and accessible urban environments that promote healthy and active aging and a good quality of life for their older residents. Similar initiatives also exist around the creation of dementia-friendly environments.

Recognition of the decreasing lifeworlds that older people inhabit, combined with policy shifts towards aging in place, has also highlighted the importance of understanding the domestic sphere and the (sometimes changing) meaning of home for older people (see Home). As a site removed from public scrutiny, the home is seen as a place where the older person can control decisions about whom to include or exclude. Such sites can provide an important buttress to an older person's sense of self and independence, particularly for those who may feel vulnerable outside the bounds of their own private spaces. The home is seen as a site of security, familiarity, and nurture that is imbued with personal meaning and which can promote successful aging in place through what Rowles later referred to as a preconscious sense of setting. That is, temporal knowledge of the home, combined with physical attachment to it and the routines performed within it, can facilitate an older person's ability to negotiate that space without coming to harm, even as physical or cognitive abilities begin to decline. But increasing frailty can lead to a breakdown of this preconscious sense of setting as the requirement for care and support increases, bringing attendant technologies of care (such as hoists, ramps, commodes, wheelchairs, etc.). Increasing dependence on both formal and informal support to maintain activities of daily life can also result in a declining power to exclude from even those most personal and private areas of the home. This process highlights the juxtaposition of private and public space and the shifting relationships of power, independence, and autonomy that accrue for older people across a continuum of physical and cognitive abilities as a consequence of these shifting juxtapositions (see Twigg 2000; Milligan 2009).

The importance attached to the meaning of home and identity has also played a significant role in work around residential care settings for older people. Here, emphasis is placed on whether it is possible to design residential spaces that facilitate the development of a sense of place or home, and the kinds of lifestyles such spaces foster and support (e.g., Peace and Holland 2001).

Much of the ongoing work in this field is grounded in conceptual and theoretical underpinnings around identity and place attachment, environmental meaning, Therapeutic landscapes, and community engagement in later life.

Landscapes of aging

Work around population aging often characterizes the older population as homogeneous in terms of their demands for social and welfare support, health care, their levels of participation in society and the workforce, and so forth. Older people are typically portrayed as more likely to place pressure on health and welfare systems and less likely to be net contributors. Such an approach fails to recognize difference and negates the considerable contribution older people make to the social, economic, and cultural landscapes of our societies.

In recognizing the heterogeneity of aging populations it is important to note that particularly in young old age, many older people in high-income countries will be healthier and better educated, and have greater disposable income and greater expectations about how they will spend their retirement years than in the past. Early retirement may be spent taking up new challenges, finding more time for existing hobbies and activities, or taking up activities once
AGING
deemed to be no longer open to older people (e.g., continued education, long-distance travel, fashion), opening up new consumer niches and new dedicated activity clubs. There is also evidence of a growing pattern of mobility and shifting migration patterns amongst newly retired populations to new locations – such as rural or coastal areas – that are seen as conducive to their quality of life and wellbeing. For others there has been a rise of so-called snowbird migration, that is, the seasonal migration of older people from (particularly) the cooler northern states of America and Canada and parts of northern Europe to the warmer climes of places such as Florida, Mexico, and Southern Europe in order to avoid the effects of cold, dark winters. Estimates suggest that some locations (for example, Florida in the United States) can swell by hundreds of thousands of temporary older migrants during these winter periods. This phenomenon can have a major impact on the resident populations of both sending and receiving communities, but has also given rise to new communities of mobile older people who seasonally migrate between these places (see Population geography).

With increasing age, however, comes a greater likelihood of experiencing a decline in both physical and cognitive functioning, increasing the demand for health and welfare services. Policy responses vary across countries and even within countries. For many high-income countries, the early decades of the twenty-first century have been characterized by austerity measures and neoliberalizing trends manifest in sweeping welfare retrenchment and a shift towards responsibilization. Risks taken throughout the life course are seen as individual, rational choices that will impact healthy life expectancy in old age. One response has been a growing call to focus on life course approaches within geographical gerontology and an engagement with sociospatial inequalities. Hopkins and Pain (2007), for example, maintained that human geography was placing a disproportionate emphasis on specific age cohorts and the extreme ends of the chronological age spectrum, arguing for “relational geographies of age” in which the focus should be on intergenerationality and life course rather than specific age cohorts.

A more established interest that has been prevalent since at least the 1980s has focused on the impact of different health-care systems for the planning, regulation, utilization, and spatial allocation of resources for older people, particularly in relation to public, private, and community-based resources. More recently, geographers have taken a critical approach that has shifted away from distribution and allocation of services for older people at national and subnational scales to consider how health and welfare restructuring is impacting older people themselves (see Identity). Theoretically underpinned by the shadow state thesis (defined by Wolch in 1990 as a parastate apparatus largely made up of voluntary and community organizations and social enterprises that are administered outside traditional democratic politics, but which have taken on many of the collective service responsibilities previously undertaken by the public sector but which remain within the purview of state control), this work has considered how welfare retrenchment is manifest in changes in accessibility and availability of services, who provides those services, and the shifting sites of delivery from institutional to community and domestic settings. Of particular note has been a widespread shift to market regulation and increased dependence on provision through the voluntary sector and social enterprise in the local, regional, and national political economies of health and social welfare. More recently this shift has also manifested in attempts to reinvigorate active communities and voluntarism as mechanisms to support aging in place and the inclusion of older people.
AGING

The critical turn in social and health geography has seen the emergence of a corpus of work that moves away from treating older people as a population statistic or as the objects of study and has instead focused on the personal and intimate and a more qualitative, in-depth engagement with older people themselves (see Critical geography). The early work of Glenda Laws and others, for example, highlighted the importance of focusing on the ways in which the body functions as a particular and fundamental determinant of the experience of places. Understanding the relationalities that exist between the aging body and places has been an important theme running through this work. A particular concern has been to examine the place of the body in everyday meanings and constructions of aging, bringing into focus what the aging body can and cannot do within places and how places can facilitate or constrain the aging body. Theoretically, this research draws on some of the early work around “environmental press” but there has also been an engagement with Bourdieu’s concept of habitus and the notion of “body capital” (see Antoinetti and Garrett 2012). This highlights the importance of focusing on the interaction between the aging body and places and how any reduction in body capital (physiological decline) not only changes habitus but also how younger age groups see older people. Diminished body capital is also viewed as diminishing other capacities accrued by the individual over the life course, creating a mismatch between the capacity of the body and the environment within which it is located (see Bodies and embodiment).

The aging body is conceived as being not only pivotal to the social construction of later life but also to the peripheralization of older people in discrete locations that may be segregated from those used and inhabited by younger people. Images of the aging body, for example, are often depicted as frail and dependent (particularly in Western societies) and as a consequence have become identified with the home, supported care, or residential settings. Within such settings there is also a strand of work around care and bodywork that has specifically looked at how gendered as well as aging bodies affect the use and meaning of space (see Gender).

From the latter half of the twentieth century onwards, there has been a gradual shift in many high-income countries away from the provision of care for the most frail of our older population within institutional settings towards aging in place. This turn has shifted the emphasis of care and support to domestic settings, where informal carers (usually family members who are largely, but not exclusively, women) have taken on many of the routinized tasks of caring for the aging body, including much of the intimate and personal bodywork involved in care, such as washing and bathing, dressing, toileting, and feeding the older care-recipient. Undertaking these normally personal and private acts gives rise to transgressions of contemporary social taboos around care in Western society – particularly cross-sex care. While the transgression of such social taboos may be less acute in spousal care-giving, it can be particularly difficult where an adult child is providing personal care for a frail older parent of the opposite sex. As a result, relationships associated with the home can be altered and challenged by the process of caring (see Caregiving).

Given the social taboos that often mark the social boundaries of bodywork in Western society, the more detached stance of the professional carer can be important in helping to make it more manageable. So the management of the care-recipient’s body and who undertakes that management can be critical to the construction of the home as a caring space. It is a body that is subject not only to management by informal
AGING

carers, but that has also been assessed by formal care services in relation to the quantity and nature of care it should receive against some institutionally defined norm. It is important, however, that the assessment of care is not interpreted solely in terms of meeting the medically defined needs of the corporeal body; if “social death” is to be avoided, the home also needs to be understood as a place where valued aspects of the social body can also be nurtured and preserved. In other words, it is important to recognize that it is not just the physical body that is attended to but that the social and emotional needs of the aging body are also recognized and met. Indeed, a growing body of research has highlighted the adverse effects of social isolation amongst older people on both their physical health and their mental wellbeing. The design of specialist housing for older people, however, often assumes an aging body that is relatively static, so requiring only limited space. This in turn can impact on an older person’s ability and opportunities to socialize within these settings. It is only through recognizing the home and body as interrelated sites and scales of analysis, that are both fluid and constantly in process, that we can gain real insight into the complex structuring of the relations that shape experiences of care.

Social and cultural stereotypes linked to public perceptions and attitudes to the aging body will shape societal responses to aging, and where these are negative, will contribute to ageism and the ongoing search for a youthful and ageless existence that acts to reinforce the “invisibility” of older people. It is important, however, to recognize that the construction of aging identities in place is both socially and culturally ascribed, hence these highly Westernized conceptualizations of the aging body will vary and be reconstituted in different ways over both time and space.

Agricultural environments

Mark Blumler
SUNY-Binghamton, USA

Other than humans, only certain ants, termites, and beetles practice agriculture; they farm underground, and have relatively little impact on ecosystems. Humans, already impacting environment especially through their use of fire, began to farm about 10,000 years ago. Since then, agriculture arguably has been the major cause of ecological and evolutionary change on the Earth. Agricultural environments are discussed here from an ecological and an evolutionary perspective.

Farming began in several regions – the Fertile Crescent, China, Mexico, the central Andes, and New Guinea – at about the same time. One or two additional regions, notably the Sahel, developed largely indigenous agriculture somewhat later. Farming enabled humans to obtain more food per unit area of land than hunting-gathering, and also allowed craft specialization and technological advances. Consequently, farmers were able to spread geographically at the expense of hunter-gatherers, or to incorporate them into their system. The focus initially, and to a large extent still today, was on fast-growing, mesic, high-yielding species. Annual or short-lived perennial seed crops characterized most of the early agriculture centers, though root crops were important in New Guinea and the Andes. The seed crops, especially grains and legumes, tended to be derived from large-seeded wild ancestors, possibly because seedlings from large seeds are easier to cultivate with a primitive technology than plants from small seeds. Over time, there was an expansion in the types of plants cultivated, and in their uses, to include textiles, ornament, and today, even biofuel.

The agricultural origin centers tend to be located in the foothills of mountainous regions, that is, they have high habitat diversity and hence also high biodiversity. In addition, there is some evidence that they have high local (alpha) diversity. The Fertile Crescent and adjacent Mediterranean, for which biodiversity patterns are best documented, has the highest herbaceous alpha-diversity on Earth. Farming was inherently an attempt to simplify these ecosystems, to favor a few staples at the expense of other species. Nonetheless, the origin regions remain highly diverse today. Many species from those regions, including some crops, are now serious overseas invaders, while the origin centers themselves have suffered comparatively little from invading alien species.

Species that underwent domestication often hit the evolutionary jackpot: for instance, wild emmer, the progenitor of most varieties of wheat, occurred naturally only in the Fertile Crescent. Today, its domesticated derivatives are grown almost everywhere that agriculture is practiced in the temperate and subtropical zones, and are even penetrating the tropics. When a species expands its range so spectacularly, inevitably, other species must undergo range contractions or even become extinct. The line in the song “America the Beautiful” about “amber waves of grain” illustrates the extent to which farming landscapes have taken over and replaced indigenous ecosystems. Global vegetation maps usually show “potential natural vegetation” rather than the actual cover; if they were to show the latter, agricultural plants...
would dominate over a major portion of the terrestrial regions (see Ellis and Ramankutty 2008, for global anthropogenic biomes).

While the domesticates benefited from their mutualistic relationship with humans, other species were able to take advantage of the newly created agro-ecosystems, despite our best efforts to control or eliminate them. These unwanted species, “weeds” and other “pests,” also benefited from agriculture at the expense of other wild species, presumably. Some weeds became so successful as to overwhelm the crop, typically as farming spread into a different environment less favorable for the domesticate, at which point if the weed was edible, farmers began to harvest and cultivate it (so-called secondary domestication). Meanwhile, the wild progenitor of a domesticate frequently would evolve weed genotypes, and complex crop-weed-wild interactions might develop (Harlan 1975).

Certain families characteristically benefited from the adoption and spread of agriculture. Proponents of the “Paleolithic Diet” argue that grains and legumes were scarcely consumed before agriculture; regardless, they certainly are very important today. The Cucurbitaceae (melons, squashes, and cucumber), mustard family, and Solanaceae (potatoes, tomatoes, peppers, and eggplants), provided vegetable crops, and the Rosaceae supplied a remarkable number of temperate fruits. Some families were pre-adapted to the combination of fertile conditions and soil disturbance that characterizes agriculture, and consequently became weeds, crops, or both: the mustard family, spinach family, buckwheat family, and so on. Others were attractive for their nutritive qualities, such as the rose family.

As farming spread, humans had to transform environments so as to resemble the origin center from which they were migrating. This process is particularly evident for spread from the Fertile Crescent. There, extreme summer drought favors dominance by annual plants, and all the early domesticates were annuals. As agriculture spread northwest into Europe into a region without seasonal drought, it became necessary to plow to remove the native, perennial vegetation. Since even the weeds were largely of Fertile Crescent origin, in effect an entire ecosystem was transplanted. Fertile Crescent agriculture also spread east to India, where wheat, chickpeas, lentils, peas, and other winter annuals are now major items of the diet. But India has a monsoon climate, with rain in summer. To grow the Near Eastern crops, Indian farmers developed the “rabe” system, from the ancient Indo-European word for mustard, which also is from the Fertile Crescent. They dry fallow in summer, plowing repeatedly to prevent weeds from utilizing the monsoon moisture; the crops are sown in fall, and mature primarily on the stored moisture.

In the Old World, farming diffused until it occupied essentially all arable land. Land that was too infertile, cold, or arid was reserved for pastoralism. Technologies such as irrigation and terraces were massively developed in order to maximize the arable land. In contrast, in the Americas population density is still relatively low; arable land is currently expanding in much of Latin America. In particular, whitewater portions of the Amazon are seeing massive penetration by peasant farmers who clear the rain forest with fire. While swidden was long practiced traditionally, it is unclear how intensively the Amazon was farmed before 1492: there are indications of dense, permanent populations along the Amazon River, before Old World diseases struck, and the widespread occurrence of terra preta, a fertile, dark-colored, anthropogenic soil, also suggests that permanent agriculture was a feature of the more fertile parts of the rain forest. In contrast, the blackwater tributaries of the Amazon are simply too infertile to have supported other than shifting, swidden agriculture.
Until the Industrial Revolution, agriculture was entirely based on renewable resources, and thus in a sense sustainable; though the degree to which accelerated soil erosion may have developed into land degradation/desertification is much debated. The extent to which early Mesopotamian civilizations may have salinized soils in the Euphrates-Tigris basin is in question; certainly much of the region is still highly productive today. Erosion of slopes at times choked valley bottoms and created wetlands that became malarial to the detriment of the local populations, but such outcomes would not have lasted forever given the natural tendency of streams to unclog their drainages. In desert regions, farmers such as the Nabataeans, Hopi, and Mixtec intentionally caused slope erosion to concentrate soil in the wadis where moisture was sufficient for crop growth. Properly maintained terraces typically produced less erosion than would have occurred naturally; though during times of war or other catastrophe, when terraces were neglected, erosion could become highly accelerated. Bali represents one of the most extreme cases of land transformation though terracing and complex water management. Almost the entire surface is given over to agricultural plants, with terraced rice paddies, and domesticated palms in un-terraced spots. Rice geneticists attempted to spread the Green Revolution to Bali, but later withdrew, admitting that the indigenous system yields at least as well as a modern system would be able to do.

The infamous Dust Bowl of the 1930s had a major influence on beliefs about soil erosion, and belief in widespread land degradation persists within the environmental movement and the United Nations. But within geography, the consensus today is that: (i) the Dust Bowl region was not permanently ruined; soils remain fertile on the whole, though today if farmed they are irrigated. (ii) There is no good evidence for desertification anywhere except on a very local scale (Thomas 1993), aside from the Aral Sea debacle resulting from a misguided Soviet irrigation scheme. (iii) Increasingly, it is recognized that when soil is lost in one place it must be gained somewhere else (though admittedly that is not always a good thing).

Farming can have major effects on off-farm ecosystems. Eutrophication of waterways due to fertilizer runoff is one of the better known and more serious examples. Construction of reservoirs for irrigation purposes can alter downstream river flow, to the detriment of many organisms. The trapping of sediment behind dams is causing a reduction in the size of deltas such as those of the Mississippi and the Nile.

Today, farming is utterly dependent upon fossil fuels. For instance, the Green Revolution, which after World War II spread modern agriculture to poor countries, entails the use of gasoline-powered machines such as tractors, artificial N fertilizer manufactured using natural gas, irrigation pumped with motors powered by fossil fuel, and herbicides and pesticides largely manufactured from hydrocarbons. As such, sustainability is inherently doubtful.

These transformations reflect, and have caused, a change from subsistence to market oriented farming, with the resulting disadvantaging of relatively infertile or otherwise marginal arable lands. For instance, much of the northeastern United States, which was given over to subsistence agriculture in the nineteenth and into the twentieth century, is now abandoned and has reverted to forest because both soils and climate are not conducive to high yields, while improving transportation technology has enabled farmers in more fertile climes to ship their produce over increasing distances and undersell local farmers. On the other hand, genetic engineering
combined with massive applications of phosphorus and other fertilizer is transforming some formerly infertile regions into arable. For instance, the Cerrado of Mato Grosso, an extremely diverse, infertile shrub savanna formerly utilized for extensive cattle grazing, is increasingly given over to soy cultivation. Legumes such as soy have a high phosphorus requirement, but once that is supplied can add the nitrogen that such soils lack.

Now, the increasing use of ever-larger machinery combined with herbicide-resistant GMO crops are causing fields to become ever larger also, as well as leading to the elimination of hedgerows and other vegetated field boundary areas. The biodiversity of these fields is extremely low. Among many other impacts is the recent decline in the abundance of monarch butterflies, which depend on a food plant, milkweed, that formerly inhabited field edges and other open areas but has been greatly reduced by spraying and plowing. Many birds and other animals that depend on weeds for food, and/or use field edges for migration corridors, are now declining rapidly toward possible extinction (Stoate 2011).

Theoretical debates over the causes of biodiversity remain unresolved. For instance, many ecologists believe that high productivity is associated with high diversity, some believe that the relationship is humped (unimodal), and still others point to the low fertility of soils in western Australia and the South African Cape, which have remarkably high plant species diversity. The best evidence is that the enormous quantities of fertilizer now being applied are causing a major loss of plant biodiversity due to competition for light. The role of disturbance also is somewhat controversial, with perhaps the consensus being that up to a point it is beneficial, but that diversity declines if disturbance becomes massive. If so, farming might originally have fostered diversity, and indeed, the evidence from traditional farming suggests that may have happened. However, the enormous scale of the current industrialized system is clearly inimical, as it reduces landscape heterogeneity, a known associate of diversity. Impacts also are likely to depend on the type of natural ecosystem within which farming is practiced. Farming fragments forests, for instance, which has the effect of favoring “edge” or ecotone species, while disfavoring species that live in the interior.

Today, there is increasing concern about diversity of the crops themselves. Globally, the human diet is becoming ever more restricted to a very few staples, though in the supermarkets of developed countries the food diversity is spectacular. In part, this reflects the conversion of agriculture in much of the underdeveloped world to cash cropping, spurred on by Western institutions such as the World Bank. The spread of Green Revolution genotypes has raised concern for the genetic diversity of crops, since much of that diversity resides in traditional varieties grown in often-marginal environments that are now subject to abandonment due to inability to compete on the international market. Attempts are being made to preserve diversity in gene banks, but these suffer from introgression, and adaptation to the environment in which the gene bank is located.

Agricultural geography

Guy M. Robinson
University of Adelaide, Australia

Traditional approaches

The word “agriculture” is derived from the Latin word *ager* and the Greek word *agros*, both meaning “field,” and from the Latin word *cultura*, meaning “growing” or “cultivation.” The term symbolizes the integral linkage between a human land-based activity and its accompanying modification of the natural ecosystem. Since the first domestication of wild plants began in the Fertile Crescent of the Near East around 10,000 years before present, people have created agroecosystems in which natural ecosystems have had socioeconomic processes and systems laid over them. In studying agroecosystems agricultural geographers have addressed agriculture as part of a nested hierarchy extending from an individual plant or animal, with its cultivator, tender, manager, or farmer, through to systems of crop and animal populations, fields and grazing lands to farms, villages, watersheds, regions, and beyond. Hence, agricultural geography has spanned a huge range of issues and interests, from descriptive mappings of the spatial distribution of crops and livestock to analysis of systems of management, the nature of linkages to the broader economic, cultural, social, political, and ecological systems, and activities that generally occur beyond the farm gate, such as processing, marketing, and consumption of food. In particular, for the last half century research in agricultural geography has focused on the economic, social, cultural, and political characteristics of agriculture and its linkages to both the suppliers of inputs to the agroecosystem and the processing, sale, and consumption of food products.

This broad focus reflects a shift from “traditional” agricultural geography, which was dominant until the 1960s. This was concerned with location and context, emphasizing the regional characteristics of agricultural activities, and examining relationships between key variables affecting farm-based production (e.g., physical characteristics, the local economy, trading systems, cultural practices). The regional focus in agricultural geography enabled this branch of the discipline to play a major role in the growth of regional geography in the 1920s as geography’s central paradigm. Large-scale regional delimitations were based on distribution maps of crops and livestock and the classification of agricultural systems. Mapping of land use assumed national significance in some countries. For example, the Land Utilisation Survey of Great Britain begun in the 1930s by the geographer L.D. Stamp provided rich material for detailed agricultural geographies on a county-by-county basis. Post-1945 the use of statistical methods enabled multiattribute agricultural and type-of-farm regions to be formulated.

The mapping of agricultural distributions was at the heart of much traditional agricultural geography, with pioneering work by O.E. Baker in the United States and subsequent innovations involving land classification, land-use classification, and type-of-farming regions. J.C. Weaver pioneered the creation of crop combination regions in the US Midwest, recognizing that
regional production complexes usually include a range of crops rather than a monoculture. Crop areas and livestock numbers could be converted into standard man days of production, enabling livestock production to be incorporated into classifications. At a global scale, different types of agriculture were recognized and mapped, such as the world agricultural classification devised by Derwent Whittlesey in the 1930s and widely utilized. In the 1970s J.T. Coppock utilized computer methods to map agricultural distributions and type-of-farming regions in the United Kingdom.

The quantitative revolution

The theoretical and quantitative revolution that swept through geography in the late 1960s was embraced enthusiastically by several agricultural geographers who applied structural models and economic theory in work on the economics of agricultural production, often based on sample surveys of farms. One of the models adopted, the Von Thünen model of land use based on economic rent for crops, dated back to the 1820s but was not popularized within geography until the 1960s when various applications were proposed. However, the economic basis for much agricultural geography at this time was a logical outcome of the formulation of general laws of agricultural location based on economic principles. A recurrent problem was the lack of suitable economic and social data as official data on farm costs and profitability are rarely suitable for geographers’ needs. In contrast, some historical farm and estate records are of sufficient detail for microscale studies which would not be possible using modern official data.

From the late 1960s the application of computing methods extended geographers’ ability to map agricultural distributions, allying computer mapping to research on regional changes in farm inputs, farm-size structures, farm incomes, and agricultural marketing. However, the model-based, positivistic, theory-driven work dominant in the 1960s and 1970s attracted criticism as new approaches made an impact. The chief complaint was that it was an agricultural geography devoid of real people, composed of robots obeying arcane economic laws that involved minimizing effort and cost, far removed from the realities faced by individual farmers. Noneconomic considerations, such as farmers’ motivations and decisions not based solely on profit maximization, were missing from mainstream work, but appeared increasingly as geographers investigated farmers’ decision-making, the diffusion of agricultural innovations, and the responses of individual farmers to economic stimuli. This work was part of a growing body of behavioral research that was still highly empirical and positivist but beginning to develop systematic analyses of the spatial outcomes of individual decisions and to focus on the role of cognitive and decision-making variables.

The behavioral approach emphasized the characteristics and qualities of individual farmers, with research defining, measuring, modeling, and analyzing statistically the attitudes and revealed patterns of behavior of farmers based on studying a selected sample of farmers in a given area. Emphasis continued to be placed on economic forces and quantitative measurements until the mid-1980s when policies supporting environmental actions by farmers led to different types of studies investigating farmers’ adoption of environmentally friendly measures.

Torsten Hagerstrand’s work on the spatial patterns associated with innovation diffusion within Swedish farming in the 1950s and 1960s gave rise to various studies on farmers’ adoption of innovations, including new policy measures. These focused initially on orderly, predictable,
and linear progressions in the adoption process, concentrating on the demand or adopter side of change as opposed to the supply or provider side. Subsequently, research recognized the importance of lead-user inventions, change agents, and commercial marketing organizations. Factors like the influence of economic inducements, rural services, and infrastructure may be inadequately accounted for by a focus on individual decision-making behavior. Hence other models investigating different elements in the decision process have been proposed, including information models, expert and decision support systems, and learning and knowledge transfer systems.

Since the mid-1990s the most popular behavioral approach within a system or network framework has been actor-network theory (ANT), first introduced in the 1990s. The actor network is an interaction between human “actors” and nonhuman “intermediaries.” Material objects may be active in configuring human actors and their relationships, and hence human and nonhuman actors may have equal status in a network. Alternatively, nonhuman intermediaries can allow objects in the natural environment to be connected to social actors. So it maps relationships that can be simultaneously material (between things) and semiotic (between concepts), though there is a diverse variety of approaches by geographers under the umbrella of ANT. In particular, ANT has been used to understand the globalization of agriculture whereby the agri-food industry has become global in terms of both supply and demand (Robinson and Carson 2014). Applications of ANT have shown how farmers’ participation in the new industrial-style agricultural networks molds their decisions, defining the types of knowledge and skills they and others in the network value, and helping to transform farming practices in favor of unsustainable production practices that rely on artificial inputs.

### Political economy

A major development within human geography in the 1980s profoundly affected agricultural geography. This was the focus on a more systematic analysis of the political and structural frameworks within which agriculture nests. This was labeled the political economy approach, to signal its incorporation of Marxist-related content. The nature of this approach initially owed much to Piers Blaikie’s work on the political economy of soil erosion in developing countries, emphasizing the social relations of production and their ramifications for land use (Blaikie 1985). This conceptualized the farm household as having two kinds of social relations: the local and the global, with the latter increasingly assuming greater prominence.

Political economy is often closely linked to the nature of the management of the economy by the state, and the focus of this work has often been on the role of the state at various levels to set the parameters within which both economic and social change occurs. However, from the outset the term “political economy” was used fairly loosely by human geographers, often eschewing Marxist ideas in favor of broad concerns for class and power relations, and the investment decisions of agrarian and industrial capital. In agricultural geography this brought recognition of the way in which farms had been increasingly absorbed into the larger agri-food system, which includes off-farm inputs such as suppliers of seeds, fertilizers, and machinery (termed backward linkages) and recipients of farm produce such as food wholesalers, retailers, processors, distributors, and consumers (termed forward or downstream linkages).

This consideration of the wider agri-food system moved the focus of agricultural geography away from the individual farmer onto a broader research focus, acknowledging the farm as part
of the wider agri-food chain, itself embedded in a multifaceted web of economic, social, cultural, and political dimensions all impacting on farm-based production. So there has been an emphasis on the need to understand agriculture as part of the global agri-food system.

The initial framework for this political economy approach focused on four elements: uneven development (with capital penetrating different regions at different rates), geographical and historical specificity (requiring locality studies to understand the process of uneven development), examining the family farm (recognizing that the basis of agricultural production is different from other sectors of the economy) and the role of state policy (where governments have supported the family farm but often inadvertently have encouraged the penetration of agriculture by corporate capital). The new approach prompted research on the growth of agribusiness, agricultural restructuring, and the diversity of social relations and cultural practices shaping accumulation and regulation. In the United Kingdom in particular, this research focus has tended to mean that agricultural geography has been subsumed within the broader scope of “rural geography” in recent decades. However, a more distinctive and vibrant agricultural geography has continued to flourish in the United States, France, and Germany.

Critiques and alternatives to political economy soon appeared, notably criticisms of its “excessive concentration” on the agricultural production sector, dominated by the farm enterprise, farm household, landownership, farm labor, and agricultural technology. Political economies stressed structural processes as opposed to active decision-making by farm families, overlooked noneconomic decisions by farmers regarding allocation of resources, and focused too much on macroeconomic factors. However, the attention given to the broad agri-food sector prompted further consideration of three broad theories for aiding the understanding of contemporary agricultural change: food regimes, regulation theory, and a restatement of the “agrarian question.”

Food regimes

Food regimes is a concept linking international relations of food production and consumption from the 1870s onward to forms of accumulation and regulation under capitalist systems (McMichael 2013). Three “regimes” are recognized, the first extending from the 1870s to World War I (based on worldwide grain and meat production involving exports from family farms in the New World and linked to the rise of nation-states); the second from the 1920s to the 1980s (involving production of durable food for the mass market, decolonization, consumerism, and the growth of forward and backward linkages from agriculture); and the putative third regime dates from the 1990s, emphasizing fresh, organic, and reconstituted foods linked to global restructuring, with the globalization of production and consumption, international regulation, and the growth of “green” consumers.

These regimes overlap, and the third regime is still evolving as a conflation of globalizing and sustainability trends involving a mixture of biotechnology, fast food, organic production, and consumption of locally produced food (Guthman 2004). This regime includes extensions of technology from the preceding regime, including biotechnology and the use of chemicals to simulate naturalness and to control the ripening of packaged fruit.

Criticisms of the concept refer to its lack of explanatory content, omission of human agency, overreliance on the experiences of the developed world, neglect of national regulatory processes, and its high level of abstraction. Nevertheless, the concept has been useful in highlighting the
emerging divergent trends within contemporary world agriculture as globalization and the reliance on industrial-style methods meets some resistance from consumer-led movements favoring organic production and foods with fresh, local, and sustainable connotations (Pretty 2002).

Regulation: productivism and postproductivism

In recognizing worldwide transformative change, such as moves from one food regime to another, geographers have examined the ways in which different forms of regulation help shape particular economic structures and social forms. Regulation theories have referred not only to government-imposed rules but also concurrent cultural representations, political strategies, and social conflicts. In agricultural geography perhaps the main contrasting periods of regulation discussed have been those of productivism versus postproductivism, an approximate parallel with Fordism and post-Fordism in that it implies a move to different work/production practices, different relations of production, and changes in the regulations governing production.

Productivist agriculture has characterized much of the post-1945 period in which commercial farming was linked to technological development encouraged by the state through its support of research and advisory services. State support aimed at raising farm production is exemplified in the Common Agricultural Policy (CAP) of the European Union, a major subject for analysis by geographers. Productivism has been associated with substantial restructuring of farm-based production involving the overproduction of agricultural goods in face of largely stable demand, rising farm indebtedness, downstream environmental consequences, major regional differentiation reflecting dualism between small, marginal family farms and large, heavily capitalized businesses, and new forms of family farming, including part-time and hobby farming (Robinson 2004).

This strong contribution to supporting productivist farming by some governments has provided rich material for geographical study. State intervention has focused on how government has attempted to create a favorable economic environment for agriculture; it has often offered specific financial inducements for farmers; and it has introduced specific regulations such as production quotas that directly dictate farmer behavior. Particular foci have been on farm policies in the United States and the various reforms to the European Union’s CAP. The latter has been of special interest because of its evident spatial consequences, distinctive price support measures, and a sequence of reforms starting with the so-called MacSharry reforms in 1992. Some comparisons between US and EU policy have been made, notably relating to different experiences of setting aside land from production. The expansion of the European Union has also offered new opportunities for research, especially on the land reforms in central and eastern Europe. A theme in the work on government agricultural policy has been the changes to traditional farmer–state relations, linked to macro-policy changes via world trade negotiations, such as the Uruguay Round of the General Agreement on Tariffs and Trade and the World Trade Organization.

The term “postproductivism” was first popularized in the 1990s, referring to some of the responses to the “excesses” of productivism. Notably this can mean a reversal of the trend on farms toward intensification, concentration, and specialization, with moves to extensification, deconcentration, and diversification (e.g., pluriactivity). An alternative view is that postproductivism is linked in part to the loss of the central position of agriculture in society
AGRICULTURAL GEOGRAPHY

and changing public attitudes to farmers, in which intensive agriculture is often regarded as a threat to the environment and the landscape. However, one of the responses to the negative environmental consequences of industrial farming methods has been the growth of policy measures promoting environment-friendly actions, known as agroenvironmental policies. These have been accompanied by reduced production subsidies, tighter pollution regulations, and changes in property rights, which have been part of some dismantling of protectionist state policies, creating new opportunities for farmers. Examples of the new opportunities include a rising demand for “quality” foods, including organically and locally produced food, as part of new forms of agricultural production (Pretty 1995), and the commodification of former agricultural resources: land, wildlife habitats, barns, and cottages. Key characteristics of the transition to postproductivism have included a shift from quantity to quality in food production; the growth of alternative farm enterprises as part of pluriactivity on farms; state efforts to encourage a return to more traditional, sustainable farming systems through agroenvironmental policy; the growing environmental regulation of agriculture; and the progressive withdrawal of government support for agricultural production.

Geographers have contributed new theory to help understand postproductivism, identifying new regulatory conditions and links to other “transitions,” and have tested the extent to which postulated changes have occurred. Yet, despite evidence of postproductivism, most farmers have remained firmly productivist and many general agricultural policy adjustments in the developed world have focused on increasing competitiveness and the need to produce food for mass consumption. Since the mid–2000s a new and more encompassing term has been introduced to the lexicon, “multifunctional agricultural regimes,” which acknowledges that agriculture, as well as having a food-producing role, also plays major additional economic, environmental, and sociocultural roles in rural areas (Wilson 2007). These roles include the generation and management of rural landscapes and ecological features, and the social role of supporting population, especially in peripheral areas. Therefore policy reforms have had to accommodate this multifunctional role of agriculture as in the reformed CAP of the European Union.

Agricultural geographers have tended to understand multifunctionality in agriculture as a policy-led process that describes current agricultural trends rather than as a concept. However, ongoing theoretical debates are now examining where multifunctionality sits within the productivist–postproductivist transition and how it contributes to broader rural multifunctionality. These debates incorporate both economic and policy-based views, as well as emerging holistic and cultural interpretations. The policy contribution highlights, for example, the European Union’s role in urging the maintenance of farm subsidies in the World Trade Organization’s Millennium Round, and its attempt to simultaneously decouple support from production while recoupling it to agroenvironmental and rural development. Other EU policies favoring multifunctionality include: its LEADER program, based on reconfiguring local resources, redefining the social role of agriculture, and increasing the value added to farm products; rural development regulations emphasizing farm diversification, rural tourism, and landscape conservation; and a raft of agroenvironmental policies. However, within agricultural geography issues relating to multifunctionality, the role of globalization, and postproductivism continue to be hotly debated.
AGRICULTURAL GEOGRAPHY

The agrarian question

A key concern of geographers has been to understand the survival of the family farm. The latter has been the bedrock of both agrarian capitalism in the New World and of rising productivity, especially in Western Europe since 1945. Yet there are apparent contradictions between the continuing survival of family farms and the most profitable forms of business arrangement. Family farms may be threatened by the growth of specialization and the “international farm crisis” in which farmers have been squeezed by rising costs and reduced prices for farm produce, in part because of the rising power of supermarkets, wholesalers, and processors. For example, the number of farms in the United States peaked at 6.8 million in 1935. Today the country has only just over 2 million farms, of which 87% are family-operated, but with a steadily rising average age of farm operator: 60% are aged 55 and over. Just 8.5% of farms accounted for 63% of production, highlighting the growing dichotomy between large, industrial-style farm operations and smaller family farms that are often reliant only on family labor (Hart 2004). Indeed the farm labor force worldwide has fallen substantially, especially in the developed world.

Family farmers have resisted conditions favoring subsumption into fully capitalist production by drawing on family labor, earning money from off-farm work, farm-based processing, and direct marketing, and introducing new sources of income, for example, farm-based tourism. Only 45% of American farmers claim farming as their principal occupation. This reflects the growth of farm diversification and pluriactivity by farm families involving pursuit of nonfarming activities, termed “other gainful activities,” in order to generate income. Some have theorized that agriculture differs from other economic activities because of its relations with “fractious” nature and the maintenance of nonwage labor on farms. Yet, there are examples of the large-scale penetration of agriculture by corporate enterprises, for example, industrial-scale fruit and vegetable operations in California. Elsewhere farmers have gained institutional support through contracts with major food processors such as Tyson Foods and H.J. Heinz, although fewer than 5% of American farms are “corporate.”

The reduction in the farm workforce reflects changes in the nature of farm work, with mechanization reducing the need for manual labor. Furthermore, gendered arrangements have also changed within farm families so that, across the world, there is far greater involvement of women in a range of farm work than 50 years ago. Distinct theoretical approaches by geographers to this development can be recognized, with socialist feminism stressing tensions with capitalism through greater reliance on female farm labor, and poststructural feminism emphasizing the need to study the diversity of farm women’s self-image and the relevant social and policy positions. These studies have especially highlighted the contribution of women to farm labor in developing countries, for example, women in sub-Saharan Africa produce and market over three-quarters of food grown outside the corporate sector.

Agri-culture and sustainable agriculture

The engagement with the wider agri-food network has led agricultural geography to extend into studies of food retailing and food consumption, and to recognize the growth of an alternative food economy (AFE). In part this reflects the “cultural turn” within human geography, where a revival of interest in cultural aspects of human life has supplemented the previous emphasis on the economic. In
agricultural geography it has been marked by a shift of focus from production to consumption, and a recognition of the dominance of global trends in consumption (typified by “fast food” outlets such as McDonald’s, KFC, Pizza Hut, and Burger King), but alongside a contrasting process of “relocalization” and “reconnection” in which mass consumption patterns are mediated by local specificities. The latter involves concerns for place or region of origin of food as part of a desire for authenticity, greater variety, and concerns over standards of mass production and processing practices (Maye, Holloway, and Kneafsey 2007).

Studies of consumption have highlighted the rise of the supermarkets and the homogenization of food consumption across the globe, with particular brands available in almost any supermarket outlet. The growth of industrial-style agricultural production to serve this agri-industrial system has dominated agriculture in much of the developed world, though definite countertrends are evident. For example, farmers’ responses to supermarkets’ growing domination of the market for groceries across the developed world have included greater recourse to direct marketing as part of an emerging AFE. AFEs include farmers’ markets, box schemes, pick-your-own, farm shops, mail order, and home delivery. These are closely linked to the development of local connections and identities, concerns for food quality, links to traditional methods of production, and new regulations such as the European Union’s protected designations of origin (PDOs) and patented geographical indicators (PGIs). PDOs and PDIs have linked particular foods, especially cheese and drink products, to specific places and regions, for example, champagne, Stilton cheese, and Parma ham. These are specialty food products (SFPs) associated with authenticity of geographical origin and traceability, representing a “relocalization” of the agri-food system in which the products command a market benefit if they are effectively marketed (Goodman, Du Puis, and Goodman 2012).

The growth of studies focusing on links between farming and environmental issues has increasingly been framed within the context of resource management problems and notions of sustainable development. Essentially debates have evolved from the recognition of negative environmental impacts arising from productivist agricultural policies, including sharp declines worldwide in biodiversity including seminatural habitats. There has been focus on the outbreaks of diseases affecting plants and animals and the rise of particular pests, and a wide engagement with the discourse of sustainable development, especially prospects for moves away from productivist modes of production. This has included policy–related research, including examinations of the inherent tensions between “sustainable” and “development,” as encapsulated in work on sustainable livelihoods in developing countries, and the concept of sustainable agriculture (Blay-Palmer 2010; Marsden and Morley 2014). Particular interest has focused on systems of production that reduce negative environmental impacts. These systems take many guises, including organic farming, integrated farming systems, integrated crop and fruit management, and biodynamic production (Pretty 1995).

Since the mid-2000s the concept of ecosystem services has increasingly been adopted within agroenvironmental measures, reflecting the ways people benefit directly from goods and services delivered by the environment, which can be valued and rewarded by various economic valuation techniques. This has enabled the environmental externalities of farming to be considered and supported through on-farm conservation efforts. Indeed ecosystem services have become the principal concept and tool used by ecologists, conservation biologists, and conservation
planners to communicate and to implement environmental management strategies. Payments for ecosystem services (PES), or markets for ecosystems services, have been introduced in many developed countries, generally through programs that combine the provision of measurable conservation benefits while preserving working farm-based landscapes for future generations. Programs typically involve farmers voluntarily providing particular conservation actions, which can be valued so that farmers receive payment for the services provided.

**Dual economies and green revolutions**

Work on changing world trade relations has enabled agricultural geographers to engage with the impacts of globalization on farming in developing countries. Contrasting views have appeared about these impacts, both positive (enabling production in the Global South to increase to meet demand in the North but with emerging firms in China and other developing countries taking a greater market share) and negative (local producers increasingly in thrall to Western multinationals). This work acknowledges the continued presence of a dual economy in developing countries, with a dichotomy between small-scale local producers, and initially many subsistence farmers producing for the local market, and a foreign-dominated sector producing for export (Bacon et al. 2009). These two sectors have become blurred in many countries, for example Ghana, while subsistence farming has retreated in the face of an advancing wave of commercialization. Debates have included the link between agricultural intensification and population pressure, environmental consequences, and social/cultural impacts. In the 1960s Esther Boserup linked population pressure to moves from shifting cultivation (equated with low productivity) toward permanent or semipermanent cultivation with high productivity (Boserup 1965). However, her model cannot be applied in many parts of the tropics, especially Africa, where fragile soils can restrict intensification unless supplementary inputs such as chemical fertilizers are introduced or particular local management systems applied. These various systems have been investigated by geographers in terms of nested sets of interrelationships operating at the global, national, and international levels so as to provide both opportunities and constraints for individual farmers and communities (De Koninck and Rousseau 2013).

The legacy of colonialism has also been viewed through an agricultural lens, notably the application of European farming methods to tropical environments where colonists frequently dismissed existing production systems as inferior to European ones. Europeans introduced changes in land tenure, the consolidation of small fragmented plots, and mixed farming across Africa via resettlement schemes or gradual integration into existing farming practice. This was often part of a process of commercialization and intensification which in Southeast Asia followed a process of transition from 1960 whereby those living on the land eventually declined in numbers as in the West, but with a dualistic structure maintained: small uneconomic family farms alongside large fully commercial units.

This duality has a long history in Latin America where colonial powers often created large estates (latifundia), geared to producing staples such as sugar for export, alongside very small holdings (minifundia), occupied by small family farmers and landless laborers. This pattern was also widespread across the Mediterranean. In both cases land reforms, dating to the nineteenth century in some cases, have sought to establish a more equal distribution of land. This has been a fertile topic for geographical research, extending
into new geographical areas when post-1989 reforms to tenure occurred in Eastern Europe. Ongoing land reforms have also occurred in parts of Africa (Juma 2011). Increasing interest has been shown in Chinese reforms involving large-scale land-engineering schemes aimed at raising agricultural productivity while contributing to major rural–urban population shifts and rapid urbanization.

Technology transfers from the rich Global North to the poor South are symbolized in the package usually termed the “Green Revolution,” popularized in the 1960s and providing wide scope for geographical study in work on its diffusion, impacts, economic outcomes, and contribution to alleviation of world hunger (Basu and Scholten 2013). The revolution consisted of high-yielding crop varieties (HYVs), fertilizers, pesticides, machinery, and irrigation, largely promoted by funding from the West. The staple cereals of maize, wheat, and rice have been targeted through the establishment of special American-funded plant-breeding centers in Mexico (for maize and wheat) and the International Rice Research Institute (IRRI) in the Philippines, from which the improved varieties have been distributed.

So-called “miracle rice” (strain IR8), bred in the Philippines in the 1960s, was part of the package spread throughout South and Southeast Asia. It is capable, under favorable conditions, of giving increasing yields per unit area. In effect, the Green Revolution was a series of adoptions of particular innovations, with various phases.

1 Initiation and early dissemination in areas of suitable climate: Yields rose, output and farm-based labor rose, and grain prices fall, benefiting consumers.

2 Emergence of significant problems, evident by the late 1960s, with crop pests and diseases causing widespread damage to IR8 crops. It proved difficult and costly to spread the crops into new areas. Some crops were not well adapted to local cultivation practices or cuisine, and required high levels of investment to grow.

3 Second-generation HYVs to genetic modification (GM): From the early 1980s new methods to control pests led to the gene revolution and, later, a variant widely adopted in North America – GM and biotechnology.

Some contend that GM crops, livestock, and foods offer the prospect of increased production on a large scale to dramatically increase the world’s supply of certain crops and livestock products. In 2012 there were 170 million ha under GM crops worldwide, with a growth rate of 10 million ha per annum. The main GM crops are soybean, maize, cotton, rapeseed, and potatoes. The United States currently has three-quarters of the global area devoted to GM crops, mostly herbicide-resistant, offering easier control of weeds, less tillage, and reductions in soil erosion.

The cultivation of GM crops has been extremely contentious in some countries, with ongoing debates between the scientific community and the general public as to their safety (Ferry and Gatehouse 2009). This has produced severe restrictions on their adoption in some countries, notably the United Kingdom and Australia. In addition, the argument that they represent a solution to problems of food shortage in developing countries is largely not substantiated. Most developments of GM crops have been for crops in temperate farming systems rather than for subsistence crops in the tropics. Those available in developing countries have also been associated with smallholder farmers being forced to buy new GM seed every year rather than following traditional practice and holding back seed from harvest to sow the next year’s crop. This
added cost can be a major deterrent. Two-thirds of all GM crops have been engineered for herbicide tolerance rather than for any intrinsic improvement in food quality or pest resistance.

**Land-use competition**

The use of satellite remote sensing technology has enabled a flourishing of research on changes in the world’s agricultural land. Particular foci have been monitoring increases of both arable and pasture in the developing world, primarily at the expense of forest, and land-use competition in the rural–urban fringes of major cities. The loss of tropical forest within the Amazon basin has attracted special attention. Despite the substantial impact of large-scale clearance of forest for cattle ranching, one-third of Amazonian deforestation is caused by small farmers, each clearing less than 100 ha. Yet, in some parts of Asia, the extent of cultivated land is falling, notably in China, with potential implications for grain production. As a result of pro-environmental programs such as Grain for Green, China’s largest land retirement and afforestation program, substantial areas of land under grain have been converted to forest and uncultivated land (converting about 15 million ha of low-yield farmland to forest and afforesting another 17 million ha). However, this may have only reduced overall grain production by 2–3% despite some significant local impacts (Zhao 2013).

To understand the dynamics of land-use competition, simple models were utilized in the 1960s, starting with distance–cost relationships associated with economic rent, as per the von Thünen model. The complexities of land-use competition have largely consigned the model to history, but several more recent studies have focused on the land market, acknowledging the impact of measures intended to protect prime farmland, especially in the United States and the United Kingdom. For the former, key ideologically based lay discourses have been significant. These include regarding farmland as a finite productive resource; maintaining food production in the national interest; farmland preservation as environmental protection; and farming as a connection between nature and society. Lobby groups associated with these ideas have also proved fertile ground for study, especially as concerns over rural amenity remain agrarian ideals well entrenched in American social and political culture.

A different conglomeration of land uses has occurred around urban areas in developing countries, especially in sub-Saharan Africa, where “urban” agriculture contributes to sustaining the urban populace. This production also provides environmental benefits, creates employment, represents a survival strategy for low-income urban residents, and utilizes urban wastes (Cockrall-King 2012).

Competition for agricultural land tends to be at its greatest in the rural–urban fringe, where relationships between the urban economy, the agricultural economy, agricultural policy, and planning policies are at their most critical. Interconnections between the physical environment, economic activities, and the resident population produce complex land-use assemblages of which agriculture is just one component. Indeed, speculative landholding and constraints on building development often produce contrasts between idle farmland and intensive production, for example horticulture and market gardening in close juxtaposition to unfarmed land. In some countries, green belt and farmland preservation policies restrict urban sprawl and maintain farmland within a distinctive rural–urban fringe. However, strict planning controls on development can also produce proliferation of small and fragmented
AGRICULTURAL GEOGRAPHY

holdings, poor quality farmland subject to trespass and vandalism, or low-intensity activity such as agistment, equine-related activities, and recreational hobby farming. The latter has increasingly reflected the growth of interest in small-scale food production as part of a broad set of lifestyle choices that emphasize rural living, food quality, working with animals and the land, and ideas of health and fitness associated with farm work and country life. There are also some links to “back to the land” ideals, which are manifested well beyond urban fringe locations.

Green belts, green wedges, and green ribbons have proved popular measures to conserve farmland in several European countries while combining this with other objectives, such as access to the countryside for urban populations, outdoor sport and recreation, retaining attractive landscapes, and securing nature conservation interests. In the United States farmland preservation policies have endeavored to slow the long-term loss of cropland to urban sprawl and other land uses. The greatest losses of cropland have occurred in the most populous counties through a “bow wave” of metropolitan expansion consuming farmland irrespective of its quality. The preservation policies are linked to four ideologically based lay discourses: the need to preserve a finite productive resource, the need to produce food in the national interest, environmental protection and retaining farming as a connection between nature and society.

University of Adelaide, Australia

The agroecosystem

Agriculture, the rearing of animals and the production of crop plants through cultivating the soil, has evolved for over 10,000 years since the first domestimations of wild plants began in the Fertile Crescent of the Near East. Sheep, pigs, goats, cattle, barley, and wheat were first domesticated in this area. There were five other independent origins of agriculture: East Asia (8400–7800 BP), producing rice, millet, pigs, chickens, and buffalo; Central America (4700 BP) and South America (4600 BP), producing potato, maize, beans, squash, llama, alpaca, and guinea pigs; North America (4500 BP), producing goosefoot and sunflower; and Africa (4000 BP), producing cattle, pigs, rice, millet, and sorghum.

Domestication spread from the Middle East into southeastern Europe, where a combination of improved cultivation methods and extensive trading networks supported first the Greek and then the Roman empires, both of which gave us the term “agriculture” to reflect the inherent link between human activity and the natural environment to provide food to sustain human societies and their domesticated animals. Essentially, human modification of the environment produces an agroecosystem that constitutes both an ecological and a socioeconomic system, operating at a number of different spatial levels from a single plot or field to broader systems of production within distinct regions linked by worldwide patterns of trade.

Unlike many elements of economic activity, the physical environment is of fundamental significance to the nature of the farming system even in developed countries, where farmers have capital at their disposal to modify certain physical characteristics of the land on which farming is based. The reliance on variable environmental conditions injects elements of risk and uncertainty into farming beyond those experienced by other areas of economic activity. Hence farming is strongly shaped by the natural ecosystems on which agricultural systems are based; the agroecosystem acknowledges the reciprocal relationship between environmental factors and agricultural activity.

In agroecosystems productivity is increased through human management and control of soil fertility, vegetation, flora, and microclimate. This control is intended to generate a greater biomass than that of natural systems in similar environments, but it can also create undesirable environmental consequences. In particular, farming alters the characteristics of soils. Agroecosystems are simpler than natural ecosystems, with a less complex structure and less diversity of plant and animal species. The long history of plant domestication has produced agricultural crops with less genetic diversity than their wild ancestors. The biomass of the large domesticated animals, such as cattle and sheep, is much greater than that of the ecologically equivalent animals supported by unmanaged terrestrial ecosystems.

Agroecosystems are more open systems than their natural counterparts, with greater numbers and larger volumes of inputs and outputs. Inputs include direct energy from human and animal
labor and fuel, plus indirect forms from seeds, fertilizers, herbicides, pesticides, machinery, and water. Under cultivation a higher proportion of available light energy reaches crops and, through crop harvesting or the consumption of crops by domestic livestock, less energy is supplied to the soil from dead and decaying organic matter and humus than is usually the case in unmanaged ecosystems in similar environments.

Agroecosystems are dynamic systems of flows of matter and energy, including water, solutes (nutrients), and solids (e.g., soil particles). Inputs include soil and nutrients derived from the weathering of underlying bedrock; energy from solar radiation; precipitation; transfers from adjacent land surfaces; and inputs from the farmer in the form of seeds, livestock, manure, fertilizer, animal feeds, and fuel energy. The major outputs are harvested crops and farm animals. Farm practices manage both inputs and outputs; for example, land drainage systems and irrigation affect water loss, while tillage, soil conservation, and crop rotation can control soil erosion. Management controls key cycles in the system, especially energy, water, and nutrients.

Agriculture has created artificial communities often dominated by a single species. By incidentally concentrating food and other key essentials for competitor plants (weeds) and animals (pests), this has led to damaging population explosions of weeds, pests, and disease vectors, which have had to be controlled. Hence, the use of synthetic herbicides, insecticides, and pesticides has become commonplace on many farms worldwide. This has contributed to the loss of biodiversity, including accidental loss of species which predate on pest species, of habitat for breeding and shelter via suppression of weeds, and of essential prey species of nontarget organisms.

Solar radiation provides the fundamental energy source to support plant and animal growth. The amount of radiation received at any location depends on latitude and albedo, which varies considerably for different surfaces. Solar energy is the driving force for recycling nutrients through the agroecosystem. Crucial aspects of this recycling are the carbon (or inorganic) and nitrogen cycles. Different farming systems and accompanying management strategies have varying effects on nutrient cycling, and so produce differential impacts on the soil base. For example, soluble nitrates are vulnerable to removal by leaching and so have to be maintained by careful management. However, nutrient deficiencies are generally easier to manage through careful husbandry than the constraints imposed by solar radiation, temperature, and rainfall. The most vital nutrients are nitrogen, phosphorus, potassium, calcium, and magnesium, which together make up 10% of a plant’s dry weight.

Sustained cultivation of the same plot of land removes nutrients from the soil, and land can be rendered infertile unless farming practices replenish nutrients via manuring, mulching, or adding artificial fertilizers. In addition, leguminous crops like beans, peas, clover, and lucerne add nitrogen to soils and hence have been widely used in crop rotations, which was first developed in East Anglia in the eighteenth century when such rotations consisted of clover, wheat, turnips, and barley. Grown in rotation, these crops enabled farmers to use a plot of land continuously without recourse to fallowing. In many developed countries, crop rotation has been replaced by adding artificial fertilizers to the soil, thereby substantially increasing overall energy consumption in farming. The overall efficiency of energy use declines as the degree of dependence on fossil fuel rises.

The dominant physical or natural resource inputs to the farming system are climate, water supply, and soils.
Climate

Average temperatures, the amount of precipitation, and their annual distribution are the greatest physical constraints on agricultural activity. More localized limitations are imposed by soil type, nutrient availability, topography, aspect, and drainage. Climate determines the broad geographical region in which any given crop can be cultivated. Despite extensions to the moisture and temperature requirements of many plants through modern plant breeding, there is still a strong degree of climatic determinism in the distribution of agricultural crops. This can be seen in agroclimatological classifications, which were first popularized in the early twentieth century in the form of zonation theory, employed by Russian geographers. This theory created a world zonal pattern based on moisture and temperature criteria translated into hydro and thermal ranges respectively. In the 1930s Glenn Trewartha produced a sevenfold world classification based on climate, vegetation, and soils. More detailed classifications followed, including those by Wladimir Köppen and Rudolph Geiger in 1936 and by Charles W. Thornthwaite in 1931; after 1945 more refinements were introduced, including that by Howard Penman and John Monteith in 1965, which focuses on evapotranspiration processes and plant-specific water consumptive use. More recently, the United Nations’ Food and Agriculture Organization’s Agro-Ecological Zones project represents the most comprehensive world classification of agroclimatic zones. This is based on land resource inventories, inventories of land utilization types and crop requirements, and land suitability evaluations, including potential maximum yield calculations and matching of constraints and requirements.

The key climatic variables for plant and animal growth are receipt of solar radiation, precipitation available for transpiration, and temperature during the growing season. Relationships between these variables are rarely linear, but optimum growth conditions can be recognized where plants give the highest yields. Generally, plants are cultivated commercially in a physical region around the optimum and well removed from the absolute limit to the plant’s growth, though economic limits to production are crucial to determining location. Provided there is sufficient water, the best determinants of crop growth are temperature and light; this effectively enables distinctions to be drawn between tropical, subtropical, temperate, and cool temperate agroclimatic regions. These are broadly related to different biochemical pathways of carbon dioxide (CO₂) fixation in photosynthesis, which, in turn, reflect basic physiological differences. Temperature affects how CO₂ is used, with distinct differences between plants that thrive in temperate environments as opposed to tropical.

For every crop, there is a temperature range within which growth and development can occur. Critical temperatures are the minimum (below which there is insufficient heat for biological activity); the optimum (where rates of metabolic processes are at their maximum); and the maximum (beyond which growth ceases and higher temperatures may cause harm). Some crops have particular temperature requirements, including certain variations between daytime and nighttime temperatures. These crop-growing habits in turn affect farmers’ phasing of planting and harvesting for annual crops, to make the most efficient use of the time and space available. Generally farmers utilize knowledge about plant-growing seasons, the period during which there is production of sufficient vegetative growth to support contiguous growth of the necessary yield-forming activities.
Microclimate modification

Various measures are employed by farmers to ensure that crops are given the best opportunity to thrive so as to produce good yields. At one extreme this can mean creating an entirely artificial environment in the form of a greenhouse, but more frequently measures to control growth under prevailing extremes of weather are applied. In temperate latitudes this often means attempting to combat damaging frosts at the start and end of the growing period of the plants concerned. These mechanisms include adapting crop selection to fit local microclimates, selection of favorable aspects (especially avoiding cold air drainage into valley bottoms) and genetic modification of crops for enhanced frost resistance.

Modifications to local climate are another common practice, such as the use of ridge and furrow or through short-term temporal adjustments involving the use of burners and smoke generators. The creation of shelters, such as temporary or permanent polytunnels, is one stage removed from greenhouse cultivation. Determining which of these various strategies is most appropriate depends on the details of crop physiology, topography, albedo, synoptic weather situation, and crop value with respect to the economic or social benefits of protection in relation to projected returns.

Longer-term protection to crops can be provided by the creation of shelter belts. Typically in mid-latitudes, these are a long-standing characteristic landscape feature. Examples include the planting of Lombardy poplars \( (Populus nigra) \) in the Netherlands and northern France and of the cypress \( (Cupressus \text{ spp.}) \) in southern France and Italy to provide shelter from the mistral. They have also been utilized on a large scale in major projects recently in China and the Sudan. Diffuse barriers are generally most effective in terms of protecting crops from damaging winds, as semiporous barriers avoid severe leeside eddying which can occur behind dense barriers. The effects of a barrier are generally experienced 15–18 times its height upwind. Hence, planting a series of cross-wind barriers may provide benefits from wind speed reduction and associated growing climate over a large area. Barriers can be used to provide direct protection to crops, especially high-value crops such as flowers and soft fruit. However, they can provide several other benefits, including the extension of growing season, promotion of early germination, reduction of water loss and exposure to wind chill and excessive evapotranspiration, avoidance of disease, prevention of soil erosion, and provision of habitats for beneficial organisms such as pollinators and the predators of pests.

Water

Water supply from precipitation is fundamental to all agricultural systems, though its management by farmers can compensate for problems in the natural supply. Water transports nutrients to and through plants, and is vital in the processes of soil weathering, leaching, and erosion. Water largely controls the input of nutrients to, and losses from, the system. Losses of water can occur through evapotranspiration, drainage to groundwater, and lateral flow as runoff and throughflow to streams. Water is stored in the soil, plant tissues, and the bodies of livestock. Worldwide, agriculture accounts for 70% of all freshwater consumed, and demand is increasing by 64 million m\(^3\) annually.

Agricultural practices disrupt the pattern of the annual water balance associated with the functioning of any natural ecosystem. The balance is the outcome of the input from precipitation minus losses from evapotranspiration. Water supplies can produce waterlogging of soils and
runoff whereas, if evapotranspiration exceeds precipitation, this produces a moisture deficit. Under deficit conditions, plants deplete the store of soil moisture until they wilt. In arid areas large soil moisture deficits can develop during the growing season. Farmers can intervene in this process by providing artificial irrigation. Some irrigation systems have a long tradition, notably in the Middle East and Spain, and can work well where seasonal water deficits are short and infrequent and occur in predictable cycles, and where access to stored water is easy and affordable.

Irrigation

Irrigation techniques vary tremendously. Surface systems, sometimes called flood irrigation, move water across the surface of farmland to infiltrate the soil, and have been the most common form of irrigation traditionally. Localized systems distribute water under low pressure through a piped network to discharge small amounts of water to each plant. Typical variants are drip irrigation, spray irrigation, and microsprinkler and bubbler systems. There are subsurface systems designed to deliver water to the plant base, while drip or trickle irrigation delivers water at the top of the root zone. This can be a highly efficient system as evaporation and runoff can be minimized. Drip systems can use advanced computing technology or high-labor intensity. In sprinkler or overhead irrigation, water is distributed across a field by overhead high-pressure sprinklers or guns. Sprinklers can be mounted on moving platforms connected to a water source via a hose. Traveling sprinkler systems are commonly used for intensively irrigated areas. A widely used form of sprinkler system is center-pivot irrigation, which leaves distinctive circular areas of irrigated land that are clearly visible in aerial photography. It usually consists of several segments of pipe joined together and supported by trusses that are mounted on wheeled towers, with sprinklers positioned along the length of the pipe. Water is fed into the system from the pivot point at the center of the arc. Hydraulic and electric motor driven systems, often with GPS, have generally replaced water-powered units. Irrigated areas increased sevenfold worldwide in the twentieth century, though the greatest contribution of irrigation to national food output occurs in countries where paddy rice is a significant crop, in conjunction with semiarid climates, notably Pakistan, China, Indonesia, Chile, Peru, India, and Mexico. Irrigation investment in Middle Eastern countries has been high in recent decades, typified initially by the opening of the Aswan High Dam in Egypt in 1969, though high costs have contributed to substantial debt in some developing countries. Worldwide there are over 3.25 million km$^2$ of agricultural land equipped with irrigation infrastructure, of which two-thirds are in Asia. Major concentrations are along the Ganges, Indus, Hai He, Huang He, Nile, Yangtze, and Mississippi–Missouri rivers.

Irrigation can dramatically improve crop productivity and enable extensions to the cultivated area in dry climate regions, but it can also produce negative outcomes associated with alterations to the natural water–salt balance, increasing the extent and risk of saline and alkaline soils. Capillary action can transport dissolved solids to the active root zone and surface areas. This has occurred on a large scale in Egypt, Iran, Iraq, Pakistan, and India, and parts of Australia and former Soviet Central Asia have also been affected, the latter associated with increased extraction of river water for growing cotton. Salinization of the soil surface is a major hazard of both open air irrigation systems and systems that draw on groundwater. Salinization is the accumulation of soluble salts of sodium, magnesium, and calcium in soil to the extent that soil
AGRICULTURE

fertility is severely reduced. Under irrigation, dissolved nutrients from the soil can be left as a residue on the soil surface unless attention is given to reducing surface evaporation or to periodic flushing to remove the salts. Salinization can also occur in coastal areas through the overexploitation of groundwater as a result of growing urbanization, industry, and agriculture. The overextraction of groundwater can lower the normal water table, leading to the intrusion of marine water. The latter was also associated with the Boxing Day 2004 earthquake and tsunami, which affected coastal zones in South Asia. Salinization affects over 322.9 million ha worldwide, one-quarter of which is in Australia and around 17% in the Near and Middle East.

Research into degraded salinized landscapes in southwestern Australia suggests that new agroforestry developments may help to restore biodiversity, desalinate soils, and improve wider ecosystem services, including water management and carbon sequestration. In the Yangtze River Basin in China, soil salinity has been reduced by leaching soluble salts out of soils with excess irrigation water. Soil salinity can also be controlled by managing the water table and flushing, in combination with tile drainage or other forms of subsurface drainage. In the Australian Riverina, salinity resulting from irrigation has been mitigated through a salt interception scheme, which pumps saline groundwater into evaporation basins, protecting approximately 50,000 ha of farmland from high water tables and salinity.

Agricultural soils

The primary agricultural management practice is cultivation of the soil, which acts as a reservoir of water, minerals, and nutrients needed for plant growth. Soils can vary considerably by virtue of changes in their structure, depth, texture, plant nutrient content, and acidity. These characteristics influence not only the types of crop that can be grown but also yields, with optimum edaphic conditions existing for particular plants. In general, most plants thrive in deep, well-drained soils (for example, potatoes, which prefer deep loams), but thin limestone soils can produce good yields of shallow-rooted cereals.

In addition to depth, other key soil variables are texture (the relative importance of particles of different sizes) and acidity (measured in the potential hydrogen (pH) scale: from 0, the most acid, to 14, the most alkaline, with 7 being neutral). The large particles of sandy soils provide light, well-drained land that is readily warmed for early spring planting. In contrast, fine clay particles retain water, are slower to warm in spring, and are heavy to cultivate. However, clay soils release potassium only slowly so they are less likely to suffer from potash deficiency. They can retain water in dry conditions but their tendency to become waterlogged has meant that underdrainage has proved particularly important in helping to improve yields. In temperate climates soil acidity is greater in areas in receipt of heavy rainfall. In such climates slightly acid soils can support good crops of potatoes and lucerne, though most crops prefer neutral or mildly acid conditions.

Geographers have produced several world classifications of soils, building on pioneering work by the nineteenth-century Russian pedologist V.V. Dokuchaev and work on soil-forming factors by Hans Jenny in the 1940s. From the 1970s there was a move away from a focus on genetic factors to definitional systems based on recognizable soil properties. New systems were developed, notably in Canada, the Netherlands, the United Kingdom, and the United States. These systems have introduced new terms to soil classification, such as “pedon” in the United States, an artificial cuboid unit
with a cross-sectional area dependent on the lateral variability of properties that define classes. The American system recognizes 12 soil orders and enables comparisons with the widely used classification developed in 1974 by the Food and Agriculture Organization of the United Nations. These various classifications highlight the delicate physical and biological balance that renders agriculture possible and restricts production in various ways, limiting it to cultivation of just 15% of the Earth’s landmass and a potential limit of around 25%, but only through huge investment in irrigation and other technological inputs.

Impacts of climate change on agriculture

Since the mid-1970s it has become clear that not only have there been worldwide climate changes throughout the past 10,000 years, which have undoubtedly affected the distribution of crops and livestock, but also that recent short-term climatic changes may be having major impacts on agriculture. This has given rise to several studies assessing the potential agricultural impacts of global climatic change. For example, the CO₂ concentration in the atmosphere is regularly monitored at Mauna Loa, Hawaii. In 2013 it was 394 ppmv, having risen from 316 ppmv in 1959, when routine recording began. This represents an average annual growth rate of around 1.4 ppmv per year, though annual increases have been greater in recent years than in the 1960s. Levels may rise to 500 ppmv by 2050. This may be beneficial for the productivity of certain plants, but increased competition from weed species may also result, and concentrations of nutritionally important minerals, including calcium, magnesium, and phosphorus, may also decrease under raised CO₂ levels. Outcomes from climate changes are complex and often difficult to predict.

Global climate scenarios are usually derived from general circulation models (GCMs), which have been used for forecasting the effects of changes to atmospheric composition or macroscale climatic properties. Historical or spatial analogs and incremental changes to the observed weather record are also used to produce climate change scenarios. Within the various scenarios are predictions that crop yields in many tropical and subtropical areas will decline for most projected increases in temperature, and that rises of more than a few degrees centigrade occurring in mid-latitude regions will also lead to falls in crop yields. In general, agriculture in developing countries appears to be more sensitive to climate changes than agriculture in developed countries. Rain-fed cropland is generally more sensitive to warming than irrigated cropland, and cropland is more sensitive than livestock. However, perhaps the most serious current predictions relate to future failures of food supplies through diminished supplies of water. Such failures are projected for the Sahelian region of Africa, South Asia, and large parts of Latin America as a consequence of shifting rain belts. It is predicted that by 2025 5 billion people may suffer from periodic deficits in water supplies, compared to 1.7 billion in 2005. A decline in the quality of water is also highly likely in parts of Asia and southern Africa. Yet some regions may benefit from global warming; for example, in Canada the cultivated area could be extended northward.

One likely consequence of global warming is rising sea level. In the Yangtze delta in China, for example, sea levels may rise 50–70 cm between 2000 and 2050. This will be of particular significance around Shanghai, where 95% of agricultural land is below the high astronomical tide level. Countermeasures are being prepared, including improvements in drainage quality and...
capacity, renewal and increase of pumping facilities, development of new crops that are tolerant of a higher groundwater table, and construction of a flood barrier.

Geographers have performed various impact studies pertaining to climate change at various scales and for specific major crop and livestock systems. This work has frequently used resource rating schemes to assign land parcels to broadly defined suitability or agroecological classes. Alternatively, there is crop yield analysis, based on interactions among crop growth factors and generating estimates of output per land unit, which can be calculated at both a farm and regional level. However, criticisms of climate change impact studies have argued that too many assumptions have been based on neoclassical economics, which assumes that land will be devoted to the best economic use, with farmers accessing the best available technology and adjusting their farming practices perfectly to suit the changing and variable climate. This approach largely ignores constraints on farmers’ choices and decisions based on noneconomic motives. However, starting with work on farmers’ responses to drought and famine in developing countries, research has shown that even in areas susceptible to extremes of weather and climate, farmers often downplay the importance of climate as a major factor in their decision-making. Indeed, there is relatively little evidence that farmers have responded to recent changes in climate by changing their farming practices or that they have much knowledge of potential future climate change. Instead they negotiate risk on an ongoing basis, as failure to do so would threaten their survival.

The Intergovernmental Panel on Climate Change (IPCC) defines adaptation as “adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities.” In many developing countries adaptation has tended to involve technical solutions imposed by government and overseas “experts,” without any input from local knowledge. Adaptation and coping strategies are sometimes combined because what may begin as temporary coping measures (e.g., reducing/increasing inputs) can become longer-term measures.

Key technologies that offset risk in the face of climatic variations are mechanical innovations (irrigation, conservation tillage, improved drainage) and biological science (hybrids, genetic modification). However, the scale of deviation away from so-called normal conditions may define the experience of climate change, thereby stretching the ability of technological innovation to provide “solutions.” Moreover, most adaptations to climate change take the form of incremental changes characterized by short-term and small-scale actions reducing potentially damaging loss of income or enhancing the benefits of variations in climate. In contrast, transformative change could involve combinations of technological innovation, institutional reforms, behavioral shifts, and cultural changes.

While research has focused on individual barriers to, and drivers of, climate change adaptation, few studies have considered how adaptation actually occurs. However, recent work has revealed the importance of formal institutions and communities of practice. The former are groups that follow rules and procedures created, communicated, and enforced through channels widely accepted as official, such as courts, legislatures, and bureaucracies. A government agency responsible for regulating natural resource management is one example of a formal institution in this context. Communities of practice are informal structures brought together through the social construction of knowledge. A community of practice exists.
when: members share a similar set of interests, expertise, roles, and goals; opportunities exist for members to interact with one another in both formal and informal spaces; and groups share a common practice or set of practices. Farm system groups are one example of communities of practice. They exist to trial new agricultural technologies and to disseminate agricultural research and development findings to their members. Members generally attend regular meetings and social gatherings, and receive the best available knowledge of farm improvement technologies including new crop varieties, soil moisture tests, new machinery, and animal and plant control measures.

Reducing greenhouse gas emissions

It is possible that changes within the agricultural sector may contribute to future reductions in greenhouse gas (GHG) emissions, and specifically to a reduction in emissions per unit of food (or protein) and fiber produced, including the three principal GHGs – carbon dioxide (CO$_2$), methane (CH$_4$), and nitrous oxide (N$_2$O) – all of which contribute to climate change. Positive mitigation can be associated with a range of measures, including the use of set-aside (taking arable land out of production), improved livestock feeding practices, and the growing of bioenergy crops. Agriculture accounts for 10–12% of total global anthropogenic emissions of GHGs, including 50% of CH$_4$ and about 60% of the N$_2$O emitted. However, the carbon mitigation potential of agricultural land is significant, and arable land has a significant CO$_2$ sink capacity. There are several land management options to increase soil organic carbon (SOC), including the use of animal manure, sewage sludge, cereal straw incorporation, no-till farming, agricultural extensification, natural woodland regeneration, and bioenergy crop production.

The United States Environmental Protection Agency has forecast that between 2005 and 2020 methane emissions from combined enteric fermentation and manure management will increase by 21%. The escape of methane from rice paddies is also a key component, but different management strategies from those practiced traditionally can reduce outputs. Another concern is methane emissions associated with the growth of cattle rearing, as a result of the increased demand for meat associated with growing affluence in the developing world. Changed dietary habits could be one solution, but this would go against current trends among the rising numbers of middle-class in countries such as China, India, and Brazil. Meanwhile, there is an upward trend in agricultural emissions of N$_2$O, which is linked to conversions of forest to agricultural land, increased use of nitrogenous fertilizers, and the rising numbers of farm livestock. The share of animal calories in diet is projected to increase from about 15% in 2013 to about one-third in 2050. Indeed, agricultural N$_2$O emissions are projected to increase by 35–60% by 2030 as a result of the increased production of animal manure and use of nitrogen fertilizer. However, advances in precision farming may offset some rises. This could involve matching fertilizer type and quantity to site and specific crop conditions using advanced computer and satellite technology, better timing and placement of nitrogen, and the use of controlled release fertilizers and nitrification inhibitors. Measures for reducing N$_2$O emissions from grasslands could include decreasing the size of cattle herds by increasing the productivity per animal via selective breeding, lowering the nitrogen content of urine through activities such as reducing the amount of nitrogen applied to the pasture, and restricted grazing, to decrease the number of urine and dung patches. However, the latter also requires investment in housing, appropriate slurry storage
basins and slurry application techniques, and indoor feeding.

**Intensifying agroecosystems**

The simplest way to increase agricultural output is via increases to the area of land being farmed. Over millennia this has enabled farming to be focused on the best land, in terms of climate, soil quality, and topography. Under pressure to produce more food to supply rising populations, farmers have exploited more marginal lands but at a risk of lower yields, more crop failures, and greater damage to the underlying biophysical base through erosion, seasonal flooding, drought, and biological infestations. The prevalence of these risks has promoted the adoption of innovative solutions such as terracing slopes to control erosion, irrigation in drier areas, and the development of crops better suited to particular environments.

With new productive land in ever-diminishing supply, the alternative is to intensify production on existing farmland by adding more nutrients to the soils, through fertilization, and by breeding higher-yielding varieties of crops. In order for such approaches to be successful, farmers must maintain soil fertility while avoiding problems linked to long-term intensive cultivation such as pests, diseases, soil erosion, and salinization. Livestock rearing may also be intensified through improved livestock housing, supplementary feeding, and more controlled breeding programs. Mechanization may improve the timeliness of agricultural operations while enabling farmers to work a large area of land more effectively.

The use of inorganic fertilizers in developed countries increased dramatically in the second half of the twentieth century, with average rates of use between 120 and 550 kg N ha$^{-1}$, often encouraged by fertilizer subsidies. Ideally, application rates should ensure that both crop uptake and efficiency of fertilizer use are high. However, in practice, efficiency of use varies from only 20% to 70%, meaning that fertilizer may be leached from the soil or removed from the fields via runoff and rainfall events, producing losses from 35 to 155 kg N ha$^{-1}$. This has contributed to problems such as the eutrophication of waterways and the contamination of groundwater and wells. In contrast, in many developing countries, the lack of use of inorganic fertilizers is giving rise to concerns for the future of soil fertility and agricultural sustainability.

Modifications to the growing medium, water regime, and inputs to the agroecosystem in the form of energy supplements, controls via herbicides and pesticides, and labor inputs supplemented by advances in mechanization have all contributed to substantial rises in outputs per unit area. However, biotechnical advances have offered perhaps the greatest advances in crop yields and animal production in recent decades. These advances can be seen as part of a continuum of agricultural development that has its origins in the pioneering work of Gregor Mendel in the mid-nineteenth century on plant hybridization, which, taken up over three decades later, introduced the modern science of genetics. Advances in livestock breeding had occurred in the eighteenth century in the English Midlands when Robert Bakewell implemented systematic selective breeding. His experiments with sheep contributed to numerous modern breeds, and he was the first to breed cattle primarily for beef. Others then built on his work to produce larger animals and with selectively bred qualities.

In the twentieth century, continued advances in plant breeding were at the heart of the Green Revolution, the name given to a package of high-yielding crop varieties (HYVs), fertilizers, pesticides, machinery, and irrigation applied to parts of the developing world, especially Mexico,
AGRICULTURE

India, Bangladesh, and Pakistan, with funding primarily from Western nations, where the new varieties had been developed, for example, through the pioneering work of Norman Borlaug and colleagues in the United States. The staple cereals of maize, wheat, and rice were the principal crops being improved to give higher yields in a series of advances from the 1960s to the 1990s. However, it proved difficult, and costly, to spread the crops beyond areas that were physically well suited to the improved crops, and they required high levels of investment to grow. From the early 1990s biotechnology entered a new phase, initially termed the Gene Revolution, but now better known by a variant popularized in North America: genetic modification (GM). This is the use of modern biotechnology techniques to change the genes of an organism, such as a plant or animal. In agriculture four main modifications have been dominant: providing protection against environmental threats such as pests and diseases; improving nutritional value; producing an organism that can generate new outcomes, for example drugs from animals; and improved qualities, for example, yields, hardiness, larger size for animals.

GM foods were first produced commercially in 1994, with the Flavr Savr tomato, a tomato engineered to have a longer shelf life. However, concerted ethical and safety concerns have been raised regarding GM foods, especially the health implications of human consumption of GM foods: for example, the potential for toxic reactions. These concerns have led to strict controls on the development of GM crops in some countries, notably the European Union, whereas in Canada and the United States the labeling of GM foods is voluntary.

The high-tech approach of GM, often allied to industrial-style farming, global food distribution, and multinational corporations, is in contrast to farming that is geared toward agricultural sustainability based on the application of key ecological principles stressing extensive, diversified, and conservation-oriented farming systems. Sustainable agriculture implies less specialized farming, which requires mixed systems of crops and livestock to reduce dependence on purchased fertilizers. It also requires farm-level decision-making that avoids disadvantageous impacts of production, such as the contamination of groundwater and removal of landscape features that may contribute to biodiversity. Organic farming is a term generally regarded as synonymous with sustainable agriculture, though it can take various forms (e.g., no-tillage, biodynamic agriculture, and polyculture). Organic farming systems rely on crop rotations, crop residues, animal manure, legumes, green manures, off-farm organic wastes, and aspects of biological pest control to maintain soil productivity and tilth, to supply plant nutrients, and to control insects, weeds, and other pests. Many countries employ organic certification schemes whose introduction has fostered the expansion of organic farming. However, there is an ongoing debate regarding the extent to which such sustainable systems can produce sufficient output to contribute significantly to the rising food demands of the world population, which is predicted to reach between 8 and 11 billion by 2050.

Agri-food multinational enterprises

Ruth Rama
National Research Council of Spain (CSIC)

Early studies and general overview of agri-food FDI

According to the UNCTAD website, “FDI refers to an investment made to acquire lasting interest in enterprises operating outside of the economy of the investor. Further, in cases of FDI, the investor’s purpose is to gain an effective voice in the management of the enterprise. The most important characteristic of FDI, which distinguishes it from foreign portfolio investment, is that it is undertaken with the intention of exercising control over an enterprise.” The distribution of foreign direct investment (FDI) is geographically uneven and varies by industry (Senauer and Venturini 2005). However, the empirical analysis poses some difficulties: data regarding FDI and multinational enterprise (MNE) activity at the sector level is frequently patchy, restricting attempts to map these activities. The few exceptions (e.g., Gabel and Bruner 2003) contain little information regarding agri-food MNEs.

The agri-food sector comprises segments such as agriculture, food and beverage (F&B) processing, research and development (R&D), and retailing. Using UNCTAD data, Senauer and Venturini (2005) have shown that food MNEs were second only to the media in their degree of internationalization, as measured by the ratio of foreign to total assets, sales, and employment. In the 1990s the rates of internationalization of these firms also increased faster than those for MNEs operating in five other industries.

Although the agri-food sector is dominated worldwide by small and medium-sized enterprises, MNEs play an important role in these substantial industries. In 2005 the world’s 100 largest food and beverage MNEs (hereafter Top 100) accounted for around one-third of the world’s turnover in the F&B processing industry, with the 15 leaders amounting to 19% of the total (Rastoin 2008). The Top 100 produced around 50% of the patented innovations available worldwide to the F&B processing industry and auxiliary industries, agriculture included (Alfranca, Rama, and von Tunzelmann 2002). FDI and trade are related in many respects, and the agri-food sector is no exception. F&B MNEs have contributed to changing the geography of international agricultural trade by influencing local dietary habits. An econometric analysis noted that the presence of US F&B multinationals encouraged local agriculture in host countries that were agricultural exporters, such as the European Union, but stimulated increased imports of agricultural goods into deficit host countries (Barkley 2005).

By the mid-1970s, food deficits were encouraging international organizations, notably the Food and Agriculture Organization of the United Nations (FAO), to put food at the forefront of development debates. The first studies on the foreign activities of agri-food MNEs were published around 1975–1980, in the context of concerns about the possible negative effects of these companies on dietary habits, food safety, land concentration, marginalization of poor
AGRI-FOOD MULTINATIONAL ENTERPRISES

farmers, and a shift to cash crops to the detriment of staples in developing countries. Rastoin’s 1975 PhD thesis, which was based on economic and financial information for 87 very large food and beverages MNEs of different geographic origins studied over the period 1963–1972, was the starting point for AGRODATA, a database containing information on the Top 100 and their approximately 8000 affiliates, published by the Institut Agronomique Méditerranéen de Montpellier since 1976 (www.iamm.fr/iamm). Arroyo (1981) published case studies resulting from a large project carried out in 14 Latin American countries by French and Latin American academic institutions. The same year, the United Nations Centre on Transnational Corporations published an analysis of multinational agri-food companies for a larger number of developing host countries (CTC 1981). The research was produced in both the Global North and South, in different languages, and the research groups remained in fairly close contact (Arroyo 1981).

These early studies aimed mainly to analyze effects of multinational agri-food companies on developing host countries rather than to systematically investigate their geographic patterns of expansion. Nevertheless, some interpretations were provided, with institutional factors in the internationalization processes of the agri-food sector placed at the forefront of explanations. The studies proposed that agri-food MNEs were only the most dynamic part of a new international food system, which promoted the worldwide homogenization of food production, commercialization, and consumption. International organizations such as the World Bank, and some national states (notably the United States), were also proactively contributing to the construction of this new system (Arroyo 1981). This notion of food systems has been criticized since the 1990s because it allegedly fails to analyze power interfaces around the food sector (Arce and Marsden 1993). In this vein, some authors propose that the globalization of the agri-food system be treated as a “contested process” (Murdoch, Marsden, and Banks 2000).

The recent geographic expansion of FDI in this sector seems to confirm early interpretations, however, since it is largely attributable to profound political and institutional changes since the end of the 1980s. According to most recently available data, outward FDI flows between 1989–1990 and 2005–2007 doubled in agriculture, hunting, forestry, and fishing – food price rises of 2007–2008 may have stimulated such investments – and quadrupled in food, beverage, and tobacco manufacturing (Table 1). To a large extent, this is due to the liberalization of capital and trade, the formation or the enlargement of trading blocs (e.g., the European Union), and the adoption of market-led systems in erstwhile state-managed economies. A new configuration of shareholders also encouraged the rapid internationalization of F&B firms (the F&B industry is considered to be a noncyclical sector, attracting institutional investors such as pension funds). This has been accompanied by demands for relentless growth and the achievement of global goals by F&B companies, which often has contributed to weakening their embeddedness in home regions by promoting their worldwide expansion (Palpacuer and Tozanli 2008).

Most FDI still originates in the developed countries, and this is also true of the agri-food sector (Table 1). Some authors note substantial changes in the composition of outward FDI in this sector between 1989–1991 and 2005–2007 (Rama and Martínez 2013; Tozanli 2005). First, the share of developed countries in outward FDI flows fell: a moderate reduction (from 98% to 95%) for food, beverage, and tobacco processing, but a substantial one (from 91% to just 52%) for agriculture, hunting, forestry, and fishing (hereafter agriculture and related industries).

This reflects the dynamic expansion of flows originating in developing countries. While the search for land may have become less important for MNEs based in the Triad of Western Europe, the United States, and Japan, as predicted by Dunning (1993), it remains a crucial strategy for MNEs based in developing countries, especially those lacking sufficient natural resources.

Agriculture

The main objective of South–South agricultural investments is to obtain cheap food for the home market, bypassing large multinational trading companies based in the North (McMichael 2013). No comprehensive data on the geographic origin of agricultural capital is available. Foreign investments can be difficult to trace owing to alliances with domestic investors or operations through strategic transit countries (Borras et al. 2012; Cotula 2012; McMichael 2013). Furthermore, very different geographies of interests may be involved in a single project, since lenders, insurers, contractors, and suppliers may come from different parts of the world (Cotula 2012).

One study reports that 66% of the demand for agricultural land is by Middle Eastern investors (McMichael 2013). In Latin America, however, the presence of FDI in land deals from the Gulf States, China, South Korea, and India seems to be quite small (Borras et al. 2012). Much more important, these authors observe, is the investment of intraregional investors, whose presence is also noteworthy in African and Asian land deals (Cotula 2012). Some authors observe the presence of new global players, such as state-owned firms (UNCTAD 2011; Zoomers 2010).

Zoomers (2010) suggests that the current geographic expansion of agricultural FDI cannot be understood without taking into account the liberalization of land markets and the conversion of collective and customary land rights into formal individual rights, a policy followed by many developing countries since the 1990s. In many countries, neoliberal policies had also contributed to the dismantling of the public agencies formerly used to provide credit, technical assistance, and insurance to small farmers.

In some cases, the operations of investors based in developing countries are not limited to land investments in other developing countries, but also involve several segments of global
value chains (GVC), including processing and distribution facilities in Russia and the West (Nazareth Satyanand 2011; Pozzobon 2008). The presence of these new global players coincided with the divestment from land by many Triad-based MNEs since the early 1980s, due to the nationalization of plantations and shifts to more rewarding business lines (e.g., agricultural technology and food processing) (Oman et al. 1989).

In 2007, 56% of the inward FDI stock in agriculture and related industries was in developing economies, 37% in developed economies, and 7% in southeast Europe and the Commonwealth of Independent States (CIS) (UNCTAD 2009). Governments of host developing countries have been instrumental in facilitating such investments, especially when the land targeted by foreign investors was defined as available marginal land or was located in agricultural frontier regions (Borras et al. 2012). Borras and colleagues (2012) observe that such processes may take some time to crystallize, a position supported by other studies. In Chile, for instance, according to some authors, the military’s government privatization of national assets such as forests, and the partial rollback of land reform, amounted to the reprivatization of formerly public goods: after 1973, massive expulsions of peasants took place (Arce and Marsden 1993). In 2007 the stock of inward FDI in agriculture and related industries received by Chile, a country with relatively limited arable land availability, was nearly 2.5 times the stock received by Brazil, a very large country with a substantial agricultural frontier (UNCTAD 2009). In the tradition of economic geography, Munroe et al. (2014) advise that the play of power between actors should be considered in analyses of international land deals.

To summarize, there has been a major transformation of the geographic pattern of agricultural FDI, as a large share of the total consists currently of South–South investment. The thesis of an expansion of agricultural FDI toward developing countries (Heffernan and Constance 1994) appears to be supported by recent statistical data, but with a caveat (Rama and Martínez 2013). The principal foreign investors at present appear to be MNEs based in developing countries (rather than Triad-based companies), a change that was obviously difficult to foresee at the beginning of the 1990s.

One of the important questions posed by economic geography is whether MNEs of different origins operate differently outside their home country (Dicken 2000). The literature points to differences concerning agricultural FDI. European and US food processors and retailers have often preferred to outsource production to local suppliers of agricultural products rather than investing in land. Though their geographic linkages with foreign agriculture are difficult to quantify, they have been documented by case studies (e.g., Echánove and Steffen 2005; UNCTAD 2009). Oman et al. (1989) describe such arrangements as new forms of international investment (not simply FDI): MNEs that outsource agricultural production often also finance, organize production, and influence the technological practices of their local suppliers, though they do not own land. Some authors opine that contracting has tended to generate power asymmetries and the denationalization of agricultural production, since it allegedly shifts the locus of control from local producers to the agri-food MNEs (Gwynne 2006).

The literature illustrates a variety of situations in relation to control along the GVC (see Gwynne 2006). Faced with foreign investors and joint ventures, the small Mexican fruit growers studied by Echánove (2005) seem to have lost control of land owing to their inability to organize in the context of neoliberal policies adopted
in the 1980s (including drastically reduced public support for agricultural R&D and extension services). By contrast, a study of fruit and vegetable small producers in Almería (Spain) emphasizes how their ability to organize into cooperatives, the emergence of a cooperative local bank, and public support for agricultural education and new technology have generated a very different kind of relationship with foreign retailers, with the vertical downward integration of producers and other local firms within the GVC (Aznar-Sánchez and Galdeano-Gómez 2011).

Some authors observe that agricultural FDI or contract farming has sometimes contributed to the displacement of small local peasants in developing countries. The term “land grabbing” generally refers to large-scale, cross-border land deals carried out by MNEs or initiated by foreign governments, deals that may displace local peasant populations (Zoomers 2010). The physical extent of this phenomenon is controversial, ranging from Oxfam’s estimate of 227 million ha to the World Bank estimate of 45 million ha, with Africa hosting around 70% of such land grabs (Borras et al. 2012).

The FAO defines land grabs in terms of three aspects: (i) large-scale land acquisitions; (ii) the involvement of foreign governments in land deals; and (iii) the negative impact of such foreign investments on the food security of the host country. Borras et al. (2012) argue, however, that this definition is too restrictive. In their opinion, the scale of the capital involved should be considered, not only the scale of land acquisition, a framework that includes contract farming. Following their criteria, land grabbing would be substantial in at least 10 Latin American countries, not just in Argentina and Brazil as suggested by the FAO. Land grabs also may involve financial companies with no particular geopolitical attachments (McMichael 2013).

**Food and beverage processing**

The corporate geography of multinational food, beverage, and tobacco manufacturing is quite different from that of multinational agricultural activities. As in other manufacturing industries, FDI in food, beverage, and tobacco is mainly a North–North phenomenon. F&B MNEs have faced considerable constraints and challenges in developed countries, including an ageing population, the preference of some consumers for fresh or artisan products, and competition from retailers’ own cheap brands. These circumstances could have predicted a geographic southward shift of FDI in this industry, but the most important recipients of F&B FDI are still developed countries, accounting for 87% of inward FDI stock in both 1990 and 2007 (UNCTAD 2009). Indeed, although inward FDI stocks in developing economies also grew, inward FDI stocks in developed economies increased more quickly. As a result, the share of the North grew from 67% to 84% of total inward FDI stocks during this period.

Within the OECD (Organisation for Economic Co-operation) area, the composition of outward F&B FDI has changed with the emergence of new source countries such as Australia and New Zealand. Several case studies also note the emergence of F&B MNEs based in developing countries (Burch and Goss 2005; ECLAC 2005; Nazareth Satyanand 2011). Information provided by AGRODATA also points to the foreign activities of very large F&B companies based in the developing world. In 2012, 32% of the Top 100 were based in Western Europe, 29% in the United States, 18% in Japan, and 7% in other developed countries; 13% were based in developing countries and 1% in tax havens (Tozanli 2015).

As noted by Sim (2007, 2), “theories and explanations on the internationalization (or
expansion across national boundaries) of firms were largely based on Western TNCs.” Burch and Goss (2005) agree that most of the current literature characterizes the model of globalization as a process activated by the dynamism of large corporations based in the Triad, failing to consider MNEs based in developing countries. Even less research, they claim, has been directed toward agri-food MNEs based in such countries, notwithstanding their significant regional and even intercontinental activities. A popular theory (Dunning and Narula 1996) maintains that there is an investment development path (IDP) according to which countries gradually reach a stage of development that allows their companies to go international. Burch and Goss (2005) argue, however, that the stages of development proposed by this theory imply a degree of uniformity that is not apparent in the food and fiber sector. In developing countries, they claim, a highly sophisticated and productive food-processing sector may be established on the basis of very different ownership and organizational forms: peasant farming, plantations, cooperatives, collective ownership, and so on. The previous discussion seems to corroborate this point of view.

The empirical literature on the determinants of the location of F&B MNEs is now revised. These firms prefer to invest in countries with large internal markets, high GDP per capita, large urban populations, high levels of protection for these industries, and easy availability of cheap inputs and raw materials; membership in a trade bloc is seen as a plus (e.g., Pick and Worth 2005). Oligopolistic rivalry may also influence their locational behavior (e.g., Rama and Martínez 2013). These companies are not especially attracted by low wage rates, however (Makki, Somwaru, and Bolling 2004; Giulietti, McCorriston, and Osborne 2004).

Determinants of F&B FDI may vary by type of country. Makki, Somwaru, and Bolling (2004) find that per capita income appears to be negatively related to US FDI in food-processing and foreign affiliates sales, probably because consumers may prefer to increase their consumption of fresh and other less processed foods in very high-income countries. Within developing countries, by contrast, per capita income is positively related to US FDI in food-processing and foreign affiliates sales. Their findings support the view that food chains rooted in local and regional contexts respond to a growing demand for quality products, and may eventually counteract globalization trends in highly developed countries (Murdoch, Marsden, and Banks 2000).

Most authors believe that the F&B industry is a multidomestic rather than a global industry. In global industries (e.g., automobiles), the company establishes an international division of labor between its affiliates. In multidomestic industries, the firm is unable to establish networks facilitating worldwide combinations of inputs, intangible assets, and so on. Nevertheless, the emergence of trade blocs may contribute to changes in the agri-food sector. Regional integration may facilitate the offshoring of some low valued-added segments of the food chain or the national specialization of foreign affiliates and its corollary, intense intrafirm trade within the trade bloc (Chevassus-Lozza, Gallezot, and Galliano 2005). Agri-food MNEs adopting these formulae can spatially centralize the production of some items and display strong intrafirm trade, like corporations operating in global industries. Nevertheless, these are exceptions: FDI in the F&B processing industry displays the lowest level of geographic concentration (Senauer and Venturini 2005). The explanation offered is that proximity to the market is particularly important in consumer-oriented industries.

Arguing that we are moving toward a homogenized world, many have announced “the death of distance” or “the end of geography.” The “flat
world” thesis implies that economic activities can be performed as readily in India as the United States. At first sight, the substantial decentralization of F&B MNEs seems to confirm this point of view. However, places remain very important in agri-food production, much more so than in other sectors. There is a “geography of quality”: consumers associate the high quality of particular foodstuffs and drinks with specific locales (Mansfield 2003). This country of origin effect (as labeled in the management literature) can limit the internationalization of F&B firms via FDI, promoting exports instead. Other studies also show that physical and cultural distance matter in this sector. With the exception of a few very large companies, F&B MNEs tend to expand within their respective home region (e.g., the European Union) rather than globally (Filippaios and Rama 2008; Gardner and McGowan 2010).

F&B companies are more likely to expand to host countries sharing the same language or other cultural features with the home country (e.g., Filippaios and Rama 2011). This is not surprising because F&B are culturally bound products. This is consistent with the Uppsala school of thought, which proposes that MNEs follow a sequence, from their home base to countries with greater “psychic distance.” According to this theory, an MNE’s penetration into different markets proceeds according to their cultural similarity to its home country. F&B MNEs may also be attracted by subnational markets displaying cultural proximity, as is the case of Mexican F&B MNEs penetrating the United States market by tapping in to the demands of Mexican immigrants (ECLAC 2005).

The organization and origin of capital may also influence the corporate geography of F&B firms. Anastassopoulos and Rama (2005) propose that Japanese F&B MNEs centralize production in fewer countries than their Western counterparts because their main businesses consist of exports from foreign locations to the home country, and the production of high-tech inputs for the food industry. They thus require contacts with fewer national markets. Palpacuer and Tozanli (2008) propose that the characteristics of stakeholders also influence the geographic patterns of F&B MNEs. Companies with smaller plant size, family or farmer ownership (cooperatives), and European capital follow a regional (EU), rather than a global strategy.

**Retailing**

Wrigley (2000) published one of the first comprehensive studies on the globalization of retailing capital. Examining food retailing, he noted the importance of mergers and acquisitions (M&A) as a strategy for firms to acquire global scale. Confirming previous studies, he observed the profitable and relatively easy penetration of Carrefour (France) into Brazil in the early 1990s. The takeoff of supermarkets occurred half a decade later in countries with previously state-controlled economies, such as China (Reardon, Timmer, and Berdegué 2004), but now is moving very fast.

The literature suggests that the presence of modern retailing may hinder or stimulate F&B FDI, or fuel competition in specific markets. In the 1980s and 1990s insufficient development of modern retailing facilities limited the spread of F&B MNEs in some countries, regardless of whether they were industrialized, because F&B requires refrigeration facilities or the frequent substitution of products on retailers’ shelves for optimal consumption. Elsewhere, the development of modern retailing has fueled competition in F&B processing markets. In Brazil, international brands faced unexpected competition from cheap local brands when smaller domestic processors were able to use these new channels.
to market their products (Farina and Viegas 2005). In other cases, the internationalization of retailing goes hand in hand with that of F&B production, as shown by examples of small F&B companies that follow a retailer abroad. This exemplifies the “follow the client” strategy studied by the international business literature in other industries.

It would be an error to conclude, however, that distance does not matter for retailers. Large multinational retailers prefer to expand in the home region rather than globally (Rugman and Girod 2003). The global sourcing of both fresh and processed products seems to be increasing, however.

Research and development

The globalization of business activities often starts with exports, followed by production activities abroad, and only then foreign R&D investment. The internationalization of R&D corporate activities has become increasingly common. Firms innovate abroad to adapt their products to foreign markets, to benefit from locally bound pools of know-how or to adjust to local regulations (Hotz-Hart 2000). Cross-sectional studies show that F&B MNEs are especially likely to undertake some R&D activities abroad, probably to adapt their products to different national tastes and food safety regulations. However, the control and management of such activities is retained within the Triad (Rama and Martínez 2013).

According to one study, major European F&B MNEs tend to retain their core technology within the EU region, albeit not necessarily in the home country (Martínez and Rama 2012). This supports the view of evolutionary economists (Archibugi and Michie 1995) that the internationalization of R&D may be largely a regional process, principally involving European MNEs innovating in other European countries.

Future directions in research

More research is needed to improve our understanding of the corporate geography of agri-food MNEs. Several of the topics discussed in this entry are new or have received insufficient attention. GVCs controlled by MNEs based in the South are a new phenomenon; until recently, the literature assumed that GVCs were exclusively controlled by companies based in the North. The role of cultural proximity concerning subnational markets for ethnic food is another new phenomenon which may acquire some importance, given the current scope of migration flows.

More meta-analyses are needed to deepen our understanding of a variety of situations regarding control along GVC. The wealth of published information and analyses has yet to be fully systematized. Land grabs also deserve more conceptual work, in addition to careful analyses of their spatial dimensions and timing. The lack of methodological consensus has hindered our understanding of this phenomenon. The role of trade blocs in the emergence of agri-food MNEs that centralize and specialize production, like MNEs in so-called global industries, is another interesting avenue for research. Finally, the geographic aspects of the relationship between modern retailing and F&B FDI deserve more attention. Research on these two types of FDI and their respective geographic patterns has proceeded independently to date, but there is evidence to suggest that they may be related phenomena.

AGRI-FOOD MULTINATIONAL ENTERPRISES

Further reading
Agroclimatology deals with the complex interaction between climate and agriculture. The significance of agroclimatology continues to increase with the exponential growth in human population and the resulting demand for food. The need to provide sustainable and robust continued sources of food and fiber has become a major challenge facing humankind. Some of the broader questions that encompass this challenge include:

• What and where can crops grow?
• What can be done to improve their productivity under limited natural resources?
• How can increased productivity be achieved with minimal impact to the climate and the environment?
• How would the vulnerabilities to agriculture crop production alter under climate change?

Other questions often posed by the agricultural community include:

• What typical planting dates would provide the most potential for highest yield?
• What are the typical risks and vulnerabilities expected in a growing season?
• What can be done to reduce their impact on crop yields?
• What yield can be expected in a typical growing season, and how does this change during an El Niño/La Niña year (when the Pacific sea surface temperatures are higher or lower than climatology and significant temperature and rainfall extremes are noted in many parts of the globe)?
• What is the expected impact on food prices and global trade?

The above questions are examples. The information sought would depend on:

• The type of crop being grown (commodity or perennial or horticultural).
• The purpose of growing these plants, that is, whether it is for food, fiber, fuel, or environmental considerations (such as fixing soil nitrogen, or for regulatory compliances).

The questions would also be specific to the geographical location as well as to what regional regulations and policies need to be considered. Answers to such questions are routinely sought by the broader community and form the crux of agroclimatology.

Background and the evolution of agroclimatology

Agroclimatology is a subgenre of climate science that combines the disciplines of agronomy and climatology. Agronomy deals with the scientific and practical understanding and application of the integrated knowledge of soils, crops, nutrients, environment, and management practices with the objective of maximizing yields sustainably. The complex interaction among factors that contribute to crop growth and sustenance is of particular interest. Climatology deals with the understanding and analysis of long-term
(decades to centuries) patterns of climate and various factors that constitute it through interactions within the biosphere (biological ecosystems including plants), lithosphere (earth and soil), hydrosphere (water and moisture), cryosphere (snow and ice), atmosphere (air), and humans.

Agroclimatology can thus be considered as a branch of science wherein climatic information is synthesized, analyzed, and applied to improve agricultural practices. Historically, belts of civilization formed around regions that were found to be climatically conducive for agricultural practices. For agriculture to sustain and thrive, the primary variables of interest include access to water or rainfall, adequate moisture and nutrient content in the soil, abundant radiation for photosynthesis, the correct temperature conducive to crop growth, and a reliable year-to-year climate pattern that allows agronomic planning. Variables relevant to agricultural variables in conjunction with information on plant response to environmental stimulus or stress constitute the core of information compiled in agroclimatic datasets.

Although many aspects of agroclimatology and agrometeorology are similar, they are considered separate fields, in part, because of their temporal scales. Agroclimatology, for example, is the study of hydrometeorological variables over an extended period (i.e., months to decades) whereas agrometeorology is concerned with variables over a shorter period (i.e., minutes to weeks). For example, agroclimatology could be used to make decisions as to what crops or horticultural plants to grow in a certain region (also known as hardiness zone maps), while agrometeorology would be used in protecting crops when a frost risk or some other immediate weather-related feature needs to be considered for agricultural sustenance.

Just like agrometeorology, agroclimatology can be applied to a broader domain or specific area, such as the agroclimatology of the Corn Belt in the Midwestern United States, or for a specific location and purpose, such as the start of a planting season in a particular field or location.

The focus of agroclimatology has evolved to understand and communicate the intricate interactions between long-term agroclimatic variables (e.g., precipitation, temperature, radiation, evaporation, soil moisture, soil temperature) that affect the agricultural system from production to distribution of food, feed, and fuel.

Indeed, this aspect of the geographical locations, regions climatology and the suitability for type of plants that can be grown is well recognized. In the simplest form, plant hardiness and heat zone maps are available that relate the cold and warm season temperatures and provide guidance on which plants can generally thrive in a given region. Additional guidance on crop and plant zones has been recognized historically through delineation of “life zones.” For example, Merriam (1898) mapped the United States to identify regions based on which crops can prosper in different combination of heat and moisture availability. Additional details related to life zones were developed by Holdridge (1967): these combined information on mean annual temperature for a region, altitude, mean precipitation, and the evapotranspiration water loss. This spatiotemporal information of climatic state and the kind of agricultural variety that can thrive has thus been a backbone of agroclimatology.

Agroclimatology encompasses a broad variety of studies from increasing agricultural productivity to how to adapt to a changing climate. Therefore, agroclimatology is an important tool that can be used for natural resource management, maintaining soil health, animal production, and as an indicator of future vulnerabilities of agricultural productivity and sustainability.
Some agroclimatology terminology

Agroclimatological information is captured in a series of variables. Over the years, technology has constantly evolved but the basic desired outcomes that form the agroclimatic information have remained the same. These typically include the meteorological and climatic variables (temperature and rainfall), derived parameters (such as growing degree days and sunshine hours), indices (such as the Palmer drought severity index, the standardized precipitation index), and patterns (first and last frost date or start and end of the rainy season).

As a first step in developing the agroclimatology of a region, it is important to document the specific climatology of that region. The primary agroclimatic variables of interest can include rainfall amounts (determines the water content in the soil), radiation available for photosynthesis, and the temperature of the environment affecting crop growth. Additionally, some terms may be different depending on the geographical region of interest. For example, in temperate regions, the crop growing season entirely depends on the frost-free dates; while in the case of tropical regions, the rainy season almost entirely determines the type of crop and its entire crop life cycle from sowing to harvesting. Maps and data showing the start and end of frost season or rainfall season are used as guidance for the crop growing season. Crops are also heavily impacted by soil variables such as the loss and availability of soil moisture and temperature due to evapotranspiration, soil-water demand, and soil-water holding capacity. Therefore, maps and information related to typical evaporation loss and water-holding capacity are also considered helpful from the agroclimatic perspective.

Agroclimatic data can be integrated into crop-cycle centric activities. The growing degree-day (GDD) is an example of an agroclimatic measure that is grounded in science and has practical utility. GDD is a measure of the amount of heat units accumulated over the crop region. Plants are known to begin their growth after a certain base temperature is reached (e.g., 50°F or 10°C) and plant growth slows at a high-temperature threshold (e.g., 86°F or 30°C). The GDD can then be estimated as the sum of daily mean temperatures that are above the base temperature required for plant growth; that is, the base temperature is subtracted from the daily average temperature to obtain the GDD per day. For corn (maize) in the United States, the base temperature is taken as 50°F (10°C). The daily mean temperature is simply taken as an average of daily maximum and minimum temperatures. For any maximum daily temperature above the high-temperature or minimum daily temperature below the low-temperature threshold, the value is replaced by the threshold value. Continuing with the above example for corn in the Midwestern United States, if the daily maximum temperature is 90°F then it is replaced as 86°F in computing the GDD averages. The sum of GDD or heat accumulation is then linked to agronomic aspects such as plant growth and pest potential. For example, a GDD of around 100 is considered adequate for plants to sprout from the ground, and 600 is considered to be suitable for tassel development. A GDD of 1400 is considered for plants at full height, and full maturity for many corn varieties is about 2700. In the United States Corn Belt, crop varieties typically need a GDD around 2000–3000 depending on the location, genetic makeup, or hybrid variety. Similarly, a threshold of GDD for hatching and feeding of leaves at around 500 is considered in the case of some plant pests. For a given location and possible planting date windows, agroclimatic curves or maps showing the GDD potential for a climatological growing season (i.e., frost-free...
period or rainy season) can be used to ascertain if a particular crop variety would or would not be appropriate (that is, whether the GDD needed for the crop cycle is expected or not). The GDD and pest information are also used in planning the use of pesticide recommendations, especially when large tracts of farmland need to be covered for effective agronomic management practices. Other such agroclimatic information could include data and maps for the number of days when the temperature is expected to exceed 95°F (35°C) and crops may incur damage, when nighttime temperatures are above 78°F; the number of days of hail occurrence, or the number of days when rainfall can exceed around three inches, or other such thresholds that can cause regional ponding and impede farm operations.

Agroclimatological parameters can also capture climate variability information such as changes in typical planting dates as a function of the El Niño/La Niña phase or the expected crop yield as a result of El Niño/La Niña. Inherent to climate variability information is that agroclimatic analysis could also include frequency or interval-based information, such as the duration of the number of consecutive periods with temperature or rainfall in excess of a certain threshold or specific to a crop cycle threshold. Plant growth is reduced if there is a lack of rain two weeks after planting; therefore, soil moisture or rainfall expectations relative to the planting date also become important agroclimatic information.

Some applications of agroclimatology

One of the main objectives of agroclimatology is to effectively assist farming practices, thereby increasing agricultural productivity and yield. By observing records of precipitation, temperature, and hours of sunlight in a region, growers have a better opportunity to predict which crops and varieties are better suited for the growing conditions of a selected region. A typical agroclimatic assessment would provide data, observations, model estimates, and maps that can be interpreted by communities or agronomic advisors and includes information on the timing and variety of crops along with associated risks and management practices.

Some additional examples of agroclimatic applications are summarized here.

Natural resource management: on a global scale, agricultural activities are one of the most water expensive enterprises. Since the type and extent of crop production can heavily influence the hydrology of an area, agroclimatology could be utilized to develop methods that would improve management of water availability. By combining climatological information with that of soil and plant science, evaporative demand can be calculated to determine specific irrigation requirements and applications throughout the year. Predicting changing hydrological patterns could be improved through urban planning by designing innovative wastewater transport and treatment facilities that can safely adapt to changes in precipitation and water runoff (particularly with fertilizer use).

Droughts and hydrological extremes: climate variability and hydrological extremes such as droughts and floods play a crucial role in determining suitable agricultural practices. Drought indices such as the Palmer drought index and the standard precipitation index are useful climatic measures to ascertain anomalies in rainfall or effective rainfall (precipitation–evaporation) over a given location. Knowledge of drought occurrence and timing aids in the understanding of the risk involved and defines corresponding management measures to cope with it. Similarly, heavy rainfall events including hail and floods can cause severe crop damage in cases of insufficient preparation. Mitigation measures, such
as irrigation plans in areas where deficits exist, drains in regions where excess rain needs to be diverted, and shelters, can prevent water logging and soil erosion.

Soil health and nutrient management: as the availability of water and soil have an interdependent relationship, agroclimatological information that provides knowledge related to both is useful when preparing land management sectors for managing soil health. For example, erosion is intensified in regions of heavy rainfall climatology. Soil moisture retention and nutrient storage capabilities are also influenced by changing climate. For the use of fertilizer, the type, amount, and timing required also vary with changes in climate and nutrient availability; agroclimatic information is useful guidance for this.

Animal production: in addition to plants, agroclimatology can also be of use in animal production, another subset of an agricultural enterprise. Different animal species have adapted themselves to have optimum growth, lactation, and reproductive functions if living under specific climatic conditions, including temperature and the availability of food resources. Beyond these parameters, animals are subjected to a variety of stresses. These environmental stresses, caused by prolonged exposure to inadequate temperatures, can hinder an animal’s ability to properly regulate their body temperature as well as control their energy, hormonal, and water balance. If their stress stems from a reduction in the quantity or quality of their food, then their growth and nutrient absorption can be adversely affected as well. These impacts collectively influence not only the animal’s health but also the health of their offspring and the production of eggs and milk. Therefore, knowing how weather, climate, and an ecosystem interact with one another is critical to the productivity and welfare of animals during animal production, and agroclimatic maps can assist in the animal facility operations.

Climate modeling studies: agroclimatic information is not only used in developing practical agronomic decisions but can also be used in climatic analysis. For example, climate model studies can have enhanced interactivity between the atmosphere, hydrology, and the land surface by incorporating rules for different regions to have a change in vegetation fraction as a function of agroclimatic inputs. This is known as dynamic vegetation feedback in the climate models; agronomic data and principles are used as the driver for these model algorithms to make them realistic.

Agroclimatology and climate change

As regional and global climates continue to change with greenhouse gas emissions, land use/cover changes, and a warming planet, food security is interlinked to future sustainability. Agroclimatic information is of interest in the understanding of impacts due to climate change (e.g., if temperature were to exceed a growth threshold such as 95°F, then it could have a deleterious impact on projected crop yields). Agroclimatic information is also important is developing adaptation/mitigation strategies related to climate change. For example, there is a tendency of a poleward shift in ecological zones of different crops, pests, and weeds due to increased temperatures in the upper latitude regions. Agroclimatic maps for current and projected climate can help prepare food and ornamental crops for the inevitable problems or opportunities that arise from such changes. Being aware of these shifts can also assist pathologists and seed companies in preparing for such demands and information needs.

Agroclimatological information thus has a bearing on the regional land use/cover in terms of agricultural crop land extent and type. It is
important to note that agricultural landscapes can alter regional climate by altering the regional albedo and temperature. Agriculture combined with irrigation has also been known to change regional moisture budgets and the atmospheric energetics, which ultimately can alter rainfall patterns. Agriculture from both animal operations as well as crop and forest production contributes to the greenhouse gas budgets. For instance, plants can absorb carbon dioxide and act as a carbon “sink,” while soils can both absorb and, when disturbed for tilling and other operations, release carbon back to the atmosphere, and so act as a “source.” Thus, agroclimatic information is also important in making decisions and synthesis related to regional climate resiliency. Ultimately, agroclimatology is a science that is best utilized in mitigating climatic risks and promoting sustainable practices for optimal yields and the longevity of various natural resources, and is intimately tied to the climate change adaptation/mitigation discussion.

Broader opportunities and challenges for agroclimatology

Agroclimatology is entering an era where it is poised to be of prime importance for global challenges, such as food security and sustainable agroecosystems in a changing climate. A number of tools and sensors are emerging with capabilities for higher spatiotemporal mapping. These include integration of information from geospatial and remote-sensed datasets and wireless sensors, mobile technology, and distributed/spatial models. Agroclimatology is expanding into a field that determines information of spatiotemporal patterns locally and geospatially in an interconnected world for agronomic decision-making. Scaling this information within the agroclimatic variables and maps is needed to provide patterns and knowledge that can aid in the decision-making from global to regional to farm scale. An example of such global linkages of agroclimatic patterns and regional and local decision-making can be seen in the role of El Niño in creating drought or crop yield changes in a certain region (e.g., South America). This reduced crop yield in South America could mean higher trade potential and crop prices for farmers in North America. As a result, deciding what crop to grow, the possible returns and risks would be the norm for future agroclimatic decision tools.

This combination of agriculture, climate, economics, management decisions, and trade is the likely trajectory of future agroclimatic applications. Teleconnections in different regions and their impact on regional agricultural practices and decisions will be an area requiring newer techniques for mapping such connections and knowledge emerging from these data and patterns. Another example of the growing need for agroclimatic information is in the study areas of crop bioengineering and genetic hybrid varietals, and integrating higher spatiotemporal resolution information that can be utilized in the development of customized seed varieties. It also follows that while climate models currently provide weather and climate information that is then linked into agronomic models and for decision tools, the next generation of coupled models will have agroclimatic outputs and products that can assist with decision-making and assessments.

Two emergent challenges with these finer resolution products include higher uncertainty in projections and developing results and an information base that would be transferable from one locale to another. This will require redesigning the agroclimatological curriculum and educational materials and tools for students, farmers, and stakeholders from the global food
security perspective. Tools and educational materials are also needed to help understand the risk, uncertainty, and value of agroclimatic products and to assist with decision-making. This will include more accessible documentation and awareness of how predictions and analyses are made and what combinations or factors are being used in making a certain decision (e.g., the likelihood that El Niño during the growing season can change the planting date or cause drought stress in some regions, and if the El Niño does not evolve as projected, then the decisions can be modified and tailored to align with changing agroclimatic patterns).

While the impact of climate on agriculture has been the defining feature of agroclimatic information, in the context of the changing world it is becoming apparent that agriculture as an enterprise also has an impact on regional climate through water use, fertilizer use, greenhouse gas emissions, and land cover albedo. Future efforts will likely have more agroclimatic products providing information on this coupled feedback with newer variables and maps to assist regional planners.

Lastly, the role of humans through management practices continues to be a challenge in developing agroclimatic information because it is still poorly understood and documented. It is likely, and expected, that in the coming years the human influence within the agroclimatic variables will be better documented and utilized in agronomic decision-making.

Conclusions

Agroclimatology is a vibrant branch of science integrating fundamental and applied scientific information from multiple disciplines under agriculture and climatology, to develop a knowledge base that is increasingly important for a world seeking to feed its growing population using sustainable means.

Figure 1 shows a summary of an agroclimate decision cycle developed by agroclimatologists focusing on the US Corn Belt (Takle et al. 2014). The outer calendar indicates the approximate time during the year when different agricultural decisions are made. The inner calendar identifies the different impacts as a result of different weather and soil conditions.

Indeed agroclimatic principles, objectives, and fundamentals will remain the same as they have been, but the future is geared toward integration of newer technologies and broadening of applications where agroclimatic information is needed and will likely make its value grow exponentially in the coming decades.

Agroforestry

Krisnawati Suryanata
University of Hawai‘i at Mānoa, USA

Agroforestry refers to a natural resources management system in which farmers deliberately grow woody perennials on the same land as agricultural crops and/or animals, either in some form of spatial mixture or in sequence. Although it has been a common practice around the world for centuries, the term “agroforestry” was coined and institutionalized in the 1970s when a broader interest in indigenous technical knowledge renewed interest in traditional practices. Descriptive and anecdotal information from different parts of the world had indicated that intercropping systems have fewer pest and disease problems, improve nutrient cycling, enhance the chemical and physical properties of soil, conserve moisture, and make generally efficient use of a range of farm resources. From the standpoint of environmental stabilization, agroforestry systems may reduce erosion and provide environmental services such as watershed protection and biodiversity conservation. An influential report commissioned by the Canadian International Development Research Centre (Bene, Beall, and Côté 1977) highlighted these advantages and called for global recognition of the key role that trees play on farms. It recommended the establishment of an international organization that would support, plan, and coordinate research on agroforestry. The result was the establishment of the International Council for Research in Agroforestry (ICRAF) in 1978, followed by the inaugural publication of the journal *Agroforestry Systems*, dedicated to publishing research related to agroforestry.

Throughout the 1980s, agroforestry scholars put together an inventory of existing agroforestry practices and knowledge, in order to understand the underlying processes of time-tested practices and the applicability of scientific principles to improve them (Nair 1992). The home gardens (*pekarangan*) and mixed gardens (*kebun talun*) of Java were cited, for example, to show the diversity and complexity of the structure and function of tropical agroforestry, in which intermingled trees, bushes, climbers, and herbaceous plants in a multistory vegetation system provide excellent protection against tropical storms (Wiersum 1981). Another commonly cited agroforestry practice was the *taungya* system, introduced by British colonial administrators in nineteenth-century Burma to establish teak (*Tectona grandis*) plantations on forestlands. Under this system, landless peasants were given permission to grow food crops on forestlands for three to four years in return for performing reforestation tasks. The system later spread throughout Asia, Africa, and Latin America and remains the primary method for recruiting and mobilizing labor in reforestation schemes.

While the bulk of studies at this time focused on the ecological properties of agroforestry, a few social scientists drew attention to the fact that agroforestry practices provide critical opportunities for otherwise disenfranchised groups. For example, Rocheleau (1987) demonstrates how women mobilize agroforestry strategies to make the best use of the minimal landholdings allotted to them. Proponents of cultural survival have argued that indigenous peoples use agroforestry systems to perpetuate their livelihoods and to
AGROFORESTRY

protect their cultural identity (Clay 1988). Dove (1990) argues that the diversity and complexity of mixed gardens in Java, which incorporate a wide range of cultivars with high use-value but low exchange-value, might have provided peasant groups with the means to effectively resist the extractive propensities of the state. In contrast, the taungya system serves as a tool of the state to effectively control shifting indigenous cultivators and to establish forest plantations with minimal labor costs (Bryant 1994).

Driven by narratives of economic growth and sustainability, research at ICRAF (renamed the World’s Agroforestry Centre in 2002) during its first two decades was geared toward improving agroforestry technologies such as alley cropping, hedgerows planted on contour lines, or improved fallows. These technologies were aimed at maximizing positive interactions between soil and plants in order to push the biophysical limits of the system and achieve higher productivity while stabilizing its resource base. Armed with this promise, institutional actors in forestry, major donor agencies, and national governments joined forces to promote integrated conservation and development projects (ICDP) utilizing agroforestry practices. However, optimism was short-lived. Reviews of large upland agriculture and conservation projects in Indonesia showed that the new farming systems depended heavily on unsustainable subsidies, and many farmers reverted to old practices soon after a project ended. Elsewhere, alley cropping (a prototype of agroforestry technology developed at ICRAF) turned out to have a low adoption rate among farmers. In addition to the technical difficulties of designing the system, the elevated labor cost of managing grasses and legumes in hedgerows was an obstacle that prevented farmers from adopting alley cropping. In the end, “the alley cropping experience has done considerable harm to the reputation of agroforestry research” (Sanchez 1995, 43), leading to its abandonment. Today the World’s Agroforestry Centre continues its investigations into improving agroforestry management, expanding tree species diversity, and improving farmers’ income from commodity production. It also examines institutional and policy innovations to reward agroforestry practices that supply environmental services such as watershed protection and carbon sequestration.

Political ecologists seek to expand the discussion beyond technocratic and managerial concerns, and draw attention to agroforestry as a site of contentious struggle with overlapping property and labor claims. Many societies recognize the separation of tree tenure and land tenure (Bruce and Fortmann 1988), and tree planting brings about new rights and pressures on existing property relations. The relative permanence of trees may impose restrictions on other uses, and the shading effect of trees may displace crops underneath as well as in neighboring fields. It is therefore critical to understand the overlapping, multiple claims that often develop following tree planting and the adoption of agroforestry (Rocheleau and Edmunds 1997; Schroeder 1999; Suryanata 1999), and how tree claimants exercise their control through intercropping dynamics. Farmers may view trees and forests as “liabilities” that impede their livelihood and effective resource control, particularly when the state has criminalized their removal (Peluso 1992; Rocheleau and Ross 1995).

Contemporary agroforestry regularly includes the integration of valuable commodity trees into the farming system. By practicing agroforestry, smallholders can presumably maintain a stream of benefits from annual crops before the trees start bearing fruit. Schroeder and Suryanata (2004) examine two case studies of contemporary fruit-based agroforestry initiatives, in Indonesia and in the Gambia, both of which were hailed as bold steps toward environmental stabilization.
In both projects, the lucrative value of fruit commodities caused tree growers to exercise exclusionary practices and marginalize cultivators of the underlying crops. They illustrate that commoditization tends to extend the property rights of tree growers vis-à-vis competing resource users, such as cultivators of underlying crops, forest product collectors, and pastoralists.

From a political ecology perspective, the strengths of agroforestry practices do not lie exclusively in the ways they can enhance economic productivity or stabilize the environment; they also rest in the opportunities afforded by the sheltering of multiple claims and uses. In the context of neoliberal governance, agroforestry practices based on high-value commodity crops are attractive technologies that increase the incentive to plant trees. But they are also strategies of private accumulation that can shift the systems’ distributions of benefits and produce a range of ecological and social contradictions.

Aid

Jamey Essex
University of Windsor, Canada

Aid refers to the transfer of goods, services, and other resources, usually from a relatively more developed state to a less developed one, on concessionary but often conditional terms, typically as a form of development or humanitarian assistance. While the contemporary system of global development and humanitarian aid has its roots in American efforts to support reconstruction and influence political and economic development first across war-ravaged Europe and later throughout the developing world following World War II, the interlocking set of institutions that today make up the global aid system includes much more than official state institutions and government-to-government flows of money and commodities. Private charitable foundations, intergovernmental bodies, and nongovernmental organizations (NGOs) are all deeply embedded in the geography of aid, directing how development programs and humanitarian and emergency interventions operate, devising policies and sharing best practices, and working with and sometimes in lieu of governments in new forms of public–private partnership.

While aid also can include various forms of military aid, institutionally most states manage military assistance separately from development and humanitarian assistance for political reasons. The more common use of the term “aid” usually excludes overt forms of military assistance. Practices and programs of aid are nonetheless closely tied to state strategies of national security and aid has long formed an important instrument of statecraft and foreign policy. In advancing sometimes complementary and sometimes contradictory goals focused on both modernization and geopolitical strategy, donors and recipients have used aid to alleviate short-term crises and to foster longer-term structural (and highly uneven) development of national political and economic systems. More generally, flows and practices of aid have strongly shaped the relationship between the Global North and South, promoting particular (usually but not always capitalist) forms of development and generally advancing the interests of donor states while often reproducing highly unequal terms of trade and power imbalances. A geographical understanding of the contemporary global aid system must first take into account how important national and international institutions developed in the wake of World War II and through the Cold War rivalry between the US and Soviet Union, and what role aid was meant to play in the development of the “third world.” The global aid landscape has changed considerably with the Cold War’s end, the rise of neoliberalism since the 1980s, and the proliferation of official and private aid actors. This has resulted in a complex geography of aid that today includes a greater emphasis on South–South connections and flows, the opening of aid provision and governance to new nonstate actors, and the inclusion of a wide array of social and environmental objectives in aid programs and projects. On the other hand, critics from across the political spectrum have begun to more directly interrogate aid’s purpose and effectiveness, calling into question widely held assumptions about the necessity of aid for development and the benefits for recipients.
The postwar system of aid, mutual security, and development

Following the end of World War II and the Cold War’s onset, the United States developed a number of programs to channel financial, military, and other resources to numerous countries in Europe and the rapidly decolonizing “third world” to rebuild shattered economies, to modernize those newly independent states seen as underdeveloped, and to shape political and social relations in an effort to combat the threat of communism. While this was most directly coordinated through the Marshall Plan, which injected $13 billion into the economies of American allies in Europe and Turkey from 1948 to 1951, several discrete, short-term, highly targeted programs of aid existed between the war’s end and the 1961 creation of a more permanent institutional home for foreign assistance in the US Agency for International Development (USAID). Many other industrialized states followed suit in the decades following World War II, moving from short-term aid programs housed under the larger umbrella of trade and economic cooperation (or even receiving aid themselves as part of postwar reconstruction programs) to the creation of official state agencies focused on development and humanitarian assistance to developing countries in the third world. In addition to the expansion and codification of aid programs as part of national states’ foreign, trade, and economic policies, aid became by the 1960s a major part of coordinated multilateral and intergovernmental efforts, especially through the United Nations and the Organisation for Economic Co-operation and Development (OECD), to restructure the international state system and world economy. Within the OECD, for example, Western economic powers worked to coordinate development and aid policy through the Development Assistance Committee (DAC), which remains an important forum and mechanism for shaping global aid policy today.

As concerted programs of aid became institutionalized amid the heightened tensions of the Cold War, it became impossible to easily and neatly separate the humanitarian, economic, and political foundations and goals of aid, even as these often resulted in competing mandates for aid organizations and programs. Postwar development thinking in the Western context often evolved directly from modes of thought and practice closely associated with the establishment and preservation of colonial empires in the nineteenth century and which had initially framed the “tropical” regions of the world through racially and environmentally determinist arguments and ideologies. After World War II, with rapid and often violent decolonization, such deterministic approaches faded “as ‘development’ and ‘environment’ began to inhabit the discourse of ‘the Tropics’, defining arenas of the discussable for such zones” (Power 2003, 47). These discourses conditioned the ways in which Western powers envisioned the purposes, goals, and limits of aid and shaped the resulting institutions and practices that programmed and delivered aid across the newly emergent third world.

Modernization theory codified much mainstream development thinking at this time, forming the intellectual backbone of Western aid programs and emphasizing that aid should provide the economic stimulus to propel transformative societal development in newly independent and impoverished states. Practitioners and policymakers in Western donor states understood aid as a pivotal component of a wider humanitarian project that proceeded through economic and geopolitical mechanisms, providing necessary capital, expertise, and support to states threatened by poverty, underdevelopment, and communist infiltration. In the case of aid’s historical role supporting both development and
geopolitical goals, it served (and continues to serve) to help diagnose and categorize states and peoples along axes of political allegiance, economic progress, and deservingness. In this way, postwar aid and development programs, institutions, and theories demonstrate how aid, rather than simply and benevolently sending needed money and goods to the world’s poorest from its richest, actually helped constitute the Cold War balance of power by promoting allies and denying enemies, identifying spaces of underdevelopment, disorder, and intervention, and creating new frontiers of capitalist market expansion.

While this was particularly true of American development assistance as organized and delivered through USAID, other Western donors’ aid programs often took somewhat different forms and foci based on historical relations with former colonies, the need to target scarce resources more efficiently, or unique foreign policy objectives and goals. In addition, the multilateral provision of aid, especially through the many agencies of the United Nations system, allowed for a wider range of political, economic, and social criteria to enter into aid strategies and objectives than those associated with American or Western geopolitical interests alone. For its part, the Soviet Union also provided large amounts of foreign aid to numerous developing countries. American policymakers even cited sizable Soviet aid programs in the late 1950s as a threat to US interests in the third world and an impetus to expand and rationalize US aid programs. Like American and other Western donors’ aid, Soviet assistance was tied to political and economic conditions that served donor interests while also articulating ideals of international and humanitarian cooperation that were often trumped by strategic considerations and objectives associated with the Cold War and domestic politics.

Despite the way it supported the superpowers’ Cold War ambitions, foreign aid nevertheless constituted an important part of development progress across many parts of the third world in the first three decades after World War II. The number of people living in absolute poverty fell, per capita incomes rose, food security improved, and economic growth and diversification occurred in many postcolonial states. To what extent this was directly the product of foreign aid remains contested, and contemporary experts and critics still hotly debate aid’s long-term track record as an effective tool for economic, political, and social improvement in poor countries and for poor people. What is clear is that much aid was (and still is, as discussed below) donor-centered, that is, programmed, delivered, and assessed primarily on whether it met the needs of donors rather than its intended beneficiaries. In this sense, the concerted, large-scale, permanent postwar aid programs and agencies helped define and assert Global North–South imbalances, tying postcolonial states into forms of economic dependency and political subordination that often looked decidedly like colonial and imperial relations in a new guise. Yet foreign aid also became a vital part of national development strategies and government revenue in many third world states, and actively shaped domestic social relations within these states. This forged emergent political and economic structures in those states, tying and reincorporating them into circuits of global and especially American capital while supporting geopolitical allies and, often, heavy-handed military governments. Indeed, as Kodras (1993) and Nijman (1995) have shown in their detailed examinations of the geographic flows of American aid dollars from the 1950s to the Cold War’s end, US aid in particular was largely concentrated in its allies, many of which received aid in exchange for specific security-related reasons.
(e.g., basing rights), to stabilize the domestic political or economic situation, or to support the procurement of US goods and services (known as “tied aid”). Aid also had profound impacts on the cultural and spatial organization of daily life, encouraging urbanization and industrialization while uprooting and delegitimizing traditional ways of life.

By the 1970s, however, global economic crisis and critiques of aid and development programs based on modernization theory and the geopolitical objectives of the Cold War superpowers started to produce significant shifts in the ideological underpinnings and practical management of foreign aid for Western donor governments and, increasingly, the international financial institutions (IFIs) of the Bretton Woods system. While these developments did not reach their full expression until after the Cold War ended in the early 1990s, they nonetheless pointed to the increasing role of neoliberal ideals and approaches in foreign aid, and in mainstream development thinking more broadly, and of the use of aid to more fully and directly support economic rather than geopolitical objectives. Dependency theorists in Latin America produced a sophisticated critique of modernist development and foreign aid emphasizing that the third world’s underdevelopment and peripheral status in the world economy was a direct product of exploitation by the core developed Western states, supported by transnational relations between capitalist elites in both sets of countries. This meant increasingly strong criticisms of Western aid from within the third world, accompanied by stringent domestic attacks on aid in many donor states, especially the United States. Domestic budget hawks in the United States had long criticized aid as an expensive handout, and the economic and foreign policy context of the late 1960s and early 1970s – economic slowdown, increasing domestic social program costs, stalemate in the Vietnam conflict, and American insistence that its European allies pick up more of the costs of global aid – also contributed to the push to put aid programs on a new ideological and programmatic footing.

Accordingly, official development assistance (ODA) agencies and increasingly the IFIs turned toward a concern for targeting aid at the poorest peoples and the provision of basic needs in the 1970s. As Lawson (2007, 101) explains, mainstream development practice came to emphasize a “weak” form of the basic needs approach in which aid helped to incorporate the poorest into development processes by encouraging their participation in development projects funded by aid dollars. This approach promised to make aid, and development generally, more responsive to the provision and improvement of life conditions for those traditionally excluded from development (especially including women) by targeting aid more directly at necessary infrastructure and social services such as education and health. Aid was thus to become less a blunt instrument of foreign policy and more a catalyst of social transformation and improvement. This shift also, however, strengthened aid programs’ and institutions’ technical capacities and foci at the expense of full inclusion for the poor in the political decision-making that shaped aid’s purpose and operation. In other words, the widespread shift in aid donors’ approach toward a weak basic needs emphasis tended to make development aid a technical exercise in including the poor in aid project delivery and completion without tackling head-on deep structural inequalities that persisted within developing countries and globally between states.

Though even a weak basic needs approach promised to alter significantly the aid system’s objectives and impacts in favor of the poorest people, further shifts in the ideological and technical focus of aid came quickly with the
AID

rise of neoliberalism in many donor states and
the IFIs. Looming debt crises across the devel-
oping world and the aggressive pursuit of trade
liberalization and global market integration as
a preferred development strategy put aid on
a different footing in the 1980s and into the
post-Cold War period. The neoliberalization
of aid and development meant that aid donors
and recipients now were to emphasize aid’s
ability to foster market development and global
integration and a suite of preferred neoliberal
reforms within developing states, including
privatization of state and parastatal enterprises,
deregulation of significant sectors of national
economies, and trade liberalization. Aid funds
again became a kind of leveraging tool for
imposing the objectives of powerful states onto
weaker counterparts in the developing world,
but now through the discipline of global market
forces and debt. Although this had always been
the case to some degree, the rapid shift toward
neoliberal approaches in aid and development
institutions, most importantly USAID, the IMF,
and the World Bank, emphasized much more
strongly than ever before the importance of
global economic interdependency and aid’s role
in the pursuit of market liberalization.

Aid retained geopolitical purposes in the
context of particular donors’ foreign policy
strategies as well, especially in the United
States. Increasingly, and especially after the Cold
War’s sudden end, geopolitical goals became
inextricably intertwined with neoliberal eco-
nomic reforms pushed through donor states’
bilateral aid and IFI-imposed structural adjust-
ment programs. Aid became a tangled mess of
complementary and competing projects and
programs aiming to achieve multiple objectives,
though all tended toward the transformative
neoliberalization of national economies and
societies in the Global South. This also opened
the door more widely to new actors, especially
NGOs and private charitable foundations, in
what was fast becoming a much more complex
and multiscalar international aid system. While
nonstate actors had long been important in the
programming and delivery of aid, the post-Cold
War environment allowed new geographies of
aid to flourish, involving multiple kinds of actors
working at different scales, creating new spaces
of aid policy formulation, and both challenging
and reproducing sociospatial inequalities tied to
intensive forms of neoliberal globalization and
the lingering effects of colonial and Cold War
systems. In sum, the Cold War’s end helped
create the conditions for consolidating a new
international aid regime predicated largely on
neoliberal ideals and policies, and restructured
existing aid institutions contending with new
mandates, new partners, and new contexts.

Aid in the post–Cold War era

Following the Cold War’s end, Western states
and international and intergovernmental orga-
nizations with large bilateral and multilateral
aid programs sought ways to restructure aid by
giving it new purpose and institutional footing
and improving its humanitarian and develop-
ment impacts. This meant finding ways to shed
aid’s geopolitical instrumentality and make it
more compatible with neoliberal globalization,
especially in terms of the relationship with
trade. Serious questions about aid’s ability to
deliver on its humanitarian and development
promises remain, however, and critics note that
aid remains tightly bound to donors’ national
security considerations and geopolitical maneu-
vering, and that aid’s record of supporting
economic growth, political democratization,
and social service provision remains spotty at
best, especially when coupled with (or for
many, compared to) neoliberal reforms. In

5
absolute terms, aid funding channeled through ODA programs and institutions located in the OECD-DAC countries dropped through the 1990s before increasing sharply around the turn of the millennium, in part due to massive new amounts of American aid flowing to Afghanistan and Iraq as part of the “global war on terror” following the terrorist attacks of September 11, 2001. Commitments to increase ODA funding made through the UN’s Millennium Development Goal 8 (which called on states to “develop a global partnership for development” to tackle problems of underdevelopment, debt, and an unequal international economic system) and G8 and G20 meetings following the 2007–2008 financial crisis, have likewise fostered renewed attention to the amount, type, and effectiveness of aid from OECD-DAC donors.

Despite this, only a handful of OECD donor states (primarily the Scandinavian and Benelux states) have ever reached the UN’s suggested target of 0.7% of GNI as a threshold for aid funding, budget concerns in most countries have made ODA funding a target for cuts amid lingering effects of global financial and economic crisis, and aid remains highly unpopular with the public in many traditional donor states. Even so, OECD statistics indicate that DAC donors’ assistance to developing countries increased from just over US$50.1 billion in 2003 to almost US$88.6 billion in 2012 (accounting for almost two thirds of global ODA), reaching an all-time high of US$94.4 billion in 2011. The impacts of the global economic and financial crisis, however, make the short to medium term prospect of increased aid funding from most OECD donors unlikely. In turn, many official donors have sought ways to streamline their operations and improve the effectiveness of their aid dollars, often by seeking more intensive partnerships with NGOs, the private charitable and for-profit sectors, and multilateral and intergovernmental organizations. Many donor states have also moved to rationalize internal operations within their own aid systems and programs, sometimes adopting a “whole of government” approach to aid and making stronger efforts to coordinate various state institutions working on and with aid accounts. In some instances, particularly in the United States, this has evolved alongside what is now commonly called the “3Ds approach” that makes development a pivotal component of national security strategies with defense and diplomacy. In this context, recent donor concerns with aid reform, effectiveness, and funding have sought to reduce long-standing problems with overlap, redundancy, and waste while also reproducing problems associated with donor-defined and -centered objectives for aid programs and their role as geopolitical instruments.

By contrast, two important trends in the global aid system indicate the extent to which the contemporary geographies of aid are changing, with the OECD-DAC states’ bilateral programs and the multilateral channels and programs they tend to dominate now representing just some of the many important mechanisms and forums for shaping a global aid agenda. The first trend concerns the entrance of new donor states into the aid system, especially major emerging economies from the Global South, and the concomitant development of new mechanisms of donor coordination. The second is the multiplication of channels and forms of privately funded development aid, which must be seen in light of two intertwined processes, one being the emphasis on trade and foreign direct investment across three-plus decades of neoliberalization and the other being the emergence of a new form of “philanthrocapitalism” through which private capital has sought ways to make philanthropic activities conducive to profit seeking investment.
Looking first at the emergence of new donor states and forms of donor coordination, Mawd-sley (2012) cautions that it is important that many non-DAC and “emerging donors” (such as China, India, Russia, and Saudi Arabia) are in fact not new to the global aid system as donors at all. Recent changes in aid governance complicate most attempts to categorize donors and throw into disarray older categories and assumptions about how aid works globally. There is today a greater emphasis on partnership, transparency, accountability, and coordination, including forms of South–South cooperation, than ever before and a number of principles regarding aid governance have been articulated through a series of international meetings and declarations. These include the UN Millennium Declaration (2000) and the Monterrey Consensus (2002), which established the MDGs and asserted new commitments to financing development efforts in support of these goals, as well as the Paris Declaration (2005), the Accra Agenda for Action (2008), and the Busan Agreement (2011), which have steadily plotted a set of international principles for assessing and ensuring aid effectiveness and expanding the governance of aid to include recipient states and emerging donors in more robust ways. Such high-level efforts have created a new, international space of aid policy formation and coordination that is more inclusive and open than global and DAC-centered aid systems and mechanisms had been previously. On the other hand, this policy space remains highly managerial in scope and approach and far removed from on-the-ground delivery of aid. Critics continue to pose political challenges to aid that efforts at better donor coordination and articulation of globally accepted principles of aid governance have yet to adequately answer. Emerging donors, with Chinese aid to and investment in sub-Saharan Africa often serving as a prime example, seem at times to replicate the donor-centered programs of their OECD peers even as they demonstrate alternative models and practices of economic cooperation and governance not tied to Western power and conditionalities.

More deeply, many critics also strongly question the continued necessity of aid and suggest that where aid creates bonds of dependency and undermines social, political, and economic innovation, full integration into the global capitalist economy remains the more just and effective path to development with better outcomes for poverty, economic growth, and democratization than any foreign aid program could hope to produce. In this respect, the role of private channels of aid, particularly from charitable and philanthropic foundations associated with some of the world’s largest and wealthiest transnational corporations and individuals and the longstanding quest to make aid and trade complementary, form a second key trend in contemporary changes in the global aid system. Fridell and Konings (2013) argue that such forms of “philanthrocapitalism” are an optimistic response to, and outcome of, neoliberal economics and the production and exacerbation of inequality widely associated with trade liberalization, structural adjustment, and poor terms of trade for developing states. Private flows of aid, particularly those provided by foundations managed by “icons” of capitalism at the pinnacle of the world market (such as Bill Gates or Jeffrey Sachs), promise to resolve through voluntary charitable action seemingly intractable problems that decades of official bilateral and multilateral aid have failed to correct, such as poor economic growth, inequitable access to health and education, environmental degradation, and even the provision of basic infrastructure. In doing so, aid will supposedly create more effective conditions for integrating people and places into regional, national, and global economies,
and produce new opportunities for product development and market creation, though the neoliberal foundations of economic and political relations remain unchanged and unchallenged. Contemporary philanthrocapitalism thus builds on the Washington Consensus policies that helped remake development aid by encouraging market liberalization and restructuring developing state forms and functions over the last three decades. This recasts deep structural problems of underdevelopment and marginalization as market failures that can be corrected through highly targeted aid interventions and appropriate private investment unencumbered by the political considerations and objectives of official development assistance. Neoliberal assumptions about the necessity of a global market orientation for proper development are thus coupled with a kind of celebrity culture in striking new ways through philanthrocapitalism and private aid, drawing attention to a narrow range of development problems and solutions while ignoring others and reproducing some of the major faults critics have identified in official aid channels and institutions.

The future of aid

The future of the global aid system and its role in promoting development, justice, and equity across a range of social, economic, political, and environmental considerations hinges on a series of fundamental questions about the conduct of aid in a radically interdependent world. What role should aid play in a global system defined by stark social, political, and economic inequalities, imperial relations of governance and subordination, and potentially disastrous processes of environmental degradation and climate change? Should aid work to foment liberalized trade and support strategic national security objectives? Should it operate primarily to soothe Western souls and placate the poor without fundamentally challenging existing social, political, and economic relations? Can the narrow and highly technical and managerial forms of aid currently favored by many donors, both private and official, actually promote and achieve full social inclusion and empowerment of the poor? Should aid solely be employed in emergency situations, such as responding to natural disasters, and leave long-term development to market forces and privatized forms of economic connection and political governance? What alternative traditions and practices might exist or evolve that can inform our ways of thinking about and delivering aid, and our relationship to distant others? Overton, Murray, and McGregor (2013, 122) provide one of the few recent comprehensive research agendas for critically investigating the rapidly shifting geographies of the global aid system, arguing that “geographies of aid should have an explicit political goal that provides progressive space for those who suffer due to the inherent unevenness” of this system. They suggest that core geographic concepts of space, place, scale, and networks should shape the way geographers as well as aid practitioners and critics answer the kinds of difficult questions about aid outlined above to highlight not only how geography shapes aid, but also how aid creates new geographies. The contemporary global aid system, uneven and unjust as it often is, thus offers a range of potential access points for critical geographic inquiry and intervention, which can potentially create spaces and mechanisms to better fulfill aid’s emancipatory promise.

Air transport

John T. Bowen Jr
Central Washington University, USA

At any one moment in 2012, approximately 1 million people were airborne on commercial flights around the world (estimate based on ICAO 2014 and methodology described in Bowen 2010, 2, note 2). Their movements and the torrent of packages, pallets, and parcels sent daily by air have brought distant markets, resources, people, places, and hazards near. At the same time, air transport is an important factor in global climate change, and likely to become more so in the future. And yet, even as the world’s airlines are catalysts for change at the global scale, aviation’s greatest impacts, for good and for ill, are felt locally: in hubs, in spokes, and in the places in between. Across several scales, the development of aviation has affected, sometimes profoundly, the world’s human and physical geography.

Both passenger and cargo traffic have grown robustly. Over the period 1950–2012, for instance, air passenger-kilometers (one passenger flown one kilometer) and air cargo tonne-kilometers grew at annualized rates of 8.6 and 9.0%, respectively (ICAO 2014; Bowen 2010); both these rates are more than twice that attained by gross world product during the same period. The pace of its expansion has propelled aviation deep into the spaces of everyday life across much of the planet. In the United States, as in other affluent countries and many middle-income ones, air travel is the dominant mode of passenger travel beyond about 1250 km (Bureau of Transport Statistics 2006), and a growing share of even substantially shorter trips involve flying – especially on low-cost carriers. Meanwhile, aviation’s share of global freight traffic is tiny in tonnage terms but substantial – about one-third when measured in value terms (Airbus SAS 2015). The importance of aviation, combined with this mode’s inherent spatial dynamism, has made air transportation the subject of intense and sustained scrutiny by geographers (Vowles 2006).

Air transport technology and the diffusion of aeromobility

By 2012, the world’s passenger airlines operated nearly 33 000 nonstop scheduled routes (OAG 2012), a skein of links that enveloped almost every part of the globe except Antarctica and the Southern Ocean. Across this network moved 3.0 billion people (ICAO 2014). These statistics attest to the remarkable advances made since the beginning of commercial aviation.

The diffusion of aeromobility (Lassen 2006), or broadly accessible airborne mobility, began in advanced economies, but has more recently spread to developing countries. In the United States, aviation first gained economic significance in the carriage of airmail, beginning with the world’s earliest such service operating between Washington, DC, and New York City in May 1918 (Bilstein 1983). By contrast, in Europe, the other early center of commercial aviation, fragmented national markets precluded the development of airmail, and nascent carriers focused on passenger traffic instead. On both sides of the Atlantic, early airlines were either state-owned...
or state-subsidized and protected, reflecting government eagerness to realize the commercial and strategic promise of the new technology.

Rapid advances in that technology during the 1920s and 1930s yielded remarkable improvements in the speed, capacity, and safety of commercial aircraft. The most influential of the early airliners was the Douglas DC-3. The 21-seat twin-propeller plane incorporated important innovations (e.g., flaps and slotted wings), and became the first commercial aircraft to regularly fly nonstop between New York City and Chicago. In fact, adequate range to link the two business centers had been an important design criterion mandated by the launch customer, American Airlines (Bowen 2010).

As air transportation grew in scale and importance before World War II, its networks continued to resemble those of the railroads and steamship lines they were supplanting. Networks were strongly linear in form. In 1940, a transcontinental journey from New York City to Los Angeles, for instance, typically required six stops en route (Wynne 2011). Intercontinental travel was similarly arduous, as exemplified by the 32 stops and 10 days required for air travel between London and Sydney in 1939 (Wynne 2011). Air travel was expensive, too; the round-trip airfare for New York to Los Angeles was $300 or about 50% of US per capita income at the time. In 2012, the average fare on the route was about $700, but that sum equated to just 2% of US per capita income.

Even in the mid-twentieth century, however, air transportation, though costly, had such a speed advantage over alternative modes, and technological change in aviation was so fast, that the airlines continued to capture traffic from surface modes. The first sustained nonstop transcontinental commercial flights in the United States began in 1953, and by 1956, nonstop services had begun between New York City and London (Bowen 2010). These flights involved turboprop-powered aircraft of unprecedented speed, size, safety, and – of course – range. Not coincidentally, the mid-1950s also marked a watershed as transatlantic crossings by plane first eclipsed and then overwhelmed crossings by sea, and in the same decade air travel edged out rail in the number of transcontinental trips within the United States (Hugill 1993).

The advent of jet airliners in the 1950s and wide-body jets in the 1970s carried air transportation to still greater heights. The first commercial jet service was launched by British Overseas Airways Corporation (BOAC) with a British-built jet, the De Havilland Comet. Though heralding the future, the sleek jet made its commercial debut in 1952 on a route that reflected Britain’s imperial past: from London to Johannesburg via Rome, Cairo, Khartoum, Entebbe, and Livingstone (Bowen 2010). Much larger, faster, and ultimately more commercially successful jets arrived at the end of the 1950s, beginning with the 132-seat Boeing 707. The big Boeing entered commercial service on a Pan American World Airways route linking New York and Paris, with a refueling stop in Gander, Newfoundland. The ensuing proliferation of services by the 707, the similar Douglas DC-8, and then a bevy of smaller jets produced by Boeing, Douglas, and manufacturers in Western Europe and the Soviet Union, defined the geography of the early Jet Age in the 1960s.

Jet travel produced striking time-space convergence: for instance, the air travel time on Pan Am between New York and London fell from just under 11 hours nonstop on a DC-7 in 1957 to 6 hours and 35 minutes on a 707 in 1963. And as dependence on jets spread, the new technology stretched the scale and increased the speed of everyday life, much as earlier aviation innovations had done. Firms were better able to spread their operations across
transcontinental and intercontinental markets. The semiconductor industry, for instance, took advantage of the spatial flexibility afforded by air transportation to spread its integrated circuit manufacturing system across the Pacific to Hong Kong and Singapore in the 1960s, and then other parts of Asia in the 1970s. Jet aviation was similarly catalytic in extending the “pleasure periphery” (Turner and Ash 1976), a phrase that refers to the set of places to which the affluent and increasingly the middle-class retreat for holidays. Hawaii, for instance, welcomed its first jet flight in 1959, the same year it became a US state; and both changes drew the islands closer to the mainland market (Bowen 2010). At a deeper level, jet travel spurred the imagination in the 1960s. From the Jetsons to the New York Jets to jet-inspired automobile designs, the new technology was invoked as a symbol of power, modernity, and confidence in the future.

The confidence of the Jet Age fueled the rapid development of still larger commercial aircraft. In the early 1970s, the jumbo 366-seat Boeing 747 and several other wide-body jets were introduced. Unfortunately, this addition of capacity occurred just as the Arab Oil Embargo and subsequent disruptions of global oil supplies triggered a severe economic contraction across much of the world. These circumstances challenged all of the aircraft manufacturers, but ultimately proved advantageous to the newest of the competitors: Airbus Industrie.

The European industrial consortium had been formed in the late 1960s to redress what French President Charles de Gaulle lamented as “America’s colonization of the skies” (quoted in Heppenheimer 1995, 203). Linking the resources of aerospace manufacturers in West Germany, France, the United Kingdom, and to a lesser extent Spain and the Netherlands, Airbus Industrie entered the airliner business with the 250-seat Airbus A300. Unlike the other new wide-body jets, the Airbus had just two engines, which gave it an inherent fuel efficiency advantage. The jet, whose development was heavily subsidized by the governments of the respective manufacturers, made its commercial debut in 1974 on the symbolically significant hop between Paris and London. From that beginning, Airbus has risen in just 40 years to become a well-matched rival for Boeing.

Indeed, the combination of industrial economies of scale, advanced technological human capital resources, and supportive governments has fostered substantial market share gains by Airbus. By the early twenty-first century, it was the only independent European manufacturer of aircraft with more than 100 seats. On the other side of the Atlantic, meanwhile, Boeing consolidated its position as the industry leader. By 2012, Boeing and Airbus accounted for 43% and 30%, respectively, of the 23,236 commercial jets in the world’s airline fleets (Air Transport World 2013). Their relentless competition with one another has encouraged a steady improvement in aircraft performance, which in turn has made air transportation more affordable and hastened its spread.

In 2012, Boeing and Airbus accounted for more than 80% of unfilled aircraft orders (airliners are commonly ordered several years before delivery), indicating that their dominance of the skies will continue. Many of the newly built airliners will be used in developing countries, which comprise a large and growing aviation market. For instance, Lion Air of Indonesia and AirAsia of Malaysia are among the largest customers for new narrow-body aircraft from Boeing and Airbus, respectively. The significance of these airlines as customers for new aircraft technology illustrates the diffusion of aeromobility.
Air transport, globalization, and the persistence of the short-haul linkages

By 2012, the longest regularly scheduled commercial flights extended more than 13,000 km nonstop, including, for instance, Sydney–Dallas–Fort Worth, Atlanta–Johannesburg, and Dubai–Los Angeles. These links are testament to the significance of globalization, a phenomenon for which relatively low-cost aviation has been a celebrated enabling factor. For instance, freshly cut flowers flown from Kenya to Europe and tuna caught off Atlantic Canada destined for sushi restaurants in Japan illustrate the power of aviation to lower the cost of distance and thereby enlarge markets.

The spatial scale of civic society and politics, too, is stretched by air accessibility. The Association of American Geographers (AAG), for example, has become an international organization; about a third of attendees at the AAG’s 2013 conference in Los Angeles came from outside the United States. The vast majority of those conference-goers, like their domestic counterparts, flew to Los Angeles. Politically, aviation has long been an important instrument for nation-building; that importance is most clearly expressed in so-called flag carriers. The political visibility of the air transportation system also helps to explain its prominence as a target for terrorist organizations: attacks on airports or airlines can be a means of projecting a regional conflict onto a global stage.

Aviation has also influenced population geography, particularly with respect to migration and the diffusion of disease. Air travel has permitted increased transnationalism, as migrants are better able to maintain a presence in their countries of origin (Bowen 2010). Meanwhile, aviation has accelerated the diffusion of some infectious diseases. One of the most striking examples was the 2002–2003 spread of severe acute respiratory syndrome (SARS) from Southern China to 25 countries and Taiwan. The epidemic’s geography was strongly shaped by patterns of aviation accessibility (Bowen 2010).

Yet while aviation has been important in enlarging the scale and increasing the pace of some features of everyday life, it is important to note that most air travel is short-haul. In 2012, the average distance traveled per air passenger around the world was approximately 1830 km, about the distance from Boston to Memphis or London to Helsinki. The busiest routes in the world tend to be short-haul and domestic (Table 1) illustrating the persistence of distance decay and of borders, even in an era of globalization. Only one of the 20 busiest routes in the world in 2012 was more than three hours long, and that linked the world’s two most dominant cities (London and New York). More characteristic of densely traveled routes is the hour-long sector between Rio de Janeiro and São Paulo.

Airlines and their networks

In 2012, there were approximately 725 airlines offering scheduled passenger services, up from 595 in 1998 (OAG 1998, 2012). Most airlines in both years were combination carriers, meaning they also offered cargo services — typically in the lower deck space aboard passenger airliners, though some combination carriers (e.g., Korean Air) also operated substantial fleets of freighter aircraft. Additionally, a relative handful of carriers, notably including FedEx Express and UPS Airlines, operated extensive scheduled freighter services but flew no passengers.

The small increase in the number of airlines conceals the tremendous flux in airline competition in the past several decades. For instance, fewer than half of the 595 airlines flying in 1998 were still flying in 2012. Among the largest

Sources: Author’s analysis of OAG Max (OAG, 1998) and OAG Max (OAG, 2012).

Airlines in 1998 that had failed or been absorbed through merger by 2012 were Northwest Airlines and TWA in the United States, Swissair and Olympic Airways in Europe, Brazil’s former flag-carrier VARIG, and Ansett Australia. Conversely, hundreds of new entrants were formed during the same period, of which 490 survived to 2012; in other words, about two-thirds of the airlines flying in 2012 had been formed in the preceding 14 years.

Both the increased size of individual carriers and the flux in competitors are reflections of deregulation. Historically, the airline industry was closely protected by governments eager to promote aviation for the sake of economic development, political symbolism, and strategic significance. In most countries, one or a handful of state-owned airlines operated state-authorized domestic networks and charged state-approved fares and air cargo rates. Even where the airline industry was in largely private hands – as in the United States – its operations were strictly controlled. International aviation, likewise, was regulated heavily. Deregulation, which began in
earnest in the United States in the 1970s, has altered the relationship between governments and the airline industry, and the result has been freer competition and greater dynamism. The diffusion of deregulation has been uneven, but generally more developed markets are more thoroughly deregulated.

A corollary of deregulation has been privatization, and that trend too is more fully articulated in richer countries. Among the dwindling number of countries in 2012 whose domestic markets were dominated by a single, state-owned airline were: Argentina (Aerolíneas Argentinas), Botswana (Air Botswana), Ethiopia (Ethiopian Airlines), Jordan (Royal Jordanian Airlines), and Laos (Air Laos). Most large markets, especially affluent ones, are now characterized by vigorous competition among mainly privatized carriers.

Prominent among the new players in the industry are low-cost carriers (LCCs) or budget airlines. Characterized by high-frequency operations over mainly short- and medium-haul sectors, LCCs typically fly one or two aircraft types, have minimal in-flight services, and rely heavily on online marketing and ticket sales. These and other strategies have tended to give LCCs a sizeable cost advantage over incumbent, full-service airlines. As a result they have gained market share in almost every market where the regulatory environment is favorable. More fundamentally, LCCs have been instrumental in democratizing aeromobility. In 2012, the largest LCCs ranked by weekly scheduled capacity were Southwest Airlines (USA), Ryanair (Ireland), easyJet (UK), gol Airlines (Brazil), and Lion Air (Indonesia) (OAG 2012). Each of these airlines is the biggest or second-biggest in its domicile in terms of seat capacity.

Nevertheless, at a global scale the airline industry continues to be dominated by legacy full-service network carriers. Table 2 ranks the largest airline enterprises, only one of which is an LCC, by revenue. The network carriers have the advantages of age – including brand recognition and control of key airport takeoff and landing slots – and size – especially economies of scale and scope. In an era of increased global traffic, the international reach of the largest airlines is an important competitive edge. As evident from Table 2, the leading carriers are now present in almost every major market – though Southwest Airlines is a clear exception.

Most of the airline enterprises listed in Table 2 comprise multiple carriers. The Lufthansa Group, for instance, includes Lufthansa, Lufthansa Cargo, Swiss, Austrian, and several other carriers that are subsidiaries of these four. The grouping of airlines reflects the advantages of size and the synergies that can come by reducing duplicate services among airlines with nearby hubs. Yet this arrangement also permits the separate airlines to retain distinct identities, which is important in an industry still redolent with nationalism and cultural preferences (e.g., the kinds of foods served in-flight).

A similar balancing act between the benefits of size and the benefits of independence has driven the growth of the airline alliances. The three largest passenger airline alliances are the Star Alliance (26 airlines in mid-2014), SkyTeam (20), and oneworld (14). Each incorporates airlines from around the world, including several major American, European, and Asian carriers each. Through schedule-meshing at major hubs (e.g., Chicago, Frankfurt, etc., for Star Alliance) and joint marketing, the alliances attempt to create an integrated service. Unlike the enterprises listed in Table 2, however, the alliances are not based on ownership, which permits them to be much more flexible in gaining and losing members.

Alliances give their members a degree of spatial coverage no single airline can match. In 2012, for instance, the Star Alliance network comprised nonstop links connecting nearly 5600

<sup>b</sup>IAG is the parent corporation for two major airlines, British Airways and Iberia, as well as the Spanish low-cost carrier Vueling.

<sup>c</sup>LATAM Group is the parent corporation for LAN of Chile and TAM of Brazil.

Sources: Air Transport World (2013); author’s analysis of OAG (2012).
city-pairs – or about one of every six city-pairs linked by any airline, more than five times the number of United, its largest single airline. Even more important, United – as large as it was – had a very limited presence outside North America, but through alliance partners such as Ethiopian Airlines and Singapore Airlines, the reach of the American giant extended well beyond the gateway hubs of distant regions.

Nevertheless, hubs remain vital in mediating contemporary air traffic patterns. Despite the many technological, regulatory, economic, and organizational changes that have transformed the airline industry, its operations are strongly concentrated in hubs. In the case of Ethiopian Airlines, for instance, 63% of all of its flights arrived at or departed from Addis Ababa Bole International Airport in 2012 (OAG 2012). United Airlines was less singularly focused, but 74% of its flights had as an endpoint Chicago, Washington, San Francisco, or Los Angeles (OAG 2012).

Conversely, low-cost carriers often emphasize point-to-point services rather than connections via hubs, as indicated by graph theoretic measures such as the gamma index (Taaffe, Gauthier, and O’Kelly 1996). Based on the number of vertices (i.e., cities served) and edges (i.e., nonstop routes), the gamma index compares the actual extent of network coverage to the theoretical ideal of a pure point-to-point network, which in an airline context would mean a nonstop route from each city to every other city in the network. Such an ideal would yield a gamma index of 1.00, but in reality Southwest Airlines has an index of 0.37. In other words, the degree to which its network is focused in particular cities differs markedly from United (0.04) or Ethiopian (0.06), but is even more distinct from the point-to-point ideal.

For the global air passenger network (all carriers combined) in 2012, the gamma index was 0.01, a remarkably low value that attests to continued concentration in hubs, but also several constraints on network development. These include technical limitations on aircraft range, uneven economic development, and the many remaining political and regulatory barriers that continue to thwart network expansion. As an example of the latter, in 2012 Ethiopian Airlines had only six nonstop cross-border routes to neighboring countries, despite the fact that its neighbors had a combined population of more than 90 million. These constraints are almost certain to ease in aviation’s second century. The upward potential for further air traffic growth is vast.

**Containing the future costs of air transportation**

For a growing share of the world’s population, aviation confers a remarkable degree of spatial freedom, but air transportation also carries formidable costs. The relative importance of these costs varies depending on the scale of one’s analysis. At the local scale, people who live near major hubs are most frequently concerned about aircraft noise. Those who live away from airports are more likely to be concerned with greenhouse gas (GHG) emissions and the role of aviation in global climate change. Containing these costs will be a daunting challenge.

With respect to both issues, great strides have been made in improving the performance of individual aircraft. For instance, the Boeing 787 is substantially quieter and far more fuel-efficient (i.e., producing fewer GHGs) than similar-sized aircraft of a generation ago. Yet those gains are partially offset by traffic growth (Bowen 2013). Indeed, in today’s extremely competitive market, airlines are likely to pass on efficiency improvements in the form of lower fares and air freight rates.
Some have argued that biofuels or radically different aircraft designs (e.g., blended-wing bodies) might permit aviation to grow rapidly while reducing this sector’s environmental costs. Yet both of these alternatives face great obstacles (Bowen 2013). A biofuel that can meet a significant fraction of aviation demand at a competitive cost, that is carbon neutral, and that does not detract from the global food supply is a prospect somewhere over the horizon. And technological lock-in means that there is tremendous inertia behind the current designs in aviation, inertia which stems in part from the 40-year lifetime of the typical commercial aircraft.

Europe’s experience offers shorter-term solutions. First, its emissions trading scheme (ETS), applied on some flights from 2012, compels airlines to purchase carbon credits equivalent to emissions. The European ETS has been highly controversial, but such a market-based approach – especially if applied at the global scale – could be useful in compelling airlines to adopt technology and practices that will contain the growth of emissions (Bowen 2013). Second, some major European airports have chosen to restrict growth in ways that ultimately limit externalities. The UK government, for instance, has so far refused to authorize a third runway at congested Heathrow Airport, and a ban on night operations has been imposed at Frankfurt Airport.

Yet in low- and middle-income markets where the majority of people have yet to fly, it seems doubtful that such constraints will be freely adopted. As recently as 2005, only about 1% of Indians had ever flown (Bowen 2010); by comparison, more than 80% of Americans have done so (Transportation of the United States 2013). The developing world is now catching up, as evidenced by the changes in the rankings of the busiest routes (Table 1). And about half of the world’s top 20 airline enterprises are based in emerging markets (Table 2); in the late 1990s, only one was.

More rapid economic and population growth in markets such as China and India, combined with the diffusion of deregulation, suggest that the upward trajectory of aviation – with its many benefits and costs – will continue.

The airport is among the most important and controversial forms of land use. One hundred years after the world’s first commercial flight, which carried a single paying passenger across Tampa Bay in 1914, about 6000 people per minute were ascending from runways somewhere across the planet. And that number continues to spiral upward with the diffusion of “aeromobility” (Adéy, Budd, and Hubbard 2007) in a growing number of countries. With rising volumes of air traffic, the airport’s cultural, economic, political, and environmental significance will continue to climb too.

The earliest centers of aviation activity were airfields and seaplane bases. The Wright brothers’ perfection of the Flyer, for instance, occurred principally at Huffman Prairie, a rough field near Dayton, Ohio. Fixed infrastructure, at sites such as College Park near Washington, DC, and Croydon near London, accompanied the advent of regular services after World War I. Yet, even as aircraft grew in size and range, a substantial share of intercontinental flights arrived at and departed from seaplane bases which permitted long take-off runs for underpowered passenger planes and minimized infrastructure costs. In the 1930s, for example, Pan Am’s famous Clippers departed from seaplane bases such as Port Washington near New York City.

By the early post-World War II period, however, aircraft had so improved in performance and the nascent airline industry had gained such stature that airports with paved runways accommodating diverse landplanes became the principal gateways to the world’s airways. As airports grew in number and importance, they expanded in their footprints too. In 1948, for instance, New York International Airport (later John F. Kennedy International Airport) opened with seven runways as long as 9500 ft (2900 m); a generation earlier, the first airport to serve the city had begun operations in Newark with a single 1600 ft (500 m) runway.

Increased dimensions have been among the factors propelling airports away from urban cores. For cities served by two major airports, the newer one (e.g., Paris Charles de Gaulle, Narita International near Tokyo, São Paulo’s Guarulhos International) is almost invariably farther from the core than the older one (Paris Orly, Tokyo International (Haneda), and Congonhas respectively). And, for large cities with a single airport, it too is often the culmination of a steady outward progression. In Singapore, for instance, the first specifically commercial airport opened at Kallang in 1937, just outside the central business district (CBD). A new airport at Paya Lebar, located 10 kilometers from the CBD, opened in 1955, and then finally Changi Airport, at the northeast extremity of the island and 18 kilometers from the CBD, opened in 1980 (Bowen 2010).

Changi Airport also illustrates “terraforming” (Fuller and Harley 2004), a feature common
AIRPORTS

to some very large airports, especially in Asia. Changi is located almost entirely on reclaimed land, and the addition of space since 2000 for a planned third runway and massive new terminal has further distorted the city-state’s coastline. Other significant airports built in part or wholly on reclaimed land include Kansai International (Osaka), Hong Kong International, Incheon International (Seoul), Beirut International, and Nice Côte d’Azur among others. Elsewhere, airports have required the leveling of hills, the redirection of streams, and other changes to landforms.

In addition to space needs, another factor pushing large airports away from urban cores is the NIMBY response to environmental externalities, especially noise. Despite substantial improvements in the noise generated by individual jetliners, the increase in the number of flights and the spread of suburbs around once-distant airports have kept this issue at the forefront of aviation concerns. In response, airports have changed – to varying degrees – the way they operate. A notable example is Frankfurt, where since 2011 there has been a complete night curfew between 11 p.m. and 5 a.m. (aircraft noise is more annoying at night than during the day). Frankfurt is the busiest airport in the world with such a ban, but it is likely that more large airports – especially in Europe – will adopt similar restrictions. In the meantime, research suggests that, at least in some metropolitan areas, the burden of airport noise falls disproportionately on less well-off neighborhoods. Such neighborhoods are often found beneath a hub airport’s main landing and takeoff corridors, where land values are lower.

And yet the major commercial airport is also a vibrant source of economic activity. Geographers, economists, regional scientists, and others have documented the myriad benefits that accompany centrality in air networks. In particular, cities with good aviation accessibility tend to have disproportionately high shares of managerial and knowledge-intensive employment. Although the relationship between such jobs and air travel is obviously two-way (managers and knowledge workers fly more), careful statistical analysis makes clear that highly accessible cities have an advantage in attracting and growing these occupational categories.

The economic benefits of airports have fueled interest in the concept of airport-centered urban development in which the airport, rather than being on the periphery of a metropolitan region, is at its core. Sociologist John Kasarda coined the term “aerotropolis” to describe this phenomenon (Kasarda and Lindsay 2011). Although aerotropolises in various stages of development have been identified or proposed in regions around the world, the concept has been most fully embraced in East Asia and the Persian/Arabian Gulf. The speed of aviation growth in these regions provides ample scope for planning urban futures around new and expanded airports. Accordingly, the most celebrated examples of the aerotropolis concept include areas surrounding the main airports in Singapore and Dubai. In older air transportation centers, conversely, rather haphazard urban development typically already envelops established airports, precluding a form of integrated land use meant to optimize the economic effects of air accessibility.

Dubai certainly illustrates the potential for well-positioned cities and regions to harness aviation for economic development. The emirate’s air accessibility has been a catalyst for tourism, finance, retail trade, logistics, and other dynamic parts of its economy. And, in turn, Dubai has experienced faster traffic growth, both for air passengers and for air cargo, than almost any other large airport in the world (see Table 1;

Table 2). In 2010 Dubai opened the first stages of the new multibillion dollar Al Maktoum International Airport, which is located 45 km from the city’s older airport.

Yet the fortunes of airports are not solely the product of larger social or regional forces. Key airlines play a decisive role in determining whether an airport’s stature is rising or falling. Emirates Airline and Lion Air, for instance, have been instrumental in the growth of passenger traffic at Dubai and Jakarta, respectively. That is even more obviously the case among the world’s leading air cargo hubs, where the importance of Memphis International Airport, for instance, is almost singularly attributable to the success of FedEx.

Each of these airports – whether a passenger hub, cargo hub, or both – is a portal to a global economy dependent on the space–time convergence fostered by aviation. As globalization’s gateways, large hubs – especially new ones – feature vast terminals whose architectural extravagances are meant to make an impression in a world of mobile people and capital. For example, the luxuriant gardens and brisk efficiency of Changi Airport are emblematic of
Singapore. For other cities, too, the airport is an important arena of place-making. This is an ironic outcome given the perception of aviation as a technology that has rendered geography less important by shrinking space.

A further irony lies in the contemporary reality that a major airport is simultaneously an opening through which it is possible to travel far and fast and a carefully controlled checkpoint through which movement is tightly circumscribed. Via a nearby commercial airport, one can be in virtually any large city in the world within 36 hours. Yet the speed, accessibility, reach, visibility, and fragility of the air transportation system have made it central to key problems in the early twenty-first century, including terrorism and the spread of infectious disease. As a consequence, air travelers and air cargo are subject to varying levels of surveillance, probing, and in some instances exclusion.

Distinguishing between native and alien species is a key criterion in nature conservation, but both the distinction itself and policies based on it are contested. Such debates are profoundly geographical, hinging on questions of space, place, scale, and environment. They are important practically, because of the impacts of invasive alien species, and also conceptually, influencing how we categorize and value components of “nature.” In turn, this shapes environmental policies, conservation priorities, and social perceptions of the nonhuman biophysical world.

Defining the terms “alien” and “native” is challenging because the terms are socially constructed, emotive, and contested (Warren 2007). Discussions of definitions dating back 150 years have yet to produce consensus or consistent use. However, as commonly understood, native species are those that evolved in an area or colonized it naturally, whereas alien species are those that have been introduced beyond their natural range by humans, intentionally or otherwise. In a vernacular sense, native species “belong” in an area, whereas alien species do not. Other common terms for aliens are “non-native,” “exotic,” and “introduced,” respectively emphasizing such species’ unnaturalness, their distant place of origin, and the human agency involved.

Trade, travel, and migration have been altering the distributions of plants and animals throughout human history. Often this has been deliberate, involving the transport of crops, livestock, quarry species, garden plants, and pets, but in many instances it has been unintentional as seeds, animals, and organisms have been unwittingly carried in soil, ballast water, or cargo holds. While this has been happening for millennia, a dramatic increase in the rate and scale of such transport accompanied the period of European colonial expansion around the globe as imperial conquests triggered “ecological imperialism” (Crosby 1986). Rates of species redistribution then rose still further with the exponential increases in global trade and travel during the late twentieth century.

Most species translocated to new environments are unproblematic and some are highly beneficial for society. Indeed, alien species are integral to socioeconomic systems worldwide through their importance in agriculture, silviculture, horticulture, medicine, hunting, and the pet trade. However, a small minority of introduced species run amok in their new habitat. By outcompeting, dominating, disrupting, preying on, hybridizing with, or spreading disease among native species they can transform entire environments with profound and often irreversible ecological impacts. Furthermore, they can severely threaten agriculture, forestry, and water management, pose risks to human health, disrupt ecosystem services and cause significant cultural impacts. Worldwide, by one estimate, the costs in losses, damage, and control expenses are equivalent to 5% of global GNP annually. Numerous case histories are detailed by Simberloff (2013), but particularly infamous examples are rabbits in
Australia, zebra mussels in US waterways, and water hyacinth in Lake Victoria. Island biotas, in particular, have proved notoriously vulnerable to bio-invasions (frequently by ship-borne rats), as have anthropogenic habitats.

Consequently, biological invasions are sometimes cited as one of today’s four great ongoing global transformations, alongside (and interacting with) climate change, enhanced biogeochemical cycles, and land use change. It is hard to predict which introductions will become “problem species,” how soon, and in what ways, but the proportion that does so is low. Nevertheless, the impacts of this small minority are sufficiently serious to have generated strong policy responses nationally and internationally; over 40 international instruments address non-native species, notably the Convention on Biological Diversity (1992) and the Syracuse Charter (2009). Such policies are commonly designed to prevent, eradicate, contain or control alien species, and to preserve or re-establish native biodiversity and functions.

Although attempts to categorize species as native or alien began in the 1830s, concern about alien species is a modern phenomenon. Indeed, until the early twentieth century, the introduction of non-native species was actively encouraged, not least by acclimatization societies, for reasons of resource provision, environmental “improvement” and/or aesthetics. Today’s concerns are commonly traced to Charles Elton’s 1958 book *The Ecology of Invasions by Animals and Plants*. The inception of the subdiscipline of invasion ecology followed 30 years later, focused on understanding, predicting, and managing bio-invasions. Today, nativeness is widely considered to be a central organizing principle in conservation, and vast expenditure and effort is invested in campaigns against aliens. Whereas Elton himself saw a place for “exotic forms,” most conservationists now disparage all non-natives. This recent growth of anti-alien sentiment represents a rapid evolution in value judgments.

There are diverse motivations for preserving native species and resisting alien species. The ecological arguments for doing so relate to the functioning of ecosystems and the preservation of biodiversity. Although the arrival of new species can enhance biodiversity locally, globally the “great reshuffling” of species decreases it, prompting fears of ecological McDonaldization and the dawn of the “Homogocene” era as biodiversity is replaced with biosimilarity (Hettinger 2001). Economic arguments relate to the huge costs of controlling biological invasions, and there are ethical and aesthetic grounds for arguing that it is good and pleasing to preserve native biota, not least the moral case that humans bear a responsibility to reduce and reverse our negative ecological impacts.

Equally, there are many economic, social, cultural, philosophical, and pragmatic reasons why different individuals and sectors of society oppose controlling some or all introduced animals and plants. Attitudes toward native and alien species, and beliefs about appropriate management, flow from deeply held worldviews and philosophical commitments; anthropocentric, ecocentric, zoocentric (animal-focused), and biocentric perspectives lead to contrasting beliefs about the rights and wrongs of natives and aliens. Moreover, perceptions evolve through time, so that the “pests” of one generation become cherished native species in the next (e.g., red squirrels in the UK) (Smout 2011). The divergent nature and groundings of these pro- and anti-motivations help to explain why the attendant discourses are so passionately contested because the issues sit at the intersection of conservation science, ethics, values, public policy, and social perception.
Controversies

Debates surrounding definitions

Although the terms “native” and “alien” are often employed as binary opposites, they actually represent the endpoints of a complex continuum, making definition both difficult and contested. Rigorous definition is undermined by their essentially relative nature, both in time and space. The terms do not describe biological characteristics but dispersal history. Consequently, no species is inherently alien or native but only with respect to a particular environment at a particular moment, and the spatial and temporal boundaries of that environment can be constructed in many different and changing ways (Warren 2007; Boonman–Berson, Turnhout and Van Tatenhove 2014). For example, to be native, how long must a species have been present and within what kind and scale of space: ecological (e.g., ecosystem) or sociopolitical (e.g., nation, conservation area)? To be alien, from how far away must it have come? If a species was introduced in pre-history by indigenous people, should it be classified as alien or native? If a once-native species which has been lost is reintroduced, is it native (because it “belongs”) or alien (because it has been transported from another locale by human agency)? Such questions do not have scientific answers, and, in practice, they are answered in widely divergent ways. Choices about spatiotemporal scale critically affect classification (and hence management policies), yet scale is socially constructed, not naturally given. The native/alien paradigm is thus “not purely dependent on objective ecological criteria, but on the kind of time–space demarcations we use to identify origin or authenticity” (Hattingh 2001, 191). Since the continuum involves sliding scales, numerous intermediate terms exist such as “locally non-native,” “naturalized,” “archaeophyte,” and “neophyte.”

The definitional lines are blurred by instances in which species introduced centuries ago have become functionally native, an integral part of the food chain, such that their removal would be ecologically damaging. Some dub these “honorary natives,” an additional, imprecise category. Opinions also diverge about the degree to which genetic data should be used in applying native or alien status, and about what constitutes human agency in the arrival of non-native species; should it, for example, include anthropogenic environmental change which facilitates migration? A final, empirical, problem in classifying species according to origin is that, for many species, scientific knowledge about their status is partial and evolving.

More broadly, the concept of nativeness is criticized for being premised on a pre-Darwinian separation of human beings from nature. It only makes sense if anthropogenic species dispersal renders nature unnatural and can only operate if humans are excluded from it. Otherwise, logically, most of humanity would be classified as invasive aliens meriting eradication, so that saving nature would mean killing ourselves. It is also criticized for fossilizing nature by implying that it is static and timeless and by specifying a fixed and historically defined list of biota which may not suit future conditions.

Such considerations have generated critical questioning of the native/alien framework and its soundness as a basis for policy and management. Its defenders, however, argue that these objections apply to only a minority of marginal cases and that in most contexts there is sufficient clarity for the distinction to be useful and applicable (Simberloff 2013).

It is important to differentiate between “alien species” and “invasive alien species” (IAS). Difficulties have arisen from the elision of these two terms, and/or from the use of the former as a synonym for the latter, not only in policy and
popular discourses but sometimes in academic writing. In this way, all alien species become associated with negative impacts, creating a dualistic “native – good, alien – bad” narrative. This is inaccurate and simplistic, and has exacerbated some of the associated sociocultural debates.

Sociocultural debates

Policies designed to control IAS rest on justifiable ecological and economic foundations, but they often clash with cultural values. Whereas conservation science promotes native biodiversity, many people welcome exotic species because of their charismatic nature and their contribution to the overall richness of landscapes, wildlife, and human wellbeing. Some non-natives have even become cultural icons in their new settings, and are woven into people’s sense of place, such as Tuscany’s cypress trees and even the much-vilified Cane Toad in Australia. The lay public is often blind to the native/alien categorization, caring little about origins but greatly about “nature.” Campaigns to eradicate alien species can therefore be fiercely resisted. When popular perceptions of “cultural belonging” collide with scientific judgments that alien species do not belong ecologically, anti-alien policies can alienate the public on whose support conservation depends. Conflicting value systems can thus create incompatible convictions about the management of species, particularly about whether the preservation of one species can justify the killing of members of another. Opponents of eradication campaigns, especially animal rights activists, point out that it is humans, not the target species, who are responsible for their being in the “wrong” place. Such fault lines can create particularly acute tensions when they separate indigenous and nonindigenous groups. Opinions diverge widely on how to balance cultural preferences with conservation objectives.

A particularly vexed issue is the criticism that anti-alien policies are racist or eco-fascist, akin to ethnic cleansing. The racist critique has been extensively articulated, supported with historical evidence of the horticultural nativism promoted in Nazi Germany and with contemporary evidence that minority ethnic groups can feel threatened and insulted by ecological pro-native rhetoric (O’Brien 2006). Invasion ecologists dismiss this accusation, arguing that the motivation for resisting alien species is not an objection to their foreign origins but the desire to avoid negative impacts and to preserve distinctive, diverse communities; although native species can become invasive, the probability of damage from non-natives is far higher. But while conservationists may be entirely innocent of racism, the parallels between arguments for preserving “genetic integrity” in nature with those for racial purity in human communities are close; in both cases, foreign influence is portrayed as contaminating and threatening, and the rhetoric employed is often militaristic and inflammatory, especially in media coverage. The widespread use of “aliens” and “invasives” as interchangeable synonyms compounds this difficulty by erroneously implying that all introduced species are inherently problematic because of their foreign origins. This is exacerbated when native status is defined using political boundaries because this directly parallels nationalism; indeed, pro-native arguments are often overtly nationalistic. In the context of the pervasive intertwining of culture with nature, the argument that an anti-foreign stance is reprehensible in human affairs but benign when applied to nature is hard to sustain; “there are compelling arguments that nativist purism is undesirable in all spheres – politically, culturally and ecologically” (Peretti 1998, 189). Some therefore criticize the vocabulary of “aliens” as prescriptive and pejorative, and call for its
replacement with more descriptive and apolitical terms. These might be the older nomenclature of “pest” and “weed” which highlights impacts rather than origins, or simple temporal labels such as “long resident” and “newly arrived.”

Natives and aliens in a globalized, warming world

The ecological and economic arguments for exercising vigilant control over the import of new species are strong, and some countries, notably New Zealand, operate strict biosecurity policies. However, in the context of a hyper-connected world, it is unlikely that biodiversity preservation policies will restrain global free trade and most ecosystems worldwide already include many introductions. Millennia of anthropogenic species mixing cannot be undone, and will inevitably continue, so aliens are here to stay. Moreover, in many cultural landscapes, removing established aliens can harm ecosystem services and have unintended consequences (ecologically and socially). These realities lead some to argue that, because “resistance is futile,” established alien species should be adopted as natives and that the ecological value of “novel” or “hybrid” ecosystems should be recognized. A similarly pragmatic, positive response is the “LTL” approach – that we should Learn to Love alien species (Davis 2009) rather than waste resources on fighting unwinnable wars. But any reclassification of aliens as “new natives” further dilutes the native/alien distinction.

It is blurred still more by the prospect that global climate change will increasingly destabilize extant biotic distributions as current assemblages of native flora and fauna struggle to adapt to rapid climate change; non-native species may enhance ecosystem resilience, thus transforming aliens into allies. Anthropogenic climate change also raises new definitional dilemmas: for instance, do climate-driven migrations constitute benign range expansions or alien invasions? Most fundamentally, the difficulties and controversies associated with both defining and applying the alien/native distinction have led some to conclude that the classification itself is sufficiently flawed, nebulous, and unhelpful that it should be abandoned. Thus Chew and Hamilton (2011, 45) contend that “nativeness is a living fossil of an outmoded phytogeography.”

Such critiques date back to the 1960s but gathered pace from the 1990s as both social and natural scientists challenged the dichotomous framing and normative prescriptions of invasion ecology (Davis 2009; Rotherham and Lambert 2011), generating sharp exchanges in the literature. Notably, in 2011 when Mark Davis and 18 fellow ecologists argued in *Nature* that we should not judge species on their origins but adopt pragmatic policies better suited to a rapidly changing world, 141 invasion scientists wrote a strong rebuttal, rejecting the criticisms as being aimed at straw men. Simberloff (2013), the author of that response, argues that abandoning the distinction and surrendering to bio-invasion is overly pessimistic regarding our ability to control invasions because there have been many notable successes, and also naively optimistic about our ability to shape “novel ecosystems” beneficially while avoiding widespread problems. A thoughtful middle way through the polarized debate is charted by Shackelford *et al.* (2013) who suggest that the longer established a species is, the less significant a criterion its origin should be.

There is increasing agreement that applying the native/alien distinction in a dichotomous, dogmatic, and universal fashion is unreasonable and unsustainable, and that, instead, a discriminating and context-sensitive approach should focus on those species which pose the greatest risks, recognizing that few aliens are invasive, that
not all invasions cause significant harm, and that invasiveness, too, is a debated term. Notwithstanding the unpredictability of species’ future behavior, this targeted, impact-focused approach is the official basis of most conservation policy and practice; pragmatic realism often trumps principled opposition to non-natives, even to the extent, in certain contexts, of conserving aliens and controlling natives. Nevertheless, a belief that native species are superior because they rightfully “belong” pervades conservation and most invasion ecologists regard aliens as inherently undesirable. The fact that a species is alien is often prominent among stated reasons for controlling it, and the precautionary principle is deployed to justify calls for eradicating all newly detected introductions. In popular conservation discourses blanket vilifications of all alien species are common, employing stigmatizing terms like “junk species,” “ecological tumors” and “biological/genetic pollution.” Yet the implicit value claim – that natural equals good – equates to the naturalistic fallacy.

The importance of differentiating between change and harm, and between description and prescription, is often highlighted. Whereas change can be scientifically quantified, harm is socially constructed and value-laden. Similarly, while understanding the influence of human agency on today’s species distributions is unquestionably important for biogeographical explanation, policy prescriptions which rest primarily on such data have been widely criticized. The value judgments cannot be read directly from the science. Context is all; a species may have positive and negative impacts at different times and in different places. It is damaging behavior not alien status per se which poses a threat, and both aliens and natives can inflict serious ecological and economic damage.

Debates concerning the conceptual coherence and practical implementation of the native/alien construct are closely related to broader discussions about nature, naturalness, and the place of our own species in the “natural” world. They also intersect strongly with debates about ecological restoration and re-wilding. The period in which the native/alien framework has attracted growing critical scrutiny has, paradoxically, seen a steady reinforcement of that framework in conservation policy, and its rise to prominence in public discourse, demonstrating a disconnect between academic discourse, policy-making, and public debate. Because the Cartesian separation of nature and culture is so deeply engrained, polarities such as natural/artificial, authentic/fake, and native/alien are likely to persist.

Native and alien species may always be the focus of debate because of the multiple, competing values attached to them. Nevertheless, it seems clear that a framework in which all alien species are proscribed and all natives are sanctified is unsupportable, and that management prescriptions based solely on a species’ geographical origins are inappropriate and often counter-productive. But the potential for introduced species to cause significant damage argues for the inclusion of data about species’ origins in management decision-making, whether or not the contentious terms “alien” and “native” are retained.

Alliances and franchises

Eirik Vatne
Norwegian School of Economics, Norway

Definitions

The term “alliance” is commonly understood as a voluntary, cooperative arrangement among independent organizations or business firms. This can involve exchange, sharing, or co-development of production, distribution, and knowledge, and include contributions by partners of capital, technology, knowledge, and other firm-specific assets. An alliance can take the form of a dyadic relationship as seen in “strategic alliances” and “equity joint ventures,” or as multilateral relationships between many firms as observed in “networks of firms.”

The term “franchise” is understood as a relationship between two independent firms based on a contractual agreement. In this arrangement a franchisor grants a franchisee the right to operate a business venture in a specific manner, place, and timespan. In return the franchisee must pay royalties/fees to the franchisor. Franchising arrangements take two general forms, as product/brand name franchising still seen in some of the distribution systems for cars or soft drinks, or as business format franchising as often observed in restaurant or retail chains.

Terms like alliance or partnership are general, but ambiguous concepts including a wide variety of institutional forms of inter-organizational relationships. Franchise is a specific contractual-based form of business relationship. Both concepts belong to the multidisciplinary research field of inter-organizational relations (IOR).

Economic governance

The traditional economic approach to understanding the organization of economic transactions is to view firms as autonomous, atomistic entities forced to compete in a free, impersonal open marketplace. The selection of a transaction partner is only based on a price/quality measurement set by the competition in a spot market. In this world there is no need for collaborative arrangements between firms. Indeed, exchanges between firms other than “arms-length” market transactions can be seen as ways to circumvent the disciplinary impulses of competition, to create cartels and to achieve monopoly power.

In a more realistic world, free market transactions will often generate costs related to activities such as simply discovering what the price would be in the market. There could be a need to handle uncertainties and risks, a need for safeguarding or monitoring outsourced production – all actions that generate costs.

If the cost of handling a market transaction is higher than the cost of internal governance, the firm will choose to internalize the transaction and a hierarchical, bureaucratic governance form will be chosen. However, if the cost of internal governance is higher than the cost generated by a market solution, the activity will be outsourced and market governance will be chosen. The firm will either make a specific item or service internally (e.g., vertical integration), or buy it in an open spot market (e.g., vertical disintegration).
ALLIANCES AND FRANCHISES

Between these two generic forms of governance, we can identify different forms of collaborative arrangements. For a given activity, a firm can create an alliance and operate jointly with the help of partners. If this is the most cost-efficient way to organize transactions, a third governance form, the hybrid or network form of governance, is chosen.

Inter-organizational relationships

Ties in inter-organizational relationships are often enduring and of strategic importance for the firms entering into them. They are most often based on attempts to gain cost reductions through a division of labor between partners, to collectively gain scale economies or to innovate by sharing information and co-producing new knowledge. Occasionally collaborative arrangements could also be an attempt to achieve monopoly profit, but the IOR field is basically interested in the value adding and efficiency seeking arguments behind inter-organizational relationships.

Table 1 illustrates some aspects of inter-organizational arrangements along the continuum from fully integrated to pure market-based governance. As shown, the degree of integration and the institutional form chosen will vary according to the strategic importance of the resources controlled by other partners, the complexity and risk of sharing resources, the degree of embeddedness, the importance of legal rules and social norms as incentives and control mechanisms, and so on.

A strategic alliance is formed when two or several firms combine resources to develop a specific activity of strategic importance for both parts. This can include activities important for maintaining the core skills of firms, reaching specific business objectives, reducing significant risks, blocking a competitive threat, or developing future business opportunities. Strategic alliances involve activities related to the competitive core of the firm and are often extended in time. Consequently, the qualities of a partner and the selection process are important, over and above contractual safeguarding. Contract-based institutional forms in the upper part of the table are normally related to strategic alliances.

A franchise involves two partners, one dominant firm with ownership of a valuable product, trademark or knowledge, and a weaker partner paying a fee to be allowed to distribute a trademarked product or set up a business concept for a specific territory. Many franchisees can be related to one franchisor. An asymmetric balance of power normally exists in franchise arrangements, and activities taking place are often standardized and easy to control. A legal, contractual agreement therefore regulates and safeguards transactions organized as franchises.

The “system area” form of institutional governance is understood as a network of multilateral relationships with many partners involved. A mutual technological or territorial context is often an important explanatory factor for the appearance, shape, and governance of the partnership. A complex supply chain connected to a large firm is often dominated by the lead firm and inter-organizational arrangements are tight and formalized. An industrial district model comprises many smaller firms collaborating in a looser and more informal way.

In all these cases, we focus on collaboration between independent firms with the purpose of achieving some common objectives to create competitive advantages through the partnership. Flexibility in starting and terminating collaborative arrangements, serving specific purposes, is a crucial argument for alliances among firms.

The choice of organizational form of an alliance depends on the purpose of the exchange,

the degree of interdependence, and the strategic importance of the resources controlled by each partner. The specificity of investments needed to realize the exchange and the social and territorial embeddedness of the partners will also influence this decision. Some factors are specifically based on rational, short-term “economic” behavior; others are based on a specific context opening up for entrepreneurship, more complex interaction, and expanding interdependencies encouraged by a common culture for sharing and collaboration and as a consequence, collective production of externalities.

**Explaining inter-organizational relations**

A few theoretical approaches dominate the literature explaining the relational aspects of inter-organizational arrangements.

The transaction cost approach has already been introduced. The main idea is that a transaction in a free market could generate considerable costs caused by bounded rationality, opportunism among exchange partners, small number of exchange partners bargaining, and asymmetric distribution of information. Williamson’s approach (1979) stressed that the cost of transactions will increase if high transaction-specific investments are involved with low or no value in other use, the definition and performance of the transaction are ambiguous, and if the frequency of transactions is sporadic. Based on these elements, the transaction cost model will predict governance form. If investments are non-specific and uncertainty is low, market-based governance will be chosen. If transaction-specific investments are high, combined with high frequencies of transactions and high uncertainty, internalization is preferable. In situations where uncertainty and asset-specificity are at an intermediate level, a hybrid governance form will be chosen and alliances are preferred. This approach emphasizes cost minimization as the main reason why firms should enter into inter-organizational relations.

The resource-based view of the firm views a business organization as a bundle of resources understood as a set of tangible and intangible assets semi-permanently tied to the firm. Many resources are firm-specific, such as specialized production technology or knowledge bases. Firm-specific resources are scarce, difficult to imitate, often intangible, heterogeneous, and complex, and therefore unique without direct substitutes. They could be property-based resources such as machinery, patents, and trademarks, or knowledge-based resources such as organizational and technological capabilities. A firm’s access to unique resources and capabilities are the foundation for the firm’s competitive strength. A bundle of unique resources are part of the firm’s core skills and are protected through internalization. Unique resources controlled by other firms can also be mobilized through collaboration. The resource dependence theory analyzes such interdependencies. If the firm-specific resources in an alliance are complementary and combined, a division of labor can be developed between the partners. Collaboration thereby expands the possibility of deepening the core skills of each firm. Combining complementary core skills also expands the capacity to learn and thus to develop unique cross skills as a combination of the capabilities of the partners. In short, the resource-based view emphasizes value maximization through the sharing and exploitation of valuable resources, not accessible through the open market.

A third approach to exploring inter-organizational relationships could be called the network approach with a specific focus on embeddedness and local tie formations. A network is in general form a set of several actors directly or indirectly connected to each other through ties. Ties connect pairs of actors, some directly, others
indirectly through individual ties to a mutual actor. The structure of a network and the position or centrality of a specific actor is important and determines an actor’s connectivity. In this perspective the formation of inter-organizational relations is also seen as a consequence of socially embedded actions. The value of an actor’s connections can be summed up as the actor’s *social capital* – a form of capital that gives an actor access to information and resources not available through ordinary, open market relations.

An additional focus on *embeddedness* has been important. Economic actions are considered as structurally embedded in a sectoral, social, and territorial context. Repetitive relations among people and business partners generate an embedded logic of exchange different from “arms-length” market relations. A high degree of specialization and division of labor inside business networks will make necessary a high degree of adaptability, coordination, and control. Under such circumstances, behavior will be institutionalized, formed by local and social institutions, and governed by economic as well as social incentives and control mechanisms. An *untraded, relational asset* is created and embedded in local communities and in networks of enduring collaboration. Under such conditions, relations can be habitually based on trust and implicit and open-ended contracts.

**Firm relationships and geography**

In economic geography, the relational problem was earlier seen through a focus on regional economic growth explained in models based on agglomeration economies and external economies of scale. Here firms in a local economy are connected through input–output relations and technological and pecuniary interdependencies. Studies of the spatiality of industrial systems emphasized the content and structure of linkages between actors and how growth impulses diffuse through these relations. Still, the discrete relationship between individual actors of the system was seldom addressed. The same could be said about the early “geography of the firm” literature preoccupied with locational and spatial-behavioral patterns of the multi-regional enterprise as the unit of study.

Studies of “Marshallian industrial districts” emphasized localized, *flexible specialization* as an alternative organizational form to large-scale mass production (Fordism). In this model, a comprehensive specialization and division of labor combined with interfir interaction between small, local firms, are at the core of explanation. An additional focus on the importance of localized sociocultural and collective assets embedded collaborative arrangements in a territorial context. This territorial model of concerted inter-organizational relationships was suggested to be flexible, cost-efficient, and well adapted to a turbulent business environment under constant transformation.

A transaction cost approach was a starting point for the “Californian School of External Economies.” Market and technological uncertainties combined with increasing international competition forced large corporations to restructure. The subsequent disintegration and outsourcing of activities created a complex system of exchanges and interdependencies that could increase transaction costs. Agglomeration of activities could, on the other hand, help to reduce transaction costs. In this model, routinized production tasks would relocate to low-cost locations and be governed through market or hierarchical transactions. More complex tasks with a need for intricate combinations and coordination of firm-specific resources would create a prerequisite for interfir collaboration.
and agglomeration of these activities. This simple linkage-transaction cost model was later extended to include other elements of community based external economies and spillovers important for the development of “untraded interdependencies.”

Other studies, based on Porter’s cluster concept, examine spatial clusters of economic agents. A comprehensive division of labor, local specialization, collaboration and rivalry, production of externalities, local institutions, and the influence of culture and politics are all part of a socioeconomic context that can create competitive strength for firms embedded in such environments. In this body of research, localized inter-organizational exchanges and alliances are highlighted as strategically important for firms.

The literature on “learning-regions,” “innovative milieus,” or “regional innovation systems” also emphasizes collaborative initiatives and proximity among actors as important for the formation of new knowledge. Region-specific assets such as institutionalized social conventions, habits, trust-based relations, and social control mechanisms, all embed the economic agent in a sociocultural context. This context minimizes transaction costs and facilitates diffusion of information and a division of labor among independent firms, opening up for trust-based interaction and sharing of firm-specific resources, facilitating interactive learning processes and joint development of support organizations and collaborative initiatives. Region-specific assets facilitating collaboration can be seen as relational assets – untraded, intangible, and localized assets that create an atmosphere for a trust-based, cost-efficient interaction among firms open for learning and knowledge exchanges.

In these approaches, economic geographers study relations between firms in the context of a territorially embedded network of producers – as systems of relations rather than discrete relations among few actors. Geographers’ specific contribution to the IOR field is therefore a deeper understanding of the importance of a socio-spatial context as a container of relational assets facilitating the formation of trust-based, inter-organizational relationships. Localized, relational assets can influence the flexibility, efficiency, and innovativeness of collaborative arrangements and the competitive strength of individual firms. This contribution relates first and foremost to the “system area” and “network perspective” of inter-organizational relations. Several of these aspects are further developed under other headings in this encyclopedia – see cross-references below.

A strategic alliance or franchise arrangement is formed when two or a few firms join resources to develop a specific activity of strategic importance for at least one part, normally for all. Here dyadic relationships or partnerships among a small number of firms are under investigation. Studies of these forms of inter-organizational relations are uncommon in economic geography.

In the literature on innovation and clusters, an important empirical result has been the observation that the region or local milieu is not necessarily the most important arena for accessing unique information or developing new knowledge. Pipelines to global resources are often as important as local dynamics. Access to extra-local, untraded resources is often secured through strategic alliances as a “research consortia” for firms or membership in “communities of practice” for individuals.

In the literature on the geography of transnational corporations (TNCs), strategic alliances such as “joint ventures” or “technology financing” are important arrangements used by the TNCs to access and utilize unique resources worldwide or to share risks and investments in capital intensive and scale sensitive activities. To
penetrate new markets and countries, TNCs need access to specific knowledge of local regulations, institutions, and markets or a fast access to production capacity or a domestic distribution system. A strategic alliance or a franchise arrangement with a host country firm is an attractive option compared to an internalized, costly, and risky expansion into new territories. The geography of TNCs also seems to show that certain cities with a heterogeneous resource endowment and interconnections to other hubs of resources are the preferred location for collaborative initiative.

In the literature on the geography of retail or service industries, franchising is seen as a strategy to achieve scale economies through rapid expansion of production and markets, based on standardization and replication of practices. Reasons why firms choose to join forces with a franchisee can be a general resource scarcity problem under rapid expansion, an agency problem, or a need to access relational capabilities such as the social capital of a franchisee and knowledge of local specific circumstances.

**Further reading**

The alternative food movement refers to recent social movements made up of diverse activists, organizations, institutions, and enterprises aiming to create food systems that differ from industrial agriculture and the industrial food system. There is considerable diversity in what is labeled as “alternative” (Venn et al. 2006). Additionally, it is more accurate to discuss alternative food movements (AFMs) rather than a singular one. Indeed, creating “convergence in diversity” among AFMs remains important political work (Amin 2011).

Agriculture in what is now the industrialized world was continuously revolutionized in the 1800s and 1900s as production for use value gave way to production for exchange value. Machinery, synthetic fertilizers, synthetic pesticides, hybrid or GMO organisms, and fossil fuels now form the backbone of industrial production. The origins and widespread adoption of these inputs have been explained as part of the treadmill of production and substitution of capital for ecological processes that is set in motion through the competitive and accumulative dynamics of capitalism (Cochrane 1979; Goodman, Sorj, and Wilkinson 1987). Industrial agriculture is supported by vast marketing, infrastructural, knowledge, and ideological systems. The rhetoric of feeding the world, called productionism, is commonly used to justify industrial agriculture, but this ignores the true causes of hunger (Lappé et al. 1998). The industrial food system that extends beyond primary production – transportation, processing and packaging, distribution, retail, and disposal – is intensive in fossil fuel use and substantially transforms most raw food ingredients into processed food by applying vast amounts of energy and anthropogenic chemicals (postharvest pesticides, preservatives, additives for coloring and taste, etc.).

Actors within AFMs argue that there is much wrong with the industrial food system. While generally productive on a per acre basis and good at provisioning food to a minority of the world’s population (those with adequate incomes and entitlements, largely in the industrialized world), critics draw attention to the industrial food system’s considerable and widespread negative consequences or “externalities” for society, public health, food access, workers, food sovereignty, gastronomy, environment, soil, climate, and animal welfare. AFMs thereby seek to change the industrial food system or create a new one. AFMs use a wide array of strategies, with most attention focused on creating alternatives to the industrial food system rather than using the state apparatus or transnational institutions to reform it. As countermovements, AFMs have generally arisen in places where the industrialization of agriculture and the food system has the longest history or in places experiencing rapid industrialization of the food system, although AFMs vary largely due to the positionalities of the actors creating them.

Since the early days of promoting alternative agriculture, many organizations – local, national,
and transnational – have come into existence. AFMs have expanded greatly from a focus on holistic production techniques and soil health to include paying farmers and farmworkers better, expanding food access and creating more just food systems, and increasing local or national control over the means of production. One process that has led to divergence within AFMs is codification of the movement’s values into formal state regulation (Guthman 2004) as this has led to critiques of “conventionalization” and new movements that seek to address issues which codification excluded.

Geographers and allied scholars have been central to a number of scholarly debates about AFMs. These debates include the extent to which alternative food truly offers an alternative, especially to neoliberal ideology and politics (Galt, Gray, and Hurley 2014; Guthman 2004; McClintock 2014; Pudup 2008); alternative foods’ accessibility both economically and culturally (Alkon 2012; Guthman 2008, 2011); and the wellbeing of farmers and farmworkers in these systems (Allen 2004; Brown and Getz 2008; Galt 2013; Jarosz 2008). There are also debates concerning specific AFMs, which show considerable diversity.

Holt-Giménez (2011) provides a typology for making sense of the diversity of AFMs. He categorizes them as reformist, progressive, and radical, each being different responses to the current neoliberal food regime. The reformist trend aims to change the industrial food system through consumer choice and through persuasion, as manifested in voluntary corporate sustainability and accountability standards. This includes the corporate mainstream faction of fair trade and organic food. The progressive trend focuses on citizen empowerment, especially through community food systems and food justice. The radical trend, increasingly framed by the concept of food sovereignty, focuses on the democratization of the food system in favor of the poor.

Organic agriculture

The roots of organic agriculture can be traced to Westerners rediscovering the wisdom and practices of peasant and indigenous producers as the industrialization of agriculture proceeded. The biological provisioning of crop nutrients and importance of soil health was a major early focus of pioneers. Rudolf Steiner in the penultimate year of his life, 1924, gave eight lectures laying out a vision or hints of an alternative agriculture that would “heal the earth.” This was arguably Europe’s first formal organic agriculture course and gave rise to what was later called “biodynamic agriculture” and “organic agriculture” (Paull 2011, 64). Around the same time, Sir Albert Howard, another progenitor of the organic agriculture movement, worked in India where he observed traditional farming and came to favor many of their practices over those promoted by Western agricultural science (Howard 1976/1940). Lady Eve Balfour (1944) played a foundational role in the early organic agriculture movement, establishing in 1939 the Haughley Experiment (the first long-term study of organic and conventional agriculture), and promoting organic agriculture for the postwar period by founding and leading the Soil Association, an international organization to promote sustainable agriculture, in 1946. In the United States, Jerome Rodale was an early advocate for organic agriculture, starting the magazine Organic Farming and Gardening in 1942 and the Rodale Institute, which promotes research on organic farming, in 1947. Another important landmark was Rachel Carson’s Silent Spring (1994/1962) which, in addition to helping catalyze 1960s environmentalism,
spurred public interest in organic agriculture and food.

According to the International Federation of Organic Agriculture Movements (2014), organic agriculture “is a production system that sustains the health of soils, ecosystems and people. It relies on ecological processes, biodiversity and cycles adapted to local conditions, rather than the use of inputs with adverse effects. Organic Agriculture combines tradition, innovation and science to benefit the shared environment and promote fair relationships and a good quality of life for all involved.” Organic food has moved from a local system of exchange between farmers and their direct consumers to oversight through organic farming organizations and eventually to institutionalization of oversight through national and international legislation which depend upon third-party certifiers to enforce the standards (Campbell and Liepins 2001; Guthman 2004). Currently in the industrialized world, most organic food is sold through mainstream channels. In the United States in 2010, mass market retailers sold 54% of organic food while natural food retailers sold 39% and the remaining 7% was mostly through direct marketing (Organic Trade Association 2014).

There has been considerable growth in certified organic farming and food in the last few decades. In the United States in 1990, organic food sales were worth $1 billion. In 2010 they were worth $26.7 billion, accounting for 4% of US food sales (Organic Trade Association 2014). Worldwide, organic sales reached $54.9 billion in 2009, and the countries with the highest per capita consumption are Switzerland, Denmark, and Luxembourg. In 2011 there were 1.8 million certified organic producers worldwide growing on 37.2 million hectares of certified agricultural land, up from 11 million ha in 1999. One-third of this land and more than 80% of producers are in developing countries, while more than 90% of consumption is in North America and Europe (Research Institute of Organic Agriculture (FiBL) 2014), which means the majority of certified organic production in many developing countries is for export. However, it is important to recognize that millions of producers in developing countries are “organic by default” – not certified, but using production practices reliant on biological/ecological processes rather than synthetic chemicals – since they cannot afford synthetic inputs or these inputs make little sense within subsistence-oriented production systems. It is in these kinds of production systems that implementing organic practices often results in considerable improvements in yields as well as other agroecosystem benefits (Hine, Pretty, and Twarog 2008).

Fair trade

Food-related fair trade as it exists today started in 1988, when an indigenous farmer cooperative in Oaxaca, Mexico, asked the Dutch development organization Solidaridad to increase its purchasing of coffee to give the coop access to mainstream European markets in volumes that would improve the small farmers’ incomes. Solidaridad created a label, Max Havelaar, which could be placed on any brand of coffee sold in any store, certifying that the farmers had received a premium price that was a “fair return.” This was when “alternative trade” became fair trade, with the focus shifting from handicrafts to food goods and into mainstream marketing channels (Jaffee 2007). The Max Havelaar label’s success led to the establishment of national fair trade groups in western European countries. Informed by dependency theory and related critiques, fair trade included a stable price for farmers and support for farming communities’ development through a fair trade premium. Sales
ALTERNATIVE FOOD MOVEMENT

Volumes increased rapidly in Western Europe. In 1997, the nationally based fair trade organizations created a worldwide umbrella certifier, Fairtrade Labelling Organizations International (in 2004 this organization split into Fairtrade International, which sets standards and supports producers, and FLO-CERT, which certifies producers and traders). In the United States, Equal Exchange, formed by activist entrepreneurs in 1986, established relationships with producer cooperatives in Latin America, Africa, and Asia, but it was not until 1999 that formal fair trade certification reached the United States through Transfair, which also coordinated efforts in Canada and Japan (Jaffee 2007).

The 1990s saw an expansion of fair trade sales and products covered by the certification. Fair trade cacao, bananas, tea, sugar, honey, rice, and orange juice appeared, mostly in European markets. Currently, 1.35 million farmers and workers participate in fair trade as covered by Fairtrade International, and there are 1149 producer groups involved. Fair trade sales recently expanded into new countries, including Kenya, Philippines, Argentina, and Lebanon, so that fair trade products are now sold in 125 countries, even though the bulk of sales remains in Europe (Fairtrade International 2013). In 2012, Fair Trade USA withdrew its membership from Fairtrade International, largely due to a disagreement about the types of producers that should qualify for fair trade. Fair Trade USA wanted to certify plantations in crops like coffee that had historically only been certified if production was organized through farmer cooperatives. Important questions remain about who should be allowed to set the terms of what is fair (Bacon 2010) and the inclusion of plantations (Besky 2013).

Civic agriculture and sustainable community food systems

A rapidly growing part of AFMs involves civic agriculture and sustainable community food systems. Civic agriculture refers to “community-based agriculture and food production activities that not only meet consumer demands for fresh, safe, and locally produced foods but create jobs, encourage entrepreneurship, and strengthen community identity” (Lyson 2004, 2). A strongly related term is a sustainable community food system, “a collaborative effort to build more locally based, self-reliant food economies – one in which sustainable food production, processing, distribution and consumption is integrated to enhance the economic, environmental and social health of a particular place” (Feenstra 2002, 100). In today’s parlance, these concepts are often referred to as “local food,” but this term can ignore embedded relationships when focusing only on distances between production and consumption.

Within these umbrella terms, there are a number of specific initiatives, from the globally connected – like Slow Food – to nationally and regionally linked – food policy councils, farm-to-school programs, and farm organizations representing smallholders – to the very locally specific – community gardens, farmers’ markets, community supported agriculture (CSA), and corner-store conversions and community markets. These variously scaled efforts are expanding rapidly, and new innovations within them are constantly being created (Venn et al. 2006). Since many of these efforts focus on community, environment, and connectedness, they often maintain more of the holistic values of the early organic agriculture visionaries than organic certification. Yet, there remain important questions about whether these alternatives allow for farmers to maintain economic viability
and farmworkers to be adequately compensated within a broader capitalist political economy (Galt 2013).

**Food justice**

Some of the most innovative initiatives to come out of building civic agriculture and sustainable community food systems belong to the food justice movement. The food justice movement “combines an analysis of racial and economic injustice with practical support for environmentally sustainable alternatives that can provide economic empowerment and access to environmental benefits in marginalized communities” (Alkon and Agyeman 2011, 6). The movement is informed by critiques of the ways that people of color and underserved communities experience the inequalities of the food system. This often manifests as a grassroots-led transition to a more equitable and sustainable food system, often within regions that have experienced the most “demarcated devaluation” occurring from the disinvestment of private capital and state support from urban areas through practices of institutional racism, such as redlining and deed covenants (McClintock 2011).

Food justice movement activists and organizations typically use the tools of civic agriculture and sustainable community food systems combined with antiracist practices. Thus, communities and organizations in Milwaukee, Wisconsin, Detroit, Michigan, and the East Bay Area of California, have been at the forefront of many food justice innovations, creating new sustainable production systems and forms of exchange serving underserved communities, providing education, and spurring greater involvement in the food system. These efforts have created higher levels of community autonomy and empowerment for groups and individuals involved (Bradley and Galt 2014; White 2011). However, there are critiques about food justice efforts that arise from the “colonial impulse” of white, upper- and middle-class activists who want to “bring good food to others” (Guthman 2008). Others have expressed concerns about food justice work underpinning the retreat of the state (McClintock 2014) and food justice organizations’ heavy reliance on markets (Alkon 2012).

**Food sovereignty**

Food sovereignty is a rapidly growing international movement that seeks to address the root causes of inequality and hunger in the world. The main goal is “democratization of the food system in favor of the poor and underserved” (Holt-Giménez 2011, 324). As envisioned by La Vía Campesina (1996), “Food sovereignty is the right of each nation to maintain and develop its own capacity to produce its basic foods respecting cultural and productive diversity.” As a movement, it stands in opposition to neoliberalism (especially the inclusion of agriculture and food in World Trade Organization (WTO) agreements) and the ever-consolidating control of large-scale agribusiness and food industry firms. In doing so, it pursues self-determination for farm workers, peasants, and family farmers by protecting their livelihoods, worldviews, and access to productive resources.

Over the last two decades, the concept has become widespread in its use, being invoked and operationalized by various groups around the world, including Brazil’s Landless Workers’ Movement (Movimento dos Trabalhadores Sem Terra, MST) and the Basque people of northern Spain and southwestern France (Masioli and Nicholson 2010). In these circumstances, food sovereignty as a concept helps groups to give coherence to historical struggles. Yet, there
remain considerable and productive debates about the scales at which it is to be implemented and how various tensions between regionally autonomous self-provisioning systems and embedded trade might best be worked out (Gibson-Graham 2006). As an example of resocializing the economy to make it serve the needs of people and the planet, the food sovereignty movement stands at the forefront (Patel 2010). As such, food sovereignty may act as a foundation for uniting AFMs since it explicitly critiques the power relations shaping the world’s food system.

References

The long-standing association between anarchism and geography can be traced across the historical landscape from the towering peaks of heightened association to the low valleys of disconnection and ambivalence. Yet if Earth writing is to be understood as “a means of dissipating … prejudices and of creating other feelings more worthy of humanity” (Kropotkin 1978/1885, 7), then it seems obvious that anarchism has much to contribute to the discipline of geography. Geographical writings from influential anarchist philosophers such as Peter Kropotkin and Élisée Reclus blossomed during the late nineteenth century, when their work contributed much to the intellectual climate of the time. Following their deaths in the early twentieth century, engagement with their work started to fade, yet the lasting impact of these visionary thinkers continues to be felt within contemporary geographical theory, influencing the ways geographers think about diverse topics from ethnicity and “race” to social organization and capital accumulation, to urban and regional planning, to environmentalism and, perhaps surprisingly, even anticipating some of the key precepts of the recent “more-than-human” turn. As realpolitik and the quantitative revolution took hold of geography during the war years of the early twentieth century, the anti-authoritarian vision of Reclus and Kropotkin seemed to be pushed beyond the bounds of what were considered to be geographical concerns. Yet, as geographers rediscovered their bearings for social justice in the early 1970s, anarchism came back into the disciplinary view and was afforded serious consideration by academics advocating for what has since become known as “radical geography.” The publication of Antipode announced a new ethic for human geography, one that refused the stochastic models, inferential statistics, and econometrics that dominated geographical proceedings at the time, subverting this trajectory with qualitative approaches that placed the lived experiences of research participants at the center of its methodological focus. Anarchism played a key role in formulating this epistemological critique, where early engagements took inspiration from Kropotkin in arguing that radical geography should adopt his anarcho-communism as its point of departure.

The publication of a special issue of Antipode on anarchism in 1978 demonstrated the ongoing influence of anarchist thought and practice on geography, as well as geography’s influence on anarchism. It was not just Kropotkin’s sociospatial contributions to human liberation that were celebrated in the issue, as Reclus also received accolades for the importance of his geographical vision for freedom. A reprinting of Kropotkin’s (1978/1885) essay “What Geography Ought To Be” was meant to further demonstrate the enduring relevance of his work, while Murray Bookchin’s (1978/1965) “Ecology and Revolutionary Thought” was also reprinted, showing how the anarchism of supposed nongeographers had a significant bearing on the radical geographical thought that was beginning to make itself known. Around the same time, the newsletter of the Union of Socialist Geographers published a themed section on anarchist
ANARCHIST GEOGRAPHY

discussions that took place at the University of Minnesota in 1976. These developments were indicative of a sense of optimism for anarchist ideas to reinvigorate a collective geographical practice that was increasingly turning its attention toward social justice. Yet, as the neoliberalism of the 1980s and 1990s began to take hold of the world’s political economic compass, anarchist engagements by geographers dwindled and were largely overshadowed by Marxist, feminist, and incipient poststructuralist critiques. Nonetheless, the decade of Reaganesque and Thatcherism did see the publication of Bookchin’s (2005/1982) *The Ecology of Freedom*, wherein he advanced an anarchist critique of nature’s domination by social hierarchy. The beginnings of some introspective reflection on geography’s colonial past and its enduring state-centricity also emerged at that time, where the foundational works of Halford Mackinder, Ellen Churchill Semple, Ellsworth Huntington, Isaiah Bowman, and Thomas Holdich were taken to task by anarchist geographers who drew on Kropotkin and Reclus in calling for the abandonment of our inherited disciplinary prejudices. The 1990s fared slightly better, where a special issue on anarchism was organized for the short-lived journal *Contemporary Issues in Geography and Education*, while *Antipode* continued to publish the work of geographers who developed new, anarchist-inspired theories related to counter-hegemonic struggle and resistance to capitalism. More recently a new generation of geographers has begun actively transgressing the frontiers of geography by situating anarchism at the center of their practices, theories, pedagogies, and methodologies, (re)mapping the possibilities of what anarchist perspectives might yet contribute to the discipline (Springer 2013). This anarchist (re)turn comes as capitalism’s house of cards begins to collapse under its own weight, where intensifying neoliberalization, deepening financial crisis, and the ensuing revolt push anarchist praxis back into widespread currency both inside and outside of the academy.

From the vantage point of the present, it is important to recognize that the reduction in direct engagements with anarchism among academic geographers since the time of Reclus and Kropotkin in no way signals the decline of anarchism as a relevant political idea, something that is now actively being rediscovered by the new batch of anarchist geographers. Instead, it speaks to one of the core tenets of anarchist praxis, centered as it is on the politics of prefiguration, where anarchism lives through the organization and creation of social relationships that strive to reflect the future society being sought. Prefigurative politics is the recognition that to plan without practice is akin to theory without empirics, history without voices, and geography without context. In other words, prefiguration actively creates a new society in the shell of the old. So, while academic geography became obsessed with the trappings of positivism, and later the class-centric economism of Marxism, the geography of anarchism simply left the academy for the greener pastures of practice: on the streets as direct action, civil disobedience, and black bloc tactics; in the communes and intentional communities of the cooperative movement; amid activists and a range of small-scale mutual aid groups, networks, and initiatives; as tenant associations, trade unions, and credit unions; online through peer-to-peer file sharing, open source software, and wikis; among neighborhoods as autonomous migrant support networks and radical social centers; and, more generally, within the here and now of everyday life. In some ways what we are witnessing today, an even deeper appreciation for anarchism than we’ve ever actually seen within the academy, is the result of a century of struggle. Reclus
and Kropotkin were not able to combine their anarchism with their geographical scholarship as they might do today, but not necessarily for lack of trying. Kropotkin was offered an endowed chair at Cambridge University, but turned it down because it came with the stipulation that he give up his political commitments. Nonetheless, the closer we move toward the present moment, the more the literature demonstrates an appreciation for praxis, where the result has been a burgeoning consideration of both sides of the theory/practice divide.

Although anarchism is frequently portrayed as a symptom of mental illness and a synonym for violence and chaos, rather than as a valid political philosophy, such sensationalism is a ploy by its detractors. While violence has informed some historical and contemporary anarchist movements, and it is difficult to deny this constituent, anarchism has no monopoly of violence; compared to other political creeds (e.g., nationalism or monarchism), anarchism is decidedly peaceful. The word “anarchy” comes from the Greek ἀναρχία, meaning “without rule,” or against all forms of “archy” or systems of rule (i.e., patriarchy, oligarchy, monarchy, hierarchy, etc.). Violence can be seen as antithetical to anarchya precisely because all violence involves a form of domination, authority, or rule over other individuals. Violence is thus a particular form of “archy,” and not anarchya at all. Similarly, anarchism refuses chaos by creating new forms of organization that break with hierarchy and embrace egalitarianism. In fact, the symbol for anarchya is meant to suggest that anarchya is the mother of order, an idea advanced by Pierre-Joseph Proudhon, the first person to identify as an anarchist. Anarchism accordingly represents an unwavering political commitment that seeks to break from hierarchical structures and unfasten the bonds that facilitate and reproduce violence. It is the notion that our shared morality should not be premised on the prejudices of life as it is currently lived through a politics of consensus that is antagonistic toward difference, but rather on a version of empathy that embraces our ultimate integrality to each other and to all that is. Such a process entails the rejection of all the interlocking systems of domination, including capitalism, imperialism, colonialism, neoliberalism, militarism, classism, racism, nationalism, ethnocentrism, sexism, Orientalism, ableism, genderism, ageism, speciesism, homophobia, transphobia, organized religion, and, of course, the state. Simon Springer (2012, 1607) has accordingly defined anarchist geographies as “kaleidoscopic spatialities that allow for multiple, nonhierarchical, and protean connections between autonomous entities, wherein solidarities, bonds, and affinities are voluntarily assembled in opposition to and free from the presence of sovereign violence, predetermined norms, and assigned categories of belonging.”

Such a holistic interpretation of anarchist geographies was first laid down by Reclus (1876–1894), whose primary contribution to the discipline was the emancipatory vision detailed in The Earth and Its Inhabitants: The Universal Geography, wherein he conceptualized a coalescence between humanity and the Earth itself. Reclus sought to eliminate all forms of domination, which were to be replaced with love and active compassion between all animals, both human and nonhuman, as a process of humanity discovering deeper emotional meaning through acknowledging itself as but one historical being in the flowering of a greater planetary consciousness. Kropotkin (2008/1902) did much to contribute to such a vision as well with his monumental Mutual Aid: A Factor of Evolution, where in partial reply to the social Darwinism of his time, he observed mutual aid as cooperation among plants, animals, and humans, including mutual forms of assistance between
ANARCHIST GEOGRAPHY

species, thereby shedding light on a grander sense of agency, foreshadowing recent theorizing within the domain of more-than-human geographies. Anarchist ideas were from the outset explicitly geographical, differing greatly from the industrial imagination of Marxists, as emphasis was placed on decentralized organization, rural life, agriculture, and local production, which allowed for self-sufficiency and removed the ostensible need for central government. Anarchists were also rooted in a view of history that has been confirmed by the anthropological record, where, prior to recorded history, human societies established themselves without formal authority in ways that rejected coercive political institutions. Although early views of anarchism have been critiqued on the basis of their naturalist assumptions, we would also do well to pause and reflect on the implicit naturalizing of hierarchical structures that suggest that hierarchies necessarily arise as societies grow, rather than analyzing the patterns through which authority is actually constructed and thinking through the innumerable anarchist alternatives that could be and are being developed.

In understanding anarchist geographies, we should begin by noting that anarchism is not about drafting sociopolitical blueprints for the future, nor does it trace a line or provide a model. Prefiguration should not be confused as pre-determination, as anarchists are more concerned with identifying social tendencies, where the focus is on the possibilities that can be realized in the here and now. Anarchism accordingly points to a strategy of breaking the chains of coercion and exploitation by encompassing everyday acts of resistance and cooperation, where examples of viable anarchist alternatives are nearly infinite. The only limit to anarchist organizing is our imagination, and the sole existing criterion is that anarchism proceeds nonhierarchically. Such horizontal organization may come in the form of child-care collectives, street parties, gardening clinics, learning networks, flashmobs, community kitchens, free skools, rooftop occupations, freecycling, radical samba, sewing workshops, coordinated monkeywrenching, spontaneous disaster relief, infoshops, volunteer fire brigades, microradio, building coalitions, collective hacking, wildcat strikes, neighborhood tool sharing, tenant associations, workplace organizing, knitting collectives, and squatting, which are all anarchism in action, each with decidedly spatial implications. So what forms of action does anarchism take? “All forms,” Kropotkin once answered:

indeed, the most varied forms, dictated by circumstances, temperament, and the means at disposal. Sometimes tragic, sometimes humorous, but always daring; sometimes collective, sometimes purely individual, this policy of action will neglect none of the means at hand, no event of public life, in order to ... awaken courage and fane the spirit of revolt. (2005/1880, 39)

Anarchist organization doesn’t seek to replace top-down state mechanisms by standing in for them; rather, it replaces them with people building what they need for themselves, free from coercion or the imposition of authority. Rather than proceeding from a centralized polity, social organization is conceived through local voluntary groupings that maintain autonomy as a decentralized system of self-governed communes of all sizes and degrees that coordinates activities and networks for all possible purposes through free federation. The coercive pyramid of the state structure is replaced with webs of free association, in which individual localities freely pursue their own political economic and sociocultural arrangements.

Anarchist geographies are actually not novel, in the sense that people have organized themselves collectively and practiced mutual aid
to satisfy their own needs throughout human history. Organization under anarchism is simply a continuation of this impulse, despite its attempted disruption by the state. As Colin Ward argued:

given a common need, a collection of people will, by trial and error, by improvisation and experiment, evolve order out of the situation – this order being more durable and more closely related to their needs than any kind of order external authority could provide. (1982/1973, 28)

There is consequently no transgeohistorical narrative to anarchism as, although it has been continuously present in human societies, mutual aid is nonetheless differentiated across space and time, taking on unique and even subtle forms according to context, needs, desires, and constraints placed on reciprocity by opposing systems such as capitalism. At certain times and in particular places mutual aid has been central to social life, while at other times the geographies of mutual aid have remained largely hidden from view, overshadowed by domination, competition, and violence. Yet, irrespective of adversarial conditions, mutual aid remains prevalent, and

the moment we stop insisting on viewing all forms of action only by their function in reproducing larger, total, forms of inequality of power, we will also be able to see that anarchist social relations and non- alienated forms of action are all around us. (Graeber 2004, 76)

It is in the spirit of seeking new forms of organization that anarchist geographies have been “reanimated” as of late (Springer et al. 2012), emphasizing a do-it-yourself (DIY) ethos of autonomy, direct action, radical democracy, and noncommodification. Arguments in favor of the radical potential of DIY culture have emphasized anarchist perspectives toward the everyday transformation of our lives, a sentiment that factors heavily in a great number of social movements, where geographers have begun thinking through how impermanent spaces may arise in response to sociopolitical action that eludes the formal structures of hierarchical control. Pickerill and Chatterton (2006) have adopted such an “autonomous geographies” approach in attempting to think through how spectacular protest and everyday life may be productively combined to enable alternatives to capitalism. Routledge’s (2003) notion of “convergence space” has similarly proven influential to anarchists insofar as it appreciates how grassroots networks and activists come together through multiscalar political action to produce a relational ethics of struggle, offering a reconvened sense of nonhierarchical organization.

The application of an explicitly anarchogeographical perspective would benefit a range of contemporary issues, each with decidedly spatial implications, from the overt uprisings of the Arab Spring and the Occupy movement, to the spectacle of street theater and Critical Mass rides, to the subversive resistance of trespassing and culture jamming, to lifestyle choices of dumpster diving and unschooling, to the mutual aid activities of community gardens and housing co-ops, to the organizing capabilities of book fairs and Indymedia. Similarly, anarchism has much to contribute to enhancing geographical theory, where it is easy to envision how new research insights and agendas might productively arise from taking an anarchist approach to themes such as sovereignty and the state; homelessness and housing; environmental justice and sustainability; industrial restructuring and labor geographies; capital accumulation and property relations; policing and critical legal geographies; informal economies and livelihoods; urban design and aesthetics; agrarian transformation and landlessness; nonrepresentational theory and more-than-human geographies; activism and social justice; geographies of debt
and economic crisis; belonging and place-based politics; participation and community planning; biopolitics and governmentality; postcolonial and postdevelopment geographies; situated knowledges and alternative epistemologies; and anti-oppressive education and critical pedagogy. Kropotkin viewed teaching geography as an exercise in intellectual emancipation insofar as it afforded a means not only to awaken people to the harmonies of nature, but also to dissipate their nationalist and racist prejudices, a promise that geography still holds, and one that may be more fully realized should anarchist geographies be given the attention and care that is required for them to blossom. Retaining Reclus’s and Kropotkin’s skepticism for and challenges to the dominant ideologies of the day has much to offer contemporary geographical scholarship and its largely unreflexive acceptance of the civilizational, legal, and capitalist discourses that converge around the state. The perpetuation of the idea that human organization necessitates the formation of states is writ large in a discipline that has derided the “territorial trap,” yet has been generally hesitant to take the critique of state-centricity in the direction of anarchism. However, unlike the limited class-centricity of Marxian geography, the promise of anarchist geographies resides in their integrality, which refuses to assign priority to any one of the multiple dominating apparatuses, because all are seen as irreducible to one another. This means that no single struggle can wait on any other, and the a priori privilege of the workers, the vanguards, or any other category over any other should be rejected on the basis of its incipient hierarchy. Anarchism is quite simply the struggle against all forms of oppression and exploitation, a protean and multivariate process that is decidedly geographical. Anarchism is happening all about us.

Ancient geography

Kent Mathewson
Louisiana State University, USA

Ancient geography and its study was once a staple, if never quite the foundation, in geography’s scholarly genealogy from the Renaissance through the nineteenth century. Well into the Enlightenment period, the wisdom of the ancients – as received through Greek and Roman texts and techniques – was the touchstone upon which both geographic theory and practice were assayed and accepted, rejected, or superseded. The terms “ancient geography” or “classical geography” have been implicitly understood to refer to times and places bounded – the Aegean realm from the eighth century BCE to the disintegration of the vast Roman Empire a millennium and several centuries later. Within this historical and geographical expanse, the key figure – or, in most accounts, the only actors – were “the Greeks and Romans.” The origins of this strand within the larger Occidental or Western civilizational trajectory were generally traced back to the Homeric epics, with Odysseus as a heroic precursor and Homer “geography’s founder,” as Strabo dubbed him. Prior to this time, or so the standard narrative goes, any trace of geography’s firm foundations melted into myth while both moving back in time and moving out beyond the Greek oecumene, or known lands. Going forward it might be said that collectively the Greek geographers practiced Socrates’s injunction: “know thyself,” given their generally keen knowledge of the corpus of formal geographic work as it developed from the sixth century BCE up through the Hellenic period and into the first century CE with the Roman conquest and absorption. Like much else with Greek scholarly and scientific achievements, the Roman ascendancy brought little innovation, but some amplification in advancing geography in its elaboration and practice. And of course, the actual geography of the Greco-Roman world was extended greatly through Roman agency. In contrast to vague and mythical beginnings, the terminus has often been depicted as abrupt and vividly real, coincident with the Roman “collapse.” Geographical scholarship, at least in the European precincts of the former empire, was thought to have largely atrophied until slowly revived some centuries later through rediscovered Greek and Latin texts and maps, and Islamic scholarly influences. In its rough contours, this history is not all that off-center. But it is these assumptions of centrality, particularly the larger histories that it ignores – the “Other” antiquities if you will – that makes it an incomplete and therefore faulty telling. On the other hand, over the past century or so, the study of classical or ancient geography has been radically decentered, to the point of near extinction. As such, ancient or classical geography as a field of study offers opportunities for introducing new approaches and perspectives, while preserving the record and evidence that demonstrates important aspects of contemporary geography’s groundings can still be located in classical Antiquity.
ANCIENT GEOGRAPHY

Antiquity’s antecedents

Eratosthenes (ca. 276–195 BCE) is credited with being the first to use the term “geography” (Earth description) in the third century BCE; however, major figures of the Milesian school of pre-Socratic philosophy from the sixth century BCE such as Thales (ca. 624–546), Anaximander (ca. 610–546), and Hecataeus (ca. 550–476) made major contributions to the broad body of knowledge and systematic discoveries that came to be called geography. Rather than seeing their accomplishments as ancient geography’s basement or beginnings, it may be more accurate to view this center of creativity in Asia Minor as one culmination or maturation of a deep and ongoing process in which proto-geographic thought and praxis had been in formation for tens of millennia in multiple sites and contexts. The immediate proximal sites and contexts that extend Milesian or Greek antecedents back into this history (only selectively recoverable) lie to the south in Egypt and east in Mesopotamia and perhaps beyond. Specifying precocity is problematic and periodically undercut by the shifting sands of cultural historical excavation and recovery. Nevertheless, by the fourth millennium BCE, Sumerian civilization, and laterally Egyptian civilization, was developing writing systems, complex mathematics, astronomy, cadastral mapping and instrumentation, and methods of data collection for reasons of state. The earliest known map associated with a civilization is on a Babylonian clay tablet. By the third millennium BCE geographical techniques and knowledge were passing between societies and civilizations from Egypt to the Indus Valley and perhaps beyond.

Martin Bernal, in his sharply revisionist Black Athena: The Afroasiatic Roots of Classical Civilization (1987) convincingly argues that not only much of what is attributed to Greek creativity and precedence has demonstrable provenance in these Afro-Asiatic civilizations, but these influences and diffusions began earlier than commonly thought. Bernal pushes the inceptions back to the onset of the second millennium BCE, suggesting the influences were continuous and substantial throughout the second millennium BCE and well into the first. Bernal also argues that the ancient Greeks themselves were well aware of these antecedents, which he calls the “Ancient Model,” but that nineteenth century Romantic and racist scholars, enamored with the vision of a largely self-generating classical Greek civilisation, sporadically invigorated by Indo-European barbarian invasions from the north, constructed what he calls the “Aryan Model” of Greek civilizational origins. This model, foundational to conventional Western civilizational views and studies from the early nineteenth century on, seriously distorts the actual history and geography of not only the “rise” of Greek civilization, but by extension the history of geography’s early development as an art and a science. Similarly, to limit the bounds of ancient geography to only a Greco-Roman perimeter, diminishes it tremendously. Each ancient civilization can be found to have its own expressions of geographical knowledge and practice.

While Afro-Asiatic civilizations of northeast Africa and southwest Asia may well have the best-recognized pre-Greek records of geographical art and science, a full accounting of Chinese innovations and accomplishments, along with official patronage of geographical scholarship, would likely match much of the proto-geographical activity on the other side of the Asian continent and its borderlands. Nor can one rule out some interaction, diffusion, or transfer of knowledge and techniques between the eastern Mediterranean/Near Eastern lands and East Asia. There is some evidence of this toward the end of the Greco-Roman classical age, but without major import. Joseph
Needham (1959) devotes an entire volume (3) of his monumental *Science and Civilization in China* to Chinese accomplishments in mathematics, and the sciences of the heavens and the Earth. He emphasizes parallels with the West, but also points out singular Chinese achievements. One striking difference is the multi-millennial unfolding of continuities in the Chinese civilizational trajectory, rendering the categories “classical” and “ancient” somewhat more problematic to fix or bound. The opposite is true of civilizations and their geographic arts and sciences outside of the Mediterranean/Near Eastern or East Asian domains. As with Rome, most have discernable termini, usually by collapse or conquest. The Harappan civilization of the Indus River Valley and the Maya civilization of Mesoamerica both experienced civilizational simplification if not outright cessation, usually thought to be from a concatenation of causes, variously diagnosed as environmental, epidemiological, political, economic, and so on. In florescence, both produced geographic knowledge and techniques comparable in some instances with those of the larger Old World civilizational centers. Other ancient civilizational trajectories were brought to abrupt and violent ends, most notably, the New World civilizations such as the Aztec in Mesoamerica and the Inca in South America. Each had sophisticated ethnoscientific traditions and practices that generated geographical knowledge and practical works, including remaking whole landscapes for astronomical-geographical research and politico-religious ideological articulation. Perhaps ironically, their geographical enterprises, along with much of the rest of their civilizational apparatus, were in part destroyed through effective Iberian marshaling of the rapid advances in Europe’s geographic knowledge and techniques in the late Middle Ages. And some of the impetus came from the “rediscovery” of the geographic wisdom of “antiquity.”

**Even earlier geographers**

There is an increasing recognition among scholars and writers delving into the pre-civilizational past that developing and utilizing geographical knowledge and skills are a part of what makes us human. Geographer Robert Sack’s (1997, 1) *Homo geographicus* is fundamentally a “geographical being,” who transforms the Earth, and in turn is transformed. For Sack, “being geographical is inescapable” whether we are conscious of it or not. Writers such as Bruce Chatwin (1986), with his lyrical account of the Australian Aborigines’ world manifesting song lines that aid navigation through both space and time, have opened windows onto what now appear to be universal traits expressed as geographical competencies. Geographer James Blaut and environmental psychologist David Stea (Blaut et al. 2003) have argued that mapping behavior is a cultural and cognitive universal, that it has been evident since at least the Upper Paleolithic, and that it is has been a key adaptation in human evolution akin to tool use and language acquisition, aiding humans in comprehending and acting effectively in the geographical environment. Earlier work in geography and numerous studies in anthropology and archaeology have supported this proposition. Franz Boas (1888), founding figure in anthropology, worked initially in geography, studying the cognitive mapping abilities of the “Eskimo” (Inuit) of Baffin Land. Boas found the Inuit to have accurate locational knowledge of their macro-environment, all the more impressive given what to a non-native seemed often to be featureless landscapes. The case for pre- or non-civilizational geography and geographers, much of it “ancient,” albeit outside of formal institutions and expression, would seem to be obvious. As with the civilizations apart from the Egyptian/Near Eastern/Greco-Roman core, the vast vernacular geographic lore and practices
ANCIENT GEOGRAPHY

of peoples and cultures preceding them should be included in any consideration of ancient geography.

Ancient Greek geography

While enlarging the scope of ancient geography to admit the other ancient civilization’s geographical accomplishments, along with the geographical knowledge and activity generated by non-civilizational peoples everywhere, clearly the ancient Greeks produced the largest and most advanced corpus of geographical work. Locating these origins in Homeric times may have struck cords with later Greeks’ own mythmaking – and the same for nineteenth century historians of geography, but as already mentioned, the base seems to have been laid in Asia Minor at centers such as Miletus in coastal Ionia. Here commercial circuits threading throughout the “seven seas” carried commodities, but also transmitted basic geographic information. The Milesian school of philosophers Thales, Anaximander, and Hecataeus not only contemplated the cosmos, they proposed methods for its investigation. Thales and his student Anaximander have been credited with initiating what can be called the “mathematical” tradition in Greek geography. Thales was concerned with the measurement and location of places on the Earth’s surface. He was also involved in commerce, and traveled widely in the eastern Mediterranean. From the Egyptians he learned principles of geometry that he cast as propositions, and then applied to geodetic questions. Conceptualizing the Earth as a whole, he envisioned it to be a disc floating on water, with water being the primordial substance. Thales also made contributions to astronomy. Perhaps his greatest contribution was moving Greek geography beyond explanations based in myth and demonstrating the practicality of mathematical approaches. Thales’s student Anaximander followed in the mathematical tradition, introducing the Babylonian gnomon or sundial to Greek science. The gnomon allowed for determining diurnal time (at noon the shadow is shortest) but also seasonal shifts – the noon shadow is shortest at the summer solstice and longest at the winter solstice. Anaximander also seems to be the first to have produced a mappamundi or map of the world. Greece was at the center, flanked by the three continents – Europe, Asia, and Libya (Africa) and surrounded by ocean. With this concept and its depiction, Anaximander can also be credited with initiating the cartographic or mapping science tradition in Greek geography. Hecataeus, the third Milesian geographer, pioneered the historiographic or descriptive tradition. He compiled the information that flowed into Miletus and complemented it with his own travel observations of Greece, Egypt, Asia Minor, and the Black Sea Basin. From this he wrote periodos ges (circuit of the Earth) or periêgês. It was divided into two books, one for Europe and one Asia, and provided information on coastal locations including mythology, ethnography, travel directions, and topographic features.

The center of classical geographic thinking and production moved westward from fifth century BCE on. Herodotus of Halicarnassus (ca. 484–428 BCE) is usually credited with conceiving and producing the first coherent historiographic work, hence his sobriquet “patrem historiae” (“father of history”). He was particularly concerned to chronicle the uniting of various Greek polities in the face of the Persian imperial threat. Rather than simply focusing on the empirical military and political dimensions of Greek warfare as Thucydides (ca. 460–395 BCE) did, Herodotus provided extensive geographical and ethnographic detail
of both the Greek homelands as well as the Persian Empire. Herodotus traveled widely in the eastern Mediterranean world, and drew on his own observations from Egypt, the Euxine (Black Sea) basin, and much of the Persian Empire in writing his histories. He can also be considered the progenitor of historically informed human geography and ethnography. Herodotus had a lively interest in physical geographic processes and offered explanations of coastal shore and delta formation, relations between temperature regimes and wind directions, and the seasonal Nile flooding. He was perhaps the first to employ the concept of the oikoumenê (inhabited world) and suggested lands beyond. He argued for a world island (Europe, Asia, Libya (Africa)) surrounded by ocean. He based this in part on a putative Phoenician expedition (ca. 600 BCE) that had circumnavigated Africa traveling down the east coast, rounding the Cape of Good Hope, and returning through the Pillars of Hercules (Gibraltar). Herodotus’s historico-geographical work was complemented by other fifth century Greek historians. Xenophon’s (ca. 430–354) historical works, particularly Anabasis, his personal chronicle of the heroic March of the Ten Thousand (Greek mercenaries) who fought their way from the heart of the Persian Empire back to Greece, provides ample and usually accurate geographical detail. Other Greeks served Persian rulers in various capacities, often commenting on the geography of the empire.

By the fourth century BCE, the inclusion of geographic details was a common feature of historiographic practice, and geographic questions had entered the philosophical arena in significant ways. Ephorus of Cyme (ca. 400–330 BCE) produced a 30 volume universal history. He is credited with separating out the strictly geographical data and placing it in two separate books – one on Europe and the other on Asia. Both Plato (428–348 BCE) and Aristotle (384–322 BCE) can be credited with contributing to ancient geography directly and, in the case of Aristotle, providing the philosophical-paradigmatic basis on which much of the geographic discourse and discovery were mediated for almost the next two millennia. Plato’s contributions lie in several areas. Epistemologically he was an idealist and favored the deductive approach. Ontologically he was a declensionist who saw change in nature and culture as necessarily a degeneration from an original perfect state. Plato was perceptive in reading the landscape record of Attica as one in which soils had been impoverished, forests destroyed, and hydrologic systems disrupted, but not in assuming that things might be different with different modes of human agency. Plato’s postulating the lost land mass of Atlantis (larger than Europe and Asia combined) fostered the idea of terrestrial impermanence and the notion of islands that disappeared, one of ancient geography’s ideas that has provoked geographical imaginations down to present times. It also lent support to the view that the Earth’s surface was immense and the eastern Mediterranean realm was just one small portion of it, albeit centrally important. At the same time Plato deduced that the Earth must be a sphere, as this shape was the most perfect, and at the center of the universe. Eudoxus of Cnidus (ca. 408–355 BCE), Plato’s student and colleague in his academy, developed the theory of klima or zones of climate by deducing that increasing slope on a sphere (the Earth) would put higher latitude zones at further distance from the sun.

While Aristotle (384–322) was Plato’s most accomplished student, his philosophical positions were the obverse of Plato’s. He was more materialist than idealist and advocated inductive rather than deductive reasoning and approaches. Ontologically he envisioned
ANCIENT GEOGRAPHY

teleological amelioration as the natural state of things. His contributions to geography were multiple. He amended Empedocles’s fourfold division of primordial substances – earth, water, fire, and air – to add a fifth, aether, which comprised the celestial bodies. Aristotle went beyond Plato’s deduction of the Earth’s sphericity to offer inductive evidence – the circular edge of the shadow produced in a lunar eclipse, and the ascent of stars above the horizon as one travels north. Aristotle refined the concept of latitudinal zones, but planted the erroneous notion that the torrid or equatorial zone was too hot for human habitation. Like Herodotus, Aristotle drew on personal travel experience to formulate some of his theories and observations. Aristotle’s student Alexander the Great carried out this advocacy of first-hand observation to heroic levels. In part, Alexander’s imperial impetus was fueled by Aristotle’s admonition to observe as well as expand the Greek domain to the limits of the ekumene. Commercial explorers of the time included Pytheas of Massalia (ca. 380–ca. 300 BCE) who is credited with many “firsts” in the annals of ancient geography: observing polar ice, venturing to the lands of the far north or Thule (Shetlands? Faroes? Iceland? Greenland? Svalbard?), “discovering” the Baltic Sea, explaining tides as the result of lunar attraction.

The third century BCE produced the epitome of Greek geography in the persona of Eratosthenes of Cyrene (ca. 276–ca. 194 BCE). He coined the word “geography” and laid bases for its articulations. He served for forty years as head librarian of the Library of Alexandria, seat of ancient learning in Hellenistic times. With the library’s resources at hand, he produced three major works: one on the form and nature of the Earth and its processes of changes, a second book on mathematics and measurement, and a third book on the nations, peoples, and politics of the ekumene. He produced a mappamundi with Alexandria as the prime meridian. He added mathematical boundaries to Aristotle’s fivefold zonation: torrid, temperate, frigid. The torrid zone was 48 degrees straddling the equator, and the frigid zones extended 24 degrees from each pole, thus only five degrees off current delimitations. Perhaps his greatest feat, however, was estimating the circumference of the Earth within 140 miles of its actual dimensions. The culmination of Greek geography both figuratively and literally was embodied in the work of Strabo (ca. 62 BCE–20 CE). Born in Asia Minor, he traveled widely in the eastern Mediterranean, living for a time in Rome and Alexandria. Strabo’s encyclopedic Geography comprised some 17 books, largely drawing on the work of his predecessors. He also passed judgment on their findings and observations, often coming to erroneous conclusions: the veracity of Homer over Herodotus, doubting Hanno’s and Pytheas’s Atlantic voyages, setting very narrow limits for human habitability (roughly between 55 and 12 degrees north). Unlike most of the earlier Greek geographers’ writings, the majority of Strabo’s work survived, and served as the main textual source of Greek geographic knowledge from the end of Antiquity through the Middle Ages.

Roman geography serves as something of a coda to classical geography. The most illustrious figure is Claudius Ptolemy (ca. 90–168 CE) who, although a Roman citizen living in Alexandria, wrote in Greek and was most likely ethnically Greek as well. Based in the library of Alexandria, Ptolemy produced three great works in astronomy, geography, and astrology that continued to be influential for the next millennium or more. His eight-volume Geographia was primarily a gazetteer with locational tables (latitude and longitude) but the first volume dealt with astronomical data and the final was devoted to maps of various parts of the world. From the gazetteer data he also produced a world
map that remained the standard for centuries. Geographic research and knowledge production in the Roman realm was largely additive rather than innovative. Those geographical pursuits that aided commerce and imperial expansion were attended to, but theorizing, research, or even compendious writings were not much in evidence.

A conspicuous exception is Pliny the Elder (ca. 23–79 CE). Pliny’s massive *Natural History* (in 37 books) is not specifically geographical, but much of the reportage is place based and books 3–6 offer a survey of regions and places within the ekumene. The Romans did energetically produce *periploi*, or travel guides, for both land and sea. Under Roman authorship, paradoxography, the literary genre that drew heavily on geographical reportage to describe natural oddities and monstrosities, usually to be found at the edges of the ekumene, flourished, enlisting figures such as Varro and Cicero. The fascination with *mirabilia* or things marvelous and incredible within geographical contexts was one of the key legacies and links between classical Antiquity and geography’s renovation in the late Middle Ages. At the same time the more practical and prosaic pursuits of ancient geographers, whether expressed in geographical description, mathematical methodology, or cartographic exposition, provided the foundations for scholarly geography’s rebirth in fits and starts over the millennium that followed its effective dissolution coeval with the “collapse” of the Roman Empire in the sixth century CE.

Affect

Ben Anderson

Durham University, UK

The term “affect” has been used by geographers and others to attune to a range of intensities and atmospheres felt through bodies: to give some examples, hostility, as racism intensifies in an encounter between racially marked bodies; the surprising force of a sexually charged glance; comfort as bodies hold together; the feeling of participation in dance; “cruel optimism” (Berlant 2011), as people are almost sustained by promises that bring them harm. While theories of affect vary, use of the term “affect” signals an attention to lived experience. Work with an interest in affect shares, then, a promise and an imperative (Anderson 2014, 9–11). The promise is of a geography that senses and discerns the subtle, elusive dynamics of everyday living and touches on how abstract sociospatial processes are felt and lived. The imperative is to understand how forms of power work through affect. For some, this discovery involves diagnosing the contemporary condition as one in which affect has become a new “object target” as forms of power emerge and change. For others, it involves (re)thinking the (geo)political as an affectively imbued scene of attachments, events, and forces.

There is no single definition of affect in geography or other disciplines, just as there is no single definition for terms such as “emotion,” “feeling,” or “mood.” Interest in affect is typically associated with the emergence of nonrepresentational theories (Thrift 2004; McCormack 2014), a body of thought that is itself plural. But work on affect owes much to a number of precursors in geography and elsewhere. In addition to humanist phenomenology, research on affect is indebted to feminist scholarship that showed how emotions matter and disrupted the marginalizing or silencing of emotional experience, traced how emotions “get into” sociospatial relations (and vice versa), and experimented with new forms for representing lived experience (e.g., Valentine 1989). Nonrepresentational theories of affect share with work on emotional geographies the insights that affects express relations, and that the rational and the emotional/affective are enfolded in a complex way. From these starting points, work on affect asks a series of questions: How are affects emergent from, and part of, encounters? How, given the contingency of sociospatial orders, is affective life mediated and organized? And how, if at all, does affective life exceed, reproduce, or otherwise relate to systems of signification or representation?

These questions are refracted through different theories of affect. Thrift (2004) identifies four theories that offer different versions of what affect is: phenomenological approaches that describe the bodily processes and states through which affects occur in everyday life; psychoanalytic theories where affects are vehicles or manifestations for the drives; naturalist accounts, often deploying the brain sciences, that treat affects as biologically rooted universals; a Spinozan–Deleuzian notion of affect as always emergent capacities to affect and be affected. Despite a nascent resurgence of interest in psychoanalysis in geography, and the continued importance of phenomenological approaches, it is Spinozan–Deleuzian theories that have been central to the interest in affect. There affect refers principally to a body’s...
or bodies’ “capacity to affect and be affected.” A body’s “charge of affect” is two-sided: that is, what a body can do and does do are a matter of intensive “capacities to affect” and “capacities to be affected.” Normally this use involves invoking an analytic distinction between affect and emotion, where “emotion” is used to refer to the ways in which affects are named, interpreted, and reflected and, by contrast, “affect” refers to the intensity of experience, a quality that provides something close to the background sense of an event or practice or space. This is not to say that affect is cleaved from emotion. In what has become a well-cited passage, Massumi describes their enfolding:

An emotion is a subjective content, the sociolinguistic fixing of the quality of an experience which is from that point onward defined as personal. Emotion is qualified intensity, the conventional, consensual point of insertion of intensity into semantically and semiotically formed progressions, into narrativizable action–reaction circuits, into function and meaning. (2002, 28)

For now, we should note that, instead of affect and emotion existing in separate unconnected levels, Massumi and others stress multiple relations between emotion as a “subjective content” and affect as bodily capacities. Emotion as qualified personal content feeds back into the emergence and organization of affect, while at the same time being the most intense expression of the capture of affect and of affect’s ongoing escape (Massumi 2002, 35).

This treatment of affect and emotion has been criticized for reproducing an objective/subjective dualism and downplaying the subjective. It has also been critiqued on the basis that it willfully or naively cleaves the nonrepresentational, in the guise of affect, from the representational, and in so doing ignores, forgets, or obscures how what a body can do is determined. Such critiques turn on the question of how exactly affect can be said to be nonrepresentational and how affects connect to other processes and forces. In conclusion, affect can be said to be nonrepresentational in three ways, each of which responds slightly differently to the imperative to think about affect politically, and each of which involves different assumptions about affect.

First, affect is nonrepresentational in the sense of being never fully accessible to conscious subjects, despite being a condition for subjectivity. Before conscious thought, affects are expressed patterns of autonomic bodily reactions. These may be shaped by past encounters and may be subject to willed intervention. This approach lends itself to an emphasis on how “affect itself” is actively shaped, with work diagnosing how new forms of power work through affective spaces.

Second, and slightly differently, affect is nonrepresentational in that it names, or orientates attention to, the generative immediacy of an always overflowing life. Affects are events: they happen; they exceed their causes. Representations always fail in relation to affect; affective life exceeds fixity and containment. Associated with the invention and experimentation of new styles of research and writing (McCormack 2014), affective life is, on this understanding, conditioned but never fully determined by existing forms of sociospatial organization. The result is a politics of witnessing and cultivating events that attunes to the hesitant, cramped formation of other ways of being and living as life happens.

Finally, but closely connected, affect is understood as nonrepresentational, in that affects are formed in the midst of encounters and are mediated in ways that are irreducible to “representational–referential” systems of signification. Emphasis is placed on how affective life is perpetually becoming organized, whether through apparatuses that take affect as an object target, through encounters that enfold elsewhere.
and elsewhens, or through affective conditions (Anderson 2014). The politics of affect that accompanies this approach is, in many respects, a well-recognized one that describes and critiques the ongoing work of mediation and affirms that contingency of seemingly settled sociospatial formations.

What the three ways in which affect might be said to be nonrepresentational all offer is an understanding of how experience is organized as it happens. They differ on a question that will remain central to work on affect in geography: How are affects formed in the midst of, and become part of, sociospatial formations?

Animal geographies

Henry Buller
University of Exeter, UK

Wild animals

Between the “human” of human geography and the materiality of physical geography’s subject matter, animals – or nonhuman animals – have been largely absent from the canon of contemporary geographical thought. Only very recently has “the animal” begun to reappear in today’s human geography. In part this was a counterbalance to the hubris of the so-called cultural turn, when representations (textual, pictorial, cinematic, etc.) were a key research focus. Animals have become the newly liberated others, now noticed by human geographers who previously took no account of nonhuman presence, autonomy, difference, and multiplicity, in form or in meaning. Human geography’s newfound posthumanism has also been an important factor here, with its metaphysical, relational, ethical, and political implications for nonhuman animals and our interactions with them. In all this, animal geography is something of an epistemological menagerie, drawing on a range of subdisciplinary trajectories and influences.

For all that, animals were very much present during the early days of an emergent “modern” nineteenth-century geography. The explorer and naturalist Alexander von Humboldt (1769–1859), often described as one of the “fathers” of modern geography, sought in his writings and in his explorations to link the spatial distribution and interconnectedness of the world’s animals (and plants) to that of its inanimate landforms in a sort of grand unified bio-geographical theory of life on Earth.

Displaying a geographer’s understanding of the interrelationship of nature and culture, Humboldt drew on the pioneering mapping techniques of the earlier Wilhelm von Zimmermann (1743–1815), who produced, albeit from secondary sources, some of the first scientific cartographies of animal distribution in the mid to late eighteenth century. A nascent “animal geographer” himself, Zimmermann, like Humboldt, saw a key relationship between species distribution and the specific characteristics of different natural environments, though his belief in an essential natural fixity was soon challenged by Buffon and later by Darwin and evolutionary theory.

This early geographical concern with the spatial distribution of animal species, defined variously as geographical zoology, zoological geography, or zoogeography, achieved its defining moment in the work of nineteenth century scientists such as Sclater, Gunther, and, perhaps most importantly, Alfred Wallace. The resultant Sclater–Wallace classification of the six major faunal realms of the Earth has proved of lasting value, and continues to define and inspire the science of biogeography today. Darwin’s own faunal mapping of mammalian distributions provided him with the means to develop evolutionary theory, though he was arguably more interested in the barriers between faunal regions and their impact on species development than in the composition of the regions themselves.

Contemporary reassessments of the work of these early explorer-geographers, keen to classify
the world into distinct biophysical regions, have been quick to identify the inherent Eurocentric epistemology that drove the “discovery” and eventual naming of these exotic animals, as Humboldt’s description of the Andean Llama as a “camel-like sheep” illustrates. Yet, ultimately, the eventual acceptance that “New World” species had a uniqueness that did not fit readily into the pre-existing north European worldview and explanation, whether cultural, biological, or theological, served an almost metaphysical role in challenging traditional models and ideas about nature’s immutability, special creation, and distinctiveness, thereby ultimately paving the way for evolutionary theory and a new understanding of the possible links between human and nonhuman. And with this came an important epistemological shift. Darwin’s evolutionary theory, with its emphasis on change and adaptation, effectively drew to a close the purely descriptive approach of classic animal geography as, later, ecology and biogeography took up the challenge of explaining the spatialities, forms, and trajectories of animal movement, responsiveness, and adaptation.

The focus of all of these early animal geographies was the “natural” distribution and location of animal species, from which grand theories of biological “life” were ultimately constructed. Of course, by the mid-nineteenth century, in many regions of the world European colonial expansion had already begun to have a major transformative effect on the faunal composition and identity of many lands. Species (and peoples) deemed incompatible with the expansionist aims of the colonizers were eradicated or pushed to the margins. New species were brought into these “new” lands, creating what DeJohn Anderson calls the “advance guard” (2004, 243) of an inexorable cultural and physical reconfiguration both of “nature” and of human–nature relations. The large-scale human-induced changes to animal distributions, and the cultural as well as ecological consequences of these changes, have been explored and assessed by a number of scholars including, notably, Virginia DeJohn Anderson, whose account of the role of European livestock in transforming not only the ecologies, landscapes, and natural fauna of North America, but also the entire semiotic and representational placing of animals within both settler and indigenous populations, is truly fascinating. In Australia similar transformative processes, often consequent on colonial expansion, have been observed and discussed by writers such as Adrian Franklin (2006) and Deborah Bird Rose (2011). “At all stages of Australian history,” writes Franklin, “the animals of Australia have found themselves at the centre of biological, moral and political puzzles” (2006, 26). They also have a more material presence against which cultural narratives might have less immediate impact relevance. “Go away! (We’re British here.),” shouts Val Plumwood at the Kakadu National Park crocodile that almost kills her (2000, 131). In other disciplines, notably anthropology, the cultural roles and placings of animals within local value systems, both symbolic and material, indigenous and imposed, have a rich history, from Geertz and Levi-Strauss to Sauer and Ingold, and these too have strongly informed the development of contemporary animal geography for which, critically, animals are so much more than merely natural objects in natural places.

Finally, and most recently, a new generation of animal geographers have found a modern relevance in some of the approaches of the classical, positivist zoogeographies of the nineteenth century. Where the early writings of Humboldt, Wallace, and others tended to conceive of animals as the passive results of particular ecological, environmental, and evolutionary conditions,
modern zoogeographers have sought to emphasize the role of animals as active subjects within their environments, responsive to the affordances and possibilities of a more intentional and agentic engagement in both natural and more humanized spaces. For example, drawing both on ecology and on human geography in his account of lizards’ and snakes’ sharing of spaces with humans, Campbell (2009, 267) shows how reptilian presence and adaptive behavior actively interact with human copresence and decision-making to create what is, in effect a more holistic zoogeography.

Farmed animals

Of course, animals and humans have performed space together for centuries within the context of domestication, whether it has been for purposes of consumption or of comfort. Although the recently emergent field of “new” animal geography has been less ready to engage with domestication, largely as a result of the explicit and obvious asymmetry of both apparent agency and moral status in the human–animal relationships associated with domestication, to which we shall return, there is nonetheless an important tradition in geography’s engagement with the animal to be acknowledged here. Whatever we may think individually of the ethical basis of animal keeping, it remains a fundamental characteristic of human societies and, in most parts of the globe, a long-standing mainstay of anthropocentric economic systems and their consequent spatialization, from the earliest Neolithic settler societies to modern intensive livestock production, with its estimated global asset value of almost $1.5 trillion.

Geography has a close affinity with agriculture, though few might admit it. Both are, to a certain degree, predicated on the operation of a relationship, itself predicated on an increasingly contested dualism, between human society and the “natural” world as a resource. Livestock agriculture is in many ways the most important, and certainly the most common, form and practice of human–animal relations, involving billions of animals and ultimately billions of human (and animal) consumers at any one moment.

By their very nature, geographies of agriculture and of livestock farming have tended, like their subject matter, to see farm animals predominantly as chattels and resources, commodified objects of value, subsidy, or edibility – a means to an end. Yet, livestock and the livestock sector offer a rich terrain for a wide range of geographical approaches that reflect, in their own way, broader shifts in the discipline’s theoretical and conceptual development. For the sake of clarity and expediency, we might identify three broad areas of interest, though these are far from being discrete and distinct.

The first is perhaps the most obvious; it concerns farm animals as units of production and sites of accumulation. Although we may not wish to label such studies specifically as “animal geography,” analysis of the livestock industry, through the lenses of political economy or policy analysis, spatial distribution, corporate structures, and rural social formations within livestock farming communities have all long been commonplace themes in economic, rural, and agricultural geographies. Such studies serve an important function for contemporary animal geography. They provide empirical detail on the significance and range of human–animal interdependencies and the manner in which these presences are so fundamental to our economic and policy structures, our practices, and their spatialization. In Watts’s (2000, 295) terms, farm animals become transformed in both economic and material terms as “sites of accumulation.”

A second contribution from the study of livestock and agriculture to an emergent animal
geography has been a more culturally informed perspective, which seeks to move away from a purely political economy approach to place the relationship of farmers and domesticated animals within a broader cultural frame. Anderson’s (1997) critical deconstruction of domestication largely sets the scene for this particular area of animal geographies, but Yarwood and Evans’s (2000) take on this is specific, namely how different breeds of livestock are “socially constructed” to inform particular spatial and cultural repertoires. Others have, since the mid-2000s, taken this broad perspective into different contexts in which farm animals and humans meet, whether they be on hobby farms, in agricultural shows, or in slaughterhouses. More recently, and drawing on both critical continental thought and the sociology of science, this particular tradition within what we might call agricultural animal geography has moved toward a greater understanding of how technology, both the material technologies of livestock agricultural infrastructure and the breeding technologies of farm animal genomics, increasingly mediates and, in some cases, replaces the relations between humans and farm animals.

Finally, there has been, since the mid-2000s, an increasing intersection between animal, agricultural, and environmental geographies. This has taken a number of forms but two in particular stand out. The first is part of a growing concern for the environmental (as well as both human and animal health and welfare) implications of modern livestock farming, while the second emerges from geographers’ increasing interest in environmental histories and, for many, the place of livestock and livestock species within them. The former has, in recent years, attained particular policy relevance, with issues ranging from water pollution from farm animal wastes to the sustainability of livestock-based agriculture at the global scale. In relation to the second intersection, Cronon’s (1991) magisterial account of the growth of Chicago as “Nature’s metropolis” reveals, along with much else, the manner in which animals (in this case bison, cattle, and pigs) and humans (here hunters, farmers, slaughtermen, and packers) first co-created the “Great West” and then, ultimately, freed its principal product, animal flesh, from the bounds of nature and geography. More recently, animal geographers, with their concern for the placing and place-making of human–animal interaction, have drawn on the environmental history tradition to contribute to often wide-ranging debates around issues such as species reintroduction (whether domesticated or “wild”) and wildlife conservation and restoration programs.

Relational animals

While these two broad areas of animal geographies have certainly made significant contributions to broader geographical scholarship and have, to a large degree, been essential precursors, animal geography as a distinct and recognizable subfield within contemporary (human) geography has nonetheless, since the mid-1990s, taken on a very different allure. Some have termed this the “new” animal geography to draw a clearer distinction between it and earlier concerns. Others refer to an entire “animal turn” within the (human) social sciences and the humanities. Whatever the nomenclature, this period has seen a veritable stampede of animals into contemporary geographical thought. Like many recent subdisciplinary themes, animal geography has emerged not out of any intentional epistemological or coherent political strategy, but rather from a disparate group of people who have sought, in different ways and for various reasons, to develop a more-than-human geography. Early collections, notably two edited books published by geographers on either side of the Atlantic (Philo and Wilbert 2000; Wolch
and Emel 1998) and two journal special issues (Society and Space in 1995 and Society & Animals in 1998) draw the initial contours of the emergent subdiscipline and tell the story of its nascent flourishing. Since that time, the subdiscipline of animal geography has grown enormously through published work, conferences, journals, and book series. It now earns its own entries in dictionaries and encyclopedias of geography as well as its own Wikipedia site and Association of American Geographers specialty group.

So what is new about the new animal geography? Arguing for an acknowledgment of the historic and global significance of human–animal relations for both human and nonhuman spatial practice, Philo and Wilbert (2000, 4) assert that “a ‘new’ animal geography has emerged to explore the dimensions of space and place which cannot but sit at the heart of these relations.” For these early pioneers of the contemporary subdiscipline, animal geography was about understanding how animals – as figures of nature – and their “spaces” were differentially defined through science, through social practice, through culture and religion, and so on, whether it be as pets, as edible, as useful, as clean, as sentient, as repulsive, as metaphors, as representations, or as others.

As the definitive sites of animal ordering, zoos were also among the first “proper” animal spaces to interest animal geographers. In a seminal article from 1995 the geographer Kay Anderson wrote of zoos “as an institution that inscribes various human strategies for domesticating, mythologizing and aestheticizing the animal universe” (Anderson 1995, 276). Zoos are about establishing and reaffirming human-made, culturally inscribed spaces, boundaries, and categories in which we place nonhumans. Being predominantly located in cities, zoos are also celebrations of that boundary-making and the human–animal encounters that boundaries facilitate but also obstruct. For Anderson, zoos are about the differential human construction of the otherness of animals. Recognizing how animal otherness has been constructed through different narratives (some metaphorical) and actions (in many cases actions of spatial ordering and regulation) has been the first step of the new animal geography.

Writing a couple of years before Philo and Wilbert, Wolch and Emel (1998) sought to explain the new animal “moment” in geography and wider social theory in slightly more critical terms. For them, echoing John Berger’s famous 1970 essay “Why Look at Animals,” animals had become invisible to the social sciences and to geography, despite the fact that they were “indispensable to the structure of human affairs and so tied up with our visions of progress and the good life” (Wolch and Emel 1998, xi). Strongly influenced by the preceding cultural turn in human geography, and by writings on feminism and race, this new animal geography focused largely on the various forms and dynamics of the cultural representation and construction of animals and their spaces. Its overarching project was, in Wolch and Emel’s terms, to “bring the animals back in” – into our accounting, our explanation, our science, our ethics, our politics – a methodological as much as an ontological or epistemological challenge. Of course, for many humans, animals are already closely experienced as integral components of shared lives, spaces, and behaviors, whether as animal carers, farmers, or zookeepers. Hence, to Wolch and Emel’s reasons for the emergence of a new animal geography, Urbanik adds a further one: “the increasing acceptance of humans’ emotional connections with animals” (2012, 7).

At one level, this new animal turn extends the range of human geography to include the multitude of ways in which the presence of the nonhuman can be brought into the geographical
ANIMAL GEOGRAPHIES

understanding and explanation of predominately human worlds. It fosters an awareness of how human–animal relations, all of them variously material, semiotic, affective, and ethically engaging, are co-constitutive of, and thereby potentially redefine, spaces and spatial practices that are no longer only human. Here, then, emerges a more inclusive animal geography in which animals are themselves actors in contexts and in “beastly spaces” that are no longer necessarily entirely “natural” (as in devoid of human presence and influence) or exclusively “human.” Animals become acknowledged agents within human narratives of place, from the home to the zoo and the “wild.” Thus, in her challenge to the traditional anthropocentric understanding of the city, Jennifer Wolch offers the notion of “Zoopolis” as a “city re-enchanted by the animal kin-dom” (1988, 135). Cities now become the focal points for a new “transspecies urban theory” (Hovorka 2008) which weaves animals and humans together into spaces, networks, and topologies of heterogeneous copresence and agency. For many, this is the new animal geography: an accounting of, and attentiveness to, the multiple interrelated ways in which both nonhumans and humans perform space together. It is, nonetheless, grounded in an essentially humanist ontology of difference.

At another level, however, the animal turn goes a lot further in that it offers the potential for a more troubling and foundational critique, one that allows for other stories, other possibilities, and other ethics. “The Great Divides of animal/human, nature/culture, organic/technical, and wild/domestic,” argues Haraway (2008, 15) “flatten into mundane differences – the kinds that have consequences and demand respect and response – rather than rising to sublime and final ends.”

For some recent scholars of contemporary animal geography, the otherness of the nonhuman, anchored in such dualisms, matters far less. Indeed, the animal walks and crawls across these divides, defying the abyss which seeks to separate them while demanding some new form of affinity. Drawing on a more radical set of approaches coming from posthumanism, from new ideas about self, subjectivity, and identity, from the methodologies of actor-network theory, ethology, and multispecies ethnography as well as from a sense of the different forms of (bio)politics that may result, animal geography has moved toward a more relational, symmetrical, and ultimately generous form of understanding that acknowledges the animal not as animal, that quintessential other, not as a singular (possibly subjective) agentic force, but as partner in creative and meaningful intra-action. “All real living is meeting,” writes Barad, “And each meeting matters” (2007, 353). This has certainly given rise to a particularly fecund period for animal geography. Inspired by writers like Donna Haraway and Jacques Derrida, and faced with a largely unexplored “kingdom” of nonhuman relational potential (though some may note a preponderance of the more familiar mammals), the subdiscipline has moved comfortably into the realms of both critical social science and critical social theory, and offers what is for many a genuinely new way not only of seeing and accounting and of doing politics, but also of being with.

Animal geography, while it has not become mainstream, now has a growing presence in geographical scholarship. It is heterogeneous and wide-ranging, ethically relevant and methodologically innovative, generic and intimate (Buller 2014). It has opened doors to other stories and other worlds, and has brought particular insights, and examples, to biopolitics and the recent relational and materialist trends
within contemporary geography. The onset of the Anthropocene – more as a scientific paradigm than a geological epoch – and the end of a particular conception of nature has perhaps ironically prompted a new academic interest in the role and place of, particularly, “wild” animals and animal conservation, introducing the possibility for a lively intra- and interdisciplinary rapprochement with biogeography and the life sciences (Lorimer 2010).

Sometimes certainly, animal geography continues to act as a qualifier or foil to more abjectly humanist accounts rather than as a starting point in its own right. Other times, there is a notable epistemological tension between seeing the animal as a theoretical or conceptual object rather than as a living, material being with whom we share an innate vitality.

Given the profundity and range of its (potential) ontological and epistemological challenge – and what is for some also a political and ethical contestation – to the mainstream humanist tradition within both (human) geography and the human social sciences, one might wish it had succeeded in achieving a greater impact than it has. Certainly, this profundity and more-than-human range provide animal geography with a particular pertinence and critical power across a range of domains in human geography. Yet its attendant ontological complexity, as well as its ethical plurality and, some might say, relativism, has also been an element of division and weakness, leading, for some outside the subdiscipline, to a too ready dismissal.

For its immediate future, there are perhaps three key challenges. The first is the challenge not to use animals simply to talk about humans – the question “What is an animal?” should not only be autobiographical. The second is the ethical challenge: How do animal geographers position themselves with respect to the manifest anthropocentrism and, for many, obvious speciesism (and violence) that endures in virtually all human–animal encounters? The third is methodological: How do we account for non-humans in ways that are meaningful not just for us but also for them? A final challenge, perhaps the hardest of all, is that of convincing human geography colleagues that theirs is, by definition, only a partial understanding of the world.

The Annales School embraces a wide group of scholars who have introduced important innovations in their studies of the past. It is named after the scholarly journal *Annales d'Histoire Economique et Sociale* founded in 1929 by historians Lucien Febvre (1878–1956) and Marc Bloch (1886–1944), who were then based in Strasbourg. Drawing on anthropology, geography, psychology, and sociology, they promoted a break with the study of monarchs, diplomatic events, and political regimes favored by most historians at the Sorbonne in Paris. Both Febvre and Bloch had been taught geography by Paul Vidal de la Blache (1845–1918), and were responsive to work by sociologist Émile Durkheim (1858–1917) and articles in *L'Année Sociologique*. They and their entourage pioneered study of long-term historical structures over individual events and of common people rather than elites. Yet, they tended to reject class-based approaches of Marxist scholars. Unlike the Paris-based focus of the “Sorbonniste” historians, studies in regional or provincial history were welcomed in the *Annales*. From 1933 it was edited in Paris after Febvre’s move to the capital; he was followed there by Bloch in 1936. During the German occupation of France, the journal still appeared but under different titles. As a Jew, Bloch was deprived of his university post but he continued to write under a pseudonym. Febvre removed him from the editorial board to comply with censorship regulations. As an active member of the Resistance, Bloch was shot by the Gestapo on 16 June 1944.

After the war, Febvre continued to foster the *Annaliste* approach, renaming the journal *Annales, Economies, Sociétés, Civilisations* (1946–1994). He mentored Fernand Braudel (1902–1985) whose ideas on different notions of time (deep geographical settings, evolving socioeconomic and human structures, and specific moments) characterized a new phase. Braudel’s publications on the Mediterranean world, capitalism and material life, and other themes raised the reputation of the Annalistes, especially in Italy, Poland, and Latin America. From the Maison des Sciences de l’Homme in Paris, Braudel promoted the notion of “total history” encapsulating adjacent areas of scholarship including human geography. He also orchestrated networks of like-minded scholars in other countries. After combining the study of structures with that of collective ideas in the 1960s, younger Annalistes, such as Emmanuel Le Roy Ladurie (b. 1929) favored work on *mentalités* and experimented with quantification. As it grew larger, the Annales School became less cohesive and distinctive. Members of its next generation, such as Roger Chartier (b. 1945), distanced themselves from *mentalités*, preferring to embrace cultural, linguistic, and literary approaches. They continued to subscribe to the founding aim of Febvre and Bloch: to demonstrate methodological innovation. In 1994, the journal was renamed *Annales: Histoire, Sciences Sociales* but its influence had waned. An English-language edition was initiated in 2013 to attempt to capture lost interest.

Historical geographers have drawn inspiration from the interdisciplinarity and voluminous
writings of several generations of Annaliste historians. It should be remembered that an earlier “Annales school” developed from the Annales de Géographie that Vidal de la Blache founded in 1891. This journal sought to diffuse his “new geography” that highlighted regional synthesis, environmental context, and cartographic representation, while acknowledging the role of the past in shaping current human activities. Modified forms of the Vidalian approach remained important in France and in countries influenced by French scholarship until the middle of the twentieth century.

The Antarctic is a large continent with a surface of 14 million km², situated around the South Pole and almost entirely covered with ice. With an average ice thickness of 2200 m it represents 90% of terrestrial ice and is equivalent to 58 m of sea level. The Antarctic continent is the world's largest ice sheet. It is entirely surrounded by oceans and isolated by large and strong oceanic currents. The sea ice around Antarctica almost disappears every summer but reaches around 18 million km² during winter. The continent is generally divided into three parts: the Peninsula, which is the northernmost part of the continent closest to South America, the East Antarctica, and West Antarctica, separated by the Transantarctic Mountains. East Antarctica is the largest one. In some places, the ice thickness exceeds 4 km. Most of the ice lies on a bedrock above sea level. In several places, high basal temperature and bedrock geometry induce subglacial lakes. The most famous is the Vostok subglacial lake, located nearly 4000 m below the surface of the ice, leading at the surface to a very flat area 250 km long and 50 km wide. The western part of the Antarctic ice sheet is smaller, representing the equivalent of “only” 3.3 m of sea level, and the bedrock mostly lies at around sea level.

The Antarctic ice sheet is the coldest, highest, driest, and windiest continent of the Earth. The surface temperature decreases from the coast toward the interior from −15 to −60°C. A temperature of −93.2°C has even been measured in the East Antarctic Plateau, the world record. This cold and dense air in the interior rushes downslope and can induce strong and persistent katabatic winds. For instance, in Terre Adélie (Adélie Land), the average katabatic wind intensity is close to 40 km/h, and the maxima can reach three to four times this value. These katabatic winds carve the surface at centimetric and metric scale, and they also produce snow drift and contribute to erosion through sublimation phenomena.

Because of the extremely low temperature, the snow accumulation rate in Antarctica is very low: less than a few centimeters per year in the interior and a few tens of centimeters near the coast. As the continent is huge, this represents approximately 2200 Gt each year, equivalent to 6 mm of sea level. The snow sinks, turns into ice, and flows down very slowly toward the coast where it calves into icebergs. Most of the flow process occurs by deformation although in some places, where ice temperature is close to melting point, basal sliding occurs. Ice velocity is extremely low in the center of the ice caps, less than 1 m/year, whereas in some places near the coast it can reach over 1000 m/year. The spatial pattern of ice flow is probably not regular: large ice streams that drain ice can be detected several hundred kilometers inland. Most of the ice is evacuated by several large outlet glaciers. When they reach the coast, they terminate either in floating ice shelves, or in grounded or floating glaciers. If the ice sheet is in its steady state (in equilibrium), ice calving might be equivalent to 6 mm of sea level each year. Because of the very slow ice velocity in most of the Antarctic ice sheet, it has become, as has the Greenland ice sheet, the repository of polar records. For
instance, from the European Project for Ice Coring in Antarctica (EPICA) at Dome C (also called Dome Concordia) it has been possible to reconstruct over 800,000 years of climate history.

The shape and the volume of the ice sheet are determined by the equilibrium between snow fall and ice flow. Given the magnitude of the input (snowfall) and output (iceberg calving), even a slight imbalance between those two components can result in a significant sea level change, which is why the mass balance of the Antarctic ice sheet has been surveyed for several decades. Both snow accumulation and ice velocity depend on climate. Precipitation and evaporation rates are clearly linked to climate variations; therefore the dynamic response to a climate change could occur over tens of thousands of years. For example, because ice is a very good thermal insulator, the temperature and thus the velocity of the central part of the Antarctic ice sheet have still not stabilized since the Holocene warming that occurred 15,000 years ago. The current state of the Antarctic results from the climate of the region tens of millennia ago. There are many uncertainties in the imbalance mechanisms so it is still very difficult to model them or even to determine the trend (positive or negative preeminence). The West Antarctic ice sheet is particularly difficult because its bedrock is under the sea surface, so that the ice flows through a complex network of ice streams. To understand the stability of the ice sheet is also a challenge.

There is considerable uncertainty over the quantity of snow fall and of ice calving or melting, the margin of error is between 20 and 30%, and consequently a direct estimation of the mass balance is quite difficult. To measure the mass balance of Antarctica or to understand, model, and predict the ice sheet’s evolution, we need to know the climatological and dynamic processes that control them. We also need observations at a global scale to enhance the models. The sheer size of the continent, its relative inaccessibility, and the weather conditions make in situ measurements difficult and many observations are missing. A few scientific stations, mostly near the coast, and a few traverses during expeditions provide sparse data. On the other hand, observations from space, particularly radar observations, which are free from atmospheric conditions and illumination, provide surface and volume information with good space and time sampling. Some data can be directly linked to a relevant parameter: for example radar altimetry allows us to estimate the topography, radar interferometry helps us to estimate the surface ice flow, a scatterometer gives estimates of katabatic wind direction, and we use gravimetry to deduce the mass balance change, or optical images to derive either surface topography or surface velocity. Other data are indirectly linked to relevant parameters: for example brightness temperature from a radiometer and backscattering from radar altimetry are sensitive to ice grain size but not to accumulation rate. A long-term analysis of the observations derived from these sensors can be used to detect temporal change in geophysical parameters.

Among these sensors, altimetry and gravimetry are efficient methods to measure volume and mass balance directly at the global scale. For the last two decades, polar regions have been surveyed by radar altimeters (the European Remote Sensing (ERS) satellites ERS-1 and -2, Envisat, and Cryosat-2) and a laser altimeter (Icesat). These sensors estimate volume changes; therefore we need assumptions on snow density to derive mass changes. Moreover, they suffer from poor sampling and significant error budgets near the coast where most of the variations occur. The second remote sensing method, gravimetry, directly measures the ice sheet mass change. However, it also has limitations. In particular, it is
sensitive to glacial isostatic adjustment, due to the isostatic response after the Holocene warming.

In coastal regions of the Antarctic ice sheet, where altimetry fails due to the steeper slopes and where its spatial coverage is poor, the often complex pattern of elevation changes can be depicted using comparisons of digital elevation models (DEMs) which are digital representations of the surface topography. One source for such DEMs has been the SPIRIT (SPOT5 stereoscopic survey of Polar Ice Reference Images and Topography) project, an International Polar Year (2007–2009) initiative by the French Space Agency (Centre national d'études spatiales – CNES) that provided numerous HRS-SPOT5 (High-Resolution Stereoscopic-Satellite Pour l’Observation de la Terre 5) images over polar regions. SPOT5 captures two views of the same scene from slightly different angles that can be used to build a DEM. In the Antarctic Peninsula, well known for its complex geography and for being one of the fastest-warming places of the Earth, the comparison of multitemporal DEMs was used to assess the response of outlet glaciers to the loss of their frontal ice shelf, in particular the catastrophic breakup of the Larsen B ice shelf in March 2002. Following this event, glaciers experienced a strong acceleration and thinned by as much as tens of meters per year. This relatively small (3000 km$^2$) region upstream of the former Larsen B ice shelf has lost 10 Gt per year since 2002. New stereo images will be acquired in 2014 by the SPOT5 stereo sensor during the SPIRIT2 project and will provide a second snapshot of the coastal regions of Antarctica before the demise of the SPOT5 satellite at the end of 2014.

The analysis of all published results shows a very great dispersal in terms of mass balance. The loss is estimated to be between 0 and 150 Gt per year, leading to a potential sea level rise of between 0 and 0.4 mm/year. East Antarctica is almost in balance, with volume change probably linked with meteorological forcing fluctuations, while West Antarctica shows a worrying loss (Remy and Parouty 2009).

Most studies indicate a clear acceleration over the past decade by approximately 10 Gt/year$^2$. For instance, the altimetry analysis suggests a near balance for the 1990–2000 period and a loss of $170 \pm 4$ Gt/year for the last decade (Zwally and Giovinetto 2011). This recent acceleration in the Antarctic ice sheet mass loss has been attributed to the dynamic response of the ice sheets to recent warming, with most of the ice sheet mass loss resulting from accelerating coastal glacier flow in particular in West Antarctica (Flament and Remy 2012; Shepherd et al. 2012). One of the possible reasons is the weakening and breakup of the floating ice tongue or ice shelf that buttresses the ice stream. Because the ice shelves are in contact with the sea, changes in ocean circulation and warming of seawater may trigger basal melting and further breakup of the shelves, causing coastal ice flow to speed up.

At the end of 2013, we had three years of observations from Cryosat-2, and the altimeter AltiKa on Saral, a joint French-Indian mission, was launched on exactly the same orbit as the previous European Space Agency (ESA) satellites ERS-1, ERS-2, and Envisat. The observations from both sensors show a large and unprecedented mass loss in West Antarctica of all the glaciers flowing toward the Amundsen Sea, reaching a total of 150 Gt/year. In the near future, the Antarctic ice sheet, in particular its western part, should be closely and carefully surveyed, especially the outlet glacier. New satellites providing altimetry data such as Sentinel-3 (from ESA, to be launched in 2015) or Icesat-2 (from NASA, to be launched in 2016) will continue to maintain the continuity in the observations.

The Anthropocene concept: definition and origin

“The Anthropocene” denotes an epoch in which the collective impact of human activities is sufficient to significantly alter the conditions of life on planet Earth. The term is said to have been coined by American freshwater ecologist Eugene Stoermer in the mid-1980s. However, it was the Dutch Nobel Prize winning atmospheric chemist Paul J. Crutzen of the Max Planck Institute for Chemistry who did most to popularize the term among Earth and environmental scientists. In 2000, he and Stoermer published a short article in the Global Change Newsletter (GCN), the “house publication” of the International Geosphere-Biosphere Programme (IGBP). The IGBP was one of several multicountry research programs designed to study contemporary environmental change on a global scale by combining the expertise of multiple academic subjects, from climatology to oceanography to biogeography. In their article Crutzen and Stoermer (2000) suggested that the intentional activities of people, such as commercial farming, traveling by car, and consuming imported foods, had unintentionally altered the “boundary conditions” defining the Holocene. The Holocene is the period of Earth surface history beginning around 11,700 years ago when the most recent “ice age” ended. Research suggests that the various climatic zones and biomes emergent during the early Holocene remained fairly stable from thereon, as did average global atmospheric temperature. The most recent centuries of the Holocene have been those where the number of *Homo sapiens* grew significantly and when large-scale migrations led to their dispersal away from centers of origin. Crutzen and Stoermer proposed that the cumulative environmental impact of people living in so-called advanced societies is such that the Holocene might be at an end – if not at the time of writing, then soon. Given how slow geological change normally is, at least when measured against an average human lifespan, the suggestion that people are now equivalent to a “natural force” (such as a large meteorite hitting Earth) was a startling one. It amounted to saying that anthropogenic climate change, already a serious scientific and policy concern by 2000, was only the tip of the proverbial iceberg.

In 2002 Crutzen presented the Anthropocene hypothesis to the wider scientific community in a short article published in the world’s leading science periodical Nature (Crutzen 2002). Counter-intuitively titled “Geology of Mankind,” the article pointed out that if current Western standards of living become globalized then people worldwide will take the earth’s biophysical systems into terra incognita. This may, he argued, necessitate technical interventions of unprecedented scale and scope, such as “internationally accepted … geo-engineering projects … to ‘optimize’ climate” (Crutzen 2000, 23). Similarly, Crutzen speculated, it may require substantial measures to engender “appropriate human behavior at all scales” (2000, 23) so as to
avoid harmful unintended impacts on fresh water resources, nitrogen cycles, oceanic currents, and much else.

The Anthropocene concept: current visibility and precursors

Since Crutzen’s Nature article, “the Anthropocene” has attracted increasing attention across a range of Earth and environmental science fields, including some branches of physical geography. The attention was by no means immediate. Even in 2006 Crutzen’s neologism rarely featured in peer-reviewed scientific research papers. However, for various reasons to be explained below, it is now a fairly familiar term in the semantic landscape of several science subjects. Indeed, a new science journal, published by Elsevier, bears the name (see www.journals.elsevier.com/anthropocene/), as does the new interdisciplinary Anthropocene Review (published by SAGE). The Anthropocene even enjoys a degree of public and political visibility, albeit currently modest. For instance, The Economist magazine devoted a whole section of a late May 2011 issue to the subject, while two months earlier National Geographic magazine ran an article by American science writer Elizabeth Kolbert entitled “Enter the Anthropocene – Age of Man.” The year ended with The New York Times publishing an op-ed on the subject (Marris et al. 2011). Meanwhile, science popularizer and environmentalist Mark Lynas used the idea of “planetary boundaries” to structure his 2011 best-seller The God Species: How the Planet Can Survive the Age of Humans. This idea, as will be explained below, is closely related to the Anthropocene concept and had already been highlighted in an April 2010 issue of Scientific American entitled “Managing Earth’s Future.” Two years later, scientists involved in the IGBP and other global environmental change research programs organized the “Planet Under Pressure” conference just prior to the United Nations Rio+20 Earth Summit. This conference, intended to capture the attention of politicians, opened with a time-lapse video of recent Earth surface change entitled “Welcome to the Anthropocene” (available online by searching on the title).

Though “Anthropocene” remains a novel term, its meaning is not entirely original. As British geologist Jan Zalasiewicz and colleagues noted, “The term Anthropocene is the latest iteration of a concept to signal the impact of collective human activity on biological, physical and chemical processes at and around the Earth’s surface” (Zalasiewicz et al. 2011, 1037). For instance, eight years before Crutzen and Stöermer’s article in the Global Change Newsletter, New York Times environmental correspondent Andrew Revkin coined the term “Anthrocene” to designate “a geological epoch of our own making” (Revkin 1992). Over a century earlier Italian geologist Antonio Stoppani (1873) had presciently talked of the “anthropozoic era.” Then, in the 1920s, the Russian geochemist and naturalist Vladimir Vernadsky was among the first to propose the idea of the “noosphere.” For him this was the realm of human imagination and desire, a constitutively social (even virtual) domain irreducible to humans’ biological capacities but with world-changing potential realizable through technology. Vernadsky had already argued that the biosphere was a force of nature akin to the movements of tectonic plates. Relatedly, his noosphere concept suggested that Homo sapiens might rise above other species to exert a global influence. In the 1940s his ideas reached a wider English-speaking science readership (see Vernadsky 1945).

These and other predecessor terms did not catch on in the scientific community (or wider
world) in the way that Anthropocene seems to have done since 2000. What explains the difference? It no doubt helps that Crutzen is a highly visible and esteemed scientist in the broader earth and environmental science community. What’s more, he has been adept at developing relationships with notable members of this community who have a professional stake in examining the Anthropocene hypothesis more closely. Among them are the aforementioned Zalasiewicz and the Australian Earth system scientist Will Steffen. In addition, the fact that anthropogenic climate change is believed by most climate scientists to be real and significant is an important background consideration. If humans can accidentally alter the world’s climate then it is not so far-fetched to take seriously the suggestion that we are taking other biophysical systems away from their Holocene norms. Relatedly, environmental measurement and monitoring systems are far more numerous and granular than a generation ago, in part because of the impetus provided by the IGBP and related research programs. This means that large claims about global environmental change are more readily testable than heretofore and easier to accept as working hypotheses that can be dis/confirmed in due course. Finally, and going back a little further in time, more than one generation of scientists, politicians, business people, and members of the public are accustomed to ideas as intellectually and practically challenging as the Anthropocene. Even prior to anthropogenic climate change (once known more pointedly as “global warming”) becoming a key term in our societal lexicon, concepts like “natural limits to growth,” global “over-population,” and “nuclear winter” were emanating from (parts of) the scientific community as far back as the mid-1960s. These concepts were taken seriously in the wider society, even if they fell out of use for various reasons. For older members of several nonacademic communities (political, commercial, etc.) the idea of the Anthropocene has thus not come out of the blue, but is only the latest – albeit most far-reaching – term used to describe human–environment relations on a global scale.

A new geological epoch?

At the time of writing, discussion of the Anthropocene remains largely confined to academic circles, especially those that Crutzen and his coauthors move in. A minority of social scientists and humanities scholars are also beginning to consider the Anthropocene, including a small number of human geographers whose arguments will be considered toward the end of this entry. Only time will tell if the Anthropocene idea becomes truly prominent outside the academic world. In the earth and environmental sciences, the debates have focused on issues of measurement and inception. The questions have been “What evidential markers can tell us whether or not the Anthropocene has begun and the Holocene ended?” and “When, exactly, did the Anthropocene start?” These questions have arisen because of Crutzen’s success in enrolling other scientists in testing his Anthropocene hypothesis. For instance, in late 2007 he co-published a paper with the abovementioned Will Steffen and American environmental historian John McNeill. Its dramatic and quizzical title was “The Anthropocene: Are Humans Now Overwhelming the Great Forces of Nature?” (Steffen, Crutzen, and McNeill 2007). The paper appeared in the peer review, multidisciplinary science journal Ambio. More detailed in evidential and analytical terms than the earlier GCN and Nature articles, it was also more confident that the Holocene is a thing of the past.
However, none of the three authors was (or now is) a geologist. By contrast, Leicester University’s Jan Zalasiewicz was, in 2007, chair of the Stratigraphy Commission of The Geological Society (located in London). He noticed Crutzen and others’ use of the Anthropocene idea. He proposed to the other 20 commission members that this idea should and could be tested using formal geological criteria for the identification of an epoch. The result was a coauthored article that appeared in GSA Today, the house periodical of the Geological Society of America (Zalasiewicz et al. 2008). Entitled “Are We Now Living in the Anthropocene?” it detailed the measures necessary to establish if and when the Holocene had ended. To quote from it at some length, “Earth has endured changes sufficient to leave a global stratigraphic signature distinct from that of the Holocene or previous Pleistocene inter-glacial phases, encompassing novel biotic, sedimentary, and geochemical change. These changes, though likely only in their initial phases, are sufficiently distinct and robustly established for suggestions of a Holocene–Anthropocene boundary in the recent historical past to be geologically reasonable. The boundary may be defined either via Global Stratigraphic Section and Point (‘golden spike’) locations or by adopting a numerical date” (Zalasiewicz 2008, 4). As a result of this paper and subsequent discussions among the academic networks of commission members, the International Commission on Stratigraphy – which is ultimately responsible for identifying geological epochs – established an Anthropocene Working Group and made Zalasiewicz its chairman. At the same time Zalasiewicz and his Leicester colleague Mark Williams joined with Crutzen and Steffen to present the question of formally establishing the Anthropocene’s epochal status to non–geologists (Zalasiewicz et al. 2010a). A set of 2011 papers in the Philosophical Transactions of the Royal Society A were intended to do the same (Ellis 2011; Steffen et al. 2011a; Zalasiewicz et al. 2011). As a consequence of these interventions, and various conference presentations by their authors, the broader environmental science community has been drawn into a geological discussion of epochal markers normally confined to earth science and normally focused on the deep past.

Which lithostratigraphic, biostratigraphic, or chemostratigraphic indicators, if any, are considered sufficiently suggestive of a phase shift in Earth surface conditions to serve agreed criteria for the Holocene’s eclipse? There are several candidates, from lake sediments to greenhouse gas concentrations to artificial isotopes produced by nuclear weapons detonations. Clearly, because these markers all pertain to both recent and ongoing anthropogenic environmental change, establishing the Anthropocene’s epochal status in a way satisfactory to geologists requires environmental scientists from a range of disciplines (including physical geography) to supply robust evidence of changes that might, thousands of years later, be considered clear stratigraphic markers by future geologists. For instance, the British Society for Geomorphology has established a fixed-term working group to advise the society on whether and how contemporary landforms might comprise stratigraphic markers (see Brown et al. 2012). The complications involved in identifying and interpreting markers of any kind are manifold (Rull 2013). First, which markers – one or several – should be taken as definitive of the Holocene’s termination? Second, given that we may only be in the very early years of the Anthropocene, it is important that any one marker be resolved to geologically precise temporal scales, like a decade or a year. This is technically challenging in many cases. Third, because the ecological impacts of human activity have been and remain diachronous,
significant environmental signatures evident in one part of the world (e.g., Western Europe) may not be replicated elsewhere until the last few years or next few decades. Finally, it is entirely possible that future environmental markers reflective of present-day human activities will prove to be more compelling indicators of the Anthropocene’s onset.

By virtue of some or all of these reasons, several environmental scientists doubt that the Holocene’s end can (yet) be measured in stratigraphic terms. For instance, in a paper about anthropogenic soils as potential stratigraphic markers Gale and Hoare (2012) conclude that “there are serious difficulties in using stratigraphic methods to define the base of the Anthropocene. In part this is associated with the worldwide diachroneity of human impact and the difficulty of establishing a single chronological datum for the epoch. Although several wide-ranging event markers exist (including bomb-produced isotopes), these fail to coincide with the worldwide initiation of [environment altering] human activity” (p. 1493). Given the several measurement issues itemized above, and given that the International Commission on Stratigraphy is very exacting about what constitutes a new geological time period, there is little chance that the Anthropocene will be declared a new epoch by geologists any time soon.

Beyond geology: current debates in the environmental sciences

This has not deterred several researchers from searching for chronometric indicators of the Anthropocene’s inception, regardless of their stratigraphic in/significance. In their 2007 Ambio paper, Steffen et al. divided the Anthropocene into three periods, beginning with “The Industrial Era” (1800–1945), followed by “The Great Acceleration” (1946–2015) and possibly followed by a period of “Earth System Stewardship” (2016–) in which humans at last take collective responsibility for their huge global environmental footprint (see also Steffen et al. 2011a). However, without discounting the chronometric significance of 1800, American paleoclimatologist Bill Ruddiman and colleagues have suggested that a global anthropogenic environmental signal can be recorded hundreds of years earlier (see the debate by Ruddiman, Crucifix and Oldfield 2011, in the pages of The Holocene). They propose that even as early as the Middle Ages (and perhaps centuries before that) collective human endeavor was able to unintentionally alter climatic conditions (see Ruddiman 2013, for a review of the evidence in favor of “the early Anthropocene hypothesis”). As with the discussion of stratigraphic markers it is unlikely that consensus will be reached on a single year or decade when the Anthropocene can be said to have begun. Instead, environmental scientists may need to accept that different worldwide anthropogenic signals of varied magnitude appeared at different times over the last six centuries. In this context, the “beginning” of the Anthropocene might be said to have been cumulative, unsynchronized, and strung out rather than punctual (see Lewin and Macklin 2013).

In light of these debates about how to measure and date a crossing of the Holocene–Anthropocene boundary, it may be thought that Crutzen and Stoermer’s hypothesis has reached an impasse a decade and a half after it was put forward. However, this is far from true. As paleoecologist Valenti Rull notes, “it is not necessary to formally define the Anthropocene as an epoch to accept that human activities have significantly changed earth system processes [and forms] during the last [few] … centuries” (Rull 2013, 4). Geologists like Zalasiewicz and Mark Williams, and environmental scientists like
Crutzen and Steffen, recognize this too. As they wrote in the journal *Environmental Science and Technology*, “quite how and when the Anthropocene is formalized is of secondary importance; its real importance is in being a means to integrate a wide range of environmental indicators [and] to consider them within the context of the whole of [the] Earth [surface]” (Zalasiewicz et al. 2010b, 6008). Consequently, it is possible for the Anthropocene to remain an informal concept in geology even as it becomes a normal part of the vocabulary of many environmental scientists. Its facility for the latter is that it denotes biophysical changes that are profound relative to the human, rather than geological, past.

One notable example of this is the recent published work of Johan Rockström and colleagues—including Crutzen and Steffen. In a 2009 paper in *Nature* (Rockström et al. 2009a) and a much longer essay published in the journal *Ecology and Society* (Rockström et al. 2009b), a large number of environmental scientists from across the disciplines have advanced the concept of “planetary boundaries.” Aside from Crutzen and Steffen, both high-profile scientists, researchers include noted ecological economist Robert Constanza and the prominent climate scientist James Hansen. Rockström et al. argue that the environmental conditions of the Holocene are preferable to those of an unknown and potentially inhospitable Anthropocene future. They identify nine global environment components constitutive of the Earth system. These pertain to climate, ocean acidity, chemical balances, atmospheric aerosols, biodiversity, land-use types, freshwater, nitrogen and phosphorus cycles, and stratospheric ozone density. For seven of these they specify a quantitative boundary, the crossing of which might take the system beyond Holocene norms (for the remaining two they are unable, as yet, to quantify the boundary). Together, the nine boundaries comprise what Rockström et al. call “a safe operating space for humanity” (2009a, 472). Modern humans, they argue, have already transgressed several of these. Recognizing that “Determining a safe distance involves normative judgements of how societies choose to deal with risk and uncertainty,” they nonetheless commend their “new approach to defining biophysical preconditions for human development” (Rockström 2009a, 472, 474).

Rockström et al.’s planetary boundaries concept is a particular version of the Anthropocene idea in all but name. We might therefore call it a “collateral concept.” It signifies environmental changes of the same scope and scale as the Anthropocene idea, but in a less politically neutral and more overtly normative way. This is not to suggest that Rockström, Crutzen, Steffen, Constanza, Hansen, and others are distorting science to serve political ends, that is, to recommend urgent action to stay within a “safe operating space.” It is simply to say that, in their view, current evidence of human impact suggests that future environmental change may pose a serious threat to human development in many parts of the world. In part, this is because the concept of multiple planetary boundaries suggests the possibility of “coupled effects,” where crossing one threshold then triggers serious biophysical changes to some or all of the other eight components of the Earth system.

Unlike the Anthropocene concept, the planetary boundaries idea has not—for obvious reasons—preoccupied geologists. It can be taken seriously without any need to satisfy formal geological criteria for the Holocene’s end. Yet, given its novelty, it has not yet received much serious scientific scrutiny outside the large network of authors represented in the *Nature and Ecology and Society* papers. It has, however, been noticed by the United Nations High Level Panel on Global Sustainability and by leading nongovernmental organizations like Oxfam and the World Wildlife.
Fund. In large part this is because it featured prominently at the aforementioned Planet Under Pressure conference in London. However, members of the American environmental think tank, the Breakthrough Institute, caution against its uncritical acceptance (Nordhaus, Shellenberger, and Blomqvist 2012). Though not practicing scientists, their evidence-based report arrived at two conclusions. The first is that six of the supposed planetary boundaries cannot be said to be global but only regional or local; the second is that there is no compelling evidence that transgressing these six “non-threshold boundaries” would necessarily diminish human welfare. Nordhaus, Shellenberger, and Blomqvist point to the choices and ingenuity humans possess to both adapt to and change their surrounding environments. They argue that people can and must “trade-off” between alternative goals and courses of action. In this light, they insist, “attempts to depoliticize [trade-off decisions] … with reference to scientific authority is dangerous, as it precludes democratic resolution of … [public] debates, and limits, rather than expands, the range of available choices and opportunities” (Nordhaus, Shellenberger, and Blomqvist 2012, 37).

The Anthropocene and planetary boundaries as strategic tools for policy relevant science

In scientific terms, it is unclear how the Anthropocene concept and the related planetary boundaries idea will fare in the years ahead. As we have seen, geologists remain open-minded yet uncertain about the former, while many environmental scientists struggle to agree on an inception date. Meanwhile the planetary boundaries idea is rather too new to have attracted sustained scientific scrutiny as yet. What is clear is that both are intended by their originators to be a scientific means to capture the worldwide attention of politicians, business people, third sector organizations, and the public. As Steffen and colleagues wrote in 2011, “The concept of the Anthropocene, as it becomes more well-known … could well drive a similar reaction to that which Darwin elicited [a hundred and fifty years ago]. There is one very significant difference, however … Darwin’s insights into our origins provoked outrage, anger, and disbelief but did not threaten the material existence of society of the time. The ultimate drivers of the Anthropocene, on the other hand, if they continue unabated … may well threaten … the future existence of Homo sapiens” (Steffen et al. 2011a, 862). Given that these authors have been directly involved in proposing it, the same can be said of the planetary boundaries idea too. Both are intended to provide “an independent measure … of the scale and tempo of human-caused change” (Steffen et al. 2011b, 756–757). They deliberately beg large non-scientific questions about what humans want for the future and how they might practically go about realizing their goals in a world of rapid biophysical change. Science can help address these questions, but only up to a point. Science is thus inserted into vital discussions about what some regard as the ultimate question, namely “How should we live?”

Cynics might argue that the multidisciplinary science networks currently advancing the Anthropocene and planetary boundaries ideas are politically canny in their hunt for future science funding. Science is expensive to pursue and highly competitive between science subjects. It could be argued that the two concepts are
eye-catching vehicles to persuade governments to throw yet more money at global environmental change science in its various forms, keeping the likes of Crutzen, Steffen, and Rockström gainfully employed for years to come. However, a different interpretation is equally, if not more, plausible. Scientists are not only scientists but also citizens, parents, members of local communities, and so on. This means they possess the same wider hopes for, and anxieties about, our future that other people possess. In many cases scientific insight can speak directly to these hopes and anxieties, without entirely dictating their content. This may explain a recent position piece published in the journal *BioScience* by – yet again – Paul Crutzen, writing with a combination of both environmental and social scientists. Entitled “Planetary Opportunities: A Social Contract for Global Change Science to Contribute to a Sustainable Future,” it argues that societies now need “useable research” from the science community that is “solutions orientated” (DeFries *et al.* 2012). The paper is framed explicitly against the “reality” of the Anthropocene and the nine Holocene “planetary boundaries” defined by Rockström and colleagues. It presents a vision of global change science at the service of societies worldwide, akin to what science policy analyst Michael Gibbons and coauthors famously called “Mode 2 research” (Gibbons *et al.* 1994). Such research, these writers argued, does not satisfy merely academic curiosity but is, instead, geared to real world “contexts of application” right from the start. Understood in this light, the ideas advanced by Crutzen, Steffen, Rockström, and allies are important not because they can ultimately be “tested” empirically but because they can frame the future conduct of societally relevant environmental science. The desire for relevance in parts of the environmental science community is currently very high. For instance, James Hansen has been a visible and vocal advocate of strong measures to mitigate future atmospheric warming. Meanwhile, British climate scientists Kevin Anderson and Alice Bows (2012) argue that too many scientists have been far too timid in emphasizing to politicians the severity of forthcoming environmental change.

The contribution of social science and the humanities

How have social scientists and humanities scholars interested in environmental change responded to the idea of the Anthropocene and its collateral concept of planetary boundaries? Some applied social scientists have used them as a (further) opportunity to argue for a new global governance architecture that can build on the not entirely successful efforts of the United Nations to ensure coordinated and decisive transnational environmental management. Notable here is the work of Frank Biermann and colleagues on the so-called Earth System Governance Project which began in early 2009. The project involves some 2000 social scientists worldwide. It is an outgrowth of the International Human Dimensions Programme on Global Environmental Change (IHDP), itself a product of the global environmental change research programs established nearly three decades ago (such as the IGBP). The project, which runs until 2018, aims to study and shape “the interrelated and increasingly integrated system of formal and informal rules, rule-making systems, and actor-networks at all levels of human society (from local to global) that are set up to steer societies toward preventing, mitigating, and adapting to global and local environmental change and, in particular, Earth system transformation, within the normative context of sustainable development” (Biermann *et al.* 2009; see also Biermann *et al.* 2010). According to this vision, social science
arguably becomes the analytical and practical twin of Crutzen et al.’s environmental science. It seeks to create, monitor, and suggest amendments to a new regulatory apparatus sufficient to govern “appropriate human behavior at all scales,” as per Crutzen’s 2002 *Nature* article.

For those persuaded of the scale and urgency of the environmental challenges encapsulated in the Anthropocene and planetary boundaries concepts, this kind of social science endeavor is both necessary and highly valuable. However, some social scientists have expressed concern. For instance, in a recent paper in the journal *Environmental Science & Policy* (Palsson et al. 2013) a mix of anthropologists, historians, and sociologists offer two criticisms of the style of “relevant” Anthropocenic social science advocated by Biermann et al. First, they worry that seemingly “objective” scientific concepts can be internalized unthinkingly by social scientists and then translated into action via policy makers. For instance, they point out that we should “view systematic boundaries as suitable constructs for a mechanistic worldview created by [scientists] … for analytical purposes and projected onto reality, rather than an intrinsic property of the observed world” (Palsson et al. 2013, 7). Second, they suggest that a rush to identify managerial “solutions” to environmental problems identified by environmental scientists may overlook the need to explore the full range of possible societal causes of these problems, and the various ways they may be perceived and felt by diverse real-world actors. All solutions are, after all, relative to how one understands the underlying reasons generative of perceived problems. For instance, a Marxist might say that profit-hungry capitalist corporations are largely responsible for unchecked global environmental change; a neo-liberal economist might say that “missing markets” are the problem; meanwhile, certain feminists might point to the deleterious effects of “masculine” reason which treats the world as a set of objects and relations to be dissected, manipulated, and exploited. In each case, the “social engineering” required to respond to the challenges of the Anthropocene and remain within a “safe operating space” would be very different than those likely to emerge from the Earth System Governance Project. And in each case we might be disposed to ask different questions about how ordinary people want significant environmental change to be tackled.

Underpinning Palsson et al.’s arguments is a clear recognition that the social sciences and humanities produce value-laden concepts, proposals, and evidence. They cannot pretend to exist “above the fray” and need to be explicit about the normative judgments written into both their analyses and proposals for alternative courses of human action. This is for the obvious reason that all values are debatable and require reasoned discussion in order to be accepted as the proper basis for social conduct and environmental husbandry. Palsson et al. are among a number of scholars calling both for more diverse and for more radical conceptions of how to respond to the challenges of our Anthropocenic times. This presents a real opportunity for social scientists and humanists to demonstrate their societal relevance, but in ways that are not narrowly instrumental or unthinkingly reproductive of the political-economic and cultural status quo. Several science policy makers are keen to maximize this opportunity. For instance, the European Union RESCUE foresight project (Responding to Environmental and Social Challenges for our Unstable Earth) created a working group focused on “revolutionary education and capacity building.” Relatedly, in key American science funding bodies (notably the National Science Foundation) “transformative research” is now seemingly de rigueur, and is conceived
ANTHROPOCENE AND PLANETARY BOUNDARIES

in wider terms than simply “transformative technologies” (like nanotechnology).

Aside from its several applied subject areas (like social work), the social sciences have long been productive of radical thought (often in a highly utopian register). This is equally true of the humanities, as they have typically been unencumbered by concerns about “policy relevance” or “stakeholder needs.” This does not render them mere ivory tower pursuits, but ensures they have the freedom to stretch the boundaries of what is thinkable and considered to be possible. Moreover, whereas social science is not terribly visible outside universities, humanistic endeavors certainly are among sections of the wider society (think of literature and poetry, for instance). During the period when the Anthropocene and planetary boundaries concepts have entered scientific discourse the so-called environmental humanities have risen to prominence within (and indeed beyond) the academy. In the broadest sense this involves non-academics and has proceeded in three connected ways. First, many professional writers in the West have been publishing works of autobiography, “faction,” literary fiction, and poetry that focus on a “rediscovery” of the nonhuman and an exploration of the role that “nature” can and should play in our everyday lives. In Britain the writings of Robert Macfarlane (2007) about the relationship of people and land are emblematic of a wider fascination with the affective significance of the material world. Second, in a range of humanities fields – most notably literary criticism – newer (like Macfarlane’s) and older (like Thoreau’s) attempts to rethink human-environment relations have produced a new body of humanistic analysis called ecocriticism (see Garrard 2013). This seeks to shine light on the content, tropes, and aims used by nature writers, photographers, and filmmakers in their attempts to have people reconsider the ways they (de)value the nonhuman. Finally, the environmental humanities have, *sui generis*, been productive of radical new conceptions of how to apprehend and register the significance of the nonhuman. Literary critic Tim Morton’s work is a good example (e.g., Morton 2010), attempting as it does to entirely eliminate the nature-society dichotomy that has for so long structured how most Westerners conceive of reality.

Geographers and the Anthropocene

How have these wider currents of thinking with and beyond environmental science influenced the discipline of geography and vice versa? Thus far, few geographers have either been involved in originating the two concepts being discussed here (University of Arizona’s Diana Liverman and University of Maryland’s Erle Ellis are exceptions) or in responding to them/fleshing out their possible significance. Given their encompassing meaning and implications, one might expect the Anthropocene and planetary boundaries ideas to engender renewed consideration of how physical and human geographers can better work together to study and improve the world. This has not happened yet but is very likely to happen in the near future. In the meantime, it is human geographers of various stripes who have so far paid the ideas most attention (or rather the first idea, since planetary boundaries have scarcely attracted geographers’ attention as yet). Since human geography has both social scientific and humanistic elements, it is no surprise that the geographers in question have offered diverse reflections on what the Anthropocene signifies for geography and/or society (see, for example, the 2014 “forum” organized by Johnson and Morehouse in the journal *Progress in Human Geography*).

In the first place, some have used the Anthropocene as an occasion to pronounce the “death”
of nature, a category that has long vouchsafed physical geography’s identity and which remains a touchstone for public pronouncements about the need to mitigate or adapt to global environmental change. According to Jamie Lorimer (2012), the worldwide ontological mixing of human forces with nonhumans definitive of the Anthropocene has profound intellectual and normative implications. For him it is creating “emergent geographies” that are spatially and temporally varied, often surprising; the implication is that we can no longer talk about a singular, asocial nature to justify various management, conservation, remediation, preservation, or restoration measures (be they large or small). He commends an “experimental ethos” (Lorimer 2012, 600) that is open-minded and reflective, challenging us to make considered, revisable decisions about how we and nonhumans might live together in a thoroughly syncretic world in whose vitality we have a big role in determining. Though Lorimer does not come out and say it, his approach to responding to the Anthropocene is almost the opposite of Biermann et al.’s vision of rule-bound institutions for “earth system governance.” His arguments are offered more in the spirit of different places and countries sharing experience and practice in the face of geographically variegated forms of future biophysical change (see also Lorimer and Driessen 2013).

Lorimer’s arguments are a challenge for environmentally minded human geographers to embrace what Morton has called “ecology without nature” (Morton 2007). They build on over a decade of research into so-called more than human geography pioneered by the likes of British geographer Sarah Whatmore (2002). In a similar spirit, but with a much keener eye on new ideas that key societal decision-makers might take seriously, Karen O’Brien (2013) has challenged geographers like Lorimer to produce “transformative research” of the kind commended by Palsson et al. – indeed she was a member of the RESCUE foresight project mentioned above (see O’Brien et al. 2013). In her view, human (and, by implication, physical) geographers need to unpick the deep and unexamined assumptions they hold about ontology, epistemology, method, and practice. Only then, in her view, can they offer nonacademic stakeholders the eye-opening ideas needed to inspire societies to travel down genuinely new roads as they face environmentally dynamic and possibly threatening futures.

In this light, ideas about the Anthropocene advanced by some more philosophically minded human geographers may appear either too radical or else too abstract to be useful as part of the “axial revolution” O’Brien wishes to see within and without geography. For instance, Kathryn Yusoff (2013) regards the Anthropocene as an occasion to discuss not the ascendancy of humanity over other life forms but the very meaning of the “anthropos.” Yet her arguments are complex, subtle, and rarefied: it is hard to imagine them being understood and acted on by many of her fellow geographers, let alone people outside the academy. By contrast, political geographer Simon Dalby (2013) points to the emergent discourses outside academia that may soon be using the “fact” of the Anthropocene to justify questionable national security and surveillance policies. Pointing to leading governmental, quasi-government, and nongovernmental actors, like O’Brien he asks what alternative, motivational concepts, and aims might be offered to them by geographers and others in the name of a more social democratic and just Anthropocenic future.

For still other human geographers, the likes of Lorimer, O’Brien, and Dalby might be regarded as too fixated on engaging (and trying to change the thinking of) mainstream societal actors, like national government ministers and
departments. Gibson-Graham and Roelvink (2009) argue that human geographers and other social researchers should both study, and actively engage with, everyday communities who want to create truly alternative ways of living. For them the onset of the Anthropocene can and should give such communities further impetus to inspire researchers and various social actors to develop real options outside mainstream thinking. For a Marxist geographer like Jason Moore (2015), however, Gibson-Graham’s arguments may appear to risk ignoring the enduring power of capitalist political economy to limit such options, even as it tries to “green” itself in order to avoid dangerous environmental change. Yet for Gibson-Graham a geographically differentiated grassroots politics lacking worldwide coordination is at least as viable a way to address the challenges of the Anthropocene as the sort of necessary, but current unviable, global anticapitalist politics that Marxists call for.

Conclusion

In sum, the Anthropocene and its collateral term planetary boundaries are arresting terms designed to characterize the human impact on the nonhuman world. It is too soon to say if they will significantly influence the terms of public debate about humanity’s future on Earth. However, they are gaining a degree of traction in Anglophone academia, and beginning to frame discussions of human–environment relations in geography. Given their enormous implications, the key question about the two terms looking ahead is: who will speak in their name, what claims will they make, whose claims will prevail, and what practical measures will follow from those claims? Like other interested analysts, geographers stand to be participants in the future discursive contests that will determine the exact answer to this important question. Though scientists can be credited with inventing and disseminating the two terms discussed in this article, it would be unfortunate if their ideas dominate future debates. By combining scientific, social scientific, and humanistic ideas about Earth’s future in a single disciplinary space, professional geographers and their students may together present the mixture of data and ideas needed to think creatively about a world to come (see Hulme 2008, for a similar argument in relation to anthropogenic climate change).

ANTHROPOCENE AND PLANETARY BOUNDARIES

Anthropogeography refers to a mode of systematic analysis, adopted in the late nineteenth and early twentieth centuries, of the geographical distribution of societies, the relationship between migration and the physical environment, and (that for which it is best remembered) the influence of environments upon societies. Although it can be placed on a continuum of a long history of studies of environmental determinism dating back to Greco-Roman times, the term comes from the title of a two-volume work, *Anthropogeographie* (1882 and 1891), written by the German geographer Friedrich Ratzel (1844–1904). Ratzel is best known for being the founder of geopolitics although his influence in shaping late nineteenth century human and physical geography (and anthropology) is increasingly being recognized. Anthropogeography was to influence the work of other prominent early twentieth century geographers, including, in the United States, the student of Ratzel, Ellen Churchill Semple, and Isaiah Bowman, and in the United Kingdom, the political geographer, Halford Mackinder, and in Europe, the German geographer, Karl Haushofer. It was, however, the taking up of Ratzel’s concept of living space (*Lebensraum*) by the Nazis in their justification for territorial expansion for which his work is perhaps still best remembered.

Ratzel’s practical and intellectual engagement in the imperialist politics of expansion is best understood in the political and intellectual context in which he worked at universities in Munich and Leipzig in the late nineteenth century of European imperialism. This political context has also defined the memory of Ratzel’s contributions to geography, serving to undermine that it was also the period in which the divides between natural science, social sciences, and the humanities were being carved out and in which geography as an academic discipline was institutionalized as the study of the Earth’s surface (Lossau 2009). Ratzel’s role in shaping these divides was seminal, involving going beyond the focus on geomorphology that occupied his contemporaries to also examine the life on the Earth’s surface. His work was to lead to the merging of human and physical geography, albeit in a way that was marked by causal explanations, natural laws, and one in which knowledge was derived from the ground (*Boden*) (views which his French contemporary, Emile Durkheim, was to critique), heavily influenced by the rise of social Darwinism, or survival of the strongest societies, and environmental determinism.

Ratzel’s book *Politische Geographie* (1897) is considered the culmination of his voluminous work and that in which he explicitly addressed geopolitics, the analysis of the relationships between geography and the practice of statecraft. As Lossau (2009) has pointed out, there are two competing geographical imaginaries in Ratzel’s work, of containment and expansionism. The first is that of natural lands (*Länder*), or the territory of a nation state which results from the interactions between a specific group of people (*Volk*) who are bonded not through kinship but through their relations to their occupied territory (*Boden*). This is the spatial
imaginary of regional geography that dominated the study of human geography in the early and mid-twentieth century. The second imaginary, central to geopolitics, is based on the view of the state as the biogeographical, or organic, unit that corresponds to its living space (*Lebensraum*). The state, as organism, was subject to laws of territorial growth and development (“the law of growing areas”) and would thus “naturally” seek to expand as its population increased leading to a constant struggle for the conquest of space among states, creating a cycle of progression and defeat, and what can be recognized as a process of uneven development (Natter 2005). Although there is disagreement among scholars as to the extent to which Ratzel’s work had a direct impact on the expansionist policies of the Third Reich, it was complicit in the national socialist ideology of *Lebensraum*. While Ratzel did not speak to the annexation of European countries or the racial superiority of Germans, the political implications of his work on geopolitics and on the practice of war were obvious and he actively developed them through his membership of the Pan-German League in which he advocated the overseas expansion of Germany and the development of its navy (Lossau 2009).

The dual imaginaries in Ratzel’s work complicate a straightforward narrative of environmental determinism; the belief that the environment determines social life has to be understood in relation to the dynamism of *Boden* and *Lebensraum*. While the concept of *Lebensraum* is strongly determinist, tied to the belief that societies are subject to natural laws determined by the land, that of *Boden* speaks more to the physical environment as a causal influence on a *Volk*. The latter, it has been argued, is the basis of the regional paradigm of modern geography and is open to less determinist understandings. However, it is clear that for Ratzel both concepts rely on the environment as a causal force with *Lebensraum* possessing the normative power to provide “an apparently scientific justification for political aims” (Lossau 2009, 146). The debate as to whether this taints his status as a founding figure of modern human geography can only continue. Certainly, his work in geopolitics laid the pathway for subsequent geopolitical theories and, arguably, of the interest in statecraft in critical geopolitics. That his work also falls into the tradition of biogeography (the study of the distribution of species and ecosystems in geographic space and through geological time), with continuities between the earlier work of von Humboldt, and that to come of Vidal de la Blache on *genre de vie*, and opening up questions of the relations between societies and the environment, is notable.

Most recently, the popular but controversial work of the geographer Jared Diamond has re-opened this debate. Although working a century apart, there are marked similarities between the intellectual trajectories of Ratzel and Diamond: both shared an education in the natural sciences (Ratzel in zoology and chemistry and Diamond in physiology and biophysics); both spent time travelling extensively, studying how societies evolved socially in relation to their environment, as a journalist in the case of Ratzel and as a popular science writer in the case of Diamond; and, finally, both turned to the professional designation of geographer. In both their bodies of work it is their understanding of culture that has been critiqued, both viewing it not in the realm of ideas but explained through environmental imperatives.

Further reading

By definition, the term *geomorphology* involves studying changes upon the surface of the Earth. Scientists who study these changes, then, are known as geomorphologists. They examine the changes by understanding how geomorphic agents such as wind, water, ice, gravity, plants, animals, and people sculpt the geographic landscape we interact with each day. To better understand all interactions among the various geomorphic agents shaping the landscape, geomorphologists often break the field of geomorphology down into various subfields, each of which describes a particular geomorphic agent. While the myriad of subfields can be confusing, and irritating to some, breaking geomorphology into these various categories clearly illustrates that many agents play a role in shaping the surface of the Earth.

Biogeomorphology is one such subfield of geomorphology that breaks from those traditional agents of change and examines transformative processes upon the Earth’s surface through the unique lens of life itself. It follows then that zoogeomorphology studies how animals exert an impact on the landscape, and much work has been done in this realm since its introduction by Butler (1992). Arguably, however, humans are also animals and the impacts they have rendered on the surface of the planet supersedes any past landscape transformation, denudation or deposition, by other species in the animal kingdom (McNeill 2000). Therefore, the anthropogenic element, or anthropogeomorphology, is yet another subfield within the discipline of geomorphology that is increasing in appearance within scientific literature. Despite the profound role anthropogeomorphic processes have within the scope of geomorphic processes, shaping the landscape more than any other natural process, it is a topic that has received scant attention and nowhere near the amount of research deserved. This lack of attention may stem from the difficulty researchers have in connecting what takes places within the “natural” realm of geomorphology with actions rendered by anthropogeomorphic processes.

Geomorphology and anthropogeomorphology alike are best understood knowing that the changes rendered upon the surface of the Earth come about from a collective body of geomorphic agents. These agents can remove material through the process of erosion, or they can add material through depositional processes. For example, heavy winds may pick up dust from a desert surface yet at some point the wind will slow down and deposit that dust at a downwind location, perhaps into a stream where that material will get carried into a body of water such as a lake or ocean where it settles to the bottom. Very rarely does one geomorphic agent act alone in sculpting a particular landscape. Instead, a variety of forces are at play, both eroding and depositing materials in a constant ongoing process. Anthropogeomorphologists study these agents as well as connecting the direct and indirect activities of humans as a geomorphic agent. Humans act as a direct geomorphic agent when they themselves are directly involved in the processes of erosion and deposition; activities such as...
excavation, mining, canal and dike construction, road building, and cratering due to warfare are all examples of anthropogeomorphic landforms. Indirectly, however, humans are also intimately related to the more traditional “natural” geomorphic agents such as wind and water. It is these indirect modifications, associated with the technology we have created to modify our surroundings, intentionally or not, that have the most profound impact of all on the landscape. For example, when humans clear a forest for agriculture, the accelerated rates of water erosion are indirectly related to the change in land cover created by human economic activities. For the anthropogeomorphologist, finding changes on the Earth’s surface are not difficult and indeed, what may prove more challenging is finding what geomorphic agents today are not related to some type of human activity.

Humans have always excelled at modifying their environmental surroundings. From the dawn of humankind until present, humans owe their overall success on this planet to their innate ability to somehow bend nature to their own will. Researchers in the archaeological community have even put forward theories that both the human and Neanderthal species at one point coexisted together before Homo sapiens pushed them out of existence (McNeill 2000). With a larger body size, Neanderthals required more calories than humans and therefore required larger amounts of food than humans. In times of environmental stress such as drought, humans were able to outcompete the Neanderthal by consuming what foods were available, literally depleting the land of its resources before moving on, and thus starving Neanderthal out of existence, in what would only prove to be the beginning of humans as the ultimate agent of landscape modification.

Eventually, being able to use the tool of fire, humans began to shape environments to produce both the wildlife and forage resources they desired (Mann 2005). What impact this had on sedimentation rates and the like is difficult to determine, yet it can be assumed that even in their beginnings, humans were playing a role as a geomorphic agent. Research also shows that it was this seminomadic lifestyle with modification of the surrounding environment that first led to the beginnings of the agricultural revolution (Diamond 2005). Although the numbers are debated and difficult to determine, researchers have placed the population of humans prior to the onset of the agricultural revolution at just around 1 million worldwide. With the onset of the agricultural revolution approximately 8000 years ago, the population of humans began a steady increase and with that increase in population came the evident abilities of humans to sculpt the Earth’s surface. Sediment records from thousands of years ago show that when humans cleared land protected by forest and grassland for more agricultural production to support their ever burgeoning and expanding populations, they accelerated erosion on hill slopes and increased rates of deposition in the valleys below (Montgomery 2007). In some cases, the accelerated erosion on soils formerly held together by forest cover was amply recognized and terracing was implemented as a means to prevent erosion. In many areas of the world, terraces remain in agricultural production and are an anthropogeomorphic landmark that testifies not only to what humans are capable of as direct geomorphic agent, but also that soil conservation measures are a viable practice when performed properly. Terracing, however, reflects human modification to the landscape as growing population is pushed out of prime agricultural valley bottom lands and into the submarginal soils of the upland. Terraces are also very labor intensive to maintain and are an exception rather than the rule when it comes
to past civilizations deforesting uplands in order to clear land for agricultural production. Grain harvest records, as well as sediment cores for a variety of depositional environments, attest to the number of great civilizations that have fallen due to intensive agriculture practiced on formerly forested hill sides. Montgomery (2007) provides a detailed perspective on how Western civilizations, including the Greeks and the Romans, were crippled by the massive amounts of soil erosion rendered by intensive and unsustainable agricultural practices.

Accelerated soil erosion due to intensive agriculture and forestry activities are not relegated to ancient civilizations and continue to shape the modern landscape. If anything, the widespread implementation of industrial scale farming and forestry operations has led to the removal of billions of tons of top soil around the world. Although this is a global phenomenon, nowhere is this more apparent than in tropical environments where humans have tapped one of the last agricultural frontiers to meet the food demands of a global population pushing over 6.8 billion. Formally forested hillsides have been put into agricultural production in environments subject to intensive rainfalls and soils weakly held together. Not only does this increase the sediment loads on streams, it also weakens the slopes and sets the scene for catastrophe. This was demonstrated in 1998 when Hurricane Mitch stalled out over the highlands of Central America and triggered landslides that killed nearly 20,000 people. Here, anthropogeomorphic processes were not directly responsible for the deaths, but the indirect and unintentional use of technology to engage in intensive forestry and agricultural practices led not only to massive amounts of material transported in slope failure, but in catastrophe as well. Hurricane Mitch was not unique either in that slope failures like this, as well as siltification of reservoirs and river channels around the world due to intensive agriculture, are only increasing.

Erosion from economic activities such as forestry and agriculture may be profound, but nowhere near as visible as what humans have done to reshape the Earth’s surface drainage networks. From the beginnings of the agricultural revolution until present, humans have transformed the way in how water moves on the surface of the Earth. This has been accomplished through dam construction, water diversion projects, levee creation, dredging operations, reservoir creation, drainage of wetlands, and shoreline modifications. To view the Earth from space would reveal a vast array of hydrologic modifications, many of which were completed over the course of the twentieth century. The construction of dams has allowed for the creation of reservoir style lakes in river valleys around the world. Some of these lakes, such as Lake Mead in the United States and the Three Gorges Dam reservoir in China, cover hundreds of square miles. Although profound, anthropogeomorphic creations like these may pale in comparison to the indirect ramifications of large scale canal projects. The Panama Canal connects the Pacific and Atlantic Oceans while the Suez Canal connects the Mediterranean with the Indian Ocean. If someone wanted to, they could sail up the Saint Lawrence River into the Great Lakes and then connect to the Mississippi via a series of canals and waterways locks through the Chicago River. The Chicago River, one of the largest overlooked engineering projects of the twentieth century, used to flow into Lake Michigan, but now has reversed its flow into the Mississippi. Diversions like these have ramifications well beyond changes in water levels; new corridors open up for transit of plants and animals whose abilities to act as geomorphic agents are profound and only beginning to be understood (Butler 1995).
Human hydrologic engineering has led to the creation of inland seas as well as the disappearance of others. The Salton Sea, formally the Salton Sink, in southern California was created when the Colorado River flooded in 1906, changing its course into a series of canals that were dug by some enterprising farmers attempting to divert waters from the Colorado to irrigate their crops in the fertile but dry soils of the Mojave Desert. Although shrinking in size due to increased urban demand for water in cities such as San Diego, the Salton Sea remains as an example of what direct anthropogeomorphic activities are capable of producing, intentionally or not. Another inland sea that is shrinking in yet another arid landscape is the Aral Sea that borders what is now Uzbekistan and Kazakhstan. Unlike the Salton Sea, however, the Aral Sea was not created due to anthropogenic mishaps and up until the 1960s was an inland sea the size of Belgium. The sea is located in arid landscape fed by rivers carrying snow melt off the Himalaya Mountains. Prior to the diversion projects that led to its demise, the sea was so large it buffered the temperature extremes of the otherwise harsh conditions of interior southern Asia. This benevolent climate attracted the attention of what was then the Soviet Union and the waters were diverted in a massive undertaking to grow cotton. Cotton production did ensue, but not without unforeseen consequences; the sea is now one tenth of its original size, the former fish population is decimated, the climate is no longer moderated by the sea, and toxic chemicals blow off the former surface – poisoning the remaining shell of a populace surrounding the Aral “Sea.”

Beyond hydrologic engineering projects, another anthropogeomorphic process quite visible from space would be landforms associated with excavation activities. Like agriculture and hydrologic engineering, anthropogenic landforms rendered by excavation extend back several millennia. Pits and mounds associated with our quest to obtain mineral resources from the Earth literally cover the planet, getting bigger and bigger with each technological advance. Interestingly enough, it was our quest to harness geologic resources that truly unlocked the human potential to become the most significant geomorphic agent of them all, and that was when we harnessed the power of fossil fuels.

Fossil fuels in the form of coal, oil, and natural gas are really nothing more than stored up energy from the sun. They represent energy taken in by plants for millions upon millions of years, concentrated in layers that humans harvest to unleash that energy how we see fit. By unlocking this power, we removed ourselves and our animals as the primary source of power for labor and were able to develop technology capable of acting as geomorphic agents never before thinkable. In addition, unleashing the power of fossil fuels also generated yet another surge in population in the form of the industrial revolution. In the agricultural revolution, population did grow, but at a linear rate. With the industrial revolution, human population began to grow exponentially. This exponential rise in population, combined with technology capable of moving more Earth than ever before, has left a significant mark on the landscape in the form of excavation activities (McNeill 2000). The footprints left in our quest for mineral and energy resources are everywhere. From the mountains of coal waste on the plains of Belgium, to open pit diamond mines of South Africa, to the widespread desolation of the tar sand mining operations of Northern Alberta province in Canada, the direct anthropogeomorphic excavation agent of change is readily apparent.

Yet another anthropogenic excavation agent, albeit not readily visible from space but very much widespread, are the billions of craters on the Earth’s surface rendered by explosive
munitions in time of war. So distinctive is the disturbance to the landscape surface associated with explosive munitions, that the geomorphic process is termed bombturbation (Hupy and Schaetzl 2006). Bombturbation is common and widespread across all parts of the globe, usually occurs in association with warfare, and the areas affected are spatially concentrated, for example, on major battlefields. For instance, on some World War I battlefields, over 50 million craters have been produced across a several hundred hectare area in a matter of a few months. Bombturbation is usually a cratering phenomenon with the explosion leaving behind a pit that is variously excavated of soil and underlying parent material with an accompanying rim of debris nearby. The event could then be considered both a denudative and depositional geomorphic process, although the displacement of materials is much more concentrated in the crated area, therefore making bombturbation mainly a denudative geomorphic agent (Hupy and Koehler 2012).

Quantifying the amount of material displaced by exploding munitions is, in large part, nearly impossible to tabulate; during World War II alone, 1.4 million tons of bombs were dropped on Europe and 557,000 tons of bombs were dropped on Germany by American heavy bombers (Hastings 2012). This number pales in comparison with the 14 million tons of bombs dropped over Indochina in the 8 years of US involvement in the Vietnam War (Westing and Pfeiffer 1972). Estimates regarding the number of munitions deployed in warfare are often conservatively based as it is difficult to keep accurate records of the number of weapons deployed in warfare. However, these conservative estimates easily place the amount of soil displaced by explosive munitions over the course of the twentieth century into billions of cubic meters. In Vietnam alone, Westing and Pfeiffer (1972) estimated, using air force bombing records and average 500 bomb crater sizes, the amount of topsoil and subsoil displaced to exceed $3 \times 10^9 \text{ m}^3$. Thus, the scope and magnitude of bombturbation is so immense, and the degree to which it can impact soils is so catastrophic, that it justifies singling it out as a major, singular anthropogeomorphic agent. Beyond bombturbative activities, warfare in itself represents a moment in history when many anthropogeomorphic agents are magnified in intensity. Because waging warfare is so costly in the form of resources, many of the anthropogeomorphic activities previously discussed in this chapter are being practiced at an increased level. The need for resources in warfare may also create conditions where, in the war effort, a nation might lift restrictions meant to reduce a particular negative geomorphic impact, such as in mining and agriculture activities. Warfare, one of the more unique forms of anthropogeomorphic disturbance is one such agent that has not received attention until recently. More research is needed in this field to truly appreciate the direct and indirect geomorphic implications of war.

In a world that contains 6.8 billion people, there are but a scant few places on the Earth’s surface that remain untouched by anthropogeomorphic forces. Few can argue that direct anthropogeomorphic activities have not proven themselves as a significant geomorphic agent. Modern geospatial technology in the form of satellite imagery, geographic information systems (GIS), and digital elevation models (DEMs) have made it possible to quantify just how profound this anthropogeomorphic footprint on the landscape really is. Additionally, with more geographers, environmental historians, archaeologists, geomorphologists, and other related scholars exploring our past, the scientific community is gaining insight into the role humans have served as a direct geomorphic agent in history. Humans
have proven themselves ample geomorphic agents by moving, via mining operations alone, more material over the course of the twentieth century than all other natural geomorphic agents combined (McNeill 2000). While mining may be one of the more obvious forms of an anthropogeomorphic agent that has received ample attention from the geomorphic community, other anthropogeomorphic agents lack considerable attention. What remains to be determined is how much anthropogeomorphic forces play an indirect role as an agent of landscape change.

Indirect geomorphic processes will prove challenging to the anthropogeomorphologist in future years. Linking what many would consider to be a natural geomorphic event or an “act of God” to anthropogenic activities proves difficult to establish causality, or even how human activities may have magnified an event. However daunting the task of linking anthropogenic activities to the larger geomorphic realm, significant progress has been made thanks to GIS technology and an increasing awareness of how significant humans are in shaping the surface of the Earth. One research frontier where much remains to be done is in the indirect consequences of climate change as an anthropogeomorphic agent. With time, research in this relatively young subfield of geomorphology will unlock many of the questions anthropogeomorphologists are currently asking.

Antiracist geography

Sharlene Mollett
University of Toronto Scarborough, Canada

Antiracism is a political discourse and intellectual commitment to the challenge of racism, essential for a cogent movement that seeks equality as a principle component of any society. It is informed by anti-essentialist understandings of race, which unsettle constructions of race as a naturalized social hierarchy of biologically separate human populations. Moreover, antiracism, whether practiced by civil society or as part of a particular state mandate, is a contestation of the authoritarianism of the state, and its governance and distribution of the benefits to a purported citizenry; it seeks to shape a morality that questions, and targets for change, the ways in which the state and its elites “other” its populations.

As well, antiracist scholarship attends to how processes of racialization, which assign people to particular racial categories, have material consequences including the inequitable distribution of material resources, spatial meanings, representations, and various forms of power. This popular movement and intellectual narrative, although seemingly concentrated in the United Kingdom and North America, has a global reach.

With beginnings in abolitionism, anticolonialism, and civil rights mobilizations in the United States, Great Britain, and South Africa, antiracist movements are also rooted in the post-World War II effort that ultimately linked multiple racial projects from concentration camps and transfer stations at Auschwitz and Terezin to slavery and segregation in the United States, and racial apartheid in South Africa. Indeed, antiracist geographers agree that there is space for antiracist dialogue across national boundaries. For instance, in Latin America, geographers have demonstrated how critical racial analysis is helpful for understanding colonial and postcolonial relationships – both past and present – and are in conversation with Latin American postcolonial and decolonial scholars working with similar frameworks around colonialism.

Antiracist scholars, however, are divided as to whether antiracism is overly influenced by the racial histories and experiences of the United States, making the field vulnerable to calls of imperialism, due to the fact that many of the conceptual and contextual insights for struggle are shaped by the US context. For instance, Bourdieu and Wacquant’s (1999) piece “On the Cunning of Imperialist Reason,” problematizes US generalizations of the black−white binary that presume “universal” understandings of race and racism and the ways these meanings travel and are inappropriately applied to other contexts. They argue that “cultural imperialism rests on the power to universalize particularisms linked to a singular historical tradition by causing them to be misrecognized as such” (1999, 4, cited in Bonnett 2006). But geographer Alistair Bonnett challenges this claim. Simply because much of the knowledge produced by antiracists builds on US experiences does not foreclose creative applications of this knowledge (and the advance of independently produced ideas) in other contexts. Furthermore, for Bonnett, antiracist projects and imperial projects cannot be mutually exclusive. He insists that critical scholars must “give sufficient attention to the close relationship that can exist between ‘resistance’
and hegemony” (Bonnett 2006, 1091) or in this case antiracism and imperialism. He explains this convergence with the example of how US theorizing is doused in the palatable lexicon of multiculturalism and diversity in such a way that it reifies and naturalizes difference, which serves the state and its racialized governance, even when the state’s goal is seemingly to eradicate racial inequality. The naturalization of race in embodied difference can embolden more conservative positions, particularly in the ways in which multiculturalism can be co-opted in racist ways through neoliberal projects.

Scholarly engagement with the concept of whiteness has become a useful tool to denaturalize race. The increased attention and debate given to the concept of racialization, namely, the “process by which racialized groups are identified, given stereotypical characteristics, and coerced into specific living conditions, often involving social/spatial segregation and always constituting racialized places,” has been a key way in which whiteness is made visible in geography (Kobayashi and Peake 2000, 393). The spatial processes of whiteness are operationalized through banal and everyday practices and not simply aberrant violent events motivated by hate. This unveiling and centering of the “normative, ordinary power to enjoy social privilege by controlling dominant values and institutions” (Kobayashi and Peake 2000, 393) through whiteness leaves little doubt among critical scholars that “racist expressions are normal to our culture, manifest not only in extreme epithets but in insinuations and suggestions, in reasoning and representations, in short, in the micro-expressions of daily life” (Goldberg 1997, 21, cited in Kobayashi and Peake 2000, 393).

These revelations have been taken up by geographers through a number of projects that include such topics as environmental racism, food justice and security, gentrification, land conflicts, international development, migration, agricultural development, music, and labor rights. Through this work, antiracist geography critically examines how, in the words of Bonilla-Silva, “racial domination generates a grammar that helps reproduce racial order as just the way things are. Racial grammar is a distillate of racial ideology and, home of white supremacy” (Bonilla-Silva 2012, 174, emphasis in original). Antiracist geography looks to counter such universalism by making visible how whiteness distorts intellectual production within the discipline of geography. Given the white majority among geographers (and the active peripheralization of critical racial studies in geography, until more recently), the motivation for change moves at a snail’s pace; however, among antiracist geographers there is a growing urgency to highlight not just whiteness as a social condition of privilege but white supremacy hidden in the walls of institutions, the practices of scholars, and what is taught as knowledge. Such antiracist theorizing is relevant to the much needed decolonizing of the discipline of geography.

Another important discussion shaping antiracist intellectual discourse and movements is the feminist antiracist tradition, particularly marked by the Canadian experience, where indigenous women have critiqued Canada as a white settler society and where an active and contemporaneous colonial process unfolds. In a similar way, antiracist black feminist geographers cogently remind us that colonial histories and histories of enslavement set the terrain for contemporary racism, woven as they are into the white settler colonial project. While such conceptualizations unite feminist antiracist projects, tensions exist as well. Canadian indigenous scholars insist “that something is deeply wrong with the manner in which, in our own lands, antiracism does not begin with, and reflect, the
totality of Native Peoples’ lived experience, that is with the genocide that established and maintains all of the settler states within the Americas” (Lawrence and Dua 2005, 121).

These claims not only have implications for the intersectional nature of antiracist feminist traditions everywhere, but also give reason for taking a closer look at how various kinds of oppressions intersect, with particular attention paid to the ongoing colonial project. As critics assert in the Canadian context, rather than contesting the ongoing white settler colonization of indigenous Canadians, antiracism scholarship furthers the colonial agendas of the present and requires increased interrogation of the question of land as a site of struggle. Furthermore, decolonization struggles must be seen as foundational, rather than as one factor in a larger antiracist struggle. Yet, it is also argued that while increased attention to indigenous knowledges and the experiences of indigenous peoples in relation to white settler societies have become more visible in geographic scholarship, some question whether these studies are uniquely placed to reinforce antiblack sentiment in geography. Increasingly, however, antiracist geography encourages studies to explore multiple and intersecting sources of oppression that are shaped by the logics of white supremacy as a way to inform our intellectual and more plural antiracist knowledges.

Overall, such debates are productive. Like all social movements, the fate of the future of antiracism theorizing and practice will be shaped not only by the spaces outside the movement, but by the attendant struggles within.

Apartheid

Maano Ramutsindela
University of Cape Town, South Africa

Apartheid manifests perceptions, views, and habits of mind that crystallized into an ideology of the Afrikaners that was subsequently pursued through the modern South African state. The main constituent parts of apartheid are the idea, policy, and measures that worked together over time to shape the South African society. Each of these parts is important for understanding apartheid as an ideology and program of action, and its residuals in a democratic South Africa. As an idea, apartheid is underpinned by and also expresses a racist ideology. The racist ideology encapsulated in apartheid is not distinctively South African but “reflected and grew out of already existing notions of human difference” (Dubow 1992, 210). It was influenced by German missiology; a local secular intelligentsia highly connected to the international scholarship of racial thought; and the segregationist practices of the American South. The tenets of apartheid are consistent with those of racial segregation in Europe and the United States. It is for this reason that apartheid in South Africa is understood as a perfection and domestication of the same racism that underpinned colonialism. On the ideological front, the division between apartheid and colonialism is superficial hence apartheid is sometimes referred to as colonialism of a special kind. Unlike British or French colonialism that was driven from distant metropolitan centers, apartheid was colonialism from within as both the colonizer and the colonized lived in the same country. This condition both sharpened the racist ideology of apartheid and provided it with a rationale distinctive from existing forms and content of racial segregation (Dubow 1992). Apartheid ideologues saw geographical proximity of the races and the potential racial relations that might emerge as an obstacle toward the ideals of racial purity founded on biological theories of racial superiority. The black majority and the business acumen of Indian immigrants also threatened white political and economic power, respectively. Under these conditions, apartheid hardened into a permanent solution to race relations at a national scale. While the threat to white domination was generally coded as the “native question,” Afrikaner nationalists conceptualized apartheid as an “answer” to that question. It became a unique formula for the regulation of human relations and a blueprint for the future of the country and its peoples. Historians differ on the date on which the term apartheid was first used by Afrikaners but there is general agreement that it entered into the body politic in the 1940s.

Apartheid is a dynamic idea which relied heavily on a bundle of rationales that were mobilized at appropriate moments in its development. Its core pillars remained unchanged. These include the inequality of races in which whites appear as inherently superior to their black counterparts; the trusteeship of whites over blacks; a complete and permanent separation of races in the cultural, economic, social, political, biological, and territorial spheres of contact. In its South African context, the apartheid idea “embodies numerous unwritten social codes and customs [and] … its fundamental core is an attitude of mind peculiar to the Afrikaner” (Rhodie and Venter 1959, 19 – 20).
APARTHEID

Although there were disagreements among Afrikaners about the scope and pace of segregation and the measures required to achieve its goals, the South African white’s views on color informed the apartheid policy, whose objectives were threefold. First, the policies were designed in order to convey conceptualizations of race and beliefs rather than to assert these openly. Second, the policies were meant to protect, preserve, and develop the heritage of the Afrikaner in all spheres of life. Third, they sought to defend racial superiority by systematically reversing and also undermining the development of black people.

In so doing, apartheid policies sought to construct and present black inferiority as a “natural order” in the racial hierarchy they projected. This objective explains why it was necessary for the apartheid state to design an inferior education for the black population. Biological theories of racial superiority found expression in policies against mixed marriages while the need for separate territorial units was articulated through policies on land, urban planning, and the Bantustan. A major step in the geographical separation of races was the passage of a century-old Natives Land Act of 1913 through which land for occupation, use, and purchase was set aside on a racial basis. The geographical separation of races in the form of Bantustans was one of the most contentious and difficult step to realize.

The implementation of apartheid policies led to the development of two main bodies of work – one feeding into and guiding apartheid measures and the other exposing human suffering and indignity. Most Afrikaner institutions were responsible for producing the bulk of pro-apartheid literature in which theology played an important part. Liberation theology developed as a counterweight to apartheid missiology. A strong body of anti-apartheid literature drew its theoretical strength from Marxist schools of thought, Black Consciousness, and postcolonial literature, and fed into anti-apartheid political thought nationally and internationally. It played an important role in connecting South African experiences with those in other countries and as the basis for the international condemnation of apartheid as a crime against humanity. The focus on the net effects of apartheid policies led to the redefinition of apartheid as a system of racial segregation, oppression, and exploitation rather than merely an idealism of Afrikaner nationalists. Thus, the notion of apartheid can be viewed from the vantage point of Afrikaner idealism and from the perspective of the victims and the broader anti-apartheid movement.

Academically, the implementation of apartheid led to the development of two useful terminologies, namely, the apartheid state and the apartheid city that embody the South African experience. The apartheid state as a state formed through and driven by a particular version of an overt racist ideology with clearly formulated goals and a program of action under a white minority government is distinctively South African. Similar ideologically driven states operate under entirely different conditions with their own objectives and programs of action. The phenomenon of the apartheid city in South Africa has its segregationist foundation in British colonialism (Christopher 1994).

The end of formal apartheid is associated with the collapse of the apartheid state in the early 1990s; the loss of political power by the National Party that ruled the country between 1948 and 1993; and the formal abolishment of apartheid laws that gave legislative power to apartheid policies. These developments gave rise to the notion of post-apartheid, which is commonly used in literature to signify a period after the end of formal apartheid and to refer to the post-1994 democratic state. The morpheme “post” in post-apartheid is silent about the apartheid idea and the conceptualizations of race it embodies.
There is evidence that a section of Afrikaners still cherish the ideals of apartheid and that racism in democratic South Africa continues in various forms. The existence of an exclusively Afrikaner state, the *volkstaat* (own homeland), in post-1994 South Africa is an expression of the same ideals of separate territorial units for the different races on which apartheid was based.

Although South African geographers emulated the intellectual trends in the Western world, the apartheid experience gave them an avenue through which they could raise new sets of research questions. As a community of scholars, geographers in South Africa were divided along the same racial lines as the rest of society. They used their professional skills to either support or oppose the apartheid project; sometimes standing on the fence or changing positions. Much geographical work on apartheid has been on apartheid policies and measures with scant attention to its ideological foundations and its connectedness to world systems of domination and segregation. A strand of critical human geography emerged in the 1970s and 1980s to expose the hardships under apartheid, while also trying to sensitize the discipline about anti-apartheid struggles. This scholarship dissipated with the dawn of democracy in 1994. We noted that land was central to the apartheid project. While geographers have researched land issues, they have yet to show a sustained engagement with questions of land. Land issues remain critical to the economic, social, political, and environmental geography of democratic South Africa.

As a universal signifier of political and racial domination, apartheid has gone full circle. It is increasingly being used to analyze the political, civil, economic, social, and cultural strangulation in other countries, including those from which it derived its motivations. Its original meaning has been expanded to include multiple forms of discrimination and segregationist practices in the academe, health, and so on. Such practices are used to describe other states as apartheid. It is also currently used to denote inequalities in national economies and in the international political-economic system. It is from those inequalities that notions such as “global apartheid” and “apartheid economy” are derived. The multiple uses and meanings of the term apartheid serve as a global repository of the South African experience but also have the potential to create much confusion on the core elements of the term. The potency of these meanings lies in the common understanding of apartheid as an evil system and on the emotions the term evokes. Future research on apartheid will need to disentangle the mutating ideology of racism to understand various forms and texture of apartheid it generates. This is a necessary condition both for a proper exposition of segregation at various levels and contexts and elimination of racist practices. Developments in post-1994 South Africa are important fodder for postcolonial theory.

Further reading

Applied geomorphology is a branch of science within the broader discipline of geomorphology that focuses on geomorphological landforms and processes of societal concern. Specifically, it involves the application of geomorphology to answering research questions of geomorphic significance to society and finding solutions to a variety of human–environmental problems influenced by geomorphic forms and processes. Applied geomorphologists provide theory, data, and analysis to answer questions such as: What is the risk that a landslide will occur on this hillslope? Why did my house flood when the insurance-rate maps place my home outside of the flood zone? What is the most suitable location for a new bridge crossing? How much sand and gravel can be mined from this deposit? How can we reduce the impact of coastal storm surge and prevent beach erosion? And how much water should we release from a dam to scour pools and restore habitat for native fish?

Problems addressed by applied geomorphologists include landforms and processes representative of the major research areas within geomorphology including, but not limited to, coastal, fluvial, karst, arid, tectonic, hillslope, mountain, glacial, and tundra environments. The theory, science, methods, and techniques from these fields are built on a foundation of basic process knowledge which has a direct relation to solving problems in the field of applied geomorphology. Although there is not a standard text on the practice of...
weathering of stone buildings and monuments, and recommendations to prevent further decay and restore architectural integrity.

Geomorphologists are well suited to contribute solutions to these problems because they are trained to read and explain the physical landscape by identifying landforms, describing geomorphic processes, and applying site-based knowledge to interpret how the geomorphic landscape is functioning. They can identify what elements of a landscape are changing, how they are changing, and what is causing them to change. They can answer questions about whether certain changes are normal – that is, the result of natural process dynamics – or are a response to human impacts. Geomorphologists are able to translate this information to explain the historical and contemporary geomorphic context and predict future event scenarios or patterns of change that may concern societal decisions or actions.

**Geomorphic maps**

An important application of geomorphology is the creation of place-based geomorphic maps as dynamic templates representing physical landscape changes. Theory and basic science inform the interpretations of landforms, while site-specific investigations of local complexity and the interdependence of multiple factors (e.g., historical contingency, feedbacks, thresholds, lags, multiple causality, nonlinearity, human impacts, etc.) inform the process dynamics influencing the direction, magnitude, and rate of geomorphic changes. Useful geomorphic maps and unit descriptions will: (i) represent contemporary and historic landform positions; (ii) show change over time relative to different environmental and human conditions influencing the geomorphic landscape formation; and (iii) discuss the various causes of change and factors affecting landscape stability or instability (Smith, Paron, and Griffiths 2011).

These map elements are important for illustrating the spatial relationships of various geomorphic forms and explaining the direction, magnitude, rate, and causes of geomorphic change over time. For example, a river channel may be mapped with varying channel positions to provide an indicator of bank stability. In other examples, the placement of different hatch marks or symbols will be used to show changes associated with different landforms and processes, including coastal shoreline erosion, eolian sand dune migration, fluvial accretion of contaminated sediments, or glacial ice retreat. Such maps characterize the geomorphic forms and processes, enabling users to identify areas of the landscape that are more or less stable across varying temporal and spatial scales.

Historically, most geomorphic mapping was accomplished in the field and supplemented with historic aerial photographs, plan table surveys, and topographic maps. Methods for mapping and modeling landforms and physical processes have improved significantly over the past few decades and have fundamentally influenced the spatial extent, resolution, scale, and cartography of geomorphic representation used for applied geomorphology (Smith, Paron, and Griffiths 2011). Technological advancements in topographic mapping including high-resolution differential GPS (Global Positioning System) surveys, total-station surveys, LiDAR surveys, and digital orthophoto imagery have fundamentally altered how and what geomorphologists are now capable of mapping. Incorporating these data within a geographic information system (GIS) has improved the processing and accuracy of digital terrain models (DTMs) and digital elevation models (DEMs) used in geomorphic mapping, providing faster and more efficient
services to users, including planners, engineers, consultants, and managers.

Not only are geomorphic maps important for interpreting physical forms, processes, and patterns of landscape evolution, but they also provide important proxies for locating resources of economic value, identifying soil types, mapping contaminant distributions in the soil and sediment (both in transport and storage), and examining underlying physical controls on biological process and pattern interactions. For example, in the United States, geomorphic and hydrologic data derived from DTMs and aerial imagery is used to improve the National Wetlands Inventory’s wetland maps through the creation of a hydrogeomorphic (HGM) wetland classification system. The Natural Resource Conservation Service (NRCS) uses the HGM scheme to develop wetland functional assessments which are required under the NRCS Wetland Protection Policy for making decisions relative to exemption, mitigation, or restoration requirements pertaining to wetland environments and development actions.

**Applied geomorphology contributions to problem-solving**

Applied geomorphologists will often begin their research with two fundamental pathways of inquiry. One is concerned with examining how geomorphic processes and landforms affect society, and the other with examining how human actions affect geomorphic processes and landforms. These are often linked, in the sense that one will have direct impacts on the other, and thus it is critical to consider them together. The following sections are organized to show the contributions of applied geomorphology to problems and services involving hazards, land use, natural resources, environmental management, and climate change, using generalized examples from different fields of geomorphology and considering the integrated perspectives of geomorphic impacts on society and society’s impact on geomorphic forms and processes. The use of geomorphic maps, models, and predictive tools within applied geomorphology are discussed in relation to the different major areas of contribution.

**Hazards**

Geomorphologists’ skills in interpreting landforms and processes give them the ability to identify natural hazards associated with different terrains that may threaten the safety and health of society. Applications of geomorphic maps, models, and risk assessments are critical to hazard prevention and represent one of the primary tools used in the diminution and prediction of hazards, particularly those associated with floods (on rivers and coasts) and mass wasting (landslides, debris flows, avalanches, coastal cliff erosion, etc.) (Smith, Paron, and Griffiths 2011). In the aftermath of a hazardous event, geomorphologists will conduct postevent surveys to quantify the changes to the land surface. Knowledge gained from postevent surveys improves our understanding of the threats posed by different hazards and can help society to prepare for future events.

The use of LiDAR technology has revolutionized the DTMs used in delineation for identifying flood-prone zones associated with rivers and coasts. A new generation of LiDAR-derived DTM flood maps are being produced by the United States Federal Emergency Management Agency (FEMA) through its flood hazard mapping program which is part of FEMA’s Risk Mapping, Assessment and Planning (MAP) division. In many locations, these updated flood hazard maps increase the
Land area mapped within floodplains and coastal environments and, as a result, improve the forecasting and predicting of flood risks for extant communities and help prevent future risks in undeveloped locations.

Predictive landslide mapping and modeling has been the responsibility of geomorphologists for decades, and will continue to be important as society continues to develop mountainous terrains, coastal shoreline cliffs, and other areas where the potential for mass wasting is greatest. GIS spatial modeling capabilities have made developing regional landslide risk assessment much more efficient. Overlays of DTMs, slopes, drainage networks, geology, soils, and vegetation are analyzed for spatial relationships of risk potential and then extrapolated to predict locations of greatest landslide vulnerability. In many instances these models are calibrated with conditions from historic landslide events, providing a more accurate representation of hazard risk assessment. Similar GIS-based spatial analysis applications can be used for predicting avalanches, mudslides, subsidence, gully formation, and soil erosion.

An area of consistent relevance of applied geomorphology to hazards involves pollutant and contaminant mapping. Historically, there was a great interest in mapping heavy metal contaminants associated with nuclear testing. While this is still very important today, most contaminant mapping focuses on contaminants produced from mining activities associated with the extraction of precious minerals, removal of mountain-top coal, and drilling by hydraulic fracturing.

**Land-use planning**

Information from geomorphic maps and hazard assessments provide important information for land-use planning. These data can be used as a component of suitability models for determining the best locations for different types of land use in agricultural, urban, and rural settings. Sustainable development of urban areas requires detailed knowledge of local and regional geomorphology, particularly in cities undergoing rapid urbanization. Geomorphic maps and associated hazard risk assessment models, particularly those that illustrate land surfaces by gradients of hazard vulnerability or morphologic instability, are useful for making decisions on the placement of transportation networks, neighborhoods, socioeconomic centers, retail markets, places of recreation, conservation easements, and energy, water, and sanitation infrastructure.

Also of concern is how the placement of different types of urban land use and their associated impacts affect geomorphic processes and cause landform change. For example, the development of a neighborhood with a high level of impervious surface may lead to increased flash flooding and channel and bank erosion. These negative effects may increase the frequency and magnitude of downstream hazards. The ability of a geomorphologist to predict these physical changes and system responses can assist with the prevention and reduction of hazards initiated by poor planning practices.

**Natural resources**

Field surveys and geomorphic maps assist the exploration and discovery of economically valuable weathered mineral resources including clay, silt, sand, and gravel. Geomorphologists can provide information on the sources, volume, and composition of available materials. Such applications are particularly common in floodplain valleys and older river terraces that store significant volumes of alluvial sediments. Geomorphologists can also advise on sustainable extraction practices and provide input for restoring or rehabilitating
land surfaces post-mining. For example, former sand and gravel pits can be restored to create wetlands used in mitigation banking.

Geomorphology has a long history of application to natural resources through globally extensive monitoring programs for water and sediment discharge. On the River Nile in Egypt, flood events and river levels have been recorded as far back as 3100 BCE. In the United States, the United States Geological Survey manages a nationwide network of stream gauges that collect data on surface and groundwater resources. Applied geomorphologists use these records to quantify patterns of stream flow and sediment discharge, and analyze how they are changing relative to natural and human impacts, such as land cover changes, dam operations, and global climate change.

Environmental and ecosystem management

Geomorphology occupies a variety of roles in environmental management, and its application in problem-solving depends on the specific nature of the management goals. Some examples of environmental management problems that integrate geomorphology include (i) site-based classifications: using geomorphic maps to provide information on physical landforms or processes used in the characterizations of landscape and riverine settings and habitats; (ii) erosion control: monitoring and controlling sources of soil and sediment erosion for a variety of different land uses and environments; (iii) engineering: geomorphic form design and maintenance, common in coastal and river applications; (iv) ecosystem restoration: using geomorphology as a soft engineering tool to restore degraded physical habitats or modify the environment for ecological benefit; and (v) conservation: conserving geomorphic forms and processes of ecological or societal significance. In addition, geomorphic conditions represent one of the many variables included in environmental impact assessments used to evaluate development projects, and can have a significant impact at the intersection of land-use planning and environmental management, particularly where wetlands are concerned.

Environmental management of coasts and rivers requires a foundational base of geomorphic knowledge predicated on understanding current processes, interpreting past conditions, and predicting future scenarios of geomorphic change. In coastal settings, geomorphologists assist with solutions for reducing shoreline erosion, replenishing beach sediment, and restoring and conserving depositional nearshore and dune landforms. Coastal engineering involves the placement and maintenance of groins, jetties, and sea walls to control shoreline sediment and erosion dynamics. In riverine environments, geomorphologists address problems related to channel and bank stability, impacts from dams (commissioning, removal, and operation) and other in-channel control structures, catchment erosion and sedimentation, and the conservation and restoration of fluvial regimes, forms, and processes. River engineering involves channel form design and maintenance for working rivers where channel straightening, dredging, diversions, and dikes are common.

Climate change

Geomorphic responses to climate change, including potential increases in the magnitude and frequency of hazardous events, detrimental effects on natural resources (particularly water and soil), and land surface changes associated with changing temperature and precipitation regimes and rising sea levels, are of great concern.
to society. A geomorphologist’s ability to model land surface changes and to use geomorphic indicators to predict environmental changes across diverse settings is especially valuable for guiding decisions and actions that will minimize the negative effects of global environmental changes.

Careers for the applied geomorphologist

Applied geomorphologists most commonly provide services as independent contractors or academic scientists, or as members on science advisory panels. Rarely will specific job advertisements seek an applied geomorphologist, yet the niche exists across a wide array of career opportunities. Careers that use applied geomorphology occur within government research and regulatory agencies, planning and developer corporations, water supply districts and river basin authorities, nonprofit conservation and land trust organizations, and private engineering and environmental consulting firms. Individuals can receive training in applied geomorphology through geography, geology, environmental, or earth sciences programs. Many applied geomorphologists practice under the title of hydrologist, geologist, or environmental scientist, with the exception of academia where the title persists.

Graf (1996) offered the opinion that geomorphologists have the responsibility to use their knowledge of basic research to the benefit of social issues concerning environmental resource management and public policy. Goudie (2002) argued that applied geomorphology is one of the more attractive attributes of the discipline for recruiting new practitioners and for bringing the relevance of geomorphology into public perception. Collectively, these assertions provide assurance that, as geomorphology becomes better recognized for its applications to human–environmental problem-solving, the role of the applied geomorphologist will continue to gain relevance and career opportunities will continue to expand.

McGregor, Duncan M., and Donald A. Thompson. 1995. Geomorphology and Land Management in a

Aquifers

Sheryl Luzzadder-Beach
University of Texas at Austin, USA

Aquifers are saturated, water-bearing geologic formations or sediment matrices found underground in the phreatic zone (at atmospheric pressure). In order for a water-bearing deposit to be designated as an aquifer, the water yield is expected to be “economically sufficient” (Sterrett and Hanna 2007). The top of the water table defines the division between the phreatic zone and the overlying vadose zone (unsaturated, below atmospheric pressure). Water at or below the water table in an aquifer is referred to as groundwater (see Groundwater). Water above the water table in the vadose zone is commonly referred to as soil water (see Soil water). Aquifers are composed of a wide variety of geologic units, and are created by numerous geomorphic and geologic processes over time. Groundwater enters an aquifer through percolation, and groundwater flow in aquifers is defined in terms of economic quantities, that is, whether or not it is useful in human terms. Groundwater may be recharged through the hydrologic cycle (see Hydrologic cycle), but withdrawing groundwater by pumping at a rate unsustainable by recharge is considered water mining. Some aquifers contain water accrued during past wetter climate regimes and are no longer recharged; this is called fossil water.

For a geologic unit to receive, store, and transmit water, it has to have certain physical properties related to its matrix, or assemblage of pore spaces and geologic material. These properties determine the volume of the voids between the rock particles or material, which is known as porosity, and the connectedness of those voids, known as permeability. These two dimensions combine to define an aquifer’s hydraulic conductivity or $K$ (Fetter 2001). Transmissivity takes this concept one step further into measuring how much water can travel horizontally through a given saturated thickness of aquifer, using a hydraulic gradient constant of 1. The measure looks like this:

$$T = bK = m^2/\text{day}$$

Hydraulic gradient measures the difference in hydraulic head in an aquifer segment along a slope length, $dh/dl$ (difference in head/difference in length). Adjusting then, for a specific hydraulic gradient and slope, applied to an area of aquifer cross-section ($A$) allows discharge ($Q$) to be calculated, in an equation first derived through laboratory experiments by Henry Darcy in the mid-nineteenth century (Fetter 2001). This equation is known as Darcy’s law (see Hydrologic flow models). A negative sign accounts for diminishing slope. One form of Darcy’s law is therefore expressed as:

$$Q = -KA\left(\frac{dh}{dl}\right)$$

A rock material can have a high porosity, but if those pore spaces are not connected it will not hold or transmit water, and therefore it will have a low hydraulic conductivity. If a rock material is impermeable or transmits water at noneconomic (low) rates, it is called a confining layer. This
AQUIFERS

is also referred to as an aquiclude (Sterrett and Hanna 2007). A related condition is an aquitard, which is more permeable than a confining layer or aquiclude, and may exchange or “leak” water to an adjoining layer. It may also store some groundwater, but has insufficient transmissivity to serve a well (Sterrett and Hanna 2007).

Porosity and permeability, then, relate to the particle size and sorting of the matrix and the voids, and void connectivity within the matrix. Many different geomorphic and geologic processes produce geologic units. Some are produced by igneous rock formation processes, and others are produced by secondary deposition and eventual burial, through sedimentary processes. Others still are produced by dissolution processes, such as the dissolution by naturally acidic rainwater infiltrating the limestone, and by groundwater throughflow, in a process known as karst (see Karst processes and landforms).

One of the most porous igneous geologic units with a high potential for porosity and permeability is lava rock (see Volcanic processes and landforms). During volcanic eruptions, molten lava (magma) may flow out of a rift zone or a volcanic mountain at the surface of the Earth, and the molten lava is full of gases. These gases form spaces shaped like bubbles and tubes as the lava flow cools to a more viscous or plastic state, and the trapped gas bubbles continue to trace their way through the slowly plasticizing material to a surface to escape. These pathways then harden into bubble- and tube-shaped voids in the cooled and hardened lava rock, creating spaces to hold and transmit water (Sterrett and Hanna 2007). The walls around and between these bubbles and tube spaces can become weakened and fracture, thereby creating more connectedness or permeability in the lava rock deposit. Some lava tubes can be quite large, where liquid molten lava flows through a tunnel-shaped void or space surrounded by more hardened lava on the relatively cooler exterior of the flow. These tubes can eventually empty of flowing lava, leaving behind cave-like spaces that can hold and transmit water. Other, denser igneous rock matrices such as basalt, quartz, or granite may not be as water-bearing if the crystals are small or if there is little connected pore space between crystals. However, any rock may be fractured or have horizontal joints or vertical columns (as in columnar basalt) between flows, and this will be a zone where water can accumulate and flow if these spaces are connected.

Consolidated sedimentary rock deposits such as sandstone, limestone, dolomite, and shale can serve as aquifers. Water moves either through the permeable matrix of the rock material itself (e.g., between sand grains in sandstone) or through cracks and joints between sedimentary layers (e.g., sandstone, limestone, shale).

Well-sorted, unconsolidated materials may also serve as infiltration, percolation, or recharge zones and aquifers when buried. Conversely, unsorted materials can serve as aquitards or aquicludes, slowing or stopping the flow of groundwater. Several geomorphic processes can transport, sort, and deposit these materials, and then subsequently bury the deposits to become aquifers (a few examples are provided here; for more detail please see Sterrett and Hanna 2007). For example, glaciers (see Glacial depositional processes and landforms) convey a high volume of Earth materials of variable sizes and shapes over great distances. These can be indiscriminately deposited in unsorted piles (moraines) or plains (till plains) as glaciers melt in place or melt back. Glacial till and moraines are unconsolidated, unsorted, and have a low hydraulic conductivity.

Materials can also be moved and sorted fluvially by waters melting and flowing out of the glaciers, either in streams running through melting tunnels underneath glaciers, or by
streams washing out in front of glaciers. The former process deposits a sorted stream bed, building up in the ice tunnel and as sediments drop from the melting roof of the ice cave. After the glacier melts back to reveal these features, known on the landscape as eskers, they resemble raised railroad beds in shape. When eskers are buried by glacial till, they will transmit water underground as aquifers, confined by the till. Sandy outwash may also be deposited by meltwaters in front of a melting glacier, and this too will potentially form an aquifer if buried.

Fluvial processes (e.g., Earth surface change by moving water) also remove, transport, sort, and deposit materials in an orderly way on the landscape, as can be observed in the sorted particle sizes on a sand bar or cobbled riverbed. When these deposits become subsequently buried by other geomorphic depositional processes, they too may also serve as aquifers (see Fluvial depositional processes and landforms). Besides buried riverbeds, alluvial fans make good aquifers as well. Alluvial fans are fan-shaped deposits of well-sorted grain sizes from sand to boulders, occurring at the base of steep streams as they enter flatter valley bottoms, lose energy due to the change in slope, and spread or fan out. As energy is lost, the largest particles are dropped out first, and so on, until a well-sorted stack forms. Water flowing from the stream then infiltrates into this feature and can flow underground in significant quantities; many municipal and agricultural wells are located on alluvial fans (Figures 1 and 2).

Eolian processes may also transport and deposit silt and sand-sized particles in organized sheets, dunes, and hills; once buried and confined or semiconfined by other geomorphic processes these unconsolidated materials may also serve as aquifers due to their well-sorted and abundant pore spaces between particles.

Sustainability of aquifers is threatened by climate change altering recharge rates, and by withdrawals by humans at rates faster than recharge. A prime example of a threatened aquifer is the Ogallala Aquifer, which underlies eight states in the High Plains portion of the United States (Little 2009). This shallow, stream-deposited aquifer stretches from Texas to South Dakota, and its depth to the top of the water table varies from near the surface to 150 m deep (Kromm 2015). As agricultural water use began booming in the 1940s and 1950s, some parts of the aquifer are now overdrawn by 30 m (Kromm 2015), and it is estimated it would take 6000 years to recharge it in the current rainfall regime (Little 2009). White and Kromm (1995) note that more effective groundwater management in the Ogallala Aquifer zone has slowed the depletion rate, but the rate remains at just under a meter per year and contamination issues remain a concern (Kromm 2015). Aquifers in other agricultural regions such as the San Joaquin Valley of California face similar overdraft threats and irreversible damage from ground subsidence, and salination from excessive irrigation and evaporation cycles in the vadose zone (Schoups et al. 2005). Subsidence occurs as the pore spaces within rapidly depleting aquifers are mined of their groundwater and collapse. Some parts of the San Joaquin Valley experienced around 9 m of ground subsidence between 1925 and 1977 (Botzan et al. 1999). Once pore spaces collapse, an aquifer can no longer be recharged, so programs in water banking and artificial recharge through interbasin water transfers may help protect aquifers (Galloway and Burbey 2011).

Further reading

Most geographical research analyzes contemporary landscapes and recent spatial processes and trends, based on direct observation in the field, the manipulation of current demographic and statistical data, and the examination of recent topographic maps and aerial photographs. However, researchers investigating past or long-term spatial processes and the reconstruction of past landscapes or regional geographies have depended heavily on archival and document research. Much of the methodology for conducting this type of research was developed during the last half of the twentieth century, as British and North American historical geographers focused on recreating the past geographies of selected places or regions within Europe and the Americas.

Archival and document research is fundamental to historical geographers, but there are only a few comprehensive and critical surveys of these sources. Two such surveys by geographers pertain to British sources (Baker, Hamshere, and Langton 1970; Morgan 1979). They address such historical materials as tax records, inquisitions, land grants, manorial court records, enclosure awards and maps, tithe maps and apportionments, population censuses, agricultural and industrial censuses, probate inventories, parish registers, directories, newspapers, and transportation records.

In terms of North America, there are several articles discussing sources for the colonial period (Merrens 1963; Merrens and Ernst 1978). These articles highlight such primary sources as tax lists, customs statistics, merchant records, family letters, newspapers, estate inventories, land surveys, local court minutes, travel accounts, ecclesiastical reports, and maps. More comprehensive studies discussing both the colonial period and nineteenth- and early twentieth-century sources have taken the form of bibliographies and bibliographic essays (Grim 1982; Grim 1983; Conzen, Rumney, and Wynn 1993; and Grim, Rumney, and McIlwraith 2001). Although these compilations have identified a wide variety of primary sources that are potentially useful, historical geographers have used some types of documents, both textual and graphic, more successfully than others.

The quantity and quality of primary source materials that are available for any particular historical geographical problem will depend on the time period in which the information was recorded, the record-keeping practices of the government bodies and individuals involved, and the archival practices of the successive holders of the documents. While it is impossible to enumerate and evaluate all the potential documents and repositories that may be useful for historical geographers, a selection of basic primary sources that researchers have successfully employed to recreate past geographies of North America is discussed here.

Qualitative landscape descriptions

Exploration and travel literature, whether in manuscript or printed format, often contain
narrative descriptions of regional landscapes or primary transportation routes. Such narratives provide a basic source for a qualitative understanding of past landscapes and geographic regions. For example, explorers’ reports and travelers’ diaries have been useful in documenting the growth of geographical knowledge or the initial perception of frontier regions. Landscape descriptions recorded in these accounts are useful for reconstructing physical landscapes, settlement patterns, economic activity, and environmental perception. Observations concerning modes of transportation and routes traveled provide an understanding of generalized patterns of movement and circulation at any given time. A significant subset of travel literature includes the reports prepared by government-sponsored exploring expeditions during the nineteenth century. Although these sources have their own inherent biases – military reconnaissance and economic exploitation, for instance – they have the potential for presenting a more balanced representation than private accounts, which may suffer from exaggeration, untruth, or literary license (Grim 1982, 87–91).

Population data

Population counts and demographic statistics, whether collected at national, state, or local jurisdictions of government, can be found in a variety of documents including general population censuses, tax rolls, and militia lists. The most familiar and probably most useful source of population information for the United States is the federal government’s decennial census. Every 10 years, beginning in 1790, the government has enumerated the population for the purpose of determining representation in Congress. The information gathering in the first census was brief (name of head of household and number of free and non-free members), but subsequent enumerations collected much more. For example, the 1850 census started listing names of family members as well as age, sex, occupation, and birthplace. The manuscript census schedules on which the field data were recorded have proven indispensable for microstudies. Currently, schedules from 1790 to 1940 are available on microfilm and open to general research (www.archives.gov/research/census). US federal census data is also available online through the Historical Census Browser hosted by the University of Virginia Geospatial and Statistical Data Center (http://mapserver.lib.virginia.edu) and United States Census Data presented by the Inter-university Consortium for Political and Social Research at the University of Michigan (www.icpsr.umich.edu/icpsrweb/ICPSR/themes/census).

The original census data is collected at very local geographical units known as an enumeration districts, but is aggregated and published according to increasingly larger geographic units such as township, ward, city, county, and state. Also of interest to geographers are the statistical atlases that accompanied the censuses from 1870 to 1920; those for 1870, 1880, and 1890 are available on the Internet (http://memory.loc.gov/ammem/gmdhtml/setlhome.html).

Demographic statistics for North America’s colonial period are not as readily available or as systematic and comprehensive in coverage as data in the federal censuses. Various levels of colonial administration made population counts and compiled tax and militia lists, but with no regularity or uniformity (Grim 1982, 95–100).

Property records

Information relating to real and movable property can be found, primarily at local
administrative levels, in such records as land patents, deeds, wills, and estate inventories. However, in order to locate pertinent land records, a distinction must be made between the public-land states – those in which the federal government was the original owner of the land – and those without public lands. These latter included the original 13 states plus Maine, Vermont, West Virginia, Kentucky, Tennessee, and Texas, in which the original ownership was vested in the colonial or state government. Records from the public-land states, including surveys and initial transactions, are housed either with the National Archives or the Bureau of Land Management (successor to the original General Land Office; see Buissere 1990, 89–109, 311–315). Records of original surveys and transactions in those states without public lands are in the custody of the respective state land offices or states archives. For all states, subsequent land sales or transfers were handled locally, usually at the county level, and normally have been maintained in a county clerk’s office. They have suffered the ravages of fire and war, and in recent years the older portions of many of these records have been centralized in state archives.

The process of surveying and disposing of the public domain in the United States has generated a wealth of records that are useful to historical geographers. Land survey records, which consist of field notes and survey plats, have a primary legal value for establishing the boundaries of a parcel of land as well as a secondary value for reconstructing vegetation patterns from witness trees and related comments recorded in the notes. Land-disposal records – patents or deeds, land-entry papers, and tract books document the sale and resale of the land and are useful for reconstructing the landownership process (Grim 1982, 101–105).

Business records

The US Census Bureau’s census of manufactures is a major source of nineteenth-century industrial statistics, but other privately created documents such as merchant and plantation accounts or company archives can provide an understanding of the economic activity of individual enterprises. For example, strong collections of business and industrial archives have been gathered together at the John D. Rockefeller, Jr Library at Colonial Williamsburg (http://research.history.org/library) and the Hagley Museum and Library near Wilmington, Delaware (http://www.hagley.org/library). Newspaper advertisements and business directories are also useful for studying a wider range of economic activity. Newspapers have been used widely to study the development of political and public opinion, but they offer great potential also for geographical studies and are widely accessible on microfilm. Advertisements, specialized newspapers, and circulation statistics provide useful spatial information about commerce, manufacturing, and agriculture. City residential and business directories provide a useful complement to the manuscript census schedules for studies of population mobility and social or economic characteristics (Grim 1983, 270–273).

Graphic sources

A wide range of graphic materials can be useful for historical geographical research. Maps (at all scales), photographs (still and aerial), and landscape sketches provide both a spatial and a visual perspective for many historical studies. Although often used casually as illustrative elements of a study, many such documents, when critically appraised for their respective biases, can stand alone as primary sources. The essays edited
by David Buisseret (1990) demonstrate the possibilities, focusing on such diverse topics as exploration and military maps, property and topographic surveys, landscape views, urban maps and panoramic views, fire insurance maps, and aerial imagery.

With the introduction of large flatbed scanners and data-compression software, it is possible to scan large maps at very high resolutions and make them readily available on the Internet. The Geography and Map Division of the Library of Congress has been a pioneer in applying these technologies to cartographic collections. This digital map collection (www.loc.gov/maps) includes maps from the sixteenth century to the present. The site provides search capabilities within the entire collection or with broad thematic categories, such as discovery and exploration, transportation and communication (railroads), cities and towns (panoramic and Sanborn maps), and military battles and campaigns (American Revolution, Civil War, and World War II). Another early pioneer in providing online access to large number of eighteenth- and nineteenth-century maps is the private collector David Rumsey (www.davidrumsey.com). During the past decade other map collections including the New York Public Library (www.nypl.org/locations/divisions/map-division), Harvard Map Collection (http://hcl.harvard.edu/libraries/maps/digitalmaps), Osher Map Library, University of Southern Maine (www.oshermaps.org), and Boston Public Library (maps.bpl.org) have provided digital access to their collections, while federate sites such as Old Maps Online (www.oldmapsonline.org) are providing access to multiple collections at one digital location.

For historical geographers reconstructing past physical landscapes, the absence of a systematic program of topographic mapping in the United States prior to the end of the nineteenth century has been a major research obstacle. Consequently, they have had to search for limited availability of topographic surveys of small, scattered localities. One of the best sources is the topographic surveys that were conducted by military engineers in preparing after-battle maps for the major battles in the America’s Revolutionary and Civil Wars. In the 1880s, when the US Geological Survey (USGS) was established, a systematic and comprehensive topographic mapping program began. Aerial photography was introduced in the 1930s as a major innovation in gathering geographic information (Buisseret 1990, 238–259, 283–309).

One of the most valuable research tools for historical urban studies is fire insurance maps, of which the D.A. Sanborn Company of New York was the major publisher. Prepared primarily for underwriters seeking to determine the risk of insuring properties, these maps provide block-by-block inventories of individual buildings in approximately 12,000 cities and towns in the United States and Canada from the late nineteenth century to the middle of the twentieth century. They may effectively be used in conjunction with city directories and manuscript census schedules (Grim 1982, 43–45; Buisseret 1990, 213–237).

The panoramic view is another type of urban map useful for determining the internal spatial structure of cities. Drawn in perspective from an imagined elevation of 600 to 900 m, these commercially published bird’s eye views depict a town’s street pattern as well as individual buildings. The drawings provide reasonably accurate portrayals of the major towns and cities in the United States and Canada from the middle of the nineteenth century through the first quarter of the twentieth century. However, these views should be evaluated for their selectivity and exaggeration because city fathers commonly commissioned the views to promote a city’s
business, commercial, or industrial attributes (Grim 1982, 45–47; Buisseret 1990, 143–163).

Archival and document repositories

Researchers studying past geographical landscapes and spatial processes can find pertinent research materials within a wide variety of institutional settings. Official government records are generally maintained by archival repositories at the national, regional (state or province), and local levels while manuscript collections, printed and manuscript maps, aerial photographs, and related graphic materials can be located at historical societies, privately endowed libraries and manuscript repositories, and large public and university libraries. Many of these institutions have prepared general summary guides to their holdings or detailed listings of specific collections (Grim 1982, 74–85; Grim 1983, 252–258). While it is impossible to describe the most important repositories and their pertinent records, it is worth mentioning the two largest repositories in the United States – the US National Archives and Records Administration and the Library of Congress.

The National Archives and Records Administration (NARA), the official repository for the noncurrent records of the various agencies of the US federal government, consists of three facilities in the Washington DC metropolitan area, 17 regional archives and federal records centers, and 13 presidential libraries (www.archives.gov). The holdings of the Cartographic and Architectural Section located in College Park, Maryland, include over 15 million maps, charts, aerial photographs, architectural drawings, patents, and ships plans, comprising one of the largest such accumulations in the world. While these graphics sources are of primary interest to historical geographers, there are many other important resources for recreating past geographies as highlighted in a 1971 symposium addressed directly to historical geographers (Ehrenberg 1975). For example, numerous records pertain to the establishment and survey of boundaries, the regulation and monitoring of commerce and trade, the founding and planning of cities and towns, the utilization and preservation of natural resources, and the financing and construction of transportation systems.

The Library of Congress, also located in Washington DC, serves as the national library. It is also the largest library in the world with more than 158 million items on approximately 838 miles of bookshelves. The collections include more than 36 million books and other print materials, 3.5 million recordings, 13.7 million photographs, 5.5 million maps, 6.7 million pieces of sheet music, and 69 million manuscripts (www.loc.gov). In the United Kingdom, the UK National Archives (www.nationalarchives.gov.uk) and the British Library (www.bl.uk) serve similar functions.

Increasingly, archival repositories, manuscript collections, and libraries are digitizing their collections and making them available on the Internet. Several websites are bringing together resources from a large number of collections, including the Digital Public Library of America (http://dp.la) and Internet Archive (https://archive.org/index.php). There are also a number of websites that focus on aggregating materials that have a thematic orientation or relate to a specific genre, such as travel literature (American Journeys: /www.americanjourneys.org/), newspapers (Library of Congress: http://chroniclingamerica.loc.gov/), or nineteenth-century weekly and monthly journals (Making of America: http://digital.library.cornell.edu/m/moa/). Another useful website is World History Unpacking Evidence at George Mason University’s Roy Rosenzweig
ARCHIVAL AND DOCUMENT RESEARCH

Center for New Media (http://chnm.gmu.edu/worldhistorysources/whmunpacking.html), which provides guides to eight types of primary sources (music, images, objects, maps, newspapers, travel narratives, official documents, and personal accounts) with links to selected digital collections.

Areal differentiation
(or chorology)

Ron Johnston
University of Bristol, UK

A definition of geography as the study of areal differentiation of “the spatial distribution of physical and human phenomena as they relate to one another” (Gregory 2009, 35) is generally associated with Carl Sauer and his classic 1928 monograph *The Morphology of Landscape* (Sauer 1976/1928), although he indicated that his definition was synonymous with that of chorology, which has a long pedigree.

Chorology

Chorology was one component of geography as practiced by the ancient Greeks. Strabo, for example, defined a geographer as “the person who attempts to describe the parts of the earth.” His approach differed significantly from Ptolemy’s, for whom mapping was the core of geography’s *raison d’être*. Those two components, chorology and mathematical geography respectively, became institutionalized in later centuries as special geography (the description of particular areas) and general geography respectively, and these were the precursors of what in the twentieth century became known as regional and systematic geography. The term “chorology” is rarely used now to depict the description and interpretation of the spatially varying characteristics of the Earth’s surface.

From chorology to areal differentiation

In the early twentieth century, the chorological approach was promoted by both Sauer and Richard Hartshorne. Sauer offered three separate identifiers of geography’s content: (i) the study of the Earth’s physical processes; (ii) the study of “life forms as subject to their physical environment”; and (iii) the study of areal or habit differentiation – between each pair of which there was little relationship (Sauer 1976/1928, 316). Geography, for him, was one of the “great fields of knowledge,” concerned with “great categories of phenomena.” “Geography assumes the responsibility for the study of areas because there exists a common curiosity about that subject,” a disciplinary specialism that no other subject had pre-empted and that would exist as one of the “great fields of knowledge” even if geography had not been invented as a discipline to specialize in its study.

Sauer argued that geography as areal differentiation was more than an investigation of what is where: “the phenomena that make up an area are not simply assorted but are associated, or interdependent” and geography portrays those associations, what he termed the “areal connection of the phenomena and their order” (Sauer 1976/1928, 318). Thus, whereas the “facts of geography are place facts; their association gives rise to the concept of landscape”: areas differ in their landscapes, because of differences in the interrelationships among phenomena across separate areas. The study of such differences meant that geography was a scientific field rather than simply a provider of gazetteers of information. Landscapes comprise two main elements: their
AREAL DIFFERENTIATION (OR CHOROLOGY)

sites, or their physical nature; and the cultural expressions within them, the “impress of the works of man [sic] on the area.” Sauer’s career focused on that impress, on decomposing the morphology of cultural landscapes and accounting for their separate characteristics – over both space and time.

The codification and promotion of geography as the study of areal differentiation is generally associated with Richard Hartshorne’s (1939) monograph *The Nature of Geography*. The two scholars’ approaches had many similarities, but Hartshorne rejected Sauer’s cultural landscape concept (he termed it “sloppy”). His extensive, though partial, archaeology of writings about geography’s nature, particularly by nineteenth-century German scholars, led him to a broad definition (derived from Richthofen) that “geography studies the differences of phenomena causally related in different parts of the earth surface” (Hartshorne 1939, 92). As such, the discipline was composed of two main parts: systematic geography, which is the “non-explanatory description” of the distributions of individual phenomena (or chorography); and regional geography (or chorology), which explores the relationships between the phenomena that define and account for the specific features of particular areas.

Hartshorne presented geography as the discipline providing accounts for differences between areas resulting from the spatially varying interactions between humans and the physical environment. That definition was widely accepted for several decades encompassing World War II, even by those who paid relatively little heed to Hartshorne’s excavation of the subject’s/discipline’s history (for critiques see the essays in Entrikin and Brunn 1989). In the United Kingdom, for example, Wooldridge and East’s (1958, 28) *The Spirit and Purpose of Geography* defined its essential purpose as addressing “how and why does one part of the earth’s surface differ from another.”

Hartshorne revised his definition of areal differentiation in his *Perspective on the Nature of Geography* (1959), a response to critiques of his earlier book. He accepted that “the science of areal differentiation” was inadequate as a definition of geography – “either meaningless or misleading” – not least because most sciences address differences in some form or another. The underlying conception was correct, but it needed a more nuanced definition; he offered that “geography is concerned to provide accurate, orderly, and rational description and interpretation of the variable character of the earth surface” (Hartshorne 1959, 21), with several of the book’s chapters unpacking that statement because, to him, it was not “self-explanatory.” Areal differentiation was a useful shorthand statement of that more detailed definition. The largely descriptive role identified in his initial definition – geography “studies the differences of phenomena causally related” – was extended by the pair of goals “description and interpretation” (emphasis added); geography sought to understand the why as well as the what of spatial differences, thus bringing Hartshorne’s definition closer to Wooldridge and East’s.

From areal differentiation to regional geography

Hartshorne’s approach became incorporated into the established practice of regional geography, much of whose work in the 1940s–1960s focused on the definition of regions, clearly bounded areas that differed in their phenomena complexes. That “containerization” of the world, at a variety of scales from the global through the national to the local, became a major focus for many regional geographers,
who to their critics were overly concerned with “drawing boundaries that do not exist around areas that do not matter” (Kimble 1951, 159) rather than portraying and accounting for interregional differences (with many regions having at best only indistinct boundaries as one landscape type merges into another).

The region had become some leading geographers’ leitmotif, however, as illustrated in American Geography: Inventory and Prospect, where Preston James declared that there “is just one kind of geography. That kind of geography is regional geography,” whose key instrument is the map, the technology whereby areal connections can be identified and areal differentiation portrayed:

Persons who undertake to carry on geographic studies must specialize in order to develop competence in a portion of the field. Nevertheless, whether they specialize on the physical, biotic or cultural aspects of geography, the analysis of the meaning of likenesses and differences among places involves the use of certain common concepts and methods: basic to the whole field is the regional concept; fundamental to the effective study of geographic phenomena is the method of precise cartographic analysis. (James 1954, 7)

To perform their academic work, he argued that geographers must define regions, the matrix within which areal differentiation of the Earth’s surface is organized.

Hartshorne recognized the relative futility of this task, however. He argued that most regions identified by geographers were mental constructions only and concluded that “it is not possible to define sections of the earth’s surface as regions that form units in reality, [so] that we cannot correctly consider them as concrete individual objects” (1939, 281). Livingstone’s (1992, 309) summary of his position was that “regions just did not exist as all-embracing units.” The region was merely a convenient mental construction – often with boundaries on maps that were difficult (if not impossible) to locate on the ground – within which to organize and present material. Livingstone therefore saw regional geography as an “incoherent enterprise”; regions were a useful means to convey the nature of areal differentiation across an area, but their identification was not a valuable end in itself.

Hartshorne clarified this difference in his Perspective, concluding that:

The great majority of geographers have recognized that the world does not consist of a mosaic of distinct regions, and that we cannot hope to classify the more complex integrations of areal phenomena in a single objective system of regions. Nevertheless, they recognize that in order to analyze complex integrations in terms of a limited range of areal variations it is necessary to divide large areas into smaller parts. The purpose in dividing the area is to secure areal sections, or “regions,” such that within each region the elements of the segment of integration under study will demonstrate nearly constant interrelations and the maximum degree of interconnections among places. (1959, 129)

Regions provided a way of summarizing areal differentiation in the interrelations between (physical and cultural) phenomena in a matrix of areas that maximized internal homogeneity and external heterogeneity. But, whereas the region was a useful tool for uncovering spatial variations in geography’s subject matter, that tool was the means, not the end, which is to understand and explain why such variations exist. Thus he concluded that “The ‘regional concept’ and the ‘regional method’ must not be confused with what we commonly call ‘regional geography’ … The regional concept is applicable, and the regional method is used in fact at every level of geographic study” (Hartshorne 1959, 129).
The demise of regional geography – but not of the regional concept

Most regional geographers followed Hartshorne’s general strictures – at least implicitly – but some went further. For the latter group regional geography remained the discipline’s ultimate goal; systematic studies were very much a means to that end and the true nature of geography was demonstrated by its integration of material into an appreciation of how interactions of their subject matter produced unique, if not singular, places – areas of the Earth with their specific characteristics revealed by the regional method.

By the 1960s, however, this approach was under considerable attack, mainly from geographers who wished to recreate their discipline as a law-making spatial science and promoted scientific studies of particular phenomena as the way forward. In this “new geography” many used the concept of the region to describe a spatial matrix (such as urban hinterlands and labor markets, and in the nascent multidisciplinary regional science) within which society was organized, but there were reactions to that approach defending “traditional” regional geography (on which see Johnston and Sidaway 2015). As late as the 1980s, for example, a president of the Association of American Geographers proclaimed that regional description was “The highest form of the geographer’s art” (Hart 1982, 1). Resonating with some of Sauer’s argument, he claimed that:

Society has allocated responsibility for the study of areas to geography: this responsibility is the justification for our existence as a scholarly discipline. Most people are inherently curious, and they want to know more about the world in which they live. … [To satisfy that curiosity] … The highest form of the geographer’s art is producing good regional geography – evocative descriptions that facilitate an understanding and an appreciation of places, areas and regions.

Hart’s argument was that providing such descriptions should reunite the discipline, which had been fragmenting since the so-called “new geography established by the quantitative revolution.” The core concept in that reunification should be the “region,” required “in order to understand why we need the diverse and variegated systematic subfields of geography” and also to meet the popular demand for satisfying “human curiosity about how much of what is where and why it’s there, about the where and why of places and people, about the land and how people have used and abused it. … we jolly well had better give them what they want” (Hart 1982, 19).

But few geographers followed Hart’s argument, and geography as an academic discipline has very largely distanced itself from the practice of regional geography. There are now virtually no university courses or books comparable to the regional texts of the immediate post-World War II decades, and – except in some introductory undergraduate courses for students with little or no previous exposure to geography (notably in the United States) – there are very few academic geographers whose core concern is to provide descriptive accounts of areal differentiation. In the third quarter of the twentieth century this was because of the focus on spatial science, on the discovery of and explanation for spatial order, addressing general patterns rather than the characteristics of specific places. The term “region” continued to be fairly widely used, but the focus was on functional organization rather than on regional mosaics.

Critiques of spatial science have since stimulated the emergence of a renewed interest in areal differentiation, albeit with different foci, such as areal variations in levels of economic development, producing uneven geographies of economic, social, and political inequality at a variety of spatial scales, but without calling
on either the regional concept or the regional method in drawing attention to and accounting for those variations. Similarly, the particularities of specific places – how they have been created, how they are currently experienced and appear – have been explored. Most recently Murphy (2013) promoted the need for geographers to produce “grand regional narratives” for nonacademic audiences as an important disciplinary role in advancing popular appreciation of the contemporary world, but the responses to his provocative piece have indicated little support.

Conclusion

The concept of areal differentiation continues – if often only implicitly – to underpin geography’s claimed raison d’être within the academic division of labor of providing accounts of differences between places: what is where, and why? Many one-sentence definitions of the discipline focus on this question in some way: a recent geography dictionary, for example, defined geography as “The spatial and temporal analysis of human and natural systems and their interrelation across scales” and human geography as “The study of the interrelationships between people, place, and environment and how these vary spatially and temporally across and between locations” (Castree, Kitchin, and Rogers 2013, 180, 223). But within such broad definitions the myriad different intradisciplinary specialisms mean that most attention is given to the parts and very little to the whole. Some overarching descriptive accounts of an area are still produced (e.g., Haggett 2013) but they are seen as neither the rationale for the discipline nor the grand synthesis of an academic career. In general, that project is left to those who promote other geographical imaginations, such as popular geographical magazines.

AREAL DIFFERENTIATION (OR CHOROLOGY)

Argentina: GÆA Sociedad Argentina de Estudios Geográficos (Argentine Society of Geographical Studies)

Founded: 1922
Location of headquarters: Buenos Aires
Website: www.gaea.org.ar
Membership: 500 (as of December 31, 2013)
President: Darío Cesar Sanchez
Contact: dario.cesar.sanchez@speedy.com.ar

Description and purpose

GÆA is one of the first nonprofit scientific and educational associations of geography in Argentina. Its aim has been, from its origin, to contribute to the production of geographical knowledge to benefit science and Argentine society.

GÆA has improved research on the vast Argentine territory, encouraging scientific exploration and expeditions, and has contributed to the academic institutionalization of geographical studies. Nowadays, GÆA shares its interests in the theory, methods, and practice of geography with other emblematic public and private institutions such as the IGN Instituto Geográfico Nacional, the Academia Nacional de Geografía, universities and teaching training institutes, and so on.

Journals or major publication series

*Boletín de GÆA Sociedad Argentina de Estudios Geográficos.* http://gaea.org.ar/BoletinGAEA.pdf

Current activities or projects

Representing a discipline with strong national and international perspectives, the GÆA outreach and research network consists of more than 7000 members in Argentina and across America and Europe. The GÆA supports and recognizes the work of professors, researchers, and professionals in geography through its many academic and scientific relationships, especially in geographical education; through research grants and awards; the annual scientific meeting devoted to geographical research and geographical education, known as Geography Week “Semana de Geografía” fosters scientific exchange and interaction; publications; and other collaborative activities, such as the library; and many conferences, workshops, and seminars about the principal geographical themes of Argentina.

Brief history

The name of the GÆA Argentine Society of Geographical Studies is composed of the Latin expression Gæa, meaning earth, followed by the subtitle “Argentine Society of Geographical Studies.” The founders intended to give it a collective, national, and scientific significance. Its emblem includes part of the peerage emblem of Felix de Azara (a Spaniard who is used as an example of the Spanish Age of Enlightenment) known as the first geographer of the Rio de la Plata. It includes the foundation year, 1922, with a symbolic value “lasting in time.”
ARGENTINA

GÆA’s principal annual contribution is the Geography Week “Semana de Geografía”. The first one was held in 1936, when these type of events were still rare. They are held annually in different cities in the country and the 75th such Semana took place in 2014. It offers a platform for the dissemination of the latest research and scholarship by high level geography teachers, as well as training opportunities, and outreach to the wider public and the media.

The members, among them remarkable foreign and Argentine scientists, have always worked with enthusiasm and perseverance. GÆA is devoted to the creation of geographic knowledge. Today members of the scientific, professional, and teaching world collaborate in this society. Their interests range from the physical/natural subdisciplines to the interdisciplinary perspectives of geography and related social sciences.

Arid climates and desertification

Thomas A. Wikle
Oklahoma State University, USA

Arid climates are often depicted as hot, sandy deserts or as barren and unproductive landscapes with little to no surface water. Although the Earth’s arid regions include hot deserts such as North Africa’s Sahara, arid climates are extremely diverse in terms of temperature, patterns of precipitation, and physical appearance. For example, some arid regions are never hot, such as the vast Antarctica ice sheet and only a small percentage are covered with sand. Rainfall alone may not explain aridity since hot locations may receive higher amounts of rainfall than other places and still be classified as arid. As a result, finding a precise definition for what it means to be “arid” can be complicated.

An element common to all arid climates is low precipitation. Unfortunately, it can be difficult to generalize rainfall in arid regions because precipitation events are infrequent and may be moderate in areas that experience winter storms or intense in locations influenced by tropical air masses. Short-duration precipitation events in arid regions are often separated by long rainless periods. In some areas falling rain may not contribute to available moisture if high temperatures cause it to evaporate before reaching the ground. An axiom applicable to arid climates is that the lower the mean annual precipitation falling in an area, the greater the variability.

As a result of evaporative losses, locations with higher temperatures may receive more precipitation than cooler locations and still be classified as arid. In lieu of using precipitation alone for measuring aridity, climatologists compare average precipitation to average potential evapotranspiration—a measure of the demand for moisture that includes both surface evaporation and plant transpiration. The index p/PET is commonly used to represent aridity where p = precipitation and PET = potential evapotranspiration as determined by atmospheric humidity, solar radiation, and wind. PET is higher during the summer, on days that are less cloudy, and during windy conditions.

Factors contributing to aridity

Covering 6.1 billion hectares or about 47% of the world’s land area, arid and semiarid climates are found on every continent. The vast area surrounding the South Pole has been described as the world’s most arid region because its cold air holds relatively little moisture. Outside of ice sheets, the most extensive arid regions are located within 25° of latitude on each side of the equator and within central and western parts of continents. Within these regions high surface pressure serves as the principal factor influencing aridity. Heated by intense sunlight, air overlying equatorial regions rises within Hadley Cells, traveling hundreds of miles in the upper atmosphere before descending in the subtropics. The dry, subsiding air warms adiabatically, creating stable atmospheric conditions and mostly cloudless skies. The Sahara, the Arabian peninsula, and portions of Central Asia and Australia owe their aridity to persistent high pressure.
ARID CLIMATES AND DESERTIFICATION

Other factors may contribute to arid climates, including mountainous regions that remove moisture as air travels inland. This happens when precipitation falling on the windward side of mountain ranges creates a dry condition called a “rain shadow” on the opposite (leeward) side. Asia’s Takla Makan Desert is located within a rain shadow created by the mountains of Tien Shan and Kunlun Shan, making it more barren than the Gobi Desert. Likewise the aridity of South America’s Patagonia Desert is strongly influenced by its location on the leeward side of the Andes. Locations may also owe their aridity to being far from sources of moisture. Arid and semi-arid regions within interior regions of North America, Asia, and Australia are influenced by continentality, referring to their distance from sources of moisture-laden winds such as large lakes, inland seas, and oceans. Ironically, ocean currents and upwelling can also be responsible for arid conditions in coastal areas where cool ocean surface temperatures contribute to atmospheric stability. Aridity can also be influenced by land cover where lighter-colored rock or sand reflects greater amounts of incoming solar radiation compared to darker vegetation that absorbs energy, contributing to rain-producing convection. Finally, variation in rainfall within arid climates can be influenced by activities far from desert regions. For example, a weather pattern associated with differences in atmospheric pressure between the Indian and South Pacific oceans called the Southern Oscillation is responsible for periods of rainfall significantly higher or lower than average.

Classifications of arid climates

Modern techniques for classifying climates follow a system developed by the ancient Greeks that divided the Earth into broad zones based on temperature. In the early 1900s German climatologist Wladimir Köppen introduced a more comprehensive system used today for classifying climates into five major types: A (Moist Tropical), B (Dry), C (Humid Middle Latitude), D (Continental), and E (Cold). Each category was defined by temperature except B-Dry Climates, which was designated on the basis of aridity. Köppen added additional letters as modifiers representing parameters such as seasonal differences in precipitation or temperature. For example, within B-Dry climates the letter h was used for dry-hot climates with average temperatures above 18 °C (64 °F) and k was added for dry-cold climates with average temperatures below 18 °C. Defined as having potential evapotranspiration exceeding precipitation, Köppen’s B Climates include the world’s deserts (BW Climates) and surrounding and comparably less dry “steppe” regions (BS Climates). B-Dry regions are further subdivided as either subtropical or mid-latitude climates.

Centered on the western sides of continents at latitudes between 25° and 30°, BWh climates are true deserts. Clear skies and high sun angles produce surface temperatures averaging 30 °C (90 °F). BWh climates have among the highest surface temperatures on Earth. On September 22, 1922, a temperature of 58 °C (136 °F) was recorded at Azizia, Libya. A distinguishing feature of BWh deserts is average precipitation that is less than half of annual potential evapotranspiration. Subtropical deserts are among the Earth’s most rainless places, with some locations experiencing decades without precipitation. Rain that does fall is delivered through convective showers of short duration; an entire season’s precipitation may fall during a single rainfall event. BWh climates have an average rainfall less than 30 cm (12 in.) with significant year-to-year fluctuations. Driven by daytime heating, winds of more than 100 kph, such as the dry passat (trade) winds of the Sahara, carry dust and
sand hundreds of miles. BWh deserts include the Great Australian, Sahara, and Arabian. The Sahara alone covers more than 9 million km², an area roughly the size of Europe.

Located in the interior of continents, BWk climates are mid-latitude deserts dominated by subtropical high pressure. A major difference between mid-latitude and subtropical deserts is seasonality. With moderately warm summers and long, cold winters, BWk areas receive the majority of their precipitation during the summer months. For example, in the US Southwest air masses originating over the Gulf of Mexico bring moisture during a “monsoon season” in July and August. Despite summer precipitation, mid-latitude deserts receive annual precipitation that is less than half of potential evapotranspiration. The pattern of precipitation within BWk climates is also influenced by their location far from oceans and position on the leeward side of high mountains that remove moisture from prevailing winds. The aridity of North America’s Great Basin Desert is the result of both its continental location and a rain shadow effect created by the Sierra Nevada and Cascade mountains. The Great Basin experiences cold winters with a significant amount of winter precipitation falling as snow. Dominated by anticyclonic conditions, winter temperatures in BWk climates remain below freezing for about half the year with seasonal extremes contributing to an annual temperature range that may exceed 28 °C (50 °F). The altitude of BWk areas can also influence temperatures. For example, while the Chihuahuan and Sonoran deserts are located at about the same latitude, the Sonoran is hotter because of its lower elevation.

**BS climates**

Covering about 14% of the Earth’s land surface, steppe (BS) climates serve as transition areas between humid and dry climates. “Steppe” is a Russian word meaning “treeless plain.” Within steppe climates annual potential evapotranspiration is more than half but less than 100% of total annual precipitation. Steppe grasslands receive precipitation from mid-latitude cyclones or shifts in the Intertropical Convergence Zone.

Found on the margins of BWh climates, subtropical steppe (BSh) is characterized by slightly greater annual precipitation (10 to 50 cm) and moderate mean temperatures (20 °C). As in the case of subtropical deserts, subtropical steppes have minimal cloud cover, contributing to nighttime cooling, especially during the winter months. Large BSh areas are found south of the Sahara, on the border of the Great Australian Desert, and in portions of Pakistan, India, southern Iraq, and Afghanistan.

Mid-latitude steppe (BSk) climates are similar to tropical steppe but receive greater amounts of rainfall and have larger temperature ranges that may extend from −40 °C (−40 °F) in winter months to 40 °C (104 °F) in the summer. The largest BSk region, the Eurasian Steppe, covers an area stretching 8000 km from Eastern Europe to China, reaching across the Ukraine and Central Asia. Within North America, mid-latitude steppe climates include portions of western Wyoming and southeastern Washington, along with parts of Idaho, Oregon, Utah, and Nevada. With an average rainfall of 81 cm, BSk climates are generally found on the edge of mid-latitude BWk areas. North American steppe lands are located to the west of clockwise advection that moves moist air away from the Bermuda–Azores high. In contrast, dry conditions within the mid-latitude steppes of Asia are the result of continentality. The dominant vegetation of mid-latitude steppe is grass that may grow to over a meter in height. Shorter grasses are found where less rainfall is received, while trees may be located near sources of water. Because of their
ARID CLIMATES AND DESERTIFICATION

Rich soil many of the world’s steppe lands have been converted to pasture or farmland.

Coastal deserts

Ironically, some of the world’s driest climates are located in coastal areas with aridity influenced by ocean water rather than atmospheric circulation or surface topography. For example, upwelling from cool ocean water off the coast of Chile and Peru affects winds as they move inland. The cooler air has a diminished capacity to hold moisture and becomes stable as it passes over the warmer land. Without convective uplift, moisture bypasses the coastal Atacama Desert as it travels eastward, depositing precipitation on the western slopes of the Andes. This process makes the Atacama the Earth’s driest coastal desert, with no more than two or three rain events taking place each century. Along with serving as a barrier to precipitation, cool ocean surfaces also contribute to high relative humidity, fog, and low stratus clouds that move inland for a few kilometers. Flowing northward, the cold Benguela Current off Africa’s southwestern coastline has a similar affect by inhibiting precipitation over the Namib Desert as winds push cool water originating near the Antarctic continent eastward. Like the Atacama, the Namib has a significant number of foggy days (200) per year.

Although aridity is most often represented in the context of large regions, arid conditions can also be observed in geographic areas of a few hundred square meters. Microclimates are small areas where tiny differences in relief, aspect, or altitude can influence solar radiation, temperature, precipitation, and/or wind speed. As a result, considerable differences in evapotranspiration may be noticeable across short distances. For example, a shaded area may have a rate of evapotranspiration half of what would be experienced in an exposed location. Variation in surface reflectivity associated with vegetation, soil type, or surface material may also alter the heat balance of small geographic areas.

Mapping aridity

Limited climatological data within some countries has contributed to difficulties in defining precise boundaries for arid and semiarid regions. To facilitate the mapping of dry conditions, the United Nations Environment Programme (UNEP) developed an index classifying arid lands into four zones: hyperarid, arid, semiarid, and dry subhumid (Table 1). Covering just 7.5% of the Earth’s land area and nearly devoid of vegetation, hyperarid areas have annual rainfall that rarely exceeds 20 cm per year. In contrast, areas classified as arid receive summer rainfall that is not enough to support agriculture without irrigation. Areas designated as semiarid support native grasses, shrubs, small trees, and sedentary agriculture and pastoralism. Although precipitation is seasonal, dry subhumid areas facilitate some rain-fed agriculture.

Deserts and climate change

Arid regions are noted to be among the world’s most responsive ecosystems to global climate change. As noted by Lioubimtseva (2004), the climates of deserts and semideserts that exist today are known to have changed across both spatial and temporal scales. For example, during the Mid-Holocene period (9000–4000 years BP) the “Green Sahara” was covered by woodlands, scrubs, and grasslands that supported giraffe and other large animals presently found much farther south. Although paleodata are useful for characterizing climate change over long time intervals

such as centuries, they are less useful for capturing shorter-term fluctuations in temperature or precipitation. As a result, the task of interpreting recent climatic change can be challenging.

Under current scenarios some arid and semi-arid regions are likely to become hotter and most will not become significantly wetter (IPCC 1996; 2007; 2013). Regions facing reduced precipitation include the American Southwest, the southern Andes, western Australia, and the Sahara. Even small temperature changes may affect aridity. For example, a temperature increase of 2 °C without an increase in precipitation would increase potential evapotranspiration by 0.2 to 2 mm per day. Many scientists believe that anthropocentric emissions of greenhouse gases are partly responsible for increasing temperatures in all deserts, and studies of global climate change suggest that desert temperatures are increasing faster than the global average. Within the last 25 years of the twentieth century, desert temperatures increased at an average rate of 0.2 °C per decade in the Atacama. Among hot deserts the rate of change has been even greater. The Kalahari and Great Victoria increased at an average rate of 0.8 °C per decade. In comparison, the average global temperature change for the same time period was 0.45 °C per decade (UNEP 2006). In addition to modifying the temperature regime, climate change can disturb sensitive ecosystems. For example, scientists have determined that increasing levels of atmospheric carbon dioxide may lead to an expansion in invasive plant species within arid regions.

**Desertification**

Desertification is sometimes represented as a process involving the movement or expansion of deserts. In fact, the term is misleading since deserts have no direct impact on desertification. Desertification is not a new phenomenon but, rather, a process dating back thousands of years and taking place in diverse locations ranging from river valleys of the Middle East to loess plateaus in central China and from lands surrounding West Africa’s ancient city of Timbuktu to deforested highlands in Nepal. The term was made popular by Aubreville’s 1949 book *Climats, forêts et désertification de l’Afrique tropicale*, where desertification was described as the transformation of productive agricultural land into desert through human-driven soil erosion. Aubreville’s definition didn’t describe desert lands as expanding outward, but rather as human-induced degradation caused by tree cutting, poor cultivation practices, and the indiscriminate use of fire.
ARID CLIMATES AND DESERTIFICATION

Although there is no consensus regarding its specific causes, most definitions treat desertification as a transformation of semiarid regions into arid land as a result of human-caused degradation. The United Nations has defined desertification as “land degradation in arid, semiarid and sub-humid areas resulting from various factors including climatic variation and human activities” (UNCED 1992). Land degradation associated with desertification is often represented in terms of reduced biological productivity through the loss of vegetative cover or as a result of soil compaction, decreased soil infiltration, and water or wind erosion (Schreiber 2006). In addition to increasing surface runoff, the removal of vegetative cover eliminates the binding action of plant roots that hold soil together. Subsequent erosion removes the organic content needed for the growth of soil organisms.

Desertification may also threaten biodiversity where land-use practices have allowed native plants to be replaced by invaders (Aronson and Shmida 1992). Dryland ecosystems are generally more susceptible to desertification in places where they have low resistance to stressors such as drought, fire, or human abuse. Given the difficulties in achieving consensus on its causes, some scientists suggest that desertification should be viewed simply as a nonreversible process associated with human activity (Prince 2002).

The first large-scale research on desertification was organized by the United Nations Educational Scientific and Cultural Organization (UNESCO) in the 1950s. During the 1960s a severe drought contributing to famine in areas south of the Sahara focused media attention on problems associated with the world’s semiarid lands. Subsequently the UN General Assembly sponsored an international convention in Nairobi, Kenya, in 1977 to discuss methods to mitigate desertification. In 1994 the UN Convention to Combat Desertification (UNCCD) was formed to foster cooperation in efforts to improve soil productivity and lessen the impacts of drought. That same year the UN General Assembly designated June 17 as World Day to Combat Desertification to raise awareness about the risks of drought and land degradation.

Desertification is estimated to be responsible for the declining productivity on more than 12 million hectares of land each year affecting more than a billion persons (UNCSD 1995). As noted by UNCCD, desertification impacts “the world’s poorest, most marginalized and politically weak citizens” (UNCCD 2006). As a result of its impact on populations, desertification is considered a significant threat to human welfare, especially in areas where local communities focus on a narrow range of economic activities such as farming and grazing.

Most scientists suggest that desertification should be viewed as a continuum of change extending from slight to severe. Rather than being treated as a strictly physical process, desertification is often framed in terms of overlapping economic, political, social, and natural factors. For example, government policies may favor unsustainable uses of land that contribute to degradation such as promoting sedentary farming over nomadic herding in areas more suitable for grazing. Coupled with drought, desertification may lead to prolonged famine, threatening food security in countries that have difficulty sustaining agricultural losses. In some cases population pressure or conflict may force people to occupy ecologically fragile areas, contributing to land degradation. Policies to mitigate desertification are often unsuccessful. For example, during the early 1980s a government-sponsored resettlement program aimed at moving people out of marginal lands in Ethiopia led to even greater levels of degradation. Land tenure policies may aggravate the impacts of drought and desertification when people who don’t own
land are reluctant to implement soil conservation practices. The impacts of desertification have been felt in locations far removed from where degradation is taking place. For example, airborne particles from dust storms in the Gobi Desert have degraded the air quality in Chinese cities located hundreds of miles away.

A common misconception is that droughts are the principal cause of desertification. Under most circumstances, droughts will not increase the likelihood of desertification unless the carrying capacity of nonirrigated lands has been exceeded. However, when it is combined with the abuse of land, droughts can amplify human hardship and suffering. Overgrazing leading to a loss of topsoil as a result of wind or water erosion is often cited as a cause of desertification. Plants in semiarid areas are often consumed by wild animals that follow patchy rainfall. This pattern has been emulated by pastoral humans who move their herds with the shifting availability of rainfall and forage. In some areas fencing has contributed to overgrazing by preventing the movement of wild and domestic animals. Soils are damaged through compaction from animal hooves that reduce permeability and increase susceptibility to wind or water erosion. In some locations water wells have enabled livestock to remain in areas with limited surface water, leading to the damage of surrounding vegetation and soil. In addition to soil loss, overgrazing may lead to a decline in palatable grass species or to the replacement of perennials with annual species less resistant to soil erosion. The suppression of wildfire has also contributed to changes in the composition of vegetation. Woody vegetation has also been lost through firewood collection, especially in areas near human settlements. The reduction in woody plant cover leads to accelerated wind and water erosion and may contribute to the destabilization of dunes.

Poor agricultural practices have also been cited as a contributing factor to desertification. For example, monocropping can lead to greater soil exposure and increased rates of erosion. Likewise, overcultivation may result in losses to soil productivity where exposed topsoil becomes susceptible to water erosion and gullying. When soils become dry they are more susceptible to wind erosion. In some locations poor irrigation practices may result in salinization – the collection of salt on soil surfaces. Within some areas increasing demand for food, driven by expanding population, has encouraged the shortening of fallow periods, resulting in the depletion of soil nutrients. Finally, the cultivation of marginal lands has contributed to desertification in locations where farming has replaced nomadic pastoralism. Short-grass steppe lands are particularly susceptible to erosion after being plowed, as nutrients anchored by grass and soil are removed by blowing winds.

Since the 1970s land degradation and drought have focused media attention on desertification within Africa’s Sahel region. Forming a 200 km wide transition region between the Sahara to the north and humid lands to the south, the Sahel has been inhabited by herders and farmers for thousands of years. A unique characteristic of the Sahel is alternating wet and dry periods that last several decades. For example, the region experienced a wet phase during the late 1880s that led to years of higher than average agricultural productivity followed by an extremely dry period beginning in 1900. Rainfall increased again in the 1930s until a sharp decline in the 1970s and 1980s that culminated in severe famine and the deaths of thousands of people and livestock.

Although a few parts of North Africa and Mauritania are threatened by migrating sand dunes, there is a false impression that the Sahara is encroaching into the Sahel with moving sands that swallow farmland. Within much of the Sahel
a natural belt of brush and trees protects agricultural lands from desert encroachment. The Sahel’s vulnerability to desertification is due to its strong dependence on rainwater for supporting livestock and sedentary farming. Contributing to problems in the Sahel are cultural practices that promote livestock as having value beyond serving as a food source.

Estimating impacts of desertification

Desertification can be difficult to measure because the world’s arid regions were created by natural processes over long periods or time and have expanded or grown smaller independently of human impacts. In many cases, borders of desertified areas are difficult to define precisely because vegetation exhibits a gradual transition from arid to more humid conditions, with xeric plants interspersed with other forms of vegetation across broad zones. Although there is no accepted threshold for determining when land is considered “desertified,” the United Nations Conference on Desertification has created an index for identifying the severity of desertification according to declining agricultural productivity. A 10–24% drop in productivity is considered moderate, 25–50% is high, and greater than 50% is considered very high.

As noted by Helldén and Tottrup (2008), scientists disagree about the geographic magnitude of desertification. Therefore, a significant need exists for better information on the spatial distribution and severity of desertification through the collection of baseline data and monitoring programs. In recent years methods for tracking changes in the productivity of vegetation over large areas have evolved including satellite remote sensing utilizing the Normalized Difference Vegetative Index (NDVI). However, while NDVI values are useful for estimating the condition of vegetation, they are often less helpful for comparing specific locations across time periods (Burgan and Hartford 1993).

Areas impacted by desertification

Desertification is found on every continent except Antarctica. Within Africa the largest areas impacted by desertification are the rain-supported grazing and agricultural lands of the Sahel and portions of North African plains. Within semiarid regions of sub-Saharan West Africa wind erosion tends to be a more significant factor, while fluvial erosion has been more severe in Maghreb countries such as Morocco, Algeria, and Tunisia. Overgrazing has also impacted arid regions of Asia such as rangelands in Central Asia and the Middle East. The productivity of rangelands in much of the Middle East and western portions of Pakistan is among the lowest found within the world’s semiarid lands. Fluvial erosion on cultivated lands has also been a problem in Pakistan, India, and highland areas of China. Growth in human and livestock populations have increased grazing pressures on some lands while cultivation has encroached into pastoral lands. At the same time, improvements in transportation have made formerly remote areas more accessible to grazing. Much of Australia has also suffered from the impacts of desertification. About one-quarter of the continent’s arid regions are not occupied because of unpalatable spinifex grasses or their distance from population centers. The most severe desertification can be found in the saltbrush and bluebrush areas of South Australia and New South Wales, mostly due to overgrazing.

Desertification has also impacted North America where overgrazing has severely altered native grass cover. The history of climate change in desert and semiarid regions of the American West and Southwest has been studied extensively
using indicators of past vegetation and climate that include the analysis of sediment and pollen samples. In some areas of North America desertification has been accelerated by overgrazing that has removed perennial grasses, leaving soils easily eroded by running water. Affecting more than 400,000 km², North America’s “Dust Bowl” created huge dust storms during the 1930s that reached the eastern United States, destroying crops, killing animals, and removing enormous quantities of topsoil. Areas of South America have likewise been impacted by desertification including the semiarid pampas of Argentina. Severe erosion attributed to deforestation, overgrazing, and the invasion of salt-tolerant plants has affected parts of coastal Chile and Brazil’s state of Minas Gerais.

**Mitigating desertification**

Techniques for mitigating desertification include farmer-managed natural revegetation and agroforestry – the planting of trees in and around crops. In some areas local initiatives to build wind barriers or to close areas to grazing and cultivation have been successful in combating desertification. Such methods have helped reduce evapotranspiration and improve crop microclimates. In China’s Tengger Desert researchers have attempted to stop drifting sand using a grid network of straw fences that reduce wind velocity. Another method has been the promotion of soil conservation through intercropping using perennials as anchors against water and wind erosion. Indigenous knowledge has also been important in fighting desertification. For example, on the steppe lands of Syria known as the “Badia,” Bedouin communities that maintain herds of small ruminants, camels, and equines cooperate with representatives of the International Fund for Agricultural Development in the rehabilitation of rangelands. Bedouin leaders have participated in the development of management plans for defining grazing limits established by evaluating seasonal rainfall patterns and the condition of vegetation. As a result of this effort some areas have been temporarily placed off-limits to grazing while others have been replanted or reseeded using forage plants acclimatized to local circumstances. An initiative organized by the African Union and supported by many regional and international organizations called the “Green Wall” targets desertification within the Sahel through a campaign to plant trees.

ARID CLIMATES AND DESERTIFICATION

Further reading

Geographers have never seemed more open to, and interested in, art as they have been in the first decade or so of the new millennium. Yet, geography’s relationship with artists and artistic practices is arguably as old as the discipline itself. Indeed, to inspect the major phases of geographical knowledge-making is to find an important place for artists, artworks, and arts practices. Moreover, at key phases of geography’s development, the discipline’s relationship with art becomes a point of critical formulation, offering a site of epistemological evolutions that come to shape disciplinary directions and hone analytic foci (Hawkins 2014). Examples include: artists onboard ship during the long period of “capes and bays” geography, the evolving place of artists and writers in the extension and critique of the chorographic traditions of regional geographies, the role of art in the evolution of humanistic geography, the place of creative practices within qualitative GIS, and within questions of the body and affect raised by nonrepresentational theorists, together with the allied debates around aesthetics and politics. To overlook this rich history is not just to pass over an important influence on geography’s development; it is to miss out on the clear analytic value that an appreciation of the diverse roles art has played offers for exploring geography’s current phase of artistic engagement.

This relationship is not one-sided. Art theorists, artists, curators, and arts organizations have also invested in an evolving relationship with the discipline of geography, its substantive concerns and its knowledge-making practices. If art, with its concerns with site and situation, has come to feel especially geographical of late, this is not a new set of preoccupations. We can think, for example, of the intersection of art and urban theory throughout the twentieth century, as well as the broader spatial turn in the arts and humanities that found perhaps its clearest form over the last two decades (Rendell 2006). Artists have also long produced artifacts and worked with practices, and knowledge (modes of mapping, exploration, preoccupations with place, and so on), that we might more normally think of as geographical.

There is therefore much common ground between geography and art, shared conceptual and methodological territory whose occupations were not, until recently, explored terribly closely. As geography’s relationship with the humanities continues to evolve, there is a growing concern to explore the form and kind of this geography–art relationship. There is interest in mapping the multiple intersections of these expanded disciplinary and practice-based fields, around both substantive topics such as landscape or the body, as well as around common practices such as mapping, and the geographies of different mediums, whether paintings, photographs, sculpture, performance, or community-based work (Dear et al. 2012). An ongoing issue has been to attend to the different forms of these art–geography intersections, with distinctions being made between dialogues, which bring geographic ideas and thinking to bear on artworks and vice versa, and doings, wherein geographers and artists collaborate, or work

separately, to bring artistic practices together with geographical practices and procedures of knowledge-making.

The broad spectrum of research that links geography and art displays a diversity of substantive foci (landscape, urban space, materialities, nonhuman geographies, environmental matters), analytic approaches (iconography, sensory ethnography, ethnography), and methodological questions. From amidst this diversity emerge three enduring areas of concern: the geographies of artworks and art worlds – namely the production, consumption, and circulation of art; the role of artistic practices in “making” worlds; and the role of artistic practices in geographical knowledge-making practices and methods (Hawkins 2014). These three dimensions are common not only to geography and art relationships, but also to creative geographies more generally. As such, they are applicable concerns with respect to creative writing, music, film, and craft practices (Daniels et al. 2012). This is not to collapse important distinctions of method, medium, and politics, but to enable tensions to be drawn out between these different modes.

Geographies of art worlds and art-making

Artistic production has long been recognized as a situated activity with complex and manifold geographies. Discussions of such geographies take account of the role of the art world, as well as the nested sites of studio, home, community, city, nation, and so on (Bain 2013). Geographers are very aware that the geographies of art are not just those of the initial site of the work’s production and consumption, and those places and locations that feature within the works, but are also concerned with the circulation of artworks, the various contexts through which they move, and the sites at which they are consumed. The sites and spaces and spatial distributions of artistic production, have been explored via a range of methodologies and to a variety of ends. These include economically and politically orientated studies of the networks, clusters, and scenes of the art world; detailed studies of the geohistories and geopolitics of the international diffusion of artistic materials, styles, and techniques; the sociologies and histories of art school or colonies of artists, as well as ethnographic studies of the embodied, material practices of studio production (Kaufmann 2004; Sjoholm 2012; Bain 2013).

Geographic research on art worlds has often taken the spatialities of artistic production as an analytic concern, whether such spatialities be those of local agglomeration – clusters – or the intersecting local and global networks of transnational production, circulation, and cultural exchange. Questions of creative clustering have developed out of art historical interest in arts colonies or schools, as well as from the economic imperatives of the creative cluster. Here we find artistic outputs shaped by social relations, common conceptual questions, and shared inspirational sources. For more economically inclined scholars these relations translate into “traded” and “untraded” interdependencies. If the former consist of connections formed from sharing, exchanging, or trading (for money, goods or services) painting materials, framing services, and so on, the latter might include the production of and benefit from the formal and informal social exchanges that constitute a shared creative and intellectual atmosphere. Informing these ideas have been discussions around “creative scenes,” whether these be historical studies of the evolution of particular locations or economic work on creative cities and city branding (Rycroft 2011). Running in parallel with such enquiries is research that deploys postcolonial
scholarship and ideas of transnationalism to query the mobilities of people, objects, and ideas in the production of different art forms from painting to performance work (Rogers 2014).

Accompanying work on art scenes is a growing body of geographic scholarship concerned with the sites, spaces, practices, and technologies of artistic projects, whether these be situated in the field, the studio, the street, the community, or the landscape. Across these sites attention is paid to the intersections of the material and immaterial dimensions of creative production to questions of embodied practice and to the role of technologies. Discussions of the studio, for example, explore the role of studio spaces as sites of inspiration, for thinking and dreaming, for archiving, for identity formation (Sjoholm 2012). In discussions of art-making in the landscape, the immediacy of “en plein-air” experience in shaping the artworks produced has been a key analytic dimension. In other words, how the embodied experience of being in the landscape informed the works, wherein what is being “pictured” becomes a more-than-visual account of what was sensed. In such a context, the role of technologies – from the camera to the paint-box – in mediating and shaping these relations is an important concern.

In considering artworks made on the street or in the community geographers have embraced the idea of these works as technologies of connection. Geographers interrogate these works for the form and kind of connections made between community and artwork, but also the relations within the community that are catalyzed by the artwork. Such an approach takes seriously the social “work” that these art projects do at the sites of their creation. Such “work” might relate to border and security concerns, to questions of urban super-diversity, rural community disenfranchisement, or the alienation brought about by urban gentrification (Hawkins 2014). It is clear from thinking about this work that the geographies of creative production cannot be set apart from the geographies that the work creates within the “frame,” nor from the geographies of its consumption.

Geographical scholarship on galleries as a site of artistic consumption has not perhaps been as voluminous as might be expected. Indeed a general trend in geographical scholarship has followed artworks as they moved from “studio to situation,” being more concerned with the artworks produced and consumption beyond studio and gallery sites than with reflecting critically on gallery spaces. If the geographies of galleries have been largely neglected, questions of audiencing have gained attention in the context of art produced and consumed in homes, on streets, in communities and in the landscape. While such works might involve a gallery-based period of display, often after their initial phase of production and consumption, such later forms of consumption are generally overlooked by geographers more intent on studying the transformative effects of these works on the spaces and peoples they are produced in and by. An appreciation of the potential of artworks to “make” worlds demands an analytic sensitivity to the intersections of the geographies of the works’ production and consumption – whether these be on the street, in the studio, or in the gallery – with the geographies within their “frames.”

Artistic practices and the “making” of worlds

That artworks do not so much “picture” worlds as “make” worlds is a central premise for geographers studying art. Looking across the last few centuries of geographical relations with art is to witness the evolution of geography’s appreciation
of the “work” art does in the world. In short, there is a shift from artworks understood as “picturing” worlds, with the latter verb understood to be an act of mimetic representation, to an appreciation of the force and potential of the making of worlds that happens in that picturing (but also of course the “sounding” and “performing”) of the world. This attention to the productive “doings” of art, its makings and shapings of worlds, subjects, and knowledge, has become one of the distinguishing features of geographical scholarship on art.

Picturing places: geographical imaginations

The value of art for providing “packets” of information about a place is how expeditionary art from the eighteenth and nineteenth centuries has often been discussed. In the midst of this “Age of Exploration,” artists commonly accompanied great voyages – such as those of Captain James Cook – in the service of science and empire. Indeed, the casting of aesthetic practices in relation to military and commercial interests, and as part of the production of enlightenment science, earned this era of artistic practice the moniker “the winter of the imagination.” An important figure in the context of exploration art is Alexander Von Humboldt, the eighteenth-century polymath for whom artistic, and aesthetic practices more generally, were a mode of apprehension equal to, and indeed a building block of and catalyst for, scientific knowledge. The influence of Humboldt’s geo-aesthetics can be traced into the eighteenth- and nineteenth-century formation of branches of geography as different as geomorphology and cultural geography. In geography’s twentieth century evolution, Humboldt’s scholarship is a touch-stone for a humanistic critiques of a scientized geography, and more recently it backstops both human geographers’ embrace of aesthetics and geopolitics, and physical geographers’ recognition of the role of enchantment and the arts in critical approaches to their methods and scholarship (Hawkins 2014).

The richly varied visual cultures of exploration produced during the sea-going voyages of the eighteenth and nineteenth centuries – from large oil paintings to informal sketches in diaries to scientifically accurate botanic drawings – were valorized for their situated geographies of production. Being produced on the spot such visual cultures provided privileged forms of evidence. They were valued over the written word for their production of “more perfect” accounts of places and species than words could create. Crucially such pictures of place were formative building blocks in the geographical imaginations of the European Enlightenment era. They provided not only scientific source material, but also pictured “exotic” places and others for those European populations who could never hope to travel there. Sent home ahead of explorers, they were hung in galleries, stored and displayed in scientific institutions (including the Royal Geographical Society), and reproduced in newspapers, their circulation creating globally encompassing geographical imaginaries (Driver and Martins 2005).

Such geographical imaginations are, of course, not neutral picturings of place. Rather, the imaging of places far distant was the result of a complex set of aesthetic geographies, often overlaying the terrains of non-Western places with the pictorial conventions of the Western world. William Hodge’s (1744–1797) images of Tahiti, for example, picture the island through a Western optic, a lens that owes much to the aesthetics of classical Italianate painting. This optic shaped everything from lighting to compositional layout, the types of plant species included, and the mode of picturing the inhabitants of
places. The complex geographies of these imagined, pictured worlds, importantly, did not just take form on the surfaces of the painted canvas, but also came to find form in the materiality of landscapes, the textures of social relations, and the topographies of Western imaginaries that were created as a result of these paintings.

Landscape art: from iconography to embodied experience

The force of painted aesthetics in shaping landscapes and lives is foregrounded in geographical scholarship on landscape painting. Scholars such as Stephen Daniels (1993) focus on the “Marxist duplicity of the landscape,” developing an interdisciplinary approach that begins from the Marxist cultural studies scholarship of Raymond Williams and John Berger. The empirical focus of this scholarship included the works of great English and American painters of the eighteenth and early nineteenth century. The surfaces of these canvases were examined as “veils,” aesthetic screens drawn across the landscape. Exploring both the symbolic codes and the affective and emotional qualities of the landscape, its beauty, sublimity, and order, such aesthetic conventions were understood to constitute a covering over and a turning away from the uncomfortable “truths” of the landscape. In many cases of the English picturesque – in paintings, for example, by John Constable, and landscape gardens by Humphrey Repton and Capability Brown – this turning away involved the picturing or recreation of a rural idyll, an aesthetic ideology that “hid” from view the “dark side of the landscape,” masking the squalid living conditions of the rural poor, their existence at the edge of starvation, and the widespread unrest that existed in the countryside at the time. Such ideological picturings of place produced and reproduced, indeed legitimized, particular types of power regimens, especially when, in addition to being “pictured,” they came to shape the materialities of the landscape. Migrating from the surface of the painted canvas to the earth, soil, stone, and flesh of rural landscapes and communities, these aesthetics re-aligned roadways and coppiced woods, and ensured houses were left to tumble down in picturesque ruin. Such aesthetic migrations were not just restricted to the national environs of their creation, but were rendered mobile by practices of colonization. The global circulation of these aesthetic principles was one way in which colonial power was made manifest in the landscapes of plantations, and in the lives and the bodies of their workers.

Nuggets of experience: more than “presenting”

Geographical perspectives on the ideology of aesthetics, and the transformative work such aesthetics did on subjects and urban and rural landscapes, dominated geographical scholarship on art for much of the late twentieth century – and rightly so (Pinder 2005). A parallel understanding running throughout geography’s engagement with arts in the twentieth century has been ideas of arts as offering geographers access to experience. Yi Fu Tuan (1973) and others writing of geography’s relationship with literature and art have been rather disparaging of this relationship, suggesting that geographers were scanning artistic and literary sources for “nuggets of experience.” In moves described as akin to stamp collecting, geographers become merely intellectual middlemen, seeking subjective accounts of place and experience in arts as sources, and sorting them for collation as data within the chorographic impulses of the regional geographies of the time.

As geography’s engagements with art and its own theoretical interests evolved, a rather different sense of the value of art in relation
to subjective experience has begun to emerge. In the light of a growing interest on the part of feminists, nonrepresentational theorists, and others in questions of the body, the senses, affect, and emotion, arts practices became re-valued. Within the context of these concerns painting, sound and installation art, dance, urban walking practices, video practices, among other arts practices, have become situated as sites in which geographical sensibilities can become extended and attuned to our sensing and experiencing of space and place. These studies often have a two-fold imperative: a remapping of bodily senses, challenging the privileged position of vision by asserting the value of other senses – for example, hearing, taste, and touch – in knowing place and self, and by exploring the complex intersection of these external senses with the internal senses. The second imperative which perhaps marks out geographic studies from other approaches, is a concern with how in knowing space, place, and self, we are not just concerned with the bodily senses, but also with their intersections with questions of habit, memory, and prior knowledge of these and other places (Hawkins 2014).

These ideas of the body have also reconfigured the set of analytic modes and questions geographers ask of and with art. If geographical studies of historical landscape paintings would commonly approach these paintings as a set of symbols to be decoded, then recent reconfigurations attend to art as productive of sensations and experiences. For some geographers this resulted in a revisiting of ideas of landscape in relation to abstract practices. In these works artists engage their embodied experiences of landscape as the subject of their work, creating canvases that are less concerned to picture than to create evocative blocks of sensation and experience that audience members feel in their bodies as well as explore with their minds.

In such a context artistic practices are the result of encounters with the landscape and environment, but also create encounters with landscape and environment for their audiences. From the recognition that arts practices enabled geographers and others to explore everyday embodied experiences of being in and moving through the world, recent geographical research has begun to examine the potential of artworks to open us out to experiences of the world and move us beyond the capacities of our human senses. This is to understand art as potentially creating ways of knowing the world beyond what is possible for our human cognition and our sense organs alone to develop. Art, as a result, holds the potential to create encounters that might open us out to experiences of airy and earthy matters, nonhumans, the organic, and the inorganic in ways that are important for shaping our future environmental imaginaries.

Artistic practices and the production of geographic knowledge

The place of artistic practices in producing geographical knowledge has evolved since artists accompanied explorers on board ships producing rich visual cultures of distant places. From this foundation based on the valorization of mimesis, it is possible to explore the alternative value that has been found in creative methods for geographers, which have become variously understood as creative, experimental, or artful geographies. Such work sees geographers across the discipline coming to embrace various creative practices – film-making, visual art, creative writing – both as the means through which research can proceed and by which it can be communicated and presented.

Primary among the justifications for practicing such creative geographies is to understand them
as a response to the discipline’s orientation toward embodied and practice-based doings. Such orientations demand the means by which to engage, research, and re-present the sensory experiences, affective atmospheres, and flows of life. Geographers’ development of artistic practices, either alone or in collaboration, is understood as a means to enable such messy, fleshy, and experiential modes of engagement to be explored and developed. Furthermore, creative writing practices offer a means by which to begin to write about, to grasp, such experiences and convey them to others.

For other geographers engagement with the artful proffers the means to grasp the messy, unfinished, and contingent – in everything from spatial imaginaries to knowledge-making practices – that a more scientifically inclined geography might orient us away from. Artful engagements might include critical reflections on the spaces and sites of the archive and other knowledge-making institutions; they might reflect a concern with how we know and write about places and spaces; or they might be a response to an epistemological turn within geography that seeks to do away with categories, binaries, and fixities, in favor of multiplicities, hybridities, and becomings. Rightly, or wrongly, geographers across the discipline, whether historical, concerned with nonhuman relations in the Anthropocene, or with modes of contemporary urban living, have found value in artistic practices and creative methods as a means to confront the epistemological challenges they encounter at their research sites.

A further reasoning behind geographical engagements with creative methods has been in terms of the contemporary extension of the long appreciated possibilities such methods offer for enrolling audiences other than academics. Long recognized to form affective means of communication, scholars are now recognizing the value of arts practices as proffering a means by which to constitute new and engaged publics for their work. Thus we see geographers creating plays, developing arts workshops, and configuring creative activities based on the recognized “social” work that aesthetic practices have been understood to do. As well as being driven by intellectual agendas, such practices should also be situated in the context of the contemporary political agendas and climates of higher education wherein concerns with moving research beyond the academy, and thinking through politics in a new way loom large. Where perhaps there is work still to be done is around the seeming absence of a more critical radical politics from these creative geographies (Marston and De Leeuw 2013).

GeoHumanities: looking to the future

Geography has had something of a return toward art and arts practices, as both empirical objects of study and as the methods by which research can proceed, and through which it can be disseminated. Furthermore, art practices and theories have never seemed more geographically engaged. The result has been a ground-swell of practice and attention to what has come to be called the GeoHumanities, with these intersections becoming increasingly institutionalized in interdisciplinary masters courses, in practice-based doctoral work undertaken within geography departments, as well as in the evolving collaborative research practices of academics and artists (Dear et al. 2012).

If these productive intersections are to continue to fulfill their not inconsiderable promise there are a number of perhaps self-explanatory, and also perhaps not so self-explanatory issues to consider. The first of these relates to an ongoing
need to be clear and respectful about the knowledge and practices being deployed and developed in these intersections. Geographers may like the idea of being artists, writers and film-makers, but enthusiasm should not outweigh a concern for the skillful nature of these practices. Equally, there should perhaps be a shared sense of such intersections not only being based in comings together that are predicated on the in common and the collapse of differences. One of the delights of finding similar interests – in practices of mapping, of exploration, or in ideas and terms such as region, topography, or vision – has to be also to commit to probing the differences between these understandings. This is not to create rifts within newly formed relations, but to ensure their intellectual integrity, and also to aid in the mutual development and evolution of such ideas.

Finally, and perhaps most importantly, in these comings together we should not lose sight of the importance of attending carefully to the geographies of creative production and consumption, not least because such perspectives enable a close attention to the kinds of “work” that artistic objects and experiences do in the world. Geographers need to attend to the changing geographies of art over the twentieth century, to remain attuned to how the imaginaries and materialities of places shaped by canvases denote but one important sort of work art does in the world. This variety needs to be appreciated alongside the refiguring of artistic regimens around eventful and relational aesthetics, wherein, aesthetic practices create opportunities for social encounters in which individual subjects and communities can become transformed.

There is a need to attend closely to the type of encounter with the world that is being created by art forms, to acknowledge how they affect us as academics, as makers, as geographers, but also what impact they might have on their audiences. This is to become attuned to the political possibilities, but also the responsibility associated with the art that geographers study, the creative practices deployed within their research methods, and the artworks that they might be involved in creating.

Artificial neural networks in geospatial analysis

Sucharita Gopal
Boston University, USA

Background

Artificial neural networks (ANN) are computational models inspired by and designed to simulate biological nervous systems that are capable of performing specific information-processing tasks such as data classification and pattern recognition. ANN seeks to replicate the massively parallel nature of a biological neural network. A neural network is a system composed of many simple processing nodes whose function is determined by network structure and connection strengths. Similar to biological neural networks, AAN can acquire knowledge through a learning process. Interneuron connection strengths known as synaptic weights are used to store the knowledge and make it available for use. Each artificial neuron receives one or more input signals and sums them to generate an output. Usually the sums of each node are weighted, and the values are passed through a nonlinear function known as an activation function or transfer function. If a weighted sum exceeds some predetermined threshold value, then an excitatory output (1) is produced. Otherwise, an inhibitory output (−1) is produced. The transfer function can be a sigmoid function or other nonlinear, piecewise linear or step function. Researchers in a variety of disciplines including engineering, psychology, mathematics, and physics have contributed to the explosive growth in the field that has continued to this day. Two standard texts in the field are Bishop (1995) and Ripley (1996).

Neural networks can be used to address a wide variety of real-world problems. They have the ability to learn from experience in order to improve their performance and dynamically adapt themselves to changes in the environment. In addition, they are able to deal with fuzzy or incomplete information and noisy data, and can be very effective, especially in situations where it is not possible to define the rules or steps that lead to the solution of a problem. Hence they are fault tolerant. In addition, the ANN information-processing model is inherently parallel. Today ANNs are used in a variety of disciplines including engineering, finance, artificial perception, and control and simulation.

The wide use of ANN in geospatial science stems from their roles in spatial data processing and analysis. Satellites orbiting and imaging the Earth produce massive amounts of geospatial data, on the order of tera- to peta-bytes. ANN, programmed on parallel neurally inspired hardware architectures, can analyze and classify this vast amount of data quickly and draw meaningful insights via mapping or modeling. ANN’s generalization capability in dealing with classification across multiple spatial scales and resolutions is a significant advantage. Moreover, many physical processes modeled in the geospatial sciences require accurate knowledge of process dynamics and such knowledge is often unknown. In this case, ANN can be used in function approximation.

The learning that occurs in ANN is not affected by the integration of multisource data. The learning process is robust and fault tolerant.
Newer learning paradigms such as *semisupervised learning* or *self-supervised learning* can deal with incomplete data, overcoming the difficulties and expenses involved in gathering training labels for geospatial sensor data. Recent studies have attempted to make ANN more spatially explicit, either by introducing fundamental spatial principles such as spatial autocorrelation directly into the neural network structure or during post-processing and labeling using spatial neighborhood relationships. When using an ensemble approach, ANN can assist in characterizing the spatial heterogeneity of the Earth’s surface and spatial uncertainty in labeling.

**Types of ANN**

There are several types of ANN based on the learning paradigm, architecture, and function.

**Learning paradigm: supervised, unsupervised, and semisupervised learning**

In supervised learning, the ANN is supplied with a sequence of both input data and desired (target) output data; the network is thus told precisely by a “teacher” what should be emitted as output. During the learning phase, the teacher can “instruct” the network about how well it performs (“reinforcement learning”) or what the correct behavior would have been (“fully supervised learning”). The ANN learns the association between input and output classes until some criterion of successful learning is met. A commonly used metric is the mean squared error, which tries to minimize the average squared error between the network’s output and the target value over all the input-output training data pairs. The well-known backpropagation algorithm for training tries to minimize this cost using a gradient descent function.

In the ANN methodology, the sample data for supervised training is often subdivided into *training*, *validation*, and *testing* sets. The distinctions between these subsets are crucial. Ripley (1996, 354) defines the following: “Training data is a set of examples used for learning that is to fit the parameters [weights] of the classifier. Validation data is a set of examples used to tune the parameters of a classifier, for example to choose the number of hidden units in a neural network, while testing data is a set of examples used only to assess the performance [generalization] of a fully specified classifier.”

In unsupervised learning, the training scheme only consists of input data. The ANN discovers some of the properties of the dataset and learns to reflect these properties in its output. The issue of what exactly these properties are, that the network can learn to recognize, depends on the particular network model and learning method. Unsupervised ANNs can discover the underlying structure of the data, as well as encode, compress, and transform data values. This type of learning presents a biologically more plausible model of learning. The self-organizing map (SOM), a well-known unsupervised ANN, learns to produce a low-dimensional discretized representation of the input space using a neighborhood function to preserve its topological properties.

Real-world applications of supervised ANN are popular but face a number of practical challenges, such as scalability and limited availability of labeled training data. In spatial mapping, obtaining labeled datasets is expensive, and sometimes impossible. A recent solution is the development of a new learning paradigm called *semisupervised learning* (SSL). In SSL, the user strategically selects the data to be manually labeled, and then lets the ANN iteratively retrain itself on its own output using the remaining unlabeled data. A variation of SSL is the Self-Supervised ARTMAP, which uses only a
subset of input features during training. This is a great advantage in GIS and remote sensing, as new information about Earth’s features is constantly being acquired.

ANN network architecture

Figure 1a shows a typical structure of an ANN network consisting of processing units (neurons) arranged in two layers, and links (synapses) between the processing units in the different layers. There are input nodes and output nodes representing inputs and outputs in a supervised ANN. In addition, there are hidden units that can vary depending on the nature of the problem. Experimentation is often required to determine the best number of hidden units. Too many hidden units may lead the network to overfit the training data, thus reducing generalization accuracy. On the other hand, too few hidden units may prevent the network from being able to learn the required function. Each connection between nodes has a weight associated with it that is adjusted during learning. In addition, an activation function converts the processing unit’s weighted input to its output activation.

ANN network function: feedforward and recurrent networks

ANNs are also differentiated based on whether there are cycles or loops in the network. In the feedforward network (Figure 1a), information signals move in one direction, from the input nodes, through the hidden nodes (if any), to the output nodes. There are no cycles or loops in the network. Hence these are called acyclic graphs. An example is a multilayer feedforward neural network. In contrast, recurrent networks (Figure 1b) are cyclic graphs since they contain cycles or loops. Some recurrent networks (e.g., Adaptive Resonance Theory – ART) can be extremely complicated.

Three ANN models

Multilayer perceptron using backpropagation

A popular ANN classifier is the feedforward multilayer perceptron (MLP) architecture. An MLP is composed of layers of processing units in a directed graph that are linked through weighted connections (Figure 1a). The first and
last layers consist of the input variables (e.g., spectral bands) and output classes. The intermediate layers, called hidden layers, provide the internal representation of neural pathways. An MLP ANN maps sets of input data onto a set of appropriate outputs. Except for the input nodes, each processing unit has a nonlinear activation function. MLP utilizes a supervised learning technique called backpropagation to train the network.

Learning occurs in the MLP by modifying connection weights after each piece of data is processed, based on the amount of error in the output compared to the expected result. This process is continued until the weights in the network have been adjusted such that the network output has converged, to an acceptable level, with the desired output. In the next phase, the fully trained network is given new data, and the processing and flow of information through the now-activated network should lead to the assignment of the input data to an output class.

Self-organizing map

The self-organizing map (SOM) is a popular tool for mapping and clustering high-dimensional data (Figure 1b). In a SOM, neurons or units are arranged in a rectangular or hexagonal group of units of predefined dimensions ($m \times n$ rows and columns). The number of units is usually small relative to the dimensionality of the input data. The SOM algorithm computes an ordered mapping, a kind of projection that forces each of the input data records to map onto a defined grid during the iterative learning process. The goal of the SOM is to preserve the similarities between samples such that similar input data records map on to the same or neighboring units in the grid, while dissimilar data records are mapped on to non-neighboring units. Thus SOM can incorporate spatial neighborhood and spatial autocorrelation effects that are commonly encountered in GIS and spatial analysis. Over the last decade, SOM has been increasingly used in a supervised fashion.

At the start of training, the grid units are initialized via a random sample of $p$ observations from the input data. Each grid unit is characterized by a codebook vector that describes the typical pattern of that unit. The aim of the SOM algorithm is to update codebook vectors so that the input data are best described by the small number of grid units. During training, the distance between phenomena in the presented dataset and the codebook vectors for each of the units is determined by a distance measure. The unit whose codebook vector is closest or most similar to the presented sample is the winning unit or node. The winning nodes’ codebook vector is then updated so that the winning unit is made more similar to the presented sample.

Self-supervised ARTMAP

Self-Supervised ARTMAP is based on Fuzzy ARTMAP (Carpenter 2013). Fuzzy ARTMAP is based on ART, proposed by Stephen Grossberg in 1976. Fuzzy ARTMAP’s internal control mechanisms create stable recognition categories of optimal size by maximizing code compression while minimizing predictive error during online learning. Fuzzy ARTMAP incorporates fuzzy logic in its ART modules. ART overcomes the stability-plasticity dilemma; namely, how a neural network can learn quickly about new objects and events (plasticity) without overwriting or forgetting previously learned memories (stability).

In the first phase of self-supervised learning, the ARTMAP system is trained with a limited set of labeled data (input features and output classes), similar to learning in a traditional supervised ANN. In the next phase, the system
ARTIFICIAL NEURAL NETWORKS IN GEOSPATIAL ANALYSIS

continues to learn using an expanded set of input features with no labels or output classes. This “unsupervised learning” enables the system to build on its existing knowledge with new information, resulting in improved accuracy, compared to that of the initial trained system, without worsening its performance. This is demonstrated by Carpenter (2013) on a remote sensing (Landsat) database of land cover related to the greater Boston region.

Review of ANN applications in geospatial science

ANN models have been used in the geospatial sciences since the 1990s. A literature review was conducted using Google Scholar to identify existing publications of relevance with key terms “neural networks and GIS,” “spatial analysis,” “spatial interaction,” or “neural networks and remote sensing.” The search was done with a five-year interval starting in 1990. A majority of publications were peer-reviewed journal articles, conference reports, and technical papers. Four key findings are: first, the number of papers using neural networks in remote sensing was much larger, likely because remote sensing is multidisciplinary, including fields such as engineering, mathematics, and physics. The number of inputs can vary up to hundreds, given the data capture capabilities of NASA’s Earth Observing System Data and Information System (EOSDIS). Classification is typically performed using supervised learning methods. In many studies, the performance of ANN has been shown to be superior to that of traditional classifiers such as Maximum Likelihood (Carpenter et al. 1997).

The measurement and characterization of changes happening on the Earth’s surface at a variety of spatial and temporal scales has long been of interest to geospatial scientists. In this context, ANN has helped to identify patterns of change through time as well as to distinguish abrupt (deforestation or forest fires) and continuous (coastal erosion) changes. This application involves mostly supervised neural networks or hybrid approaches, where classification is done at two time periods and the differences are then classified and mapped.

The main objective of clustering is to group large amounts of data into meaningful categories last category, optimization, is less prevalent in the remote sensing field. Fourth, function approximation and estimation applications are popular in climatology and hydrology and in modeling physical processes.

Common applications of ANN

Let us consider the most common applications of ANN geospatial science – classification, change detection, clustering, function approximation, and forecasting or prediction.

The goal of classification is to assign an input pattern (like spectral bands or sociodemographics) represented by an input feature vector to one of several output classes. The best known application is land use/land cover classification in remote sensing and GIS involving multisensor, multidate, multisource, and multiscale data. The number of inputs can vary up to hundreds, given the data capture capabilities of NASA’s Earth Observing System Data and Information System (EOSDIS). Classification is typically performed using supervised learning methods. In many studies, the performance of ANN has been shown to be superior to that of traditional classifiers such as Maximum Likelihood (Carpenter et al. 1997).

The measurement and characterization of changes happening on the Earth’s surface at a variety of spatial and temporal scales has long been of interest to geospatial scientists. In this context, ANN has helped to identify patterns of change through time as well as to distinguish abrupt (deforestation or forest fires) and continuous (coastal erosion) changes. This application involves mostly supervised neural networks or hybrid approaches, where classification is done at two time periods and the differences are then classified and mapped.

The main objective of clustering is to group large amounts of data into meaningful categories
that can be disjoint, overlapping, or organized in some hierarchical fashion. A category or cluster is characterized by maximum similarity among its members and minimum similarity between its members and the ones belonging to other classes. Unsupervised ANNs are often used in this context, focusing on exploratory data analysis and visualization of clusters extracted from massive data with many dimensions.

Suppose an unknown function $\Phi(x)$ (subject to noise) has generated a set of $n$ input-output pairs $\{(x_1,y_1), (x_2,y_2), \ldots, (x_n,y_n)\}$. The task of function approximation is to find an estimate of $\Phi^*$ of the unknown function $\Phi$. ANN can approximate functions with arbitrarily high degrees of nonlinearity with a sufficient number of nodes and layers. These advantages have led to the recent use of ANN estimation algorithms for geophysical parameter retrievals. Typically, supervised ANNs are used in this context to solve forward and inverse remote sensing problems.

The goal of optimization is to find a solution that satisfies a set of constraints such that an objective function is maximized or minimized. The most famous problem relevant in GIS is the Traveling Salesman Problem, an NP-complete problem where a traveling salesman must visit $N$ number of cities with the following constraints: start and end the trip at the same location, visit each city only once during the trip, and minimize distance traveled during a trip. The order of visits in the trip does not matter for finding the solution. The ANN used in this context is the Hopfield model. Related modern applications include vehicle routing (such as FedEx, UPS) where the goal is to minimize the number of vehicles involved in delivery, total travel time, and total delivery time.

Given a set of $n$ samples $\{(y(t_1),y(t_2),\ldots,y(t_n))\}$ in a time series, $t_1, t_2, \ldots, t_n$, the task is to predict the value $y(t_{n+1})$ at some future time $t_{n+1}$. Two important issues must be addressed in this application: the frequency with which data should be sampled, and the number of data points which should be used in the input representation. These issues are settled empirically in most application contexts, but results from work in complex dynamic systems have employed heuristics. Typical examples of this supervised ANN approach are market predictions (price of crude oil or gold), climatological (modeling ENSO (El Niño Southern Oscillation) events using large-scale climatological parameters), and network traffic forecasting (spatial interaction in terms of flows between origin and destination pairs).

Present technology trends and the future of ANN

During the last decade, there have been changes in both ANN hardware and software. The new processors used in real-time ANN consist of electronic components that can be connected by circuits that are designed to mimic biological synapses. They are known as “neuromorphic” processors since they are based on large groups of neuron-like elements. The development of “deep learning” algorithms that can be embedded in these neuromorphic chips has led to substantial growth in real-time applications. These developments will vastly impact geospatial sciences in the next decade.

Artificial neural networks

A-Xing Zhu
University of Wisconsin, USA

Artificial neural networks ANN are motivated by the functioning of biological neural networks. An ANN solves a problem in a stepwise fashion by first developing a memory associating a large number of input patterns with a set of resulting outputs through training on examples, and then by applying this association to produce an output when presented with a novel input pattern. A detailed account of ANN types and their applications is beyond the scope of this entry. Readers are referred to the following review articles and books for detailed discussion on ANNs: Masters (1993) and Graupe (2013). A number of studies on the application of ANNs in geography also are available (e.g., Clair and Ehrman 1998; Maier and Dandy 1996; Pachepsky, Timlin, and Varallyay 1996; Zhu 2000; Pu et al. 2008; Blackwell and Chen 2009). The following subsections provide a background on the structure, training, operation, and application of multilayer feedforward networks, the type of ANN most often used in geographic applications.

Network structure

A multiplayer feedforward network is made of many processing elements (neurons). These neurons are usually arranged in layers: an input layer, an output layer, and one or more layers in between called hidden layers (Figure 1). The neurons in one layer are connected to the neurons in the next layer with different strengths of connection, which are referred to as weights. Links support information flow (signals) with different levels of strength, as controlled by the weight. The neurons in the input layer are used only to receive external inputs, but the neurons on the hidden and the output layers have information processing capabilities (Figure 2). The processing neurons first perform a weighted sum of the inputs from different neurons in the previous layer and transfer this sum into the range [0,1] through a transfer function of sigmoidal shape (see Figure 2).

The structure (the numbers of layers and the number of neurons in each layer) of a multiplayer feedforward network is problem specific. Masters (1993, 85–88) reports that, for most problems, a three-layer model should be sufficient unless the problem domain is highly discontinuous. The number of input neurons should be equal to the number of inputs and the number of output neurons should be equal to the number of attributes that define the output. For example, if one was to use an ANN to predict soil types from environmental variables (such as elevation, slope gradient, geology, temperature), then the inputs should be the values of these environmental variables and the outputs should be the soil types. The number of hidden neurons depends on the complexity of the problem (Masters 1993, 176–177); simple problems require fewer hidden neurons. The exact number of hidden
Network training

Network training (learning) is used to determine a set of weights that will produce the best possible input/output mapping. Most network training employs a supervised approach in which the network is presented with a set of input patterns and a set of corresponding desired outputs (together referred to as training data). The training process starts by initializing all weights to small nonzero values. Then, training samples are presented to the network one at a time to produce corresponding results. A measure of error between the network outputs and the desired outputs is computed and weights are updated to reduce error. Many iterations or epochs (from presenting training samples, to measuring error and updating weights) may be required before a network reaches an acceptable level of accuracy.

The magnitude of error is determined by the combination of weights for a given network. There exists an error surface that can be described as a function of weights. The objective of network training is to find a set of weights that will minimize the error function. A number of network learning algorithms can be used to minimize network error functions (Graupe 2013; Askarzadeh and Rezazadeh 2013; Nur, Radzi1, and Ibrahim 2014).

One common method, the conjugate gradient method, improves upon the conventional back propagation method by using adaptive approaches to the determination of learning rate ($\mu$) and momentum ($\eta$), which control the convergence and the speed of network training (Masters 1993, 105–111). The learning rate determines the rate at which the weights should be modified during each epoch. The momentum controls the direction to search for a minimum. The conjugate gradient method first employs the Polak-Ribiere algorithm to determine the best direction to search for the minimum. It then uses a directional minimizing process to determine the location of the minimum.

The error surface of weights for a neural network can contain a large number of local minima since a large number of weight permutations...
Figure 3  Operation of a three-layer feedforward neural network.

will produce similar input/output mappings. These local minima can make network training even more complicated. Avoiding false (local) minima consists of two steps. The first is to avoid initiating weights in the vicinity of minima and the second is to determine if a found minimum is local. If it is, attempts should be made to escape from this local minimum. Masters (1993) describes two techniques, simulated annealing and genetic algorithm, for initially avoiding and then escaping local minima. Interested readers are referred to this book for further reading on these topics.

Network operation

The operation of a feedforward neural network is rather simple. The inputs from the neurons in the input layer are respectively fed to each hidden neuron in the hidden layer through the weighted sum approach. Each hidden neuron then transfers the sum into a range $[0,1]$ as the output of this hidden neuron. This output is then used as the input to each of the output neurons on the output layer. The best way to show how an artificial neural network operates is to work through an example as shown in Figure 3.
This section focuses on the critical issues that must be considered when applying an ANN to a problem domain. The first issue is the determination of network structure, and in particular, the number of hidden neurons in the hidden layer. This is because the number of input neurons and the number of output neurons are determined by the problem, and the size of the network depends solely on the number of hidden neurons. Learning capacities increase with increasing numbers of hidden neurons. At the same time, however, larger networks require more training samples and they are much more readily over-fitted, at which time the trained network describes random error instead of the underlying relationship. On the other hand, if the size is too small (too few hidden neurons), the network is too simple and an under-fitting situation is created in which the trained network cannot model the underlying complicated relationships. Although an optimal network structure is difficult to achieve, methods can be employed to minimize the risk of over-fitting and under-fitting (Zhu 2000).

A second issue is based on the quality of the samples used for training and validation. High-quality samples are representative of the population. Typically, two sets of samples are used for network training: the training samples, which are used to develop the association between input patterns and the output patterns, and the validation samples, which are used to examine the accuracy of the trained network. A biased sample set, particularly biased training samples, would lead to a biased network. The sample sets should be sufficient in size, otherwise, the network becomes undertrained. Prescribing a number of samples sufficient for a particular case is a challenging task. Masters (1993) has suggested that, given that the sample set is representative of the population, the minimum number of training samples for a neural network with \( m \) inputs and \( n \) outputs should be \( 2^* (m+1)^* n \), and a reasonable number of training samples should be \( 4^* (m+1)^* n \). Bartlett (1998) suggested that for good generalization performance the number of training examples should grow at least linearly with the number of adjustable parameters in the network. Recently, improved methods for sample size determination have been explored (Nuchitprasittichai and Cremaschi 2013).

The third issue concerns the applicability and portability of trained neural networks. Trained neural networks, very much like regression models, are only applicable in the domain in which they are trained, and they cannot be generalized to other domains. For example, a soil-mapping neural network trained over an area with granite parent materials will not perform well over areas with limestone parent materials because the underlying relationships are different. In geographic applications, it is extremely rare to port a neural network trained in one area to another area unless the user is sure that the underlying relationships between the two areas are the same and the training samples used are also representative of the area the network is to be ported to.

A fourth issue is the interpretability of the relationships discovered by the trained network. Unlike regression models and decision trees, the relationship, or mapping, between the input patterns and the output patterns extracted by neural networks is in the form of a weight configuration. These weights have no physical meaning in the application domain. They are simply used to match the input patterns with the expected output patterns during training.
Summary

Artificial neural networks first develop a mapping between input patterns and output patterns through training. They then apply the mapping to predict an output pattern for a given input pattern. Neural networks are capable of learning nonlinear relationships between a set of input variables and a set of output variables. However, the learned relationship is in the form of a network weight configuration that is not meaningful in the application domain. Neural network training often requires a large number of samples and any learned relationship is not transferable to areas (domains) in which the training samples are not representative. Given these properties, ANN is effective for applications in which the provision of samples is not expensive and the problem domain is fixed.

Despite these advantages, applications of ANN in geography have limitations. First, the provision of a large set of representative samples is often expensive. Second, the heterogeneity of geographic phenomena (over space and time) makes the application domain not as stable as one would hope. Third, a major goal for many geographic analyses is to understand the relationships between the inputs and the outputs. Neural networks cannot provide those relationships in a meaningful form.

Atmospheric aerosols

Shiyuan Zhong
Michigan State University, USA

Rahul Zaveri
Pacific Northwest National Laboratory, USA

Definition

Aerosols are suspensions of tiny solid and liquid particles in a gas (Hinds 1999). Atmospheric aerosols generally refer to the mixture of particles and the suspending gas, which is air. The particulate portion of an atmospheric aerosol is referred to as particulate matter or PM, but in common practice the name aerosol is used to refer to particles only and often the terms “aerosol” and “particulate matter” are used interchangeably. Examples of common atmospheric aerosols are dust, smoke, and sea spray. Aerosols vary in shape, size, and chemical composition, and they have both natural and anthropogenic origins. Despite their tiny size, atmospheric aerosols have a profound impact on climate, visibility, biogeochemical cycling, and human health.

Size distribution

Atmospheric aerosols span a wide range of sizes from a few nanometers (nm) in diameter, the size of the smallest viruses, to around 100 μm (micrometers) in diameter, about the width of a human hair (Willeke and Whitby 1975; McMurry et al. 2000). Aerosol particles are usually considered as belonging to three size modes (Seinfeld and Pandis 2006). Smaller particles with diameters less than approximately 0.1 μm are known as Aitken mode particles; however, some describe the smallest group of particles, of 0.01 μm or below, as nucleation mode. These particles are formed by a nucleation process in which gaseous molecules of low volatility condense to form solid, semisolid, or liquid matter (Hinds 1999). Aitken mode particles in the atmosphere quickly grow through processes of coagulation or gas-to-particle conversion to form new aerosol particles that reside in what is known as the accumulation mode of approximately 0.1–1 μm in diameter. Particles greater than approximately 1 μm in diameter are referred to as coarse mode and they are typically generated through physical or mechanical processes such as erosion of the Earth’s surface or sea spray, rather than through the nucleation, condensation, and other chemical processes. Collectively, all aerosol particles with diameters smaller than 2.5 μm (PM2.5), which consist of Aitken mode and accumulation mode particles, are known as fine aerosols or fine particles. Particles with diameters between 2.5 and 10 μm are correspondingly known as coarse particles.

Sources, sinks, and composition

Aerosols may be either natural or anthropogenic in origin (Seinfeld and Pandis 2006; Figure 1). Aerosols that are directly emitted into the atmosphere are called primary aerosols while those that are formed via gas-to-particle conversion processes in the atmosphere are referred to
as secondary aerosols. Nearly 90% of the aerosol mass, which is dominated by coarse aerosols, comes from natural sources. In contrast, the aerosol number concentration is dominated by fine particles. The largest natural source for aerosols is soil dust, generated as strong winds whip small pieces of mineral dust from deserts or other arid areas on Earth into the atmosphere. Because two-thirds of the Earth’s surfaces are covered by oceans, sea salt is the second largest aerosol contributor. Sea-salt particles can enter into the atmosphere by bubble bursting through the sea surface microlayer or wave crashing and they consist mainly of sodium chloride and small amounts of other salts and dissolved organic matter present in seawater. Both sea salt and dust, the two most abundant aerosols in the atmosphere, consist of mainly coarse particles, although they are also present in fine mode. Volcanic eruption, which injects huge columns of ash, sulfur dioxide, and other gases into the atmosphere, is also an important natural aerosol source. Major volcanic eruptions may inject millions of tons of sulfur dioxide high up into the stratosphere, yielding sulfate aerosols upon oxidation. Once there, these aerosols may stay in the stratosphere for about two years and they partially reflect sunlight back to space, thereby reducing the amount of solar energy reaching the lower atmosphere and the Earth’s
Aerosols can also be produced naturally through biological processes – pollens, spores, and plant waxes are examples of biological aerosols (Despres et al. 2012). The fine aerosols in the atmosphere originate from both natural and manmade sources. Primary smoke particles from tropical deforestation constitute a large fraction of manmade aerosols in the atmosphere. Biomass burning, a common practice in agriculture and land management, also introduces primary smoke aerosols into the atmosphere. Smoke aerosols are dominated by black carbon and heavy organic materials. Automobiles, airplanes, ships, smelters, and power plants that burn oil, coal, and compressed natural gas are major sources of pollution aerosols in the atmosphere and are composed of sulfate, nitrate, ammonium, organics, and soot or black carbon in varying amounts (Bond et al. 2007). Sulfate and nitrate aerosols are secondary aerosols that are typically formed from oxidation of sulfur dioxide and nitrogen oxide gases to sulfuric and nitric acids, respectively, which condense on pre-existing aerosols and react with gaseous ammonia (largely emitted from agriculture and livestock operations) to form their corresponding ammonium salts in the particle phase (George and Abbatt 2010). A significant fraction of fine aerosols is composed of secondary organic aerosols formed from oxidation of volatile organic gases that are emitted from natural sources such as vegetation and forests as well as vehicular exhaust (Andreae and Crutzen 1997). Sulfuric acid can also nucleate to form new particles, some of which may be lost due to coagulation with larger particles, while the rest may grow to larger sizes via condensation of various secondary trace gases. Oceanic phytoplankton emit trace gases such as dimethyl sulfide, which upon oxidation can lead to the formation of secondary sulfate and methanesulfonic acid aerosols in the marine atmosphere. Secondary aerosol compounds can also be produced via chemical reactions inside clouds, followed by evaporation of the cloud droplets.

Aerosols in the atmosphere have lifetimes ranging from a few minutes to several days depending on their sizes and atmospheric conditions (Seinfeld and Pandis 2006). Newly formed nanoparticles and Aitken mode aerosols have a relatively transient existence in the atmosphere, with lifetimes ranging from minutes to hours, because they transform rapidly into coarser particles via coagulation and condensation processes. The accumulation mode particles may remain in the atmosphere for several days because they are too small to settle out rapidly from the air under gravity and too large to be subject to rapid Brownian motion; the slow random motion reduces coagulation rate, thereby inhibiting further growth and removal. Because of their long lifetime, these particles can be transported by winds to thousands of kilometers downwind from their origin. In contrast, the heavier coarse mode aerosols tend to settle out relatively rapidly from the atmosphere, with lifetimes ranging from hours to days. Aerosols injected into the upper atmosphere (above the boundary layer) can remain suspended in the air for several weeks to months. Eventually, however, all aerosols are removed from the atmosphere by either settling down under gravity, referred to as dry deposition, or through scavenging by cloud droplets and subsequent rain out, referred to as “wet deposition.”

Impact

Atmospheric aerosols have significant impact on people and environment. These tiny particles
ATMOSPHERIC AEROSOLS

play an important role in the Earth’s climate system, affect visibility, provide sites for chemical reactions to take place in the atmosphere, and, when in high concentrations as found in urban environments, are a respiratory health hazard.

Aerosols have a direct effect on the Earth’s climate by altering the planetary radiation balance through scattering, reflection, and absorption of solar radiation. The sulfate aerosols ejected to stratosphere by major volcanic eruption reflect sunlight and thereby reduce solar energy reaching the lower atmosphere and the surface of the Earth (Charlson et al. 1992). Aerosols can also affect climate indirectly by influencing cloud formation and lifetime. Aerosol particles may serve as condensation nuclei, causing cloud droplets to increase in number but decrease in size, and thus becoming more reflective to solar radiation (Hess, Koepke, and Schult 1998). There is also a so-called semi-direct effect of aerosols in which some aerosols, particularly black carbon, absorb solar radiation and heat the atmosphere, resulting in a decrease of cloud cover. Black carbon aerosols, when deposited on snow, ice, and other bright surfaces, reduce surface reflectivity and produce a warming effect. The combined direct, indirect, and semi-direct climate effects of aerosols are estimated to be comparable in magnitude, but opposite in direction to those of increasing concentration of greenhouse gases in the atmosphere (Boucher et al. 2013). However, large uncertainties still exist in the estimates of the indirect radiative effects of atmospheric aerosols.

The scattering properties of aerosol particles may cause visibility degradation. Particles in the accumulation mode typically reside in the size spectrum similar to the visible range of the solar spectrum (300–400 nm) and according to Mie’s scattering theory, these particles can effectively scatter sunlight, preventing light from reaching objects in the distance and thereby impairing visibility.

Aerosols, especially those with urban origins, influence atmospheric chemical processes by providing a surface for heterogeneous chemical reactions to occur (Andreae and Crutzen 1997). The most well-known reactions are those related to stratospheric ozone destruction. Aerosols injected into the stratosphere over the polar region help to form polar stratospheric clouds and the large cloud droplets provide surfaces for chemical reactions that lead to the formation of large amount of reactive chlorine responsible for ozone destruction (Portmann et al. 1996).

High aerosol concentrations are often found in major cities and areas surrounding and downwind of the cities. The primary concern of high aerosol concentrations in these urban environments is their impacts on human health (Schindler et al. 2009). Studies have linked short-term increases in particle pollution to increased emergency room visits or hospitalization for patients suffering from respiratory diseases and long-term exposure to increased risk of death associated with lung cancer and cardiovascular diseases (Samoli et al. 2008; Stanek et al. 2011). Fine particles are found to be more harmful to human health than large particles because fine particles have longer residence time in the atmosphere and are able to penetrate into the deepest part of lungs (Downs et al. 2007).

Atmospheric/general circulation

John A. Knox and Pamela N. Knox
University of Georgia, USA

The general circulation of the atmosphere (also known as the planetary circulation) is, in its most basic sense, the large-scale flow of the atmosphere across the entire planet. It is described by averages of horizontal and vertical motion of air over time and space as well as temporal and spatial deviations from the average conditions. These deviations include both large-scale waves linked to land–ocean differences and orography, and also seasonal and multiseasonal variations around the mean conditions.

The primary driver of the general circulation of the atmosphere is the differential heating of the Earth by the sun. Figure 1 depicts how solar radiation near the equator is direct and nearly perpendicular to the Earth's surface, strongly heating the tropics by direct radiation. By comparison, the same amount of incoming solar radiation is spread across a much larger area near the poles where the radiation strikes the Earth more obliquely. The solar intensity and length of day varies with season as the Earth's pole tilts towards or away from the sun.

The three-cell model

The classical description of the general circulation of the atmosphere breaks the atmosphere down into a three-celled circulation in each hemisphere (see Figure 2). The cell closest to the equator is called the Hadley cell after George Hadley, an English lawyer and amateur meteorologist, who in 1735 provided one of the earliest descriptions linking the surface trade winds, which blow generally from east to west between the equator and about 30° north and south, and a vertical convection cell driven by strong solar heating near the equator (Persson 2006). In the classical Hadley cell, warm rising air at the equator spreads out at high levels in the atmosphere and sinks at approximately 30°, returning to the equator as a surface return flow which flows from east to west due to the effects of the rotating Earth. The band of rising vertical convection near the equator, usually associated with deep clouds and heavy rainfall, is known as the Intertropical Convergence Zone (ITCZ). The band of clear skies and high pressure associated with sinking air at 30° is known colloquially as the “horse latitudes” because of the calm conditions which sometimes necessitated sailors throwing their steeds overboard to lighten their ships when caught in the calm conditions. Subtropical lands beneath the sinking portion of the Hadley cell are often arid deserts due to the lack of clouds and heating from the sinking air. Since this circulation is caused by the direct heating of the sun, it is known as a “direct circulation.”

Another major cell in the classical circulation model is the polar cell. It is also a direct circulation caused by sinking air over the frigid poles, which spreads out at the surface in the form of polar easterlies and rises at mid-latitudes, returning to the poles at high altitudes.
The third cell in the classical circulation model is known as the Ferrel cell, proposed by William Ferrel (1856). The Ferrel cell is an indirect circulation (warmer air sinking, colder air rising) which fills the gap between the Hadley cell in the tropics and the polar cell in the polar regions. In the Ferrel cell, air sinks at roughly $30^\circ$ in concert with the sinking branch of the Hadley cell, flows at the surface poleward and from west to east (the “mid-latitude westerlies”), rises at the border with the polar cell, and joins the upward flow of the polar cell in the vicinity of $45–60^\circ$ latitude, returning air aloft from pole towards the equator.

Jet streams, or regions of strong wind blowing generally from west to east, occur above the boundaries between the three cells of the classical circulation model. The subtropical jet marks the border between the Hadley cell and Ferrel cell and often serves as a conduit for tropical moisture to enter the mid-latitudes. According to classical theory, the polar jet stream is located roughly between the Ferrel cell and the polar cell, although in reality it is usually located above the area of maximum surface temperature gradient and marks the transition from warm tropical air to cold polar air. The ring of strong upper-level winds around the polar cell is sometimes called the “polar vortex,” an area which delineates the area of coldest surface air near the pole.

Because of the tilt of the Earth’s rotation axis relative to the sun and the heating changes associated with sun angle, the cells move north and south with the seasons, leading to temporal changes in the position of the ITCZ and the subtropical high-pressure regions over the year. These seasonal changes contribute to changing climate regimes, particularly at locations near the cell borders. For example, in a Köppen climate classified as Aw (tropical wet and dry), the ITCZ will lie over the region for part of the year, bringing rain and cloudiness to the area for a time. When the sun angle shifts due to the different orientation of the Earth’s axis later in the year, the ITCZ moves away, leading to a complementary dry season.
Advances to the three-cell model

While many textbooks still leave the impression that Hadley’s initial 1735 work is correct, this is not the case. For example, as Persson (2006) notes, Hadley’s theory explained only the direction, not the magnitude, of the trade winds and is flawed as an explanation for the general circulation because of the decided lack of conservation of angular momentum, among other reasons.

Furthermore, air parcels themselves do not obey the three-cell model. The Ferrel cell arises from calculations done with respect to a fixed location (Eulerian), but a single-cell equator-to-pole circulation is found using flow-following (Lagrangian) calculations and/or calculations using vertical coordinates that follow the motion of air parcels more closely than altitude, such as potential temperature. The best way in which to understand the Ferrel cell, then, is that it is a circulation driven by mid-latitude eddies (mid-latitude cyclones and the even larger planetary waves) in which the forcing on the atmosphere by these eddies (known as the Stokes drift) causes cooler air on its northern flank to rise and warmer air on its southern flank to sink (Holton 2004, 324). But, again, the Ferrel cell’s existence is reference-frame and coordinate dependent.

The most notable, relatively recent advance upon the early theory of the general circulation is that of Held and Hou (1980), who – in contrast to Hadley – studied an angular momentum-conserving frictionless model of the atmosphere. Their results for this idealized model connect the poleward extent of the Hadley cell with both the equator-to-pole temperature gradient and the planetary rotation rate. Held and Hou’s results are consistent with observations of both Earth’s and other planets’ atmospheres, and continue to be highly influential on research on the atmospheric general circulation of Earth and other planets.

Zonally asymmetric circulations and monsoons

The classical understanding of the equator-to-pole general circulation is also inadequate for understanding Earth because land and oceans are not equally distributed across the planet. Oceans, because of their high heat capacity, warm and cool slowly under solar radiation compared to the higher temperature variability of land surfaces. This difference in surface heating causes zonal asymmetries in the flow of air around the Earth and allows enhanced transfer of energy from the equator to the poles, warming polar regions and cooling the tropics by heat transport in poleward ocean currents like the Gulf Stream at lower latitudes, and by air currents at higher latitudes (Seager et al. 2006).

Because of the presence of continents that provide differential heating, the surface circulation patterns are broken up into discrete cells related to land–ocean position. This is most noticeable in the descending branch of the Hadley circulation and is seen in the persistent centers of subtropical high pressure which are observed over the oceans and land surfaces. The oceanic circulation patterns, including the gyres of surface circulation, are related to the winds which occur in the presence of these high-pressure cells.

One of the most notable current large-scale circulation patterns caused by land–ocean differences in heating is the monsoon. The monsoon is a seasonally reversing wind circulation caused by regional differences in temperature between land and water. Monsoons occur where there is a large land mass in the mid-latitudes next to a tropical ocean. In summer, the land mass warms up relative to the ocean and creates rising air,
Interannual variability and oscillations

Over time, climatologists have observed that the monsoons are not identical each year, and that in some years the monsoon has failed to appear, bringing drought and famine to areas that are expecting the monsoon rains to replenish their soils. This year-to-year variability is caused by a number of factors, including aerosol loading as well as changes in the ocean surface temperatures over time, that shift the patterns of high and low pressure which drive the global winds and their associated weather systems.

The most well-known of these patterns of interannual variability is the El Niño Southern Oscillation (ENSO), which is related to a quasi-periodic shift of atmospheric pressure which is centered between the eastern and western Pacific Ocean but which extends its influence across the globe. In one phase of ENSO, El Niño, a reduction in the speed of the trade winds allows warm water to pile up in the eastern Pacific Ocean, causing an increase in thunderstorm activity above it which pushes higher-level winds away from their neutral position. In the opposite phase, La Niña, the trade winds are stronger than usual, pushing the pool of warm surface ocean water to the central and western Pacific, shifting the area of convection with it and shifting the upper-level winds in a different direction. This oscillation of winds, which in the Pacific is called the Walker circulation, is related through long-distance interactions (“teleconnections”; Figure 4a, b) to observed changes in weather patterns across many parts of the Earth, including the strength and timing of the Indian monsoon in summer (Philander, Holton, and Dmowska 1989).

Another zonally asymmetric feature of the tropical atmosphere is the Madden–Julian Oscillation, or MJO (Madden and Julian 1972). It is also known as the 30–60-day oscillation,
and is triggered by tropical thunderstorms. From there, a slowly propagating pattern moves east at about 4–8 m s⁻¹ from the Indian Ocean to the Pacific. The MJO interacts with monsoons and tropical cyclones, and has received increasing attention in recent years for its possible downstream effects on North America.

Tropical convection also triggers a pattern of interannual variability in the stratosphere, known as the quasi-biennial oscillation (QBO;
Baldwin et al. 2001). The QBO consists of alternating descending westerly and easterly winds in the lower tropical stratosphere with a period of approximately 27 months. These wind patterns are caused by the breaking or absorption of small-scale gravity waves that are caused by the thunderstorms near the surface. The QBO can indirectly impact tropospheric weather by modulating planetary wave propagation and breaking in the stratosphere, which can then affect the troposphere.

In addition to the modes of tropical variability described above, there are also a number of oscillations which are centered on the extra-tropical region (see State Climate Office of North Carolina (2016) for explanations and current conditions for many of them). These extra-tropical oscillations include the Arctic Oscillation (AO), the North Atlantic Oscillation (NAO), the Atlantic Multidecadal Oscillation (AMO), and the Pacific Decadal Oscillation (PDO).

The AO, also referred to as the Northern Hemisphere Annular Mode, is defined by winds in the lower troposphere blowing counterclockwise around the Arctic at the approximate latitude of Edinburgh, Scotland. In the positive phase of the AO, these winds are fast and trap cold air near the pole. The negative phase of the AO is characterized by weaker westerlies, a more undulating polar jet stream, and incursions of cold air and storminess in the mid-latitudes. These phases alternate interannually, but can also change within a single winter. The NAO captures the same phenomenon as the AO, but is calculated using differences in sea level pressure between Iceland and the Gibraltar/Azores region (see Figure 5).

The AMO, discovered in 1994, captures an oscillation of a little less than a century in ocean temperatures in the North Atlantic. It may have an effect on tropical cyclone frequency and intensity in this basin. The PDO, a similar sea
surface temperature oscillation but at somewhat higher frequency in the North Pacific, has been more widely researched. Its phases, similar to ENSO, are statistically correlated with temperature and precipitation anomalies, as well as impacts on fisheries, across the Pacific basin and also across adjacent continents.

**Climate change and the general circulation**

On the longest timescales, the cumulative effects of changes in orbital parameters or large-scale changes in the location of land masses and mountain ranges due to movements caused by plate tectonics have caused significant changes in the pattern of the general circulation on Earth. For about the last 2 million years, with the continents in close to their modern configuration, small changes in sunlight due to oscillations in the eccentricity, tilt, and precession of the Earth's rotational axis have changed the yearly distribution of sunlight across the Earth, leading to the rise and fall of ice ages as snow accumulated or evaporated at higher latitudes on the continents. Collectively, these changes are known as Milankovitch cycles (Imbrie and Imbrie 1986). On longer timescales, the changing position of the continents or the opening or closing of oceanic passages changed the flow of heat through the ocean or the vertical convection cells caused by land–sea temperature differences, further altering the Earth's general circulation.

The advent of anthropogenic climate change has generated much interest recently with regard to its effects on the general circulation. Some researchers (e.g., Francis and Vavrus 2012) have hypothesized that fundamental features of the general circulation could be altered by a weakened north-south temperature gradient – which is the result of more pronounced warming at high latitudes, for example the Arctic regions, than at mid-latitudes. For example, a weakened polar jet stream could lead to more persistent and potentially more extreme weather patterns in the mid-latitudes. These “Arctic amplification” linkages to the general circulation are the subject of active research.

While much of the theory of general circulation in the atmosphere is well established, there is still much ongoing research. Please see Further reading for summaries of unsolved questions at both introductory and advanced levels.

Augmented reality

Nick Hedley
Simon Fraser University, Canada

Augmented reality (AR) is a real-world environment that is augmented with synthetic (virtual) objects or information. AR is a specific subtype of mixed reality (MR). Mixed reality is a continuum of possible combinations of reality and “virtuality,” anchored by the extremes of pure virtuality and pure reality at each end of this spectrum.

Context: the power and shortcomings of virtual environments

Virtual environments (VE) are synthetic, spatial (usually three-dimensional (3-D)) environments constructed from 3-D modeling, spatial data (not just 3-D data), and other digital content. They are typically seen from first-person perspectives, using one or more types of display (desktop LED/LCD screens, head-mounted displays (HMDs) such as Oculus’s Rift). Users navigate and control virtual environments using various transducers and input/output devices. Combinations of displays and control devices allow a range of sensory information experiences to occur. Examples of VEs include HMD-based immersive CAVE (cave automatic virtual environment) environments supporting single or multiple users, or semi-immersive desk environments (with a “driver” and multiple viewers). Interaction modalities and interaction design together determine the way VEs can be controlled and explored, and strongly influence the “information experiences” that result.

Throughout the 1990s, VEs were explored as tools for training, communication, collaboration, and education, delivering unique and powerful experiences and abilities (i.e., fly anywhere, move under water, through outer space, inside molecular structures into the future, to manipulate phenomena and time, and to see abstract or normally invisible phenomena). Research demonstrated that VEs may allow users to form useful mental representations of large real-world spaces that they can lead to distorted spatial perception, and that previous user knowledge and experience and interface interactivity were perhaps more significant predictors of performance than the “immersiveness” of VEs.

As VEs and their enabling technology became more accessible during this period, geographers became interested in the potential of their capabilities to deliver new forms of geovisual analysis. The geovisualization community, in particular, explored geovisual VEs and methods (see Dykes, MacEachren, and Kraak 2005), and engaged the concepts of immersion, interactivity, information intensity, and intelligence of objects (MacEachren et al. 1999; Slocum et al. 2001).

One of the lessons learned from the 1960s–1990s era of VE research, however, was that in many respects VEs were too much of an abstraction from reality to be a realistic part of it. Immersive VEs often delivered dramatic and engaging visual experiences, but they suffered from limitations of expense, accessibility, and
AUGMENTED REALITY

Mixed reality: the foundation of augmented reality

In order to understand augmented reality and its significance for geographic research, one must understand the relationship between reality, virtual environments, and mixed reality. Augmented reality (AR) is a subclass of mixed reality (MR). Milgram and Kishino (1994) define MR as “technologies that involve the merging of real and virtual worlds.” Their virtuality–reality continuum construct is well known in the human–computer interaction (HCI) community, placing all interface types on a spectrum between completely real (reality) to completely virtual (virtuality) (see Figure 1).

Between these two extremes lies a middle ground of mixed reality interface technologies and environments that combine elements of reality and virtuality. Within this middle ground, MR interface environments differ by proportion of real and virtual content used. This leads to two distinct subcategories of MR: augmented virtuality (AV); and augmented reality (AR). Augmented virtuality environments are those that are predominantly virtual, enhanced by information from the real world. By contrast, augmented reality (AR) interface environments are predominantly real interface environments, augmented by virtual digital information (see Azuma 1997 and Tamura, Yamamoto, and Katayama 2001).

Defining augmented reality

AR interfaces combine real environments with virtual objects—allowing access to both real and virtual environments simultaneously. This is achieved by superimposing digital virtual objects on views of the real world (Milgram and Kishino 1994), made possible by tracking and registration (alignment) of virtual objects with real objects or geographic spaces, and display technologies that allow the user to see virtual objects in geographic space.

Azuma (1997) defined AR interfaces as those that: superimpose virtual information on the real world (i.e., they combine virtual and physical objects in the same interaction space); are interactive in real time; and are spatial—meaning the virtual objects are registered and interactive in 3-D space. As a broader range of AR techniques have emerged in the early twenty-first century, many AR researchers have adopted a broader mixed reality world view, where augmentation does not require 3-D virtual objects (Azuma’s specification), but only that virtual objects are registered in 3-D physical space in relation...
to other physical objects. This stance helps to accommodate a multiplicity of mixed reality and AR interface permutations, but also helps reinforce the difference between user interfaces (UI) that augment the 3-D space of reality versus the “annotated vision” provided by heads-up display (HUD)-type UIs.

**Types of AR**

There are various permutations of AR. Some are considered “annotated vision” interfaces, in which real views are enhanced through real-time annotation on the display surface, rather than registered to the 3-D space being viewed. Other more advanced AR systems include novel applications where users “fly into” immersive virtual worlds and participants can leave their real surroundings behind, and join others to collaborate in shared virtual spaces (see Billinghurst, Kato, and Poupyrev 2001). Two popular subtypes of AR are tangible AR (TAR) and mobile AR (MAR).

Tangible AR interfaces enable tangible user interface (TUI) control and manipulation of virtual digital content. Examples include attaching virtual 3-D objects to physical cards (see Figures 2 and 3), physical pages of books (such as the well-known Magic Book AR project), and turntables (see Figure 4).

The resulting effect is simple yet dramatic. As the user moves the card, the virtual object stays anchored to the card, and moves as if attached to it. This effect is made more powerful due to direct physical touch and control. What were previously mouse or button-actuated and metaphor-mediated activities, such as zoom, pan, and rotate in WIMP (windows, icons, menus, pointer) interfaces, are now achieved by moving the augmented objects in one’s hands — no different than if one were inspecting a coffee cup (to inspect, rotate, hold closer or further away, zoom, or pan). One of the most sophisticated examples of tangible AR in the early 2000s was the exhibit (designed by the author) for Boston Museum of Science/Lucasfilm’s *Star Wars: Where Science Meets Imagination* (see Figure 4).

![Figure 2](image-url) Examples of tangible AR, where 3-D virtual objects are attached to fiducial markers printed on physical objects (cards). Left image shows abstract 3-D object used for cognitive AR experiments. Right image from collaborative geovisualization research by Shelton and Hedley. Hedley *et al.* 2001, with permission of the author (left); Shelton and Hedley 2004, reproduced by permission of Old City Publishing (right).
Inspection of virtual 3-D content using tangible AR interfaces is very similar to everyday manipulation of real objects, and is therefore a quite intuitive interface requiring little specialized training. A further trait of tangible AR interfaces is their strong proprioceptive cues and feedback – something Hedley (2001), Shelton and Hedley (2004), Woolard et al. (2003), and others have studied empirically, in the context of geovisualization, and geographic learning.

Mobile augmented reality (MAR) is a rapidly maturing interface technology that has the potential to extend our ability to combine virtual and real worlds (Azuma et al. 2001). Notable examples include Columbia University’s Touring Machine (Feiner et al. 1997), the Naval Research Laboratory (NRL) Battlefield Augmented Reality System (Julier et al. 2000), wearable MAR for tourists visiting Greek archaeological sites (Vlahakis et al. 2002), and
real-time 3-D augmented gaming in real-world spaces (Piekarski and Thomas 2002).

**How AR works**

AR interfaces are made possible by three main ingredients: tracking, registration, and display technologies.

Tracking is important for 3-D applications involving user interaction with 3-D virtual spaces. Tracking is used to provide information about object and user location and orientation in real 3-D space (including the position/orientation of hands/head/limbs and various types of control/feedback devices) to accurately correspond to their position in virtual spaces. Accurate, low-latency tracking is critical to delivering high-performance virtual environment experiences, where the position, geometry, and actions of users and objects in the real world have one-to-one correspondences with their equivalents in virtual 3-D spaces. Different types of tracking are used to support a wide range of 3-D applications and their needs. Common forms of tracking include magnetic tracking, motion capture (“MoCap”), and eye tracking. In AR, tracking is used to determine positions of objects in real-world space, so that digital virtual objects can be registered to them. This can be achieved in several ways. It can be done using fiducial markers and computer vision software – where unique patterns can be recognized by algorithmic analysis of video feeds. When a marker’s unique pattern is recognized, its orientation and position relative to the user’s (camera’s) viewpoint can be calculated. This information allows the AR software to place and render virtual digital objects at the marker’s location and alignment. This is a common tracking method for tangible augmented reality, where black-and-white markers are printed on cards to enable 3-D augmentation of the cards that can be physically touched, held, rotated, and inspected (see Hedley et al. 2002; Shelton and Hedley 2002; 2004).

This form of tracking is vulnerable to variable light conditions. Low light conditions can make it very difficult for AR software to detect visual markers, and high brightness conditions can “wash out” video feeds, thereby undermining an ability to track objects in space and provide registration needed for rendering 3-D objects in views of the real world. Advances beyond single unique marker tracking include “natural feature tracking,” where software can be trained to recognize unique objects (such as pages of a magazine) or geographic locations (coordinates), based on unique visual patterns. A challenge in natural feature tracking is the persistence of those unique visual patterns over time. If they change, the software’s ability to recognize them as a basis for spatial/locational tracking is undermined.

A unique adaptation of tangible and regular AR interfaces uses “augmented mirrors” to achieve hands-free tangible AR without the need for an HMD. In this configuration, large displays are adapted to deliver digital AR reflections of the people and scenes in front of them. This method has been used to study AR geographic pedagogy and media production (Woolard et al. 2003). One of the most developed examples of this technique is the tangible AR interface (designed by the author) for Boston Museum of Science/Lucasfilm’s Star Wars: Where Science Meets Imagination exhibit (Figure 5).

In geographic spaces, tracking for registration of AR objects increasingly uses global positioning system (GPS) information. Hedley’s (2008) and Mower’s (2009) early geographic mobile AR work explored how to combine GPS tracking with tablets for geographic AR, before spatially enabled tablets (such as iPads) became widely available. Nowadays, many (if not most) mobile
devices (smartphones, tablets, cameras) are location aware, using embedded GPS sensors and accelerometers, enabling tracking of position and orientation in three dimensions, without having to have a device’s camera “see” an entire visual marker. Location-aware devices, fused with widespread spatial (meta)data, have led to the arrival of numerous AR “apps.” Yelp and other social media applications have experimented with AR. However, more research is needed to improve the design (and rationale) for social media augmentation of real views.

The final ingredient necessary to view real space augmented with virtual objects registered and rendered to features tracked in geographic space are displays. Most tangible AR interfaces use HMDs in order to leave users’ hands free for physical manipulation of virtual content attached to physical objects (such as cards). A number of early mobile AR applications used wearable computers (computing hardware is carried in a backpack or belt (see Touring Machine, Feiner et al. 1997; see TinMith, Piekarski and Thomas 2002), aiming to leave users’ hands free for gestural interaction. Recent advances in quality, affordability, and accessibility of HMDs such as the Oculus Rift and Samsung’s Gear VR (Figure 6) have stimulated renewed interest in HMD devices. Whereas previous technologies were highly specialized, expensive, and rare, a significant difference now is that these displays are being designed to operate seamlessly with open source game engine platforms, such as Unity3D. This fact (plus trends in Kickstarter funded technology innovation) is not just relevant to new display technology; it also defines a new model of societal use and interoperability between mainstream and homegrown VR and AR.

A more recent development has been the emergence of systems which, rather than engineering dedicated niche HMDs, are designed to transform smartphones into VR displays. Samsung’s Gear VR system transforms smartphones into location-aware, orientation-aware HMDs (Figure 6). Another notable example is Google Cardboard, which transforms a smartphone into a basic VR headset with an origami-like cardboard enclosure and a software development kit (Figure 5).

With advances in camera, GPS, accelerometer, and display technologies embedded in mobile devices, an emerging vector of AR research has been the use of tablets and smartphones as AR displays. Jun Rekimoto (1997) was one
of the first to suggest it. Instead of wearing a cumbersome/expensive HMD, the user can hold up a smartphone/tablet as if taking a photograph and is able to see an augmented view of the world through the “window” of a mobile device running AR applications. This has been taken forward considerably by researchers in HCI and spatial interface research (see section on research progress, below).

Research trends and progress

While AR can be traced back to Sutherland’s groundbreaking work using half-silvered optics in the 1960s, a key pulse of AR research and development took place in the HCI and computer science communities (see Azuma 1997; Azuma et al. 2001). Much of the early work in AR concentrated on improving AR registration and tracking (Feiner et al. 1993). AR developed rapidly during the 1990s. In the late 1990s in particular, advances in displays (such as the commercial availability of new HMDs such as the Sony Glasstron™), computer vision, and tracking solutions led to more reliable platforms. Not unlike the maturation of GIS tools, this stability provided a basis on which to try more sophisticated applied research.

MAR has been implemented for various spatial applications so far. Columbia University’s Touring Machine (Feiner et al. 1997) was a self-contained backpack-wearable computing system that included differential GPS, compass, inclinometer, mobile computer, and see-through HMD. The user sees world-stabilized information (labels attached to locations of buildings) about an urban environment. This system might constitute “augmented vision” in that it annotates views of the real world, as opposed to placing 3-D virtual objects in the view of the real world.

Some might consider Dutton’s 1978 American Graph Fleeting (a cylindrical device designed to display “holographic” 3-D maps) an early experiment in 3-D geographic visualization interfaces. Unlike tangible AR, however, there was little to no direct free-form user interaction possible. In the geographic community there was some work

Figure 6  Examples of HMD. The Oculus Rift being used to view 3-D geovisualization (left). Samsung Gear VR (right). Image © Nick Hedley/SIRL 2015 (left); Samsung, public domain (right).
AUGMENTED REALITY

done to implement “annotated vision” interfaces in the early 2000s.

Over time, MAR researchers have found that some applications favor the hands-free interaction that HMDs provide (such as Piekarski and Thomas’s TinMith research (2002)), while others have started to explore applications that may favor embedded MAR capabilities in handheld computing devices, such as tablet PCs.

Exploratory work by Radburn (2006), Priestnall and Polmear (2006; 2007), Hedley (2008), and Mower (2009) investigated how we might use handheld devices to enable mobile augmented geographic visualization and interaction in everyday spaces.

The enabling technologies and research of the 1990s and early AR research in the 2000s led to new devices and applications that integrate location awareness, video cameras, and sufficient computational power to run the tracking, computer vision, and rendering elements of many AR software libraries. This in turn led to the emergence of publicly available AR authoring software and tools, such as ARToolkit, Junaio, and Metaio.

During this transitional period, there has been a growing interest in spatial uses of AR. While it is still true that many applications of AR simply use the novelty of seeing virtual 3-D objects attached to cards and other real-world objects, there has been a steady increase in geographic uses of AR, including empirical assessment of tangible AR for geovisualization (Hedley 2001), collaborative tangible AR for geovisual interfaces (Hedley et al. 2001; 2002), dynamic tangible AR map spaces (Cheok et al. 2002), cartographic information (Schmalstieg and Reitmayr 2007), building information overlays (such as Kamat and El-Tawil’s 2007 earthquake building damage assessment tool), underground infrastructure viewing using AR (Schall et al. 2009), and broadly geographic tasks (Dünser et al. 2012).

The recent interface research of Veas et al. (2013) implemented static spatial information overlays. However, while technologically advanced, the spatial information (contour maps overlaid on real views) was not correct (contour lines draped irregularly on landscapes as textures, rather than spatially rigorous alignment to a datum) – perhaps due to approaching the problem only from a computer science perspective, rather than from a geovisualization/GIScience/geoscience perspective.

Geographic researchers in Canada recently combined spatial analysis, spatial gaming, and MAR to deliver a suite of environmental situated spatial gaming applications (see Harrap et al. 2012).

Spatially focused MAR geoscience visual analytics systems that can perform serious analyses and simulations are a major next goal for geographic MAR research. Two of the first examples of this were recently completed at the Spatial Interface Research Lab, at Simon Fraser University. A Touch of Rain enables real-time 3-D particle fluid simulations to be run in urban environments (Hedley and Lonergan 2012; Lonergan and Hedley 2014; Figure 7). More recently, researchers have succeeded in implementing the first example of using mobile augmented reality to run a 3-D physics-based tsunami simulation in situ at a coastal field site in British Columbia (the system is called Tsunamiulator) (Lonergan and Hedley 2015). Significantly, both of these recent examples do more than just deliver MAR interfaces; they actually enable on-the-fly switching between virtual and MAR space – introducing the term flexible mixed reality (FMR). These recent advances suggest that we are perhaps as close as we have ever been to realizing “augmented GIS” using situated mobile augmented reality, and importantly, linking virtual spaces of analysis and simulation with real spaces of sense-making and interpretation.

AUGMENTED REALITY

Theoretical perspectives and opportunities for new sociotechnical research

With a whole-discipline audience in mind, it is important to note that augmented and mixed reality interfaces are far more than interface technologies. The real power of emerging geovisual interface technologies is not just their ability to deliver new ways to represent, explore, and understand complex geographic phenomena. It is their ability to be used by citizens, absorbed into social practice, to create new places of engagement, and new spaces of representation. In particular, they may enable us to link a multiplicity of social and cultural relationships with the same geographic spaces – allowing us to better understand the many forms of human encodings of landscape, and the way we (do and could) link these meanings to social and virtual inscriptions. In short, they define new spaces and forms of geographic representation, mediation, experience, and knowledge exchange. There is much to be done to develop new theory about augmented and mixed realities as sociotechnical hybrids.

In geography to date, interactions with geographic information and enabling tools have been engaged by research communities of GIScience, geographic visualization, geovisualization (Fisher and Unwin 2002; Dykes, MacEachren, and Kraak 2005), and more recently, geovisual analytics (Andrienko et al. 2009). However, society’s use of spatial information in “virtual” spaces (such as the Internet, social networks, massively multiplayer online games, shared virtual environments) has proliferated in a way that influences – and has become intertwined with – real spaces, social practice, behavior, and environmental perception (e.g., persistent virtual environments, AR-capable location-based apps). These trends have resulted in new questions about where reality as we know it ends, and where virtuality begins. A burgeoning field of discourse has emerged on the notion of “cyberspace” (Gibson 1984). Cyberspaces have been defined and debated in geographic discourse (see Benedikt 1991; Batty 1993; Graham 1998; Dodge and Kitchin 2001; Kitchin and Dodge 2011). Much of this discourse has focused on conceptualizations of space and place modified by the emergence of information communication technologies (ICT), virtual spaces, and new forms of representation and data in a socially networked society. Kitchin and Dodge (2011) remind us that “space is not simply a container in which things happen; rather, spaces are subtly evolving layers of context and practices that fold together people and things and actively shape social relations.” More research is needed to understand the amorphous linkages and entanglements that occur between real and virtual spaces, and how they are appropriated and mobilized in society – something that Batty (1993) seemed to envision, and implicit in “metaverses,” introduced by Neal Stephenson in 1992. Stephenson’s Snow Crash (1992) helped us begin to consider that cyberspace is not just a separate place to be viewed from without or within but a multiplicity of potential places defined by those who use and share it. Moreover – and crucially – metaverses coexist with traditional geographic spaces, enabling humans to step seamlessly between them. With a groundswell of social networking culture we now regularly “tap into,” use, share, and transact social and professional actions through many metaverses on a daily basis.

Major opportunities exist to study situated virtuality, and mobile augmented reality embedded in human social and cultural contexts, as sociotechnical hybrids. In doing so, we may consider the multiplicity of ways in which
spatial knowledge and awareness are represented and transacted – contributing to wider understandings of emerging geovisual information environments as sociotechnical hybrids, rather than just as technological gadgetry.

Theories of sociotechnical hybridization, cyberspace, cyborgs, code/space, and metaverses might inform new research into: the nature of emerging transactions between humans in real and virtual spaces; the potential (and implications) of mobile augmented reality to deliver new forms of situated geovisual analysis of human activities; the transduction of geovisual information between real and virtual space; new forms of narratives in geographic space; the identification of the geo-information and geo-experiential transactions that can occur between reality and virtuality; the exploration of the synchronicity of these transactions, and the modification of time; the emergence of forms of presence, tele-presence and multipresence; the investigation of the relationship between AR geovisual information experiences and recoding geographic space.

**Summary**

This entry provides an introductory overview to AR, its technical foundations, and its conceptual context. A cross-section of selected nongeographic and geographic AR research (including TAR and MAR) has been presented to provide the reader with a sense of key research to date. Recent examples by geographic researchers demonstrate the emergence of AR geovisualization, geovisual analysis, and mixed reality situated simulation as new capabilities for our discipline. This research establishes a foundation on which to develop new ways to link geographic spaces of fieldwork, interpretation, and communication with virtual spaces of analysis, simulation, and visualization. New empirical research will be needed to evaluate the impact of mixed reality interfaces on geographic tasks and knowledge construction. New geographic AR capabilities also open up new opportunities to extend existing theories of cyberspace and metaverses, and develop new theory for geographic mixed realities as sociotechnical hybrids.

AUGMENTED REALITY

Australia: Geographical Society of New South Wales (GSNSW)

Founded: 1927  
Location of headquarters: Sydney  
Website: www.geogsoc.org.au  
Membership: 150 (as of March 17, 2013)  
President: Gordon Waitt  
Contact: gwaitt@uow.edu.au

Description and purpose

The Geographical Society of New South Wales is a professional society whose members are geography academics, teachers, practicing geographers from both the public and private spheres, and other interested members of the public. The society's mission is to advance geography in New South Wales and throughout Australia. It is dedicated to the promotion, support and, when necessary, the defense of geographical research, scholarship, and education. It encourages geographical submissions to appropriate authorities on the management of environmental and social issues in Australia. The society aspires to an expansion of geographical literacy among the public of New South Wales.

Journals or major publication series

Australian Geographer. http://www.tandfonline.com/toc/cage20/current

Current activities or projects

The society is responsible for Australia’s oldest academic international geography journal, Australian Geographer. The society also holds an annual prize night at which it recognizes excellence in the governance, teaching, and the study of geography through awarding prizes. It organizes the annual Honours Conference for final year undergraduate students to present findings from their research and awards prizes for the best presentations. It also hosts regular events for postgraduate students engaged in geographical research. The society organizes a program of study tours and runs the Travellers Club where members regularly give presentations of their travels.

Brief history

The first meeting of the Geographical Society of New South Wales was held on August 10, 1927, with Associate Professor Thomas Griffith Taylor elected as its inaugural president. In 1928, the society launched the first issue of its journal, Australian Geographer. Since the 1960s, the society has sponsored and led more than eighty study tours to many overseas countries. Participants in these study tours encouraged the society to establish its Travelers Club in 1988. To recognize the achievements of its members, it established the Macdonald Holmes Memorial Medal in 1977. The society has also awarded its Fellowship biennially since 1969. Prizes to university undergraduates have been awarded since 1943. As part of its outreach, the society
has sent delegates to the National Committee for Geography at the National Academy of Science in Canberra since 1995. It has been represented on the Geographical Names Board of New South Wales since its establishment in 1966. Since 1997, the GSNSW has hosted an annual conference where final year undergraduate honors students present the findings of their research. The society sponsored its first conference expressly for post-graduate students in 2007 and continues to hold regular events for early career researchers.

Submitted by Garth Lean
Description and purpose

To represent geography and those who contribute to it in Australia. The aims of the institute are: to promote the study and practice of geography in Australia; to advance the study of Australian geography internationally; to hold and sponsor meetings and conferences to present, discuss, and disseminate geographical studies and research; to publish the results of geographical research in a journal; to represent the interests of professional geographers in Australia; and to cooperate with other organizations with kindred purposes.

Journals or major publication series

Current activities or projects

The IAG holds an annual conference, moving between cities, with a joint conference with the New Zealand Geographical Society every 4 years (www.iag.org.au/conferences-events). It promotes research through the publication of refereed journals, *Geographical Research* and *GEOView* (which publishes undergraduate research). The IAG provides substantial financial support for postgraduate student members to attend the International Geographical Union Congress. It supports nine study groups with additional groups under consideration (www.iag.org.au/study-groups). Finally, the IAG presents awards to recognize the achievements of geographers in the discipline, the institute, and fostering international links for Australian geography (www.iag.org.au/about/awards-of-the-iag).

Brief history

The IAG was formed in 1958 with its first conference held in 1960. Prior to this time, geographers had been meeting annually within the Australian and New Zealand Association for the Advancement of Science (ANZAAS). The lack of a national organization for Australian geography prevented affiliation with the International Geographical Union, and the existing state-based geographical societies covered only Queensland, New South Wales, and South Australia.

By 1963 the three objectives for the establishment of the IAG had been fulfilled. There was a specialist conference for geographers separate from ANZAAS, Australia had been accepted as a member of the International Geographical Union (in 1960), and there was a national geographical journal called *Australian Geographical Studies*. This journal title was changed to *Geographical Research* in 2005.

Throughout its history, the IAG has been the principal body representing geographers and promoting the study and application of geography in Australia, and for advancing the study of Australian geography internationally.

Description and purpose

The main purpose of the ÖGG is to support the dissemination of geographical research and knowledge throughout society and the scientific community. To accomplish this aim, ÖGG publishes the (SCSI-referenced) journal, *Mitteilungen der Österreichischen Geographischen Gesellschaft* (Communications of the Austrian Geographical Society), organizes lectures, symposia, and field trips in Austria and Europe, and honors the scientific work of young scientists in all fields of geographical research by awarding several prizes. ÖGG’s headquarters are located in Vienna, while branches exist in several other Austrian cities. Thematically, ÖGG is composed of working groups devoted to specific research fields of geography and cartography. Membership categories are honorary, ordinary, and student members with or without subscription to *Mitteilungen der Österreichischen Geographischen Gesellschaft*. The general assembly, which convenes annually, elects the executive board, the president, and other officers.

Journals or major publication series

Current activities or projects

A poster exhibition on the transformation of the Austrian Alps on the 25th anniversary of the International Alpine Convention is shown at several locations in Austria and Germany.

A symposium was held in Vienna on December 3–4, 2014 with the title “10 Years of EU Eastern Enlargement – The Geographical Balance of a Courageous Step.”

Brief history

Founded in 1856, the ÖGG is one of the oldest geographical societies worldwide and experienced its heyday in the period between its foundation and World War I. Founded as the Imperial–Royal Geographical Society in Vienna, it had the support and recognition of the public, the scientific community, and political elites. Well-funded by the state and private promoters, the ÖGG conducted several exceptional international expeditions, for example, to the eastern Sudan, to Congo, and to the North Pole in 1872–1873, which led to the discovery of the Franz Josef Land archipelago.
AUSTRIA

The collapse of the Austrian-Hungarian Empire after World War I and the end of the age of European discoveries led to a decline of ÖGG. In the 1920s and 1930s, ÖGG faced adverse conditions including financial cutbacks and a decline in membership. During World War II, ÖGG was incorporated into Nazi-affiliated organizations related to teaching, which led to further decline.

After World War II, when academic institutions expanded and new universities were founded in Austria, the restored ÖGG was again able to expand its activities and to increase its membership in Austria and abroad. New branches were established and ÖGG succeeded in becoming a recognized institution in the academic landscape. Current challenges are the support of students as they embark on a scientific career as well as introducing academic research into public debates demonstrating that geography is relevant for society at large.

Autobiography

David Butz
Brock University, Canada

Autobiography is generically defined as a factual account of a person's life, recounted by that person using the first-person singular voice. However, authors and their audiences routinely code as autobiographical a wide range of communicative acts that exceed this narrow understanding, thereby signaling the inadequacy of equating autobiography with the formal characteristics of a particular type of first-person communicative artifact: “an autobiography.” Rather, what unites the variety of ways in which the designation is employed, and what distinguishes autobiography from other forms of communication, is that its subject and object of signification are understood to be the same, or to overlap significantly. This characteristic – or attribution – gives autobiography distinct epistemological status: to produce or receive communicative acts as autobiographical is to assert and open to challenge knowledge claims based on privileged and often exclusive insider access to the circumstances, experiences, and feelings being communicated and analyzed. Autobiography, then, is a specific epistemological orientation toward communicative acts on the part of their producers or by those who receive them; it has less in common with biography (despite shared focus on “life-writing”), than with in-depth interviews, oral testimony, ethnography, storytelling, self-directed photography, autoethnography, and everyday conversation, all of which to some degree claim authority and veracity on the basis of close correspondence between who is communicating and what is being communicated.

The assertion that autobiographers are articulating themselves from a privileged position of access is simultaneously autobiography’s key feature, its strongest attraction, and its most complicating characteristic, for those who produce autobiographical communication and who view autobiography as a potential source of data. As an often intensely and self-consciously subjective mode of address, autobiography is understood to enable the communication of personal experiences, situated understandings, subjugated perspectives, self-reflexive analyses, emotion, and affect, all of which are gaining legitimacy as aspects of geographical knowledge and expression. At the same time, the seemingly straightforward simultaneity of representer and represented in autobiographical communication can mask difficult epistemological questions about individuals’ capacity to access, analyze, and articulate their own experiences; the relationship between individual lives as told autobiographically and the social contexts through which they are constituted; the relationship between autobiographical authors and their audiences, including the capacity of audiences to understand and analyze autobiographical communications; and the power relations inherent in efforts to articulate social reality via self-narration. Purcell (2009, 235) calls these issues “critical destabilizations” that lead scholars involved with autobiographical expression to “accept that they confront a complex and mutable set of interrelationships between self and other, individual and society, and author and audience.”

Geographers have acknowledged these critical destabilizations to varying degrees, and in
various ways, as they have used – or avoided – autobiography as a means of communication and analytical resource. Pamela Moss remarked in 2001 that “autobiographical approaches are not widely accepted as a standard method of geographical research” (p. 190). The ambivalence toward autobiography Moss describes may be traced to two countervailing tendencies within geography: a lingering positivism that dismissed autobiography for lack of scientific objectivity, and a poststructuralist cultural turn that viewed suspiciously the imbrication of autobiographical accounts in larger discourses of power and subjugation. Since then, the productive potential of autobiography and associated practices of authoethnography and storytelling have gained greater recognition, in part because autobiographical practices have matured in response to post-structural critiques, but also because developments in theory have reduced geographers’ inclination to view the individual and particular solely as expressions of larger ideologies and power structures.

**Autobiography as academic practice**

**Humanistic**

Prior to the poststructural turn that transformed much social analysis in the 1980s, autobiographical accounts were typically represented as authentic expressions of a relatively autonomous humanist subject. This traditional approach conforms most closely to autobiography’s generic definition, and deals with the critical destabilizations of self-narration largely by ignoring them. Humanistic approaches may be subdivided into two subcategories. One of these, the so-called great person approach (Purcell 2009), pursues the goal of comprehensively recalling an important or influential person’s life, usually with the implication that it is worth understanding on its own terms, and also – in the case of pre-eminent geographers – because of what an important insider’s self-narration may reveal about the development of the discipline. This style of autobiography experienced a minor resurgence in the early 2000s, and continues occasionally to be employed in geography, typically as an instrument of disciplinary identity, continuity, or self-questioning. One of the purposes of this style of autobiography is to “set the record straight”; therefore, it claims a degree of facticity, if not outright objectivity, that subsequent approaches to autobiographical expression avoid.

The same epistemological move is evident in many of the autobiographical gestures that routinely and unselfconsciously pepper works that are not otherwise coded as autobiographical. As Moss (2001) notes, geographers frequently insert personal examples and anecdotes, mini-confessions, arrival stories, vignettes from the field, and first-person asides, to lend their writing warmth and personality, and to bolster its legitimacy as knowledge, often through the disguised or explicit assertion: “I was there, I should know.” Often – as in much ethnography – such empiricist claims are at odds with a work’s overall epistemology. In other increasingly common instances self-referential interjections are treated more reflexively.

The second subcategory of humanist autobiography is phenomenological self-narration. Here the objective is less to establish an individual’s importance within a given social context, than to articulate the nuances of everyday human experience. In this case an autobiographical subject’s ordinariness may be more important than his or her pre-eminence. If the great person approach flirts with assertions of objectivity, the phenomenological approach emphasizes autobiography’s intense subjectivity on the grounds that the most important aspects of human experience, including place experience,
must be accessed and articulated subjectively. Phenomenological autobiographers narrate their own lives because only their own subjective experience is sufficiently accessible to them to describe with the required “thickness” of detail.

**Reflexive**

As part of a feminist and poststructural critique of objectivity that became influential in the mid-1980s, geographers and others began to question the conventions by which their disciplines constructed and represented knowledge. A so-called crisis of representation ensued in which conventional scholarship was criticized for denying the partiality and positionality of its knowledge claims, thereby reproducing the flawed assumption that academic knowledge is unrelated to the subjectivity that produces it. One solution that was proposed was termed critical reflexivity: that is, explicit, systematic self-scrutiny on the part of researchers regarding their subject position vis-à-vis their objects of research, with the goal of understanding and turning to analytical advantage the inevitably situated nature of the research process and the knowledge it yields. Critical reflexivity inevitably involved a turn to more autobiographical forms of communication. However, unlike the humanistic styles of self-narration outlined above, the goal of reflexive autobiography is not to legitimize the facticity of knowledge or to focus analysis exclusively on researchers’ own lives, but rather to destabilize academic authority by emphasizing the socially and politically constituted nature of knowledge claims, and to gain legitimacy in a different register by demonstrating attentiveness to epistemological critiques of objectivity and impartiality.

Various styles of reflexive autobiographical writing have recently been grouped under the umbrella term “autoethnography” (Butz and Besio 2009), because the objective of self-narration is to focus introspectively on the self in order to illuminate some exterior worldly phenomenon: hence an ethnographic objective. Moreover, to the extent that critical reflexivity is predicated on blurring the lines between knowing self and known other, the subject/object of reflexive autobiography is often plural, and in this sense ethnographic rather than conventionally autobiographical.

Butz and Besio (2009) enumerate five main categories of autoethnographic practice, most of which predate the crisis of representation, which together give some sense of the range of reflexive autobiographical communication (see Table 1). Although these practices vary considerably in terms of their objectives and emerge from a range of speaking positions, they all involve a reflexive transition, whereby authors move along a continuum between agent and object of signification. This reflexive ontological move helps to break down the conventional distinction between knower and known that was the focus of political critique associated with the crisis of representation.

The first three autoethnographic categories involve academic researchers narrating individual or collective self-experience in order, respectively, to understand some social or cultural phenomenon that is informed by but exceeds their experience, to analyze the epistemological and political implications of their fieldwork relationships and the resulting knowledge, and to gain some methodological or interpretive benefit from insiderness. In these cases the transition is from agent to object of signification. The second of these, so-called narrative ethnography, is by far the most prominent in geography, and it accounts for much of the discipline’s modest recent uptake in autobiographical expression. The last two forms of autoethnography involve members of historically subordinated groups

producing collective self-representations that attempt to intervene in dominant accounts of themselves and their worlds, thus claiming status as agents of signification. In the case of indigenous ethnography this occurs from within or at the margins of academic circuits of knowledge, whereas subaltern autoethnography is a nonacademic assertion of self-identity and self-determination intended for metropolitan audiences. Insider research, native ethnography, and subaltern ethnography have much in common with what Purcell (2009) calls insurgent autobiography, the objective of which is to destabilize dominant assumptions and discourses, often from the perspective of the marginalized or oppressed. In geography, insurgent autobiographies have been written, for example, from the perspectives of women, visible minorities, graduate students, and nontenured professors. Critical destabilizations of the relationships between self and other, individual and society, and author and audience, are acknowledged and employed productively in each of these forms of autoethnographic practice, although not without occasionally lapsing into simplistic claims of identity, a tendency that is most apparent in some insider research and indigenous ethnography.

Generative

Drawing primarily from feminist, postcolonial, and antiracist theorizing, and in keeping with the assertion that the personal is political, geographers have frequently used individual self-narratives in hopes of generating social, political, and intellectual change. Feminist geographers, in particular, have insisted on the importance of narrating and analyzing individual women’s experiences as a way to challenge the totalizing discourses of a masculinist discipline and society. Other marginalized subjectivities within geography have engaged in similar autobiographical projects. In these cases, personal storytelling is employed as an epistemological resource to generate knowledge that contests the partial and ideological nature of geography’s dominant theories, assumptions, findings, and disciplinary practices, and also to build political solidarity within and among groups that have been marginalized in authorized circuits of knowledge. Some of this personal narrative work also aims to be generative in the additional
sense of storying into being new subjectivities and realities. This is to an extent implicit in the notion of forging oppositional political solidarity, but for authors like J.K. Gibson-Graham (2006), autobiographical writing has the potential to be something more, a “performative ontological politics,” which Cameron (2012, 580) describes as “a practice that involves writing about, engaging with, performing, and taking seriously the alternatives they wish to see in the world as an act of conscious, political, and creative (re)production.” It includes narrating oneself in ways that erode subjectification to dominant discourses while resubjectifying the self to alternative emergent possibilities: that is, modeling in the self the future that one desires. Gibson-Graham has applied this approach to their own self-narratives, and has guided research participants to do the same. In this and other examples of generative autobiography another of autobiography’s critical destabilizations may be discerned: between an already existing narrating subject and an emergent subject of narration. A similar destabilization is characteristic of subaltern autoethnography, which requires a certain transculturally oriented reconstitution of self.

Affective

Recently a small number of geographers have employed autobiographical expression with the goal of either building or representing affect. In terms of the former, for example, the idea that personal stories can emotionally move both storytellers and listeners in ways that create openings for the construction of communities of solidarity based around affectual connections is an important part of Gibson-Graham’s performative ontological politics. The emphasis is as much on the embodied practices of telling and listening – sharing personal narratives – as on the specifics of content. Personal stories are understood as more than exercises in critical reflexivity that speak to audiences in a rational or intellectual key: they also build affect by appealing to the embodied, placed, felt, and intersubjective attributes of narrating and listening subjects. This form of autobiographical address is more often oral and face-to-face than mediated by text, and may involve drama, music, or other performative modes. Other work in this vein is less concerned with building collective identity through the affective power of personal narrative than with disrupting existing lines of affiliation and communities of identity that are formed around axes of exclusion and oppression (Pratt 2009; Cameron 2012). In both cases the objective is to produce transformative ethical relations, although this outcome is never assured. The key critical destabilizations of autobiographical acts aimed at building affect pertain to the relationships between self and other, author and audience.

Another emerging strand of affective autobiography finds inspiration in nonrepresentational and (post)phenomenological currents, and strives to articulate (rather than construct) affect. Like phenomenological autobiography in the humanist tradition, this work is interested in the fine details of human experience and feeling, but with greater emphasis on embodied affect, especially as it relates to place, terrain, landscape, and movement. The objective is to articulate affect in ways that keep it affective, forestalling the rush to rational critique. The resulting texts are often highly lyrical, and like personal experience narrative autoethnographies have been criticized as difficult to assess, generalize from, intervene in, or relate to a world beyond themselves. Practitioners of this style of affective autobiography respond that such criticisms miss the point, which is not to present conventional
arguments or offer sources of generalization, but rather to evoke fleeting experiences, or hit readers with a flash of recognition that exposes new thinking possibilities. This critique and its response suggest that geographers need to develop new methodologies of reception that enable them to be affected by self-narratives operating in an evocative register. The imperative for better-developed methodologies of reception applies to other forms of autobiographical address as well, as many geographers continue to find first-person self-narration too personal, subjective, and self-indulgent to be useful.

Autobiography as data

In addition to its utility as a productive form of academic practice, autobiographical communication is often also understood as a useful form of data, notwithstanding what some perceive to be its overly anecdotal and solipsistic character. The distinction between autobiography as practice and as data is heuristically useful, but also somewhat artificial, for two reasons. First, autobiography is primarily a knowledge claim based on the attribution of close correspondence between who is communicating and what is being communicated. That claim can be made either by selves who produce communicative acts, or by selves who receive them as autobiographical data. To use autobiography as data is also to define certain categories of expression as autobiographical; this too is autobiographical practice in its epistemological sense. Second, various forms of reflexive autobiography – especially personal experience narrative and narrative ethnography – produce self-narrations for authors’ explicitly analytical purposes, thus blurring the line between representing self and analyzing self-representations.

Geographers have employed autobiography as data in six main overlapping and sometimes contradictory ways. First, autobiographical accounts have been useful for accessing perspectives and experiences that are otherwise difficult to obtain. The lives of Canadian pioneer women, for example, received scant attention in official contemporary documentation, but are accessible through autobiographies, journals, and correspondence. These materials may be useful for establishing the “facts” of life on the frontier, as well as for analyzing the discourses associated with, for example, settlement and colonial femininity. Second, so-called great person autobiographies provide useful material for unpacking disciplinary histories, especially as they relate to the relationship between personal biographies and intellectual currents, and several have been written with this purpose in mind. Insurgent autobiographies by marginalized subjects within geography have similar value as data, both to construct and deconstruct geography’s history. Third, geographers have found autobiographical material valuable for its emotional, experiential, and subjective characteristics. Like other types of qualitative data, autobiographical accounts offer insights into people’s opinions, values, experiences, behaviors, and feelings. Most qualitative data has an autobiographical dimension, which often accounts for its compelling depth. Fourth, geographers are turning increasingly to autobiographical communication for what it can teach them about affect, and especially the affective nature of geographical experience. A difficulty here is that often the more effective an autobiographical act is at evoking affect, the more difficult it is to treat analytically as data. Fifth, autobiography has become an important tool and object of analysis.
for scholars who produce self-narrations for critical reflexive purposes. By analyzing their own imbrication in a social context, a field of power, or a set of research relationships, scholars hope to gain a more rigorous grasp on their research object, as well as on the epistemological characteristics of knowledge they generate. Sixth, some geographers working in transcultural contexts of structured inequality are finding utility in examining the subaltern autoethnographies of those they are researching, both for what they can learn about their research subjects’ strategic self-definitions, and as a resource of critical reflexivity. The latter is aided by recognizing that researchers are an important intended audience for subaltern autoethnography.

**Epistemological tensions**

The various practices and uses of autobiographical expression are cross-cut with tensions as to whether self-narrative material should be received as a source of self-evident facticity, as a resource for identifying and deconstructing cultural ideologies and broader discourses of power, or as something in-between: “small stories” (Lorimer 2003) that express local instances of everyday lived experience in some of their contingent particularity, mundaneness, corporeality, and affectivity. These tensions express theoretical and epistemological differences regarding the nature of human experience, the relationships between subjectivity and environment, and the epistemological characteristics of human self-expression, and reflect some of human geography’s broader social-theoretical divisions. Although these differences are unlikely to diminish as autobiography continues to gain legitimacy in geography, perspectives that treat the autobiographical as either reflexive or post-representational articulations of the self are likely to gain influence in relation to empiricist or humanist approaches. Geographers therefore need to develop better ways to receive, evaluate, and incorporate evocative and affective self-expression into geographical thought; that is, to create more effective autobiographies of reception.

Avalanche meteorology

Jordy Hendrikx
Montana State University, USA

Snow avalanches are a significant natural hazard in the mountainous regions of the world, destroying property, disrupting transportation networks, and causing physical hazard. Global estimates of avalanche fatalities range from 200–500 per year, with a high level of inter-annual variability. According to the Panel on Snow Avalanches (1990) annual mortality rates in the United States due to snow avalanches exceed the average mortality rate due to earthquakes as well as all other forms of slope failure combined. Furthermore, avalanche fatalities are rising in the United States. Since the 1950s, when the five-year moving average was less than five fatalities per year, the average has increased to close to thirty avalanche fatalities per year (Logan and Witmer 2012). In addition to these fatalities, avalanches cause widespread disruption and damage to infrastructure and transportation corridors.

To mitigate avalanche hazard, daily avalanche forecasts are produced for many mountainous areas around the world. Avalanche forecasting is conducted at a range of scales from a given slope (micro) to several mountain ranges (synoptic). Avalanche forecasting is a probabilistic enterprise with a number of factors which need to be considered, all with varying weights that change over time and space. The factors used to forecast snow instability are commonly placed into three categories which, in order of decreasing entropy, are: Class III: meteorological factors; Class II: snowpack factors; and Class I: instability factors (McClung and Schauer 2006). Class I factors are direct measures or observations of instability such as recent avalanche activity and provide the most direct evidence of instability. Class II factors provide further evidence of instability such as snowpack structure or total snowpack depth, but are much less direct. While the Class II factor information is relevant to snowpack instability, it is of less importance than Class I factors. Finally, Class III factors provide indirect measures of current and or future snow instability. Furthermore, they are commonly not recorded in the start zone of avalanches so are considered proxy measurements that provide an index measure of instability. As the spatial area of the forecast increases, the overall accuracy and resolution generally decreases. For example, when avalanche forecasting for a mountain range, there is increased reliance on meteorological data (i.e., Class III factors) to forecast mountain weather and its role in producing avalanches. This is where the intersection of avalanche and weather forecasting occurs and has been termed avalanche meteorology.

Meteorologists work with, or sometimes as, avalanche forecasters, providing detailed, area-specific weather information for mountainous areas. Avalanche forecasters integrate this information with their knowledge of snowpack and terrain to create a more comprehensive avalanche hazard forecast that describes the instability of the snowpack and likelihood of avalanche occurrence. In the absence of detailed snowpack data, avalanche potential can be estimated based on weather information alone; however, the quality of the forecasts are not as complete or accurate under these circumstances. Similar to weather forecasting, avalanche
forecasting combines observations with scientific understanding and expert judgment. The avalanche forecasting problem is compounded by the number of weather variables involved, the complexity of the terrain, the spatial and temporal variability of the snowpack, and the lack of continuous detailed on-site weather and snowpack observations. This complexity results in a high degree of uncertainty and results in the avalanche forecaster having a central role in the creation of the forecast. This requires forecasters to develop their skills through obtaining years of experience to make accurate decisions in the light of high uncertainty about the likelihood of avalanche occurrence. This diverse and dynamic combination of factors also means that current computer forecasts of avalanche conditions have limited use without expert interpretation.

The process of avalanche forecasting is dependent on the combination of the weather preceding the current conditions, the current and future conditions, and to a much lesser extent the avalanche climate. When we consider the current or forecasted conditions (or Class III factors) we often focus on a subset of variables that are well understood to relate to instability. These factors commonly include, but are not limited to, depth and water equivalence of new snow, wind speed and direction, air temperature, solar radiation, and snow surface conditions.

Depth and water equivalence of new snow is one of the more important variables as it represents an additional weight on the snowpack. As the depth of snowfall and thereby snow water equivalence increases, so too does the load on a buried weak layer. Instability and the likelihood of avalanche activity usually increases with increased snowfall. This factor is often accompanied by wind, which through preferential loading and scour in mountainous terrain can lead to areas of increased and decreased load on the snowpack. Depending on the surface conditions of the snowpack, the wind can cause increased loading even in the absence of concurrent precipitation. Wind drift is often estimated as the cube of the wind speed, so even small increases of wind speed above the required threshold for drifting can result in substantial increases in loading for areas that receive preferential deposition (e.g., wind sheltered or lee slopes and features). Both the mean value and trend of air temperatures during a storm is important. The air temperature controls the temperature and thereby, in combination with the wind speed and humidity, the density of the snow that is deposited. Fluctuating air temperatures can result in low-density cold snow being overlaid by higher-density warmer snow leading to buried weaknesses within the storm snow. Solar radiation can change the physical properties of the surface layers of the snowpack and can affect snow stability. This is especially the case in spring on solar facing aspects where the snow undergoes rapid changes due to the balance of incoming and outgoing radiation. Some of these factors have been used to develop and train statistical models that predict avalanche days for a specific operation (e.g., road or rail corridor) with some degree of success. However, these resulting models are only of limited value when applied to another location and also struggle to achieve overall prediction rates exceeding 85% (Hendrikx, Murphy, and Onslow 2014).

While these Class III factors clearly control the avalanche activity, the nature, magnitude, and impact of these factors are commonly functions of the avalanche climate and specific location. Using a simple threshold for one parameter (e.g., depth of new snow) will not necessarily translate across avalanche climates or locations. So while an avalanche climate alone will be of limited value for avalanche forecasting, due to the highly dynamic temporal variability of the
snowpack which responds to short-term weather parameters as discussed above, an avalanche climate can describe the typical weather patterns (or climatology) and resulting conditions of the snowpack, which result in a characteristic snowpack. Given that the characteristic avalanche behavior varies between avalanche climates, this approach provides a useful framework for discussing avalanche forecasting and meteorology in general terms and aids a forecaster in understanding the critical Class III factors.

In a study from the United States, Mock and Birkeland (2000) identified three primary avalanche climates: maritime (or coastal), continental, and intermountain. These terms are used globally with the intermountain term often being replaced by transitional. These avalanche climates are differentiated by their respective average snowpack depth, average winter time temperatures, and frequency and average density of new snow. When considered over climatology time frames (i.e., 30 years), locations will often be characterized into a typical avalanche climate, but may experience years in which conditions are more continental, intermountain, or coastal.

Continental climates have colder average winter time temperatures, more clear skies, and less snowfall, all of which are very conducive to the formation of depth hoar and other persistent weak layers. Typical examples of this type of avalanche climate include the Colorado and eastern British Columbia Rocky Mountains in North America, the Brooks Range in Alaska, and the Pamirs of Asia. As with other avalanche climates, most avalanches in a continental avalanche climate are caused by snow loading from direct snow precipitation or snow drift; however, the major avalanche cycles are often associated with buried persistent weak layers. Due to these weak layers, large and destructive avalanches in continental areas may result from only small snowfalls or wind events, sometimes many days or weeks after new precipitation. Mock and Birkeland (2000), using data from 48 locations in the United States, identified an average winter temperature of less than \(-7\, ^\circ C\), December snowpack temperature gradients of greater than 10\, ^\circ C, as defining criteria for continental avalanche climates.

In contrast, maritime avalanche climates have warmer temperatures, cloudier skies, and more snowfall and potential for rain, resulting in the formation of fewer weak layers. Typical examples of this type of avalanche climate include the Cascade Range in the United States, Coast Mountains of British Columbia, Canada, and the mountains of western New Zealand and Norway. Avalanches in maritime avalanche climates tend to be the result of large snowfalls and they often involve only the new snowfall, therefore relying predominantly on daily to multiday precipitation variables. As a result of this, most of the avalanche activity in this climate occurs within 24 hours of the new snowfall. Mock and Birkeland (2000) identified an average winter temperature warmer than \(-3.5\, ^\circ C\), snow water equivalence of greater than 100 cm, and more than 8 cm of rain as defining criteria for maritime avalanche climates.

Intermountain or transitional areas have intermediate conditions between these two zones. However, intermountain areas are ones with much variability as during some winters the avalanche climate will have characteristics that can be predominately continental or coastal. Coastal conditions might spread inland or continental conditions might extend toward the coast. Mock and Birkeland (2000) identified an average winter temperature warmer than \(-7\, ^\circ C\) and snowfall greater than 560 cm as the defining criteria for intermountain maritime avalanche climates when compared to continental avalanche climates.
AVALANCHE METEOROLOGY

Since avalanche forecasting techniques vary depending on the climate type, understanding and being able to predict these seasonal shifts in climate types clearly has important implications for enhancing avalanche forecasting and ensuring that the most pertinent weather parameters (i.e., Class III data) are being observed and focused on by the avalanche forecaster. While lower entropy factors like direct observations of avalanche activity provide more direct information related to snow stability, avalanche forecasting using an understanding of avalanche meteorology principles can be of critical importance when forecasting for large and or remote regions with spare snow and avalanche observations.

Description and purpose

The Institute of Geography Azerbaijan National Academy of Sciences was organized in May 1, 1945. The main scientific work focuses on: the development and environment of Azerbaijan including study of its natural resources and their ecogeographical variation; problems of production, social infrastructure, and economic and geographical problems of territorial organization of population; constructive and regional problems of the republic; desertification processes; and factors causing the changing levels of the Caspian Sea and the study of its ecological conditions.

Now employing 210 people, the institute has 13 research departments: landscape and landscape planning; climatology and agroclimatology; hydrology of land and water resources; economical and political geography; geography of the population of Azerbaijan and social development; history of geographical thought; geomorphology and natural risk; paleogeography; geography of land resources of Azerbaijan; ecogeography; problems centered around the Caspian Sea; cartography and geographical information; and the Pirgulu station for geographical research.

The institute also coordinates several councils, such as the Scientific Council; Dissertation Council; Doctoral Council; Council of Young Scientists; Coordination Council on “Geography”; Coordination board of Caspian Sea’s problems; and the Council for the Scientific Library.

Current activities or projects

Activities and projects include: ecochemical properties of the oil polluted landscapes of the Absheron peninsula and methods of remediation; information about the industry and environment of the Caspian Sea; climatic changes and ecosystem of the Caspian Sea (model research); Landscape planning in the southern Caucasus; monitoring of oil pollution with utilization of ground observations with a multisensory, multiplatform approach; interdisciplinary analysis of the ecosystem of the Caspian Sea (MACE). IG ANAS also hosted an international conference, Estimation and Rational Utilization of Natural Resource Potential of Geosystems under Conditions of Global Changes, in Baku in 2013. The Institute has a doctoral program enrolling 35 students.

Brief history

The Azerbaijan branch of the Academy of Sciences of the USSR was established in 1937, based on the 1925 report of the Central Committee of Azerbaijan entitled On the Study of Natural
AZERBAIJAN

Resources of Republic and Region. This effort laid the foundation of the Azerbaijan geographical school which began systematic geographical research in Azerbaijan. On May 1, 1945, the Institute of Geography of the Academy of Sciences of the Azerbaijan SSR was organized. In July 1945 the departments of physical and economical geography and cartography began operation. One of the main themes of research was the geography of mountainous countries. At first, none of the staff had scientific degrees. However, by 1947, eleven of the twenty staff held scientific degrees and three were enrolled in the graduate program. By 1950, the institute consisted of six departments. As of 1959 the Centre of Problems of the Caspian Sea has been part of the Institute of Geography.

Description and purpose

The BGS was established to enhance and disseminate geographical knowledge and to promote education and research through its journals, occasional monographs, newsletter, and other publications; local and international seminars, workshops, annual meetings; and public displays and exhibitions. It has published a number of research monographs, conference proceedings, and anthologies. The society is supported through membership subscriptions and the sale of its journals and publications. The society receives an annual grant from Dhaka University and occasional grants from the Ministry of Science and Technology and other sources. The society was first represented at the IGU meeting in Canada in 1972 and became a member of the IGU in the same year.

Besides publication, the BGS plays professional and academic roles in developing the discipline of geography and environment in Bangladesh and applying geographical knowledge and research in education, business, and government. Its members play an important role in national development.

Journals or major publication series

Bhugol o Poribesh (journal, in Bengali)
Bhugol Porikroma (newsletter, in Bengali)

Current activities or projects

Being the oldest professional geographical society in the country, the BGS encourages students by giving the Nafis Ahmad Memorial Award to the most meritorious MSc student of geography at Dhaka University every year in honor of the founding president, the late Professor Nafis Ahmad. Another award – the Rizvi Memorial Award – is given every year to the best student of the BSc (Honors) course in geography at Dhaka University. Since its inception, the society has had exchange programs with various research and professional organizations in other countries.

Brief history

Established as the East Pakistan Geographical Society in 1955 and renamed the Bangladesh Geographical Society (BGS) after the war of liberation in 1971, it is the oldest professional body of geographers in the country. The then head of the Department of Geography of the University of Dhaka, Professor Nafis Ahmad,
was the founding president of BGS. The society was inaugurated by the eminent British geographer, Sir Dudley Stamp. The Department of Geography (renamed the Department of Geography and Environment in 1996) at Dhaka University offered space for the BGS. The society has four categories of membership — donor member, honorary life member, life member, and general member. There are institutional members at home and abroad. BGS maintains a reference library that is used by students, researchers, and members.

Base flow

Douglas A. Howard
Georgetown University, USA

Base flow is the groundwater contribution to stream flow. This is accomplished as groundwater intercepts a stream channel and initiates groundwater discharge into the stream from points of higher to lower elevation in the water table. Streams that receive large portions of their flow from groundwater base flow tend to have relatively low variability and are more reliable water sources. Precipitation infiltration recharges groundwater reservoirs and as the water table rises, groundwater discharges into nearby streams will also increase. For base flow streams (perennial or intermittent) the amount of groundwater discharge is directly proportional to the hydraulic gradient toward the stream.

Langbein and others (1947, 6) defined base flow (also referred to as base runoff) as “sustained or fair-weather flow” that “may be considered as composed largely of ground-water effluent.” Although the modern definition of base flow does not explicitly include anthropogenic influence on the stream, here we will adopt the definition referring to naturally occurring streams.

Stream flow water is derived from components of the hydrologic cycle, primarily runoff and base flow and, in lesser amounts, throughflow, interflow, and direct precipitation. Base flow, originating from the saturated zone within the groundwater table, hydraulically connects groundwater to stream flow and contributes about 40% to the total annual stream flow volume. Base flow is a direct contribution from the saturated zone within the groundwater table, while throughflow and interflow provide highly variable water volume contributions from the unsaturated zone (vadose zone). Given that no part of the hydrologic cycle exists in isolation, base flow is a significant contributing factor. As such, the interaction between groundwater and surface water flow regimes is a topic of extensive research to understand the exchange of both naturally and anthropogenically introduced contaminants and pollutants in our water resources.

The contribution of groundwater to stream flow varies based on climate, hydrogeological responses to seasonal regional weather conditions, and topographic and hydrogeologic constraints, as well as anthropogenic activities. Over long dry periods, between water-input events such as rain or snowmelt, aquifers contribute the bulk of water to streams where the groundwater table is elevated higher than the stream channel. The water table establishes a hydraulic gradient, generally following the slope of the topography, which causes groundwater to flow. The direction of groundwater flow is from points of relatively higher to relatively lower elevation (hydraulic gradient). Hydrogeological constraints to base flow velocity and discharge through the aquifer and into the stream channel are highly dependent on the hydraulic conductivity of the rocks and soils through which the water flows. Therefore, base flow and aquifer residency will be different for fractured rock versus glacial till aquifers.

Persistent base flow is most evident in perennial streams where water continually flows from the groundwater table to the stream channel. It is a major contributor to stream flow especially when considered over a time span that includes...
BASE FLOW

dry periods of little to no precipitation. In upstream reaches, a river gains water from base flow (when the water table exists above normal stream stage level) and is referred to as a gaining or effluent stream. Gaining or effluent streams have an over-discharge increase downstream. Otherwise, if the water table is below the stream level, the stream will discharge part of its flow over the reach as a losing (influent) stream causing a groundwater mound below the streambed. Ephemeral streams that only flow in response to input events are considered losing streams. Perennial streams may also have reaches that experience influent conditions. For example, groundwater levels may be lowered by substantial groundwater pumping, reducing base flow locally to a level of becoming a losing stream (lowering the groundwater table and decreasing the hydraulic gradient) while reaches upstream and downstream may continue to be effluent.

Hydrographs are used to show the overall flow conditions of a stream as measured by a stream gauge at a given time or duration and location along the stream. The hydrograph provides a graphical representation of stream discharge versus time to show storm events and seasonal and long-duration flow conditions. Unfortunately, stream gauges and derived plots are unable to separate the direct contributions from runoff or base flow and lesser contributions from direct precipitation into the stream, throughflow, and interflow. Nevertheless, because the latter can be considered negligible contributions to the hydrograph, runoff and base flow can be estimated through various hydrograph separation methods.

Hydrograph separation methods serve to answer the question of what is the proportion of runoff to base flow contributions to the stream hydrograph. As would be expected, these contributions will differ between storm events and seasonal or long-duration hydrographs. The basis for hydrograph separation is due to the premise that surface and groundwater are hydraulically connected, so when physical (volume) and chemical changes occur in one the other will be affected.

During storm events, base flow hydrograph contributions are less than runoff but greater than direct precipitation, throughflow, and interflow. In a seasonal hydrograph, periods of precipitation show jagged rising peaks while dry season periods of the year are represented by smooth curves of discharge recession when the stream is primarily sustained by base flow. This recession in stream flow is a function of water table decline and base flow contribution. It is apparent then that base flow is the most significant contribution during a seasonal flow hydrograph period.

Although hydrograph separation is based primarily on graphical methods, base flow analysis and recession analysis utilize the base flow recession equation. Using this equation and multiple seasonal hydrographs enables the prediction of stream flow (discharge) at a given time during stream recession. The base flow recession equation is $Q = Q_0e^{-at}$, where $Q$ is the discharge at some time, $t$, after the recession of an input event, $Q_0$ is the discharge at the beginning of the recession, $e$ is the exponential function, $a$ is the base flow recession constant, and $t$ is the time interval duration (Watson and Burnett 1995, 145). Solving for the recession constant, $a$, enables prediction of the estimated stream flow discharge at a given time during recession.

Nonetheless, base flow analysis, separation, and recession analysis all attempt to identify groundwater contributions to stream flow by analysis of stream hydrographs (Hall 1968; Tallaksen 1995). The use of chemical and isotopic tracers (e.g. $\text{SO}_4^{2-}$) can also be used to identify the various water sources of stream flow. These geochemical methods are based on water quality and can help to determine
the long-term groundwater storage component from the rainfall runoff component.

Behavioral geography

Neil Argent
University of New England, Australia

Behavioral geography is a sub-branch of human geographical enquiry that became influential during the 1960s and 1970s. It emerged essentially as a reaction to the “quantitative turn” associated with the spatial sciences paradigm of the 1950s and 1960s. Fundamentally, behavioral geography is concerned with producing understandings of how and why people perceive the geographical environment surrounding them in the way they do, and how these perceptions affect their spatial behavior. Behavioral geography, which was largely responsible for introducing behavioralism to human geography, is perhaps best thought of as an approach rather than as a separate subdiscipline, given the breadth of the philosophical perspectives, research foci, methodologies, and epistemologies that were broadly attributable to it.

Behavioral geography: its origins, intellectual development, and main themes

In numerous respects, behavioral geography developed as a reaction against the then dominant paradigm in the geography of spatial science and its accompanying positivist epistemology, ontology, and quantitative methodology. For some human geographers, the spatial science school and the accompanying quantitative revolution had taken human geography into uncomfortable philosophical and methodological territory. Dissatisfaction with the direction in which quantitative spatial science was taking human geography centered on two main concerns. First, many felt disenchanted with its highly abstract and deterministic models of spatial behavior, conceptually underpinned as they were by principles borrowed from Newtonian physics and orthodox neoclassical economics. Gravity models applied to predict human migration flows were regarded by behavioralist geographers as stripping all human agency from what is usually a deeply complex decision-making process and form of spatial behavior. Second, to the extent that such models did recognize human subjectivity at all, this approach was based on the abstract notion, drawn from neoclassical economics, of rational economic man. Inherent in this postulate is the belief that individual decision-making is governed solely by the individual’s desire to pursue his/her own self-interest and to maximize his/her own economic welfare. Critics argued that the importation of the principle of individual welfare maximization from neoclassical economics provided a one-dimensional explanation for actual spatial decision-making and behavior. Unsurprisingly, then, these models could only provide, at best, partial explanations of real-world phenomena.

In a more positive sense, behavioral geographers responded by introducing the epistemology of behavioralism to human geography. Behavioralism is a body of thought that holds that humans are actively thinking beings who use their cognitive powers and abilities to gain, organize, and deploy knowledge to inform their overt behavior (Gold 1980). Behavioralism stands in direct opposition to behaviorism, a
BEHAVIORAL GEOGRAPHY

branch of psychological thought that holds that human behavior is best explained by examining stimulus–response relationships within the brain. Behavioralism became influential in human geography as individuals reacted against the growing dominance of behaviorism in other social science disciplines, such as economics, architecture, sociology, anthropology, and, of course, psychology. One particularly influential epistemological position in the development of behavioral geography was transactional constructivism, a philosophy imported from gestalt psychology (Walmsley and Lewis 1993). Put briefly, in its applications to human geographical research, transactional constructivism holds that humans interact with the environment in order to pursue their own needs and wants, but do so by drawing on past experiences, together with the relevant historical and current social contexts.

In their reactions against the quantitative turn of the 1950s and 1960s, behavioral geographers were concerned to reinstall the human actor as an active, sentient agent to the center of thinking about spatial decision-making, not as an abstract postulate behaving in an a priori purely self-interested rational fashion, but as a fallible social being operating in conditions of imperfect knowledge, bounded rationality, and, at times, conflicting goals. The behavioral school, then, sought to reverse the direction of explanation and theory building from the ideal aggregate spatial pattern produced by notional rational economic actors to the individual social agent. Previous research had already revealed that “economic agents” (e.g., workers, entrepreneurs) rarely made locational decisions based purely on the notion of least effort and highest economic return. This was not to imply that people were always bound to act irrationally but that individuals tended to operate on the basis of imperfect information and “bounded rationality.”

Therefore, an important aspect of the behavioral approach to human geography is the recognition that substantial variability exists in the manner in which individuals perceive and produce mental images; and that person-to-person differences in, inter alia, age, sex, ethnicity, socioeconomic status, physical capacity, and psychological makeup affect spatial decision-making processes, regardless of differences in spatial cognition. A crucial advance produced by the behavioral approach, then, was an appreciation that people respond to the space around them not as it is, in an objectively measured sense, but as they perceive it. A fundamental goal of behavioral geography, then, was to seek to understand how and why people perceive environments the way that they do, and how these perceptions affect actual spatial behavior; however, the philosophical and methodological pathways taken to achieve this goal varied quite substantially within the overall behavioral geography approach. This variance in approach became quite a point of contention and controversy between behavioralists, and also between the various other branches of human geography more broadly (Walmsley and Lewis 1993).

An important element of the behavioral approach to human geography was its explicit attempt to relate observable patterns across space (i.e., macro- or mesoscale phenomena) to processes (i.e., microscale phenomena). That environmental knowledge and spatial behavior are stratified was perhaps first recognized by Kirk in his model of the decision-making environment. Drawing on gestalt psychology, Kirk (1952) distinguished between an objective environment, containing “phenomena” or “facts,” and a behavioral environment – including a perceptual realm – provided by each human agent in his/her own contemplation of “the world of physical facts” (see Figure 1). In other words, Kirk saw the coexistence of two logically separate but
BEHAVIORAL GEOGRAPHY

Figure 1  Kirk’s schema of the behavioral environment and the human decision-maker.

tightly interrelated realms: that of the objective, physical environment, and that of the sentient human agent in active contemplation of this objective world, the former's perceptions of this world influenced in a potential multitude of ways by “a highly sensitive filter of cultured values” (Gold 1980, 36). Although Kirk’s model was later heavily criticized, the basic idea came to influence the subsequent development of behavioral geography profoundly.

In the earliest phases of the behavioralist approach to geography, the insights from Simon’s research – such as “bounded rationality” – were corroborated and extended by geographers working in the fields of natural hazards and agriculture. Kates’s (1962) research on settlement location on floodplains supported the finding that humans make locational decisions on the basis of bounded rationality, in which human agents are aware of only a subset of the entire range of factors that might impinge on the optimal location. Relatedly, Kates (1962) argued that his respondents were largely “satisficers” in that their spatial decision-making reflected a compromise between a range of sociocultural, emotional, strategic, and economic factors, and therefore fell short of the goal of economic optimization. Within a behavioral geography approach, relations between the human individual and her/his surrounding environment are seen as reflexive, with human behavior regarded not simply as bounded, or controlled, by physical environment settings but also as a factor in the modification of that environment. This recognition of human agency as a factor in environmental change sets in train a reflexive chain of action and decision-making in which each environmental modification triggers further changes in the human interpretation of that environment and, hence, the possibility of yet further human intervention.

Wolpert’s (1964) field research with Swedish farmers further supported Kates’s findings concerning the “satisficing” behavior of economic agents, and marked the beginning of his contribution to behavioral geography research, which included notions such as “place utility,” which would become influential in studies of human migration. A related and influential development in this regard was Pred’s (1967) “behavioral matrix” (Figure 2). This concept – and its accompanying diagram – contrasted the “ideal,” self-interested decision-making of the rational economic man of neoclassical economic theory (homo economicus) with that of the everyday human being, with the quantity and quality of information forming one axis in the matrix, and the human decision-making unit’s capacity to process this information forming the other. Although Pred’s matrix reinforced the notion that human locational decision-making rarely, if ever, conforms to the so-called ideal (located in the far bottom right-hand corner of the matrix), he also intended the matrix to be dynamic, revealing how decision-making and spatial behavior changed in response to trial and error, and hopefully evolving toward, if not necessarily achieving, the rational ideal. Pred’s matrix
also incorporated one of the key principles of the behavioral approach: that human spatial decision-making and behavior and the physical and sociocultural milieu in which these occur are mutually influential in a reflexive fashion.

This recognition led to a significant research effort into the cognitive structures and processes by which individuals make sense of real and imagined spaces and places. This became known as the cognitive mapping school. Although many associate cognitive mapping research with the popular notion of mental maps (see Gould and White 1974), the field was much broader than this generalization allowed. Early research efforts homed in on attempts to break into what was widely regarded as the black box of the mind–environment interface so as to better understand how individuals perceive their surroundings, and how such perceptions influenced actual behavior, if at all (Downs 1970). In the words of Thomas Saarinen (1979, 465), an influential figure in behavioral geography’s intellectual development, “The fundamental argument of behavioral geography is that: (i) environmental images exist; (ii) these images can be identified accurately …; and (iii) there is a strong relationship between environmental images and actual behavior.” Downs’s (1970) own schemata drew on Kirk’s dichotomous model but reversed the analytical focus by explicitly considering the dialectical links between an individual’s passive perception of the world via her/his “perceptual
BEHAVIORAL GEOGRAPHY

receptors” (essentially the perceiver’s five senses), and his/her belief system and sociocultural context (value system) and the preconceived or stored image of the real world that the individual already possesses in her/his mind. This cognitive process was then seen to lead to a decision on the most satisfactory (not necessarily the optimal) form of spatial behavior (e.g., to move or stay). Importantly, Downs’s schema contained a feedback loop which enabled the perceptual image of reality stored within the individual’s mind to be updated in the light of the post-decision-making experience. This loop allows for the fact that the process of environmental learning, together with subsequent behavioral responses, is dynamic and iterative.

Downs’s schema helped advance cognitive mapping research conceptually but was still regarded as overly general and lacking in the capacity to generate testable hypotheses. Subsequent attempts sought to correct this flaw, with mixed results (see Kitchin (1996) for a review). Gold’s (1980) schema, later adapted by Golledge and Stimson (1987), incorporated Kirk’s (1952) model of the physical and behavioral environments but sought to explicitly disentangle the perceptual and cognitive processes located within the perceiver’s mind and to explore these in greater detail than heretofore (see Figure 3).

An ambitious attempt to integrate insights from environmental psychology into cognitive mapping schema was proposed by Kitchin (1996; see Figure 4). Incorporating the principles of behavioral geography outlined earlier, Kitchin’s (1996) schema was also informed by five key theoretical propositions: (i) Golledge’s (1993) “cognitive counterparts” theory; (ii) the partial hierarchical structure of spatial knowledge theory, where knowledge of places and spaces is organized superordinately, depending on the individual decision-maker’s use of that information; (iii) Golledge’s (1978) “anchor point” theory, where information about new and unfamiliar places tends to be linked with established spatial knowledge in a hierarchical way, largely as a mnemonic device; (iv) “dual coding,” where cognitive maps are felt to be stored both as images and in propositional form; and (v) that humans use heuristic frameworks to both store and access, broadly termed, environmental knowledge. As Kitchin (1996, 72) put it, “Individuals construct schemata of everyday situations and use them when they encounter those situations. These schemata influence what we expect to see, what we look for and how we respond.” The complexity of Kitchin’s (1996) own schema is apparent in its diagrammatical representation (see Figure 4), attempting as it does to capture the multidimensional and multiscale (temporal as well as spatial) workings of the human mind in its perception of the real world.

True to the original aims of the cognitive behavioralist strain of behavioral geography (also referred to as “analytical behavioralism” by Walmsley and Lewis (1993)), cognitive mapping research focused on three main areas. First, a number of researchers were concerned with the ways in which different groups in society (e.g., children, nonmainstream ethnic groups, the disabled) constructed and organized their own mental maps. The idea here was that a person’s positionality, together with his/her sheer physical capacities, could affect his/her perceptions of, decision-making in, and interactions with, different spatial settings. The second area focused on people’s understandings of urban environments – an increasingly prominent field given the increasing pace of urbanization during the latter half of the twentieth century. This topic was largely pioneered by Lynch’s (1960) well-known work on urban legibility. Lynch’s research subjects produced simplified sketch
maps of select US cities, highlighting, inter alia, largely egocentric landmarks and greatly simplified routeways. Accordingly, Lynch argued that urban residents organized the mental images they held of their lived environment into five main categories: (i) **paths** – the routeways people move along; (ii) **edges** – the built and natural boundaries that demarcate urban regions; (iii) **districts** – large tracts of the city which have an identifiable character; (iv) **nodes** – chiefly major transport hubs, such as railway or bus stations; and (v) **landmarks** – fixed strategic points in the urban landscape which help orient residents in their travels (Lynch 1960).

In contrast to the broadly positivist, cognitive behavioralist approach discussed earlier, a more humanistic strain of behavioral geography also emerged in reaction against the quantitative...
Figure 4  Kitchin’s (1996) integrative conceptual mapping schema (reproduced from SAGE Publications).
BEHAVIORAL GEOGRAPHY

turn. Early humanistic geographical research was strongly influenced by the notion of geosophy introduced to the broader discipline developed by Lowenthal (1961). Lowenthal stressed the role that personal imagination plays in selectively filtering environmental stimuli, thereby pioneering research into landscape perception, a field that would develop into a substantial subdisciplinary area during subsequent decades. Other important and related humanistic research in this vein included Tuan’s, Saarinen’s, and Relph’s work on phenomenology, landscape perception, and place attachment respectively, and Buttimer’s research on values and beliefs in environmental appreciation. Importantly, Tuan (1974) developed the notion of topophilia in human geography, a research theme that greatly advanced the philosophical development of humanistic and, later, cultural geography. Overall, this humanistic approach was very concerned with revealing the deeply personal links between the individual and his/her surrounding environment (both physical and behavioral) as a lived totality rather than the examination of the two-way relationships between people and their environments.

With its fundamental concerns with the affective bonds that people form with environments and environmental features (broadly termed), the humanistic and cognitive-behavioralist approaches eventually parted ways.

Another important contribution to behavioral geography – and to human geography more broadly – was Hägerstrand’s research on migration and the related concept of time–space geography. As with others reacting to the sterile mathematical models of, inter alia, locational behavior, Hägerstrand began from the perspective that an understanding of human spatial interactions must begin with the individual human decision-making unit rather than with the large aggregated populations central to, for instance, gravity models. As with the first passes at cognitive-behavioral geography which recognized that an individual’s perception and cognition of her/his environmental surroundings was conditioned to at least some extent by a range of sociocultural and physical factors internal to that person (e.g., gender, socioeconomic status, ethnicity, physical ability), so Hägerstrand’s time–space geography explicitly accounted for the differential capability, capacity, and authority constraints on individuals’ everyday activities. For example, the diurnal activity spaces of a middle-aged employed male will be very different to that of a single mother with three pre-school-aged children, as would their individual experiences of the physical and behavioral landscapes that they inhabit (Hägerstrand 1970).

As already alluded to in this entry, behavioral geography played an important role in broadening – and deepening – human geography perspectives on human–environment relationships, and in forcing geographers to think more seriously about philosophical and epistemological issues within the discipline. However, this broad approach was not without its detractors.

Critiques and criticisms

At the heart of behavioral geography, at least in its initial phase, was the attempt to reclaim the agency and subjectivity of the individual in the analysis of human spatial behavior. The philosophical and methodological avenues taken by researchers in pursuing this aim varied quite substantially. Eventually, the divergent paths taken by those reacting against the quantitative revolution created schisms within behavioral geography. Those of a more humanistic bent felt that some cognitive behavioralist research, in its quest to understand the links between spatial perception, cognition, and actual behavior, had
actually slipped, philosophically, into behaviorism. Other criticisms homed in on the ongoing positivist nature of much behavioral geography research. Hägerstrand, in spite of his antipathy toward positivist spatial science and his avowedly humanistic stance, had himself earlier employed Monte Carlo random number statistical modeling methods to predict the spatial diffusion of innovations and human migration behavior. Such reductionist approaches to explanation, arguably, denied human agency as much as the spatial science and neoclassical economic schools of thought that behavioral geography was supposed to render redundant. Relatedly, criticisms were raised regarding the reliability and capacity of the various cognitive mapping techniques employed to access and supposedly capture an individual's spatial cognition, as process and/or image (Walmsley and Lewis 1993).

Perhaps more troubling were the stinging critiques and criticisms that came from the broadly labeled “radical” school of human geography. These attacks on behavioral geography were both philosophical and political in tone and content. This “radical” school, inspired chiefly by Marxian political economy perspectives, was also reacting against the mechanistic and reductionist style of reasoning inherent in spatial science, and sought to make human geography more socially and politically relevant to the times. It is important to bear in mind that the late 1960s and early 1970s saw the rise across many Western nations of second-wave feminism, student riots and uprisings, the US civil rights movement, a growing environmental consciousness, and an emergent concern over the inequality (and inequity) between the so-called first and third worlds. In these troubled contexts, behavioral geography’s concerns with recovering the locational decision-making processes and patterns of urban residents were perhaps easy targets for the epithet of “bourgeois” geography. 

Similarly, normative criticisms were made of the early behavioral geography research on natural hazards. In this case, the reliance on microscale psychosocial phenomena such as “bounded rationality” in explaining agrarian communities’ location in flood-prone territory was attacked for overlooking the structural forces at play both within and outside the host society that effectively dictate where the poor can, and cannot, live. Behavioralist accounts of urban residential location came under attack from the same quarter for their perceived voluntarism. That is, behavioral geographers were accused of limiting their analytical focus to demand-side factors (e.g., relative proximity of housing to work locations, shopping, potentially harmonious social groupings) and, therefore, neglecting supply-side influences (e.g., the role of capitalist housing markets, state and nonstate institutions). As an explanation for intraurban residential differentiation and uneven urban development, such research was regarded as potentially tautological and symptomatic of behavioral geography’s want of explanatory depth. Cumulatively, these attacks on the behavioral approach to human geography saw it fall from favor within the broader discipline after the late 1980s, with few explicitly labeling their work as “behavioralist” thereafter.

Behavioral geography now and into the future

In spite of behavioral geography’s relegation to the margins of mainstream human geographical thought and practice during the 1980s, its influence on at least some subdisciplinary fields has endured. The reaction against Marxian structural determinism during the 1990s is probably most strongly associated with the emergence and growing popularity of rival political theories
BEHAVIORAL GEOGRAPHY

such as postmodernism and poststructuralism; however, this shifting tide of academic opinion also created the space for a reappraisal of the value of a behavioral geographical perspective to a host of contemporary social and economic issues of public policy concern. For instance, in the context of the growing popularity of neoliberalist-inspired “self-responsibility” principles across a swathe of policy fields, from welfare to superannuation and pensions, some economic geographers have called for a renewal of a behavioral approach in the subdiscipline. This parallels the revived fortunes of behavioral economics since the early 1990s. A behaviorist perspective on contemporary unemployment, social welfare, and retirement policies is seen as necessary to counter the atomistic ontology of the neoclassical economic principles central to such “reforms,” and to provide much needed perspectives on the often information-poor contexts and “bounded rationality” in which many of the newly responsibilized citizens are forced to make, and act out, potentially life-changing investment decisions. Similarly, behavioral insights are being brought to bear on the critique of liberal, paternalistic public policies and strategies which attempt to inculcate changes in human decision-making across a vast range of fields, from sustainable household energy use to public bathroom etiquette. In select cases, then, cognitive behavioralism’s continued relevance can be seen in the renewal of earlier research agendas (as in economic geography), whereas in other subdisciplinary fields it was never really diminished. A further indication of the ongoing relevance of behavioral geography is its key role in the development of the progressively influential field of evolutionary economic geography. Cognitive mapping theory and methodology also continue to be influential in different parts of the discipline – witness the recent interest in children’s geographies across many subdisciplines – and in human geography’s ongoing interrelationships with other disciplines.

In summary, the advent of a behavioral approach to human geography facilitated a greater engagement with philosophical and epistemological issues, helped forge productive interactions and relationships with cognate disciplines, and laid the conceptual and methodological groundwork for human geographers to engage with contemporary social, environmental, and political issues of public policy relevance, given the increasing importance placed on individual behavior.

Description and purpose

The society promotes the dissemination of geographical knowledge through the publication of an international scientific journal. It aims also to popularize geography among the general public. The society represents Belgian geography at EUGEO, the association of the European geographical societies.

Journals or major publication series

*Belgeo*: The SRBG published a journal from 1876 to 1961 when the title was changed to *Revue belge de géographie*, emphasizing its scientific character, and published under this title until 1999. In 2000, the journal merged with the *Bulletin de la Société belge d’études géographiques*, another Belgian geographical society, now dissolved, taking on the name *Belgeo*. In 2012, *Belgeo* became a free open access e-journal, published in collaboration with the Belgian National Committee of Geography. *Belgeo* normally publishes papers in English and in French and less often in Dutch. www.belgeo.revues.org

*Hommes et paysages* (Men and landscapes), a series of booklets presenting popularized topical geographical field trips through Belgium. Founded in 1986, it has published 37 titles to date.

Current activities or projects

The main activities of the society are the publication of *Belgeo* and *Hommes et paysages*. The society also organizes occasional field trips in Belgium. The library and the map collection of the society are partly located at the French-speaking Free University of Brussels (Université Libre de Bruxelles) and partly at the library of the Belgian Royal Academy for Science, Letters, and Fine Arts.

Brief history

The society was founded just a few days before King Leopold II opened the Brussels geographical conference, which aimed to promote colonization in Africa and to improve knowledge of the world. At that time the society was strongly supported by entrepreneurs, colonial companies, and the king himself. Most of the more than one thousand members were businessmen, military officers, lawyers, and so forth. Some were naturalists or professors, but very few were true academic geographers: in Belgium, geography has only been taught as a full discipline at university from 1929 onward. The young society
supported, for instance, Henry Morton Stanley’s expeditions to Congo and Adrien de Gerlache’s polar expedition to Antarctica in 1896. Following the development of academic geography after World War II, the society increasingly became a pure scientific society closely associated with academic research, especially at the Free University of Brussels. In 1997, the society was a founding member of EUGEO, the association of the European geographical societies.

Description and purpose

The Société Géographique de Liège (SGLg) was founded to encourage research in geographical sciences, to promote diffusion of progress in applied and theoretical geography, and to enhance geographic education. It contributes to the formation of a network of scholars, researchers, practitioners, and students mainly in Belgium.

The society offers a discussion forum on the link between societal challenges and progress in geographical sciences. Through the publication of a scientific journal and the organization of conferences, SGLg contributes to the advancement of innovations and high-level international research in geography and related topics.

Current activities or projects

The SGLg creates a network of geographers in Belgium through four axes. First, the society organizes conferences for scholars, practitioners, and students. Lecture topics underline the contribution of geography to societal debates and knowledge progress. Speakers are local and international researchers or practitioners. Second, it publishes an international scientific peer-reviewed journal dedicated to all geographical topics. Publication of BSGLg is supported by the National Fund for Scientific Research (FNRS). Third, it organizes thematic field trips in Belgium or neighboring countries. Fourth, the society maintains contact with members through a website and a newsletter.

Brief history

The society was created in 1927 by Joseph Halkin under the name of Cercle des géographes liégeois (Circle of Liège’s geographers). It was set up by the geography department of the University of Liège (Belgium). The aim of the society was initially to promote the research of Liège’s scholars and to assist networking between geographers. In 1965, the name was changed to the current name. It extended the scope of its activities to the publication of a peer-reviewed scientific journal. This major change coincided with an increase in the number of members and the transformation from a local association to a scientific society articulating local and international research.
Between 1965 and 2013, 61 issues of the *Bulletin de la Société Géographique de Liège* have been published. In 2010 the journal has been renamed *BSGLg* and is now available both in hard and electronic copy.

Furthermore, the society also organizes conferences and field trips. These activities link Belgian geographers with the international scientific community as well as with local initiatives.

The association is facing new challenges and opportunities coming from changes in international scientific communities, exchange of scientific information, increasing specialization, and ambiguity of geographical fields of research.

Submitted by Michel Erpicum
By all accounts, the eponymous Berkeley School of Cultural Geography (hereafter “the Berkeley School”) began when Carl Ortwin Sauer moved to Berkeley’s Department of Geography at the University of California in 1923 from the University of Michigan. Prior to that, Sauer had undertaken graduate work in geology and geography, first at Northwestern University and then the University of Chicago. As Entrikin notes, Sauer’s graduate training “provided him with a model of scientific inquiry that encouraged field observation, historical explanations in terms of origins and a skeptical attitude toward abstract theoretical or philosophical debates as well as toward disciplinary boundaries” (Entrikin 1984, 389). Accordingly, Sauer also drew heavily from German intellectual traditions, especially from the works of Herder and Hettner, which later provided the bedrock for his subsequent ideas on the evolution of cultural landscapes.

While the intellectual development of an academic movement can rarely be attributed to a single person, in the case of the Berkeley School Sauer’s central role is clearly indisputable. Indeed, any discussion of the Berkeley School is inseparable from Sauer himself as a scholar and teacher who had inspired great affection and loyalty from his students. Among the key flag bearers of the Berkeley School are some of Sauer’s well-known students including Fred Kniffen, Wilbur Zelinsky, James Parsons, and David Sopher. Over the course of his career, Sauer had supervised close to forty PhD dissertations in geography ranging from topics such as the cultural geography of the prairies in southwest Louisiana, sea nomads in Southeast Asia, to the ecology of the Serengeti in East Africa.

It is also worth mentioning that Sauer’s childhood growing up in a German Methodist farming community in Midwestern Missouri among the rural setting of prairie plains had invariably shaped his later academic outlook and personal predisposition, in particular, his love for small rural places and archaic cultures. The Berkeley School also differed fundamentally from Midwestern American geography, however, with the latter being focused more on the highly practical aspects of geographical education. But more importantly, the Berkeley School that Sauer led sought to challenge the paradigm of environmental determinism that was dominant in the early twentieth century.

Sauer (1941) in particular offered what he considered to be the “three point underpinning” of geography with the emphasis on the foundational importance of studying the history of geography; that “American geography cannot dissociate itself from the great fields of physical geography”; and that “the human geographer should be well based on the sister discipline of anthropology.” Indeed, Sauer’s admiration for the discipline of anthropology and its importance for geographical inquiry is readily apparent in his proclamation that “Methodologically, anthropology is the most advanced of the social sciences, and one of its best developed methods is that of geographic distribution” (Sauer 1941, 6). Also noteworthy is the “instrumentalist character of Sauer’s epistemology” and his “pragmatist and neo-Kantian intellectual heritage” that could be traced to his

Not surprisingly, an intellectual hallmark of the Berkeley School is its strong advocacy for an interdisciplinary perspective that combines insights from anthropology, history, and natural science as well as a general disdain for positivistic social science. For Sauer, the key theme of human–environment interaction was best captured in his 1925 landmark publication *The Morphology of Landscape*, which sought to put the study of culture right at the core of geography’s intellectual project. In particular, the term “landscape” was proposed by Sauer “to denote the unit concept of geography, to characterize the peculiarly geographic association of facts” (with “area” and “region” used in equivalent terms) (Sauer 1963/1925, 300). Perhaps the most often quoted programmatic statement associated with Sauer has to be his broad invocation of cultural landscape as an entity that “is fashioned from a natural landscape by a culture group” where “Culture is the agent, the natural area is the medium. The cultural landscape the result” (Sauer 1963/1925, 343).

Also germane to the concern of the Berkeley School are ideas relating to cultural ecology – primarily understood in terms of the cultural history of human inhabitation and adaptation of the natural environment that are shaped by prevailing cultural norms and conditions, as well as the diffusion of such culture traits in the formation of cultural regions. As noted earlier, in keeping with Sauer’s upbringing, another salient feature in the works of the Berkeley School is its strong predilection for studying the rural landscapes and associated material artifacts and cultural relics such as barns, fences, animals, plows, houses, and so on. Such fascination with human-induced landscape changes was carried through detailed empirical case studies not only in the United States but also in more exotic foreign settings such as Latin America (the main focus of Sauer’s lifework). Indeed as Price and Lewis (1993, 11) point out: “Given the international orientation of the Berkeley School, ‘culture’ was a shorthand for those foreign people in whose lands geographers muddied their boots.”

To the extent that culture seems to be so loosely defined by Sauer and his colleagues to signify the diverse cultural patterns of (archaic) human communities, such a position also opens itself up to some of the most vehement critiques by scholars such as James Duncan who took the Berkeley School to task for allegedly adopting a “superorganic” notion of culture. In his view, Sauer had erroneously reified culture as a larger-than-life force dictating human behaviors and cultural traits, thereby giving short shrift to the complex inner workings of cultural processes and downplaying the agency of individuals.

In essence, the critics charged that Sauer in his earnest endeavor to provide a corrective to the prevailing paradigm of environmental determinism had replaced it with a form of cultural determinism. Following suit from Duncan’s critique, which essentially challenged the intellectual core of the Berkeley School, a second wave of attacks came from a cohort of young (mainly British) geographers such as Peter Jackson and Denis Cosgrove who questioned the social relevance of the Sauerian-inspired cultural geography, which they saw as being contented with the “static mapping” of esoteric cultural artifacts while urban crisis and social upheavals loomed large in American and British societies in the late 1970s. By the 1980s and 1990s, the sustained critiques of the Berkeley School were joined by a chorus of critical voices from Marxist and postmodernist geographers.
Notwithstanding these critiques, a more sympathetic assessment of the Berkeley School may be found, for example, in Price and Lewis’s (1993) defense of the Sauerian tradition. As they countered, much of the criticisms out there were “off-the-mark” and the term “Berkeley School” is never actually defined by those who attempted to discredit it (Price and Lewis 1993, 6). In addition, Entrikin (1984, 390) also points out that it is not entirely accurate to paint Sauer as quixotic scholar and “a reluctant participant in philosophical debate who entered the arena only when forced to do so.” Such a misinterpretation occludes Sauer and by extension the Berkeley School’s methodological contribution to the systematic study of social science as cultural history.

Nevertheless, by the late twentieth century, the Berkeley School had been ascribed the rather ignominious status as “traditional cultural geography” that is to be overtaken by the innovative waves of “new cultural geography” approaches. As many commentators have noted, however, the Sauerian tradition of cultural geography has left an indelible legacy that continues to have varying impacts on contemporary intellectual developments in the subfield. Most significantly, the enduring themes of cultural ecology, ethics of human–environment interaction and responsible environmental stewardship that Sauer had championed are all the more pertinent today than ever with the resurgence of global environmental concern.

The etymology of “big data” can be traced to the mid-1990s, when the term was first used to refer to the handling and analysis of massive datasets. It is only since 2008, however, that the term has gained traction, becoming a business and industry buzzword. Like many rapidly emerging concepts, big data have been variously defined, but most commentators agree that they differ from what might be termed “small data” with respect to their traits of volume, velocity, and variety. Traditionally, data have been produced in tightly controlled ways using sampling techniques that limit their scope, temporality, and size. Even very large datasets, such as national censuses, have been restricted to generally 30–40 questions, and are carried out once every 10 years in most countries. Advances in computing hardware and software and in networking have, however, enabled a much wider scope for producing, processing, analyzing, and storing massive amounts of diverse data on a continuous basis. Moreover, big data generation strives to be exhaustive, capturing entire populations or systems (n = all); fine-grained in resolution and uniquely indexical in identification; relational in nature, containing common fields that enable the conjoining of different datasets; and flexible, holding the traits of extensionality (new fields can be easily added) and scalability (can expand in size rapidly). Big data thus consist of huge volumes of diverse, fine-grained, interlocking data produced on a dynamic basis. For example, in 2012, Walmart was generating more than 2.5 petabytes (250 bytes) of data relating to more than 1 million customer transactions every hour, and Facebook was processing 2.5 billion pieces of content (links, comments, etc.), 2.7 billion “Like” actions, and 300 million photo uploads per day. Such big data, its proponents argue, enable new forms of knowledge that produce disruptive innovations with respect to how business is conducted and governance enacted. Given that much big data are georeferenced, they enable new kinds of geographic analysis and insights.

Sources of big data

Big data are produced in three broad ways: through directed, automated, and volunteered systems. Directed systems are controlled by a human operator and include closed-circuit television, spatial video, and LiDAR (light detection and ranging) scans. Automated systems automatically capture data as an inherent function of the technology and include the recording of retail purchases at the point of sale; transactions and interactions across digital networks (e.g., sending emails, Internet banking); the use of digital devices such as mobile phones that record and communicate the history of their own utilization; clickstream data that record navigation through a website or app; measurements from sensors embedded into objects or environments; the scanning of machine-readable objects such as transponders and barcodes; and machine-to-machine interactions across the Internet. Volunteered systems rely on users to gift data through uploads and interactions and include engaging in social
BIG DATA

media (e.g., posting comments, observations, photos to social networking sites such as Facebook) and the crowdsourcing of data wherein users generate data and then contribute them to a common platform (e.g., uploading traces supplied by global positioning systems (GPS) to OpenStreetMap).

Analyzing big data

Given their volume, variety, and velocity, big data present significant analytical challenges to traditional methods, which have been designed to extract insights from scarce and static data. The solution has been the development of a new suite of data analytics that are rooted in research around artificial intelligence and expert systems, and new forms of data visualization and visual analytics, both of which rely on high-powered computing. Data analytics seek to produce machine learning that iteratively evolves an understanding of datasets using computer algorithms, automatically recognizing complex patterns and constructing models that explain and predict such patterns and optimize outcomes. Moreover, since different approaches have their strengths and weaknesses, depending on the type of problem and data, an ensemble approach can be employed that builds multiple solutions using a variety of techniques to model and predict the same phenomena. As such, it becomes possible to apply hundreds of different algorithms to a dataset to ensure that the most illuminating insights are produced. Given the enormous volumes and velocity of big data, visualization and mapping have proven a popular way for both making sense of data and communicating that sense. Visualization methods seek to reveal the structure, pattern, and trends of variables and their interconnections. Tens of thousands of data points can be plotted to reveal a structure that is otherwise hidden (e.g., mapping trends across millions of tweets to see how they vary across people and places) or the real-time dynamics of a phenomenon can be monitored using graphic and spatial interfaces (e.g., the flow of traffic across a city).

Pros and cons of big data

There is good reason for the hype surrounding big data. Big data offer the possibility of shifting from data-scarce to data-rich studies of all aspects of the world from narrow to exhaustive samples; static snapshots to dynamic vistas; coarse aggregations to high resolutions; relatively simple models to complex, sophisticated simulations and predictions. Furthermore, big data consist of both qualitative and quantitative data, most of which are spatially and temporally referenced. Big data provide greater breadth, depth, scale, and timeliness, and are inherently longitudinal in nature. They enable researchers to gain greater insights into various systems. For businesses and government, such data hold the promise of increased productivity, competitiveness, efficiency, effectiveness, utility, sustainability, and securitization, and the potential to better manage organizations, leverage value and produce capital, govern people, and create better places.

Big data are not without negative issues, however. For example, most big data are generated by private corporations such as mobile phone operators, app developers, social media providers, financial institutions, retail chains, and surveillance and security firms, none of which are under any obligation to freely share the data they generate. As such, access to such data is at present limited. There are also concerns as to how clean (error- and gap-free), objective (bias-free), and consistent (few discrepancies) the data are, and as to their veracity and the extent to which they accurately (precision) and
faithfully (fidelity, reliability) represent what they are meant to. Further, big data raise a number of ethical questions concerning the extent to which they facilitate dataveillance (surveillance through data records), infringe on privacy and other human rights, enable social sorting (provide differential access to services), pose security concerns with regards to identity theft, and enable control creep wherein data generated for one purpose are used for another.

Geography and big data

Geographers have long engaged with massive datasets and nascent big data such as remote-sensing imagery and meteorological records, seeking to map and model environmental and climate change. More recently they have pioneered the analysis of volunteered geographic information (see Sui, Elwood, and Goodchild 2013), such as the mapping of georeferenced and locative social media data (e.g., data from Twitter and Foursquare) (Shelton et al. 2014), and begun to model large-scale urban data, such as the constant flow of passengers through a transport system (Batty 2014). They have also been at the forefront of debates concerning the sociospatial implications of big data technologies to urban systems and everyday life. Nonetheless, big data do pose a major challenge to the discipline, namely that, given their volume and velocity, analyzing such data requires a fundamentally different skill set to analyzing traditional forms of data, but as yet few geographers possess such skills.

Biodiversity

Thomas W. Gillespie  
University of California, Los Angeles, USA

Biodiversity can be defined as the variation of life forms (genetic, species, taxa) within a given ecosystem, region, or the entire Earth. Terrestrial biodiversity tends to be highest near the equator and generally decreases toward the poles. However, the distribution of biodiversity is complex and is based on a number of unique geographic, environmental, and anthropogenic factors over different spatial and temporal scales. The simplest measure of biodiversity is species richness or the number of species per unit area (i.e., trees per hectare, reptiles per square kilometer). The term “diversity” is more complex; technically it refers to a combination of species richness and weighted abundance or evenness data and is generally quantified as an index (e.g., Simpson index, Shannon index). These indices are used to define alpha diversity, which is the species diversity in one area, community, or ecosystem at the local scale. Beta diversity refers to the amount of turnover in species composition from one site to another or identifies taxa unique to each area, community, or ecosystem. Gamma diversity is the overall level of diversity of a region, continent, or island and this provides the best general overview of patterns of biodiversity at a global spatial scale. Yet measures of biodiversity are fundamentally multidimensional and not easily reduced to a single number. It is clear that the Earth is undergoing an accelerated rate of native ecosystem conversion and degradation as a result of human activity, and there is increased interest in measuring, modeling, and monitoring biodiversity.

This entry has three primary objectives. First, it examines the history of the study of biodiversity. Second, it examines biodiversity gradients associated with latitude, elevation, islands, and empirical patterns of biodiversity in terrestrial and marine environments. Finally, it examines threats to biodiversity and techniques that are being used to protect biodiversity into the next century.

The study of biodiversity

Humans have undertaken classifications of life for thousands of years. The Greeks and the Chinese have the longest historic records of classifications of organisms and their uses. Carl Linnaeus laid the foundations for the modern biological naming scheme by developing binomial nomenclature and greatly improved our understanding of biodiversity. The Linnaean classification systems of life began to describe species in Latin, and documented each species with voucher specimens in a standard and repeatable fashion. This coincided with broad interest in natural history collections in Europe and expeditions around the globe by naturalists that collected and described thousands of species a decade. With the publication of Charles Darwin’s *On the Origin of Species* in 1865, people began to understand the relationships between species and the mechanisms that drive evolution. Alfred Russel Wallace’s definition of zoogeographic regions based on comparative species distribution data was the first attempt to identify global patterns of biodiversity, and clearly identified Wallace as...
the founder of biogeography, a field that is today
to long-term
concerns of the fate of biodiversity.
Between the nineteenth and twentieth cen-
turies there was a rapid increase in collections of
species and estimates of biodiversity. Estimates
of the total biodiversity on Earth have ranged
widely. Recently, Mora et al. (2011) showed that
the higher taxonomic classification of species
such as phylum, class, order, family, and genus
follows a consistent and predictable pattern from
which the total number of species in a taxonomic
group can be estimated. They predict 8.7 million
eukaryotic species (any organism whose cells
contain a nucleus enclosed within membranes)
globally, of which 2.2 million are marine species.
This suggests that, in spite of 250 years of taxo-
nomic classification and over 1.2 million species
already cataloged in a central database, some 86%
of existing species on Earth and 91% of species
in the ocean still await description.
A rapid evolution of genetic techniques and
geographical information systems (GIS) databases
has changed the way biodiversity is understood.
The Tree of Life project has been developed
which shows the evolutionary relationships
between all living organisms and estimates of
their relationships over time. Currently, entire
genome sequencing for a diversity of taxa is
being undertaken at a host of international
institutions. Indeed, some groups, such as fungi,
are now being identified with genetic tools so
rapidly that there is no time to apply scientific
names to them in the classic Linnaean sense.
During this time, there have also been significant
improvements in the geographic analyses of
biodiversity in the twenty-first century. The
locations of species and species ranges have been
included in a number of GIS databases. These
databases contain millions of species records,
with the spatial resolution ranging from an
exact location on Earth to 1 or 2 degree grid
cells. This has revolutionized the way biodi-
versity is studied and understood at multiple
spatial scales (i.e., site, landscape, regional, and
global).

Spatial patterns of biodiversity

Latitudinal gradients

Species distributional patterns associated with
climatic regions have been known since Aris-
totle. As one goes from the poles toward the
equator, species richness generally increases.
However, there are exceptions to this pattern in
the forms of Mediterranean ecosystems, which
have higher diversity than many other ecosys-
tems at lower latitudes (i.e., deserts). Latitudinal
gradients of biodiversity are extremely dynamic
over geologic time scales and have fluctuated
from the poles to the equator over time. During
the Pleistocene (2 588 000 to 11 700 years ago),
vegetation types and their associated levels of
diversity have generally decreased in extent
during glacial maxima and expanded toward the
poles during interglacial periods.

The individual mechanisms behind latitudinal
patterns of biodiversity have been long debated,
but it is clear that the observed patterns are a
result of a combination of factors over different
spatial scales. Gradients of temperature and
precipitation along with area, environmental
stability, and geographic uniqueness explain a
majority of these biodiversity patterns for many
taxa. In the extreme Northern and Southern
hemispheres cold temperature and low rainfall
results in lower floristic and faunal diversity
and a number of widespread species. It should
be remembered that these ecosystems in high
latitude are relatively recent. Indeed, in places
like Canada, tundra, boreal forest, and grassland
ecosystems are relatively new to their current
locations because most of Canada was covered
by ice sheets and glaciers 18,000 years ago. At the middle latitudes or temperate regions, warm temperatures and high rainfall result in high-diversity forest areas and dry summers result in unique Mediterranean ecosystems. However, it is the tropics that clearly have the highest biodiversity in the world at almost all taxonomic levels from plants and insects to mammals. Indeed, biodiversity has flourished in the tropics for over 250 million years. Alfred Wallace was one of the first to suggest that tropical landscapes were so diverse because of the stability of the tropics. The lack of extreme seasonal variation in the tropics has led to intense competition for the resources for life and this has resulted in the evolution of species with unique ecological niches not found in higher latitudes. The tropics also cover a large geographic area of the globe, and relationships between area and biodiversity are well established.

There has been extensive research into the patterns of species and taxonomic groups since the 1980s examining latitudinal gradients in biodiversity and suggesting theories for the pattern. An extensive study by Hillebrand (2004) found that latitudinal gradients in species richness occur in terrestrial, marine, and freshwater ecosystems in both the Southern and the Northern hemispheres. The gradient appears most pronounced for taxa with more species (i.e., beetles, hummingbirds), for larger organisms in marine and terrestrial environments, and at the regional spatial scale. There are a number of exceptions for specific taxonomic groups and geographic regions such as shorebirds, penguins, freshwater zooplankton, and pinnipeds. However, it is clear that biodiversity generally increases toward the equator, and a combination of factors such as climate, area, environmental stability, and geographic uniqueness explains a majority of these biodiversity patterns for most taxa.

Elevational gradients

Elevational or altitudinal gradients in biodiversity have been known for years in mountainous regions. As one goes from sea level to the top of mountain ranges or volcanoes, there is a general decrease in levels of diversity across taxa. However, elevational gradients are complex and range from microtopography gradients in regions that were once glaciated or in low-lying regions like Florida to mountain ranges like the Rockies, the Himalayas, and the Andes. Alexander von Humboldt was one of the first to synthesize this information by collecting plants and comparing the distribution of species on mountain ranges in the Andes and temperate regions (Figure 1). He noticed that temperature drops with increasing elevation, and that vegetation communities and forest structure decrease along elevational gradients. His essays on the geography of plants were based on the then novel idea of studying the distribution of life as affected by varying physical geographic factors. These included the effects of temperature and precipitation on vegetation on mountains, the impact of the locations and elevations of the mountains (Massenerhebung effect), and interactions of the species and associated forest structural characteristics. With the increasing resolution of species distributional data from elevational gradients, it has become clear that vegetation types on mountain ranges do not occur as linear cross-sections and are significantly impacted by orographic processes and precipitation which result in a wetter and a drier side of mountain ranges and volcanoes. This impacts the location of different vegetation types and diversity on either side. In general, species diversity decreases with elevation; however, a number of studies have identified a mid-elevation bulge in diversity. This mid-elevation bulge in diversity is generally explained by overlapping ranges between lowland and montane species, by increases in
precipitation due to orographic processes, and by a decrease in area associated with increasing elevation. The tops of isolated mountains and mountain ranges almost always have fewer species than lowland areas; at the same time, these mountaintops act as sky islands and contain a high proportion of endemic species and taxa from higher latitudes.

A number of environmental factors have been hypothesized for determining relationships between species richness and ecosystem structure found along elevational gradients. Area, climate, and unique niches have all been identified as associated with levels of biodiversity similar to those found for latitudinal gradients. The area of a mountain range is associated with the number of species, and it has been proposed that high-elevation regions have lower species richness than middle-elevation regions because of the smaller area extent at high elevations. There is a well-known decrease in temperature with elevation (lapse rate) of about 3.5°F for an increase in 1000 feet around the globe. This results in colder temperatures on the tops of mountains and lower diversity. Rainfall has been correlated with species richness up to 4000 mm and mountain ranges can receive the highest rainfall at mid-elevations as a result of orographic precipitation. The heterogeneity of mountain ranges in the form of slope, aspect, and elevation has resulted in a number of niches that are not available at higher or lower elevations. Indeed, cloud forests in the tropics provide a myriad of niches for trees, epiphytes, and other species.

Although it is not possible to identify a single mechanism associated with the biodiversity of all taxa, a combination of factors mold current patterns of elevational diversity.

**Figure 1** Alexander von Humboldt's 1805 vegetation map of tropical vegetation gradients.
Islands

It has long been known that islands have lower diversity than continents, and island biodiversity has been of wide interest to biogeographers. Biogeographic metrics, such as area and isolation of islands, have long been associated with species richness at various scales. The first widely used models in island biogeography used area to predict species richness: \( S = cA^z \), equating to \( \log S = \log c + Z \log A \) when logged on both sides, where \( S = \) number of species/diversity, \( A = \) Area, and \( c \) and \( Z \) are constants (MacArthur and Wilson 1967). In this model, area serves as a correlate of other interlinked factors, such as habitat diversity or elevation, and species diversity is envisaged as the result of an equilibrium between colonization and extinction, which are influenced by island area and isolation (MacArthur and Wilson 1967). Recently, Whittaker, Triantis, and Ladle (2008) proposed a model called the general dynamic model of oceanic island biogeography, by adding the age of an island, defined as time since island emergence, as another important predictive variable for native species richness and single-island endemics on oceanic islands.

Compared to continents, islands have significantly higher endemism or unique biodiversity per unit area. This is most pronounced on island continents like Australia, large oceanic islands (which have never been connected to the mainland) such as Hawai‘i, which has 90% plant endemism, and continental fragments that broke off from continents millions of years ago which saved relict species from a previous time period such as Madagascar and New Caledonia.

Terrestrial environments

Theories of the latitudinal and elevation gradients of biodiversity have significantly advanced over the last century, but there have also been advances in the empirical locations and analyses of terrestrial biodiversity. The most accurate ways to collect biogeographic data on biodiversity are intensive field surveys or inventories of species in the field. High-resolution maps of species are available in the United Kingdom where inventories of plants and birds have been undertaken for over a decade at a 10 x 10 km resolution. Plant and animal distribution data are also available at a 50 x 50 km resolution in Europe, Australia, the United States, Canada, and South Africa. These inventories require skilled individuals and a significant amount of time in the field, and can be extremely expensive. Even in relatively well-studied areas, different field data sources can lead to dissimilar or biased maps of species distributions and diversity, and in areas such as the tropics species occurrence and distribution data are relatively coarse and not well collected. However, there has been an increase in high-resolution data and maps for a number of regions and biogeographers are continuing to research ways to map species distributions and diversity. There are a number of large spatial scale geospatial databases that have been used to measure, model, and interpret patterns of biodiversity at a global spatial scale. This has largely been done by mapping the location of a species occurrence within 1 degree grid cells. These biodiversity studies have generally focused on well-known groups such as vascular plants, reptiles, amphibians, birds, and mammals.

Vascular plants, which first evolved around 360 million years ago, now cover 70% of the Earth’s land surface and provide the structural foundation for a diversity of taxa. Native plant species richness is highest near the tropics, with exceptional levels of diversity in northern South America, followed by Southeast Asia and tropical mountain ranges (Figure 2). Other regions of high diversity occur between 30° and 40° latitude including Mediterranean ecosystems, subtropical
forests, and the Himalayas. Indeed the Mediterranean basin contains 11 700 endemic plant species. Plant diversity is clearly lower in hot and cold deserts and in low-lying areas near the poles.

Reptiles arose between 310 million and 320 million years ago and reached their peak in the Mesozoic era. Reptiles consist of approximately 10 000 species, 90% of which are lizards, snakes, or worm lizards. Lizard diversity and endemism are highest in Australia and in arid regions near the equator, and less diverse toward the poles where low temperatures limit their distribution. Snake diversity is very high in tropical forests along the equator, where they have radiated to take advantage of available niches afforded by complex forest structures. Reptiles such as turtles inhabit a wide range of freshwater and saltwater ecosystems, with the highest levels of diversity in Southeast Asia, although some tortoises have dispersed to oceanic islands.

Amphibians are composed of approximately 7000 species and, as their name suggests, live at the interface between terrestrial and aquatic habitats and require freshwater for some part of their life cycle. Most amphibians occur in the tropics and generally have small ranges and poor dispersal ability. The highest diversity of amphibians is in South America and Southeast Asia, and they are notably absent from most oceanic islands (Figure 3).

Currently, there are over 9000 bird species that are found on every landmass in the world. The highest diversity of birds occurs in South America, which was an island in the tropics for millions of years before connecting to Central America (Figure 4). High diversity in South America is also attributed to the extent of tropical forest and elevation gradients in the Andes. Other areas of high bird diversity are the East African rift zone and mountains in Southeast Asia.

There are over 5400 land and marine mammal species that occupy most of the Earth’s habitats. Land mammals have the highest levels of species richness in the Andes, Afromontane regions in

Africa, and mountains of southwestern China, peninsular Malaysia, and Borneo (Figure 5). Schipper et al. (2008) compiled data from 1700 experts and mapped 5487 mammals. They found that global macroecological patterns are very different for land and marine species but suggest common mechanisms driving diversity and endemism across systems. They suggest that diversity is similarly driven by energy availability and topographic complexity. Overall, the species richness patterns for land mammals are similar to those found for birds and amphibians; however, species richness does not always overlap with threatened species richness or rare species richness (Figure 6).

Marine environments

It is clear that all terrestrial biodiversity evolved from marine environments. Indeed, many of the oldest life forms are still in existence in marine ecosystems. Patterns of diversity are similar to latitudinal and elevational gradients on land, with diversity decreasing with depth and temperature. The isolation of deep cold regions of the Earth has given rise to some of the most unique ecosystems based on thermal vents. The highest diversity clearly occurs in coral reef ecosystems. Indeed, 25% of all marine biodiversity can be found in coral reef ecosystems that cover an area the size of British Columbia. Coral reefs are a stark contrast to highly productive temperate and polar waters because of the low levels of nutrients. However, the structural complexity of corals has resulted in the highest biodiversity in marine environments. Tittensor et al. (2010) examined global patterns and predictors of species richness across 13 major species groups ranging from zooplankton to marine mammals, and found two major patterns of marine biodiversity (Figure 7). First, coastal species showed maximum diversity in the Western Pacific. Second, oceanic groups consistently peaked across broad mid-latitudinal bands in all oceans. Sea surface temperature was the only environmental predictor highly related to diversity across all 13 taxa.

Biodiversity threats

Gradients of biodiversity have been shaped by millions of years of evolution and environmental changes; however, increases in human populations have significantly changed the levels and patterns of biodiversity. The increase in human densities and distribution in the last 12 000 years has altered levels of biodiversity for megafauna (>100 kg) across all continents and continues to impact smaller taxa. This has resulted in global, regional, and local extinctions of species at a higher rate than extinction events in the past. Indeed, scientists currently define this increase in human population and associated land-cover conversions as a geologic time period, the Anthropocene, which has been in existence for at least 12,000 years before the present. During this time humans have had significant impacts on biodiversity patterns and processes at a global spatial scale.

Threat by taxa

These threats are not evenly distributed across geographic regions or taxonomic groups. In particular, some groups, such as plants, freshwater fish, amphibians, and mammals, have been disproportionately impacted by human activities (Figure 8). The Sampled Red List Index for Plants randomly selected a sample of 7000 out of the world’s 380,000 known plant species, and discovered that that one in five plants are
threatened with extinction, and around a third of plants are so poorly known that we do not know if they are threatened or not. Habitat loss due to the conversion of natural habitats for agriculture and livestock grazing is the biggest threat to plants’ survival. Other taxonomic groups that require freshwater, such as freshwater fish and amphibians, have also experienced high rates of global, regional, and local extinction as a result of habitat conversion, pollution, competition from non-native species, and disease. Mammals, our closest relatives, also have a disproportional degree of threat, with one in five species potentially threatened at a global spatial scale. The mammals that are most threatened are generally carnivores that have large body sizes and small geographic ranges, and require large areas of contiguous habitat. These species are significantly impacted by the destruction and fragmentation of habitat, hunting, and human air, land, and water pollution. Although all taxonomic groups are important to preserve, the threats to plants, freshwater fish, amphibians, and mammals are currently critical issues to address in biodiversity research.

**Figure 8** Proportion of taxa threatened, from several major taxonomic groups which are listed as critically endangered (red), endangered (orange), or vulnerable (yellow) on the 2007 IUCN Red List of Threatened Species.

**Threat by regions**

Threats to biodiversity are not evenly distributed across the globe, and there has been an increasing interest in prioritizing regions and landscapes that have a high conservation priority at a global spatial scale. Early research identified biodiversity hotspots or regions around the world with exceptional concentrations of diversity and endemic species that are experiencing an exceptional loss of habitat (>70%) due to human activity (Figure 9). The goal of biodiversity hotspots is to identify regions around the world where conservation priorities should be focused. The rationale is that the funding and resources available for conservation are inadequate to protect all threatened and endangered species in the world and, therefore, it would be more effective to concentrate conservation efforts in areas with the highest levels of biodiversity and endangerment that are experiencing the greatest amount of habitat loss. A total of 34 biodiversity hotspots have been identified which cover only 2.3% of the Earth’s land surface but contain over 50% of the world’s plant species and 42% of all terrestrial vertebrate species. Millions of dollars have been raised to help protect and preserve biodiversity in biodiversity hotspots since 2000.

**Conservation priorities by species**

At a global scale, the International Union for the Conservation of Nature (IUCN), founded in 1948, has led the way in conserving biodiversity by developing the Red List of Threatened Species. Since 1964, the IUCN has been ranking species conservation status as “Extinct,” “Extinct in the Wild,” “Critically Endangered,” “Endangered,” “Vulnerable,” “Near Threatened,” “Least Concern,” and “Data Deficient.” The goal of the IUCN Red List is to set standard criteria to evaluate the extinction risk of species and subspecies, and to educate natural resources
managers, policymakers, and the general public on the urgency of conservation in order to reduce the extinction of species.

Policy and law

There have been a number of global, national, and local conventions and laws established to protect the Earth’s biodiversity. The Convention on Biological Diversity has been signed by 193 nations and hopes to protect at least 17% of the planet’s biodiversity-rich areas in protected areas by 2020. The Convention on Biological Diversity is a multilateral treaty that seeks the conservation of biodiversity, sustainable use of its components, and fair and equitable sharing of benefits arising from biodiversity resources. The convention was opened for signature at the Earth Summit in Rio de Janeiro in 1992. In 2010 the Nagoya Protocol was adopted which provides a transparent legal framework for the effective implementation of the fair and equitable sharing of benefits arising out of the utilization of genetic resources, thereby contributing to the conservation and sustainable use of biodiversity.

Regionally there are a number of nations that have enacted policy to ensure that species do not go extinct. In the United States, the Endangered Species Act of 1973 tries to ensure that no species goes extinct by listing species that are threatened with extinction and by developing survival and recovery plans for species and critical habitats. The ultimate goal is to remove species from the Federal Endangered Species list. As of April 2014, there were 2149 species listed by the US Fish and Wildlife Service. However, there are recovery management plans for most of these species and a number of successful delistings of species such as the bald eagle (Haliaeetus leucocephalus).
leucocephalus), the gray wolf (Canis lupus), and the peregrine falcon (Falco peregrinus). These international and national laws are some of the best tools for protecting biodiversity.

**Protected areas**

Protected areas are widely regarded as one of the most successful measures implemented for the conservation of biodiversity, drawing on traditional and community-based approaches, governance regimes, scientific and traditional knowledge, and contemporary practices of governments and conservation agencies. The IUCN and United Nations Environment Programme (UNEP) and World Conservation Monitoring Centre (WCMC) world database of protected areas identify the extent of protected areas at a global spatial scale. This database contains IUCN categories of protected areas that were assigned by governments for their national territory. Such integrated baseline data are important for determining global conservation, research, and funding priorities. In countries with strong and well-funded natural resource management institutions, such as the United States National Park Service, there are standardized management practices to preserve species and landscape dynamic protocols related to land-cover change. In the tropics, where some of the largest decreed protected areas exist, natural resource agencies have been developing trained individuals to manage landscapes and protected areas, although resources in the tropics are still limited. It is clear that protected areas are an important component to preserve biodiversity for future generations to enjoy.

**Conservation geography**

Humans have had significant impacts on biodiversity patterns and processes at a global spatial scale. However, there are a number of methods that scientists and geographers have and will continue to employ to analyze and preserve biodiversity with the goal of reaching zero extinction. Inventorying and monitoring of species in the field continue to increase and scientists have developed new methods to identify species genetics, presence, and density, such as remote cameras, and microphones to study soundscapes, as an indicator of ecosystem health. Biodiversity and geographic data are also being displayed at higher resolutions online to help inform the public and preserve biodiversity. The Map of Life, for instance, contains data on terrestrial vertebrate and fish species for 150 million point-occurrence records from the Global Biodiversity Information Facility (an intergovernmental warehouse of digitized species data), expert range maps from the IUCN, and regional presence/absence checklists from the World Wildlife Fund, as well as citizen scientists’ databases such as eBird, which contains empirical location and density data on bird species in or near real time (Gewin 2002). Monitoring all biodiversity is not possible, so there has been an increasing interest in species distribution models and remote sensing techniques that can quantify patterns of biodiversity. There has been a rapid evolution of airborne and space-borne satellites, sensors, and techniques to measure, monitor, and manage terrestrial and marine species. There have been significant advances in baseline vegetation mapping and land-cover classifications by combining field data, multisensors, and classification techniques. High-resolution spatial (<0.5 m) and spectral (220 bands) sensors provide important near real-time data on environmental issues that are region- or site-specific, and can be used by natural resource managers to support conservation efforts. There has also been an increase in time-series remote sensing datasets on anthropogenic impacts, such as water use,
Biodiversity

fire, and land surface temperature, that have been used to assess the status of biodiversity. These types of geospatial data inform management practices, policy, and the general public on the status of biodiversity across the globe, and identify gaps where future research and management are needed.

Emergence of modern biogeography

Biogeography is the science that seeks to understand spatial patterns of biological diversity and how those patterns have changed through time, at geographic scales ranging from the entire planet to small islands and local habitats (Lomolino et al. 2010). Traditionally biogeographers have dealt with the diversity and distributions of organisms (species, genera, families, etc.), but today they study the geography of diversity across levels of biological organization ranging from genes to communities and ecosystems, often within the rapidly emerging subdisciplines of phylogeography and macroecology. The emerging subdiscipline of conservation biogeography seeks to develop a template and predictive framework for understanding the consequences of human activities—including habitat fragmentation and loss, invasive species, and climate change—on spatial patterns of biological diversity.

While observations regarding geographic variation in the diversity of life can be traced back through the Greek philosophers and explorers, the roots of a modern discipline of biogeography can be traced to observations derived from the expansion of knowledge about global patterns of biological diversity during the eighteenth-century age of exploration. However, few if any scientists would have called themselves biogeographers until late in the twentieth century, with the term “biogeography” probably first used in the late nineteenth century (Ebach and Goujet 2006; Schickhoff, Blumler, and Millington 2014).

Carolus Linnaeus (1707–1778) proposed in 1781 that all species originated on the slopes of a “Paradisical Mountain” and subsequently spread, without evolution, to stations on newly formed continents similar in habitat to respective elevations on the mountain. In 1761 Georges-Louis Leclerc, Comte de Buffon (1707–1788), proposed an alternative scenario with a rudimentary evolutionary component. He envisioned species originating in northwestern Europe and migrating southward as climates cooled. Importantly, he observed that different regions with the same abiotic conditions (e.g., the New World vs Old World tropics) contain different species. Because species dispersing southward from the north would have had to cross inhospitable country to get to their current locations, they would have evolved along the way, providing an explanation for why the tropical biotas of the New and Old Worlds shared few species. While wrong in details, the notion that “environmentally similar but isolated regions have distinct assemblages of mammals and birds” (Lomolino et al. 2010, 20) became the foundational principle of biogeography (Nelson 1978) and is known as Buffon’s Law.

Throughout much of history biogeography has been divided into two largely independent themes that have come down to modern times as historical biogeography and ecological biogeography (Nelson 1978), although Ebach and Goujet (2006) suggest instead that the division is better thought of as regionalization versus dispersal pathways, and that these both incorporate
BIOGEOGRAPHY: HISTORY

historical and ecological components. The historical versus ecological themes are generally traced to an essay in 1820 by Augustin P. de Candolle (1778–1841), who – in the tradition of Buffon’s Law – recognized historical factors that determined the regionalization of biotas (“habitats”), and wrote about ecological factors such as climate and terrain changes that determined the composition of what today we would call local habitats (“stations”) (Nelson 1978). Through much of the twentieth century, historical biogeography was closely associated with other historical disciplines (including evolution, paleontology, and systematics), whereas ecological biogeography had stronger connections to population, community, and ecosystem ecology. The historical versus ecological dichotomy in biogeography is increasingly being replaced by a more integrative biogeography that draws from – and often informs – disciplines in biology including ecology, evolution, and molecular biology; and others in earth sciences including geomorphology, sedimentology, paleontology, and climatology.

Persistent themes and shifting approaches

Four persistent themes in biogeography (Lomolino et al. 2010) can be traced to eighteenth- or nineteenth-century naturalists or geologists, often emerging in association with revolutions in technology and commerce (e.g., those that motivated the age of exploration), or revolutionary thinking in science, for example the hierarchical system of biological classification developed by Linnaeus; ideas on the mutability of species originating with Charles Darwin (1809–1882) and Alfred Russel Wallace (1823–1913), which required an “old” Earth, as provided by geologists such as James Hutton (1726–1797) and Charles Lyell (1797–1875); and the elucidation of an ice age by Jean Louis Rodolphe Agassiz (1807–1873), now known to consist of a series of glacial and interglacial cycles in relatively recent Earth history. The most influential naturalist to advance a modern-looking science of biogeography in the late nineteenth century was Wallace, often considered the father of biogeography. Many of the biogeographic principles that he modernized with sound evolutionary, ecological, climatic, and geological underpinnings are still being investigated today (see Lomolino et al. 2010, box 2.1).

Theme 1: The delineation and classification of terrestrial and marine biogeographic regions

By the mid-nineteenth century, data on the distribution and diversity of life were sufficient to motivate several seminal attempts to ascertain “the most natural primary divisions of the Earth’s surface, taking the amount of similarity or dissimilarity of organized life solely as our guide … supposing them to have been the result of distinct creations” (Sclater 1858, 130). Philip Lutely Sclater (1829–1913) used the distribution of avian taxa to derive essentially the six terrestrial biogeographic regions that were later generalized by Wallace in 1876, incorporating data on mammals and other groups of vertebrates and invertebrates. Sclater also attempted, less successfully, a regionalization of the oceans in 1897—newer approaches have been more widely adopted (Riddle et al. 2011). Intracontinental regions have also long been recognized (e.g., in 1852 Wallace recognized four distinct regions in the South American Amazon bounded by large rivers); recent approaches combine distributional with landform and ecosystem data into units called ecoregions.
Theme 2: reconstructing the history of diversification, distribution, and extinction of lineages and biotas, often in the context of events in Earth history

Application of a grand idea in geology, that land masses “drift” across the face of the Earth over time, to biogeographical questions might have coincided with the publication of *Die Entstehung der Kontinente und Ozeane* (*The Origin of Continents and Oceans*) by Alfred Wegener (1880–1930) in 1915, but because he got a number of details and mechanisms wrong, the revolutionary theory of continental drift was not generally accepted by geologists until it was resurrected as the model of plate tectonics in the 1960s, at which time it rapidly became foundational for students of diversification and distributional dynamics.

Prior to acceptance of the plate tectonic model of continental drift, historical biogeographers would often account for faunal and floral evidence of historical affinities in the distribution of terrestrial organisms between continents and large oceanic islands by proposing geologically implausible land connections spanning ocean basins (e.g., past continents or land bridges between the Gondwanan land masses of South America and Africa across the Atlantic Ocean, and between Africa, Madagascar, and India across the Indian Ocean) – the sorts of long-distance dispersal events envisioned earlier by Buffon and Linnaeus were a dominant theme shared by late nineteenth-century naturalists including Lyell, Darwin, and Wallace. At the same time as evidence was growing in geology for the plate tectonic model of a dynamic Earth, the biogeographer Léon Croizat (1894–1982) was amassing distributional evidence for animals and plants that he would use in his approach called panbiogeography to argue that “earth and life evolve together” (Croizat 1962, 605). Subsequent biogeographers have established that a weakness with panbiogeography was Croizat’s rejection of the formal method of phylogenetic systematics (i.e., cladistics) developed by Willi Hennig (1913–1976) for evaluating relationships of taxa – indeed, both Darwin and Wallace recognized the need for a “natural” system of taxonomy that grouped taxa on the basis of evolutionary relationships, and Hennig’s cladistics provided the method for doing so. In 1966 Lars Brundin (1907–1993) did blend Hennig’s cladistics with Croizat’s panbiogeography into an approach he and Hennig called phylogenetic biogeography, while denouncing the earlier practitioners of dispersalist biogeography with a scathing condemnation of one of its most visible and latest practitioners, Philip Darlington (1904–1983). During the 1970s, historical biogeography was guided by a cladistic-based cadre, including Gareth Nelson, Norman Platnick, and Donn Rosen (1929–1986), into the methodologically rigorous approach called vicariance biogeography, wherein taxon cladograms from codistributed taxa were used to find general relationships between a set of geographic areas, which in turn were utilized to postulate historical relationships resulting from the splitting (vicariance) of those areas by geological events. It is easy to see how this approach was motivated by the acceptance of the plate tectonic model of continental drift. More recent methods have sought to reincorporate dispersal, along with vicariance, into analytically rigorous approaches; some have shifted the emphasis away from the analysis of area histories into a more direct analysis of taxon range evolution (reviewed in Lomolino et al. 2010). Phylogeography has blended phylogenetic and population genetic approaches to develop a biogeography within species and across closely related species. The entire discipline has been transformed by, and continues to include, innovations in the use of molecular genetics to
BIOGEOGRAPHY: HISTORY

reconstruct phylogenetic and population genetic patterns.

Theme 3: Explaining differences in the numbers and types of species between geographic areas, and biotic turnover along gradients of area, isolation, latitude, elevation, and depth

A very pervasive pattern in nature, the species–area relationship, was recognized as soon as eighteenth-century voyages began to visit islands of different sizes, and became a backbone of biodiversity knowledge with a mathematical underpinning early in the twentieth century. A theory with profound influence entered biogeography in the 1960s when Robert H. MacArthur (1930–1972) and Edward O. Wilson used the species–area relationship, along with the species–isolation relationship and evidence of a dynamic turnover of species on islands, to motivate development of the equilibrium theory of island biogeography. This theory was elegant in its simplicity, predicting the species richness of islands (or isolated “habitat islands”) as a dynamic process countering immigration and extinction, predicted by island area and island distance from a larger adjacent source pool of immigrants. Nonrandom patterns of species richness across continents and oceans, as well as islands, are of great interest when biogeography is utilized to generate data for biodiversity conservation issues (e.g., recognition of biodiversity hotspots).

Biogeographers have long recognized that tropical rainforests spanning the equator are particularly rich in species, and that a latitudinal gradient in decreasing species richness stretches from the equator to the poles – a pattern replicated in many terrestrial and marine taxa. Recent attempts at a general explanation include both ecological and evolutionary components (summarized in Lomolino et al. 2010). Species turnover along gradients of elevation were of great interest to Alexander von Humboldt (1769–1859) early and C. Hart Merriam (1855–1942) later in the nineteenth century.

Theme 4: Examining geographic variation in characteristics of individuals and populations within and among closely related species, including trends in morphology, physiology, behavior, genetics, and demography

Along with the aforementioned subdisciplines of phylogeography (the study of genetic architecture within and between closely related populations) and macroecology (a statistical approach to identifying patterns and processes underlying the assembly and structure of biotas), a series of ecogeographic rules have been developed that represent attempts to explain changes in morphological features across geographic gradients and include Allen’s (limbs becoming shorter in colder climates), Bergmann’s (body mass increasing with latitude or colder climates), and Jordan’s (number of vertebrae in marine fish increasing in cooler waters). Predictable morphological size changes in island populations have led to the island rule (gigantism and dwarfism in island populations). Areography attempts to elucidate the structure of geographic ranges, including variation in their sizes, shapes, and overlap.

The modern field of biogeography studies the distribution and dynamics of nonhuman species and ecosystems in geographic space and through geological time. It tends to focus on physical geographical variables (such as latitude, altitude, climate, size, and isolation of an area) combined with additional biological factors (such as the location of other organisms and species communities). The subdiscipline of conservation biogeography examines human impacts on natural systems and applies the principles of biogeography to inform efforts toward biodiversity conservation. In this mode of biogeography, analysis tends toward the quantitative and is proudly “scientific” in epistemology.

There also exists a variety of alternative approaches to investigating the geographies of the “bio” that, although neither referred to nor self-identifying as biogeography, can be considered in these terms because of their comparable commitments to mapping and explaining the dynamics and distribution of nonhuman life. These alternative approaches, which are reviewed in this entry, are generally associated with human and environmental geographers, but cannot simply be understood as attempts to integrate scientific modes of biogeography with the insights of social science, though such work does exist.

Biogeography has long accommodated an interdisciplinary strand. Indeed, Alfred Russell Wallace, hailed by many as the founding figure in biogeography, paid as much attention to anthropological patterns as to the distribution of faunal and floral diversity in his classic *The Malay Archipelago*. However, the alternative approaches reviewed here have emerged out of attempts to mobilize new conceptual and methodological resources to address the core concerns of biogeographic inquiry. They have sought to expand the scope of these inquiries, to understand environmental science as a social practice and to bring politics into considerations of diversity and distribution. Sometimes these alternatives have been developed in ignorance of established work in biogeography. At other times they respond to its perceived deficiencies. Occasionally they result from conversations with its key authors.

They have emerged for three (sometimes overlapping) reasons. First, human geographers have rejected the binary distinctions between human and nonhuman life and between natural and social spaces that underpin much traditional biogeographic study. A widespread realization of the scale of human impacts on the diversity and distribution of life, notably conceptualized in the controversial logics of the “Anthropocene” (Steffen *et al.* 2011), questions the adequacy of a field that, more often than not, positions modern humans as alien to rather than inextricably implicated within contemporary ecologies. Second, the notion of the Anthropocene exemplifies a widespread and multipronged critique of the adequacy of the forms of biological knowledge that underpin much traditional biogeography. This critique includes challenges to prevalent ecological models founded on notions of equilibrium and balance on internal (coherence) and external

(relevance) grounds as well as questioning the status of biological science as a singular, objective route to truth outside of politics and circuits of economic value. These concerns regarding the provenance and politics of scientific knowledge necessitate new ways of engaging publics in biogeographical decision-making. Third, diverse work in animal and (to a lesser extent) plant geographies has drawn attention to the political and ethical status of those organisms that are the subjects of biogeography – but frequently only feature as populations of species. It identifies the multiple and conflicting ways of categorizing and valuing the nonhuman world, exploring both the cultural politics of relating to and governing nonhumans. This work has also flagged the need to understand the lived experiences of nonhumans to develop biogeographies of plants and animals themselves.

This entry introduces the alternative approaches to biogeography that have been developed in the face of these challenges. It is organized into five sections that explore: (i) expanding the spaces and places of biogeographic inquiry; (ii) knowledge politics; (iii) biopolitics; (iv) biocapital; and (v) animal geographies. It evaluates their intersections with traditional biogeography, their contributions and limitations, and identifies likely future directions.

Expanding the spaces and places of biogeographic inquiry

The challenges listed above have forced a widening (or rethinking) of the “where” and the “why” in both traditional and alternative biogeographies. Traditional biogeographers have begun to look in earnest at life outside of the familiar islands and reserves in which so much historical research has focused, recognizing that ecologists need to be able to say more than feral, weedy, and non-native about the wildlife of the Anthropocene. Increasing attention is thus being given to “novel ecosystems” (Hobbs, Higgs, and Hall 2013) and “anthromes” (Ellis and Ramankutty 2008); these terms describe the unprecedented, anthropogenic ecologies that increasingly characterize the planet and in which the majority of life resides. Archetypal novel ecosystems include agricultural landscapes, cities, and island ecologies subject to large-scale colonization by non-native species. These are understood as hybrid ecologies with unprecedented, networked biogeographies of species provenance in which the vectors of globalization have scrambled evolved distributions. The likely outcomes for biodiversity of such ecological globalization are the subject of much debate. Meanwhile the impending and actual dynamics of ecologies adapting to accelerated climate change in inhabited landscapes create new, nonlinear temporalities of biogeographical change. Conservation biogeography informed by this thinking imagines new territories and forms of connectivity for mobile species as well as ambitious plans to unleash ecological processes to facilitate adaptation. Nature here is social, contingent, and on the move. The past is a guide but not a mirror.

Geologists’ diagnoses of the end of nature have been anticipated for some time by work in environmental geography, environmental history, and the social studies of science (Demeritt 1994). Two of the most influential critics of the modern idea of a nature removed from society are Donna Haraway (2008) and Bruno Latour (2004). Their respective “cyborg” and “hybrid” ontologies of dynamic and mixed forms challenge the coherence and politics of appeals to a singular nature. This work informed Sarah Whatmore’s (2002) hybrid geographies in which nature is understood as the purified outcome of various forms of modern science, rather than a transcendent reality. There is a growing body of work...
examining the implications of these approaches, characterized by multiple immanent natures akin to those found in discussions of novel ecosystems. For example, geographers have concerned themselves with the political ecologies of agriculture and biotechnology – including lab animals, livestock, and genetically modified organisms. Other research has examined the geographies of biosecurity – focusing on the mobile, sometimes pathogenic organisms that unsettle popular geographies of cosmopolitanism and globalization. A further strand of work explores the wildlife and people that flourish in urban, postindustrial, and other marginal habitats far from the purview of traditional conservation. The catalog of the places and spaces relevant to biogeographical inquiry continues to proliferate.

New frontiers for biogeography have also emerged as a result of engagements with developments in the human sciences, biophilosophy, and animal studies. For example, postgenomic research on the human microbiome is encouraging a radical reappraisal of the biological coherence and identity of the human. This work presents the human as a super-organism; a more-than-human ecology in which cells or genetic material with a distinct “human” signature are in the minority. For Donna Haraway (2008), the human, with all of its formerly special properties, should be rethought as a “companion species.” The human thus becomes a multi-species achievement vulnerable to and dependent upon the biological exchange of materials. Dissolving the coherence of the human (and, by implication, nonhuman) subject has uncertain implications for a traditional biogeography that remains, for the most part, organized around the biological species (as genetic material or morphological expression) as the primary units of analysis; and indeed reflects the wider tension between relational and essentialist ontologies (and resulting epistemologies) that currently permeates the academy.

Knowledge politics

The spatial and ontological challenges to the categories nature and human have important epistemological and political implications for biogeography. If natures are multiple, nonlinear, and discordant then what knowledge counts and through what processes might this be decided? These anxieties are compounded by the popular proliferation of knowledge controversies concerning the entanglement of the biological sciences in a range of environmental and health issues. There is thus a degree of ambivalence about the place of science among alternative approaches to biogeography, somewhat at odds with the traditional discipline. This ambivalence is infused with an understanding that certain sciences have been complicit in enabling the environmental crises associated with the Anthropocene. The resulting distrust is balanced by recognition of the roles played by scientists in both diagnosing environmental problems and delivering solutions.

The various challenges to the status of scientific knowledge production unsettle the popular (if frequently caricatured) figure of the objective biologist in possession of a singular and universal route to truth, operating in a domain outside and in advance of politics. They have informed an established literature critical of this figure and that is in search of alternative ways of bringing the biological sciences into democracy (Latour 2004). For example, geographers and others concerned with the practices of the biological sciences have mapped the difference space and place makes to its current and historic conduct (Kohler 2002; Livingstone 2003). They have sought to locate bioscience and other forms of natural
knowledge, focusing on a range of discrete places in which they are conducted. Analysis has focused on archetypal scientific locations including laboratories, hospitals, museums, and field stations as well as more vernacular places like homes, gardens, and the Internet. Furthermore, ethnographic research with scientists has documented how science involves experience, engaging in processes of learning to be affected. Here scientists and other experts calibrate their bodies and instruments to attune to relevant forms and processes. This embodied, affective epistemology has informed a range of investigations of biological science in action. Drawing on work in science studies, geographers of science have thus recognized that singular, universal forms of knowledge are a geographic achievement, involving regular and power-laden knowledge practices through which some privileged actors come to speak for others at a distance, including the world at large.

Others argue that the diagnosis of the Anthropocene (and its associated controversies) demonstrates that the experiments of modern science have escaped their laboratories and have taken over the world. Laboratory science can no longer be understood as a bounded, private, and inconsequential affair. Analysis suggests that we are all now implicated in the conduct of experiments like climatic change and “invasion ecologies,” have valuable knowledge about their drivers and consequences, and ought to be engaged in their research and governance. There has thus been a growing interest among geographers in developing concepts and methods for deliberating with multiple forms of biological expertise. This work builds on long-standing concerns among political ecologists with the colonial roots and exploitative nature of forms of biogeographical knowledge that come to inform conservation. It is most manifest in conservation controversies in the Global South characterized by stark differences in cosmology as well as political and economic power. Collaborative methods take this critique further by recognizing amateurs as experts and by developing constructive methods for working with various forms of natural knowledge (Ellis and Waterton 2005).

The collaborative ethos has driven progressive efforts to shift the point of public engagement in scientific controversies “upstream” and has involved a movement from participative to deliberative and lately to collaborative methods of democracy (Whatmore 2009). In the latter, affected and interested public comprising multiple forms of expertise come together at the advent of a research project or political decision and remain involved throughout its duration and implementation. In their most radical forms these deliberative approaches to democratic biogeography seek experimental, open-ended encounters with social and ecological difference. They are less concerned with testing hypothesis and more interested in allowing the research questions, accepted evidence, and forms of explanation to emerge during the conduct of the research. In part this ethos emerges from the ontological shifts that were outlined in the previous section. Cast off from the certainties of a fixed nature, geographers are learning to live with a nonlinear and interconnected world.

Biopolitics

Further strands of work by geographers have focused more explicitly on the human shaping of the “bio,” attending to the practices and politics through which certain groups come to speak for, benefit from, and ultimately shape the world. Some have turned to and developed the writings of Michel Foucault on biopolitics. Foucault identified two political strategies original to modern forms of government. The first, which he termed “governmentality,” described the rise
of powerful knowledge practices that construct standardized models of normal, rational healthy citizens, and inform technologies that discipline individual adherence to these subjectivities. Social scientists have reworked this concept to describe forms of “environmentality” associated with powerful efforts to create environmental citizens in the interests of conservation.

The second political strategy Foucault identified is the emergence of modern forms of “biopower” where the concern shifts from the behavior of individuals to the management of life at the scale of the (often unruly and unpredictable) population. Foucault highlights how modern “biopolitics” involves productive and destructive processes through which life is made to live or left to die. The concept of biopolitics is now commonplace in the social sciences and informs critical analysis of the deployment of biological knowledge to manage populations to secure human and environmental health.

Foucault was resolutely human in the foci of his analyses of biopower and notoriously ambivalent about animals and the environment as political problems. Post-Foucauldian scholars have developed the concept of biopower to identify and analyze the multitude of modes of nonhuman biopolitics that characterize late modern governance. This work has been influenced by Giorgio Agamben’s writings on the “anthropological machine”: the categorical procedure through which lines are drawn between human, political life (bios), and bare, animal life (zoe). Critics have argued that this approach is rather too totalizing, anthropocentric, and deathly. It presents biopolitics as the control over life and neglects both the generative dimensions of securing life and the ability of life to do otherwise.

Recent scholarship offers a range of livelier and more affirmative approaches to biopolitics that are willing to afford some power to the “bio.” One key source is Donna Haraway (2008), who presents biopolitics as processes of “living with”; modes of companionship figured as unequal, power-laden but nonetheless contingent relations. Her approach culminates in an appeal for a “cosmopolitics” – a concept she takes from Isabelle Stengers – premised on the flourishing of multispecies difference. Haraway’s cosmopolitics resonates with work in geography by Steve Hinchliffe and Sarah Whatmore and their co-researchers on the biopolitics of biosecurity and urban conservation. For Hinchliffe a cosmopolitics for living with aggregate nonhuman populations involves anticipating, nurturing, and managing events that emerge from the circulation of human and nonhuman actors in diverse spatial formations (or topologies). This cosmopolitics is not about rendering the present eternal, but involves a “careful political ecology” that is open to the immanence of nonhuman life.

These writings are part of a growing body of empirical work mapping different modes of nonhuman biopolitics, including agriculture, forestry, fishing, biosecurity, animal welfare, hygiene, hunting, and pet-keeping. Each has its own aims, privileged knowledge practices, and desired norms and subjects. Cutting across these modes, this work identifies a range of common and significant biopolitical practices concerned with understanding and intervening into the character, distribution, and dynamics of nonhuman populations. These include knowledge practices for identifying, classifying, counting, surveying, mapping, and calculating. Databases and models are key here, as are the assemblages of technologies through which governance happens. These knowledge practices inform practical management actions like culling, fencing, translocating, vaccinating, breeding, and planting.

This work traces the performative power of different modes of biological – and biogeographic – knowledge. It examines how systematic efforts to
secure the future of a valued life (both human and nonhuman) at the scale of the population come to shape different worlds, cutting up the flux of life to perform particular ideas of what life should be saved (and where it should live). Donna Haraway (2008) terms this process “ontological choreography.” Annemarie Mol (2002) explores the “ontological politics” that results from tensions between different ways of choreographing life. Drawing on this work Hinchliffe (2007) proposes an understanding of life as multiple, comprising incommensurable ontologies of individuals, species, genes, ecosystems, and processes. Politics emerges at the interface of modes of governance associated with securing versions of each.

Biocapital

In his writings on governmentality and biopolitics Foucault was especially concerned with the rise of neoliberalism. The ascendance of this mode of political economy in the last forty years has troubled a further strand of geography concerned with the growing neoliberalization of forms of environmental and social governance. Often described by the label political ecology, this work offers further alternatives to biogeography. In particular it attends to the processes of commodification through which common and public forms of life are privatized and reconstituted as “bio” or “lively” capital. This work intersects with the poststructuralist work on biopolitics reviewed above but is conceptually more aligned with neo-Marxist critiques of contemporary “biocapitalism.”

The neoliberalization of nature and associated forms of biocapital take diverse forms, but are united by at least six common properties: (i) a central focus on privatization, or the enclosure and assignation of property values to resources that were previously commonly held; (ii) a belief in self-regulating markets as the best and most efficient means of allocating value and tackling problems; (iii) which requires the commodification of everything; (iv) a resistance to what is seen as state interference, except to defend property rights; (v) resulting in both deregulation and reregulation, including the rolling back of the state, shifting governance to supranational scales, voluntary agreements, and empowering NGOs; and (vi) a focus on empowering citizens as consumers to make choices through new markets.

The critique of “neoliberal natures” has been developed in work on the political ecology of nature conservation (and elsewhere), which shows how appeals by biogeographers and others to a pure “nature” tends to naturalize certain unequal forms of valuation. Concern here focused initially on the creation of protected areas and the privatization, commodification, and iniquitous exploitation of the land and wildlife they contained (Buscher et al. 2012). This work has expanded to explore forms of value created through the circulation of spectacular imagery and the commodification of encounters with wildlife. These images and interactions are understood to fetishize certain charismatic species and places, with problematic consequences for the scope, culture, and politics of conservation.

A further strand of work has focused on the commodification of the generative, reproductive potentials of biological life, critically examining the financialization of nature. Focal products for securing the environment include carbon offsets, wetland and other forms of biodiversity banking/prospecting, and the increasingly prevalent frameworks for valuing “ecosystem services” and “natural capital.” Importantly, the fungibility performed by these commodifying practices has significant implications for the resulting geographies of valued life; the
location of a particular species and/or habitat may derive more from the confluence of development projects, associated land deals, and translocations than from ecological histories. Understanding the diversity and distribution of neoliberalized natures thus often requires paying significant attention to political economy as well as the contingencies of evolutionary processes.

Animal geographies

Further alternative approaches to biogeography are offered by animal (and plant) geographies. Since the late 1990s these subdisciplines have been the subject of a great deal of interest, connecting to the wider “animal turn” that has taken place across parts of the science, humanities, and social sciences. Here cultural and environmental geographers have examined individual and aggregations of animals as geographical subjects (Urbanik 2012). They have sought to bring the animal back into geography and in so doing have pluralized and politicized the species- and ecosystem-based approaches of traditional biogeography.

The most developed strand of this work connects with the approaches reviewed above and seeks to attend to “animal spaces” (Philo and Wilbert 2000). These are the various real and imagined geographies that humans create of and for animals. This work includes analyses of the cultural politics, biopolitics, and forms of biocapital caught up in the ordering of animal lives. It also explores the ontological politics associated with different ways of classifying and governing the “bio.” For some, this represents a political effort to address a perceived “speciesism” in the formulation of human geography. The focus here is on the rights and welfare of animals inhabiting some of the most oppressive animal spaces. For example, work has focused on the spaces of agriculture, hunting, and laboratory testing as well as more affirmative relations of domesticity. There has been limited engagement here with the political domain of conservation, which most centrally concerns orthodox biogeography. Although such concerns for animal suffering are more evident in other parts of critical animal studies, these approaches offer an important alternative form of biogeography.

A further strand of this work attends to the “beastly places” (Philo and Wilbert 2000) of animals themselves, conceiving of animals (and to a lesser degree plants) as lively bodies active in the making and sensing of place. Here various researchers have developed approaches to biogeography that are more aligned with those practiced by physical and natural scientists. Conjoining methods from ethnography and ethology, authors have sought to mobilize the expertise of field scientists as well as a wider range of people engaged in a diverse array of interspecies spatial practices – including herding, fishing, bird-watching, surveying, and dog-walking. This approach proposes the existence of comprehensible sensibilities of proximal nonhumans that can be understood across species differences. Working with field scientists and other experts, using their methods and technologies, geographers are beginning to map animals’ geographies – recognizing the varied experiences, mobilities, and topologies that characterize the nonhuman world.

To date these animal geographies have tended to focus on affirmative relations with species that are “big-like-us”; large animals are the central concern of much popular conservation and most amenable to these modes of multispecies ethnography. Field studies often concern novel ecosystems rich with interspecies interactions and adaptations. In keeping with the wider diversification in the taxonomy of animal
studies, there is a growing movement to expand the scope and character of documented inquiries and develop a more systematic comparative approach to this mode of biogeography.

Future prospects

The alternative approaches to biogeography reviewed here encompass a wide range of spaces, concepts, and methods. This is still an emergent field and is perhaps better understood in less bounded terms as an ongoing series of interdisciplinary conversations; but with the diagnosis and popularization of the Anthropocene, these approaches are likely to experience significant interest in the coming years. Likely future developments include a growing interest in a range of spaces that have been neglected by biogeography to date, including, for example, water (especially oceans), the microbiome, and synthetic biology. Methodologically there is much to be gained from the interdisciplinary collaborative approaches between different types of biogeographers that are beginning to emerge. These would harness the potential of new technologies for sensing, visualizing, and modeling the “bio” while facilitating the upstream engagement of affected publics in the formulation of and deliberation over research. Finally, the future prospects for conceptual innovation are rich. This field has benefited greatly from geographers’ ongoing enthusiasms for social theory, most specifically the growing familiarity with and contributions to work in biophilosophy and animal studies.

Biogeomorphology

Martin A. Coombes
University of Oxford, UK

Biogeomorphology as an overarching framework

Biogeomorphology is a relatively young area of earth system science concerned with the interactions and feedbacks between living organisms (ecology) and the physical landscape and the processes that shape it (geomorphology). It is very much an overarching framework of environmental study that encompasses aspects of a whole variety of more traditional fields, including physical geography, ecology, hydrology, biogeography, materials science, and engineering. In its broadest sense, biogeomorphology considers two types of interactions: (i) the contributions of organisms to the formation of landforms and the evolution of landscapes over time, and (ii) the influences of landforms and landform-forming processes on the distribution, development, and interaction of organisms (Figure 1). Under this broad framework, various terms have been used to describe more specific areas of study. “Phytogeomorphology” is the study of the influence of topography on plant growth and distribution (Howard and Mitchell 1985), whereas “zoogeomorphology” is specifically concerned with the geomorphic impacts of animals (Butler 1995). Much less studied by geomorphologists, but no less important, are the influences of micro-organisms in Earth surface systems, the study of which has been called “microbial geomorphology” (Viles 2012).

As a term, biogeomorphology is sometimes used synonymously with “ecogeomorphology” (Butler and Hupp 2013), although this has more often been applied to fluvial and wetland environments, typically focusing on plant-geomorphology interactions. Ecohydrology, hydroecology, and ecohydromorphology are related terms sometimes used to describe biogeomorphological research in fluvial environments, although not exclusively. Finally, “geoecology” is also used to describe ecological interactions with the physical Earth, often over much longer timescales and larger space scales. Biogeomorphology ultimately recognizes that landforms, landscapes, and the life forms that inhabit them are linked at various scales and in complex ways. Biogeomorphologists seek to understand this complexity so that they can explain and predict past and future landscape change.

The development of modern biogeomorphology

Biogeomorphology was first formalized in the late 1980s with the suggestion that geomorphologists had largely ignored the roles of organisms in Earth surface processes (Viles 1988). Some important work on the topic certainly existed before this, most notably Charles Darwin’s classic studies on earthworms and soil-forming processes, but the idea that landscapes were largely “abiotic” (i.e., nonliving) had prevailed in most geomorphological research. In contrast, increased recognition of the abundance and
diversity of life in virtually all environments on Earth has led to an appreciation of the often intimate associations between organisms and their physical habitat. Accordingly, study of how living (biotic) and nonliving (abiotic) aspects of the environment interact is now recognized as highly worthwhile.

As a developing field, biogeomorphology had received some early criticism given that organisms are unequally distributed in space and their individual impacts are often small and, therefore, seemingly insignificant for landscape evolution. Such issues of “scale” have remained central to the development of biogeomorphology as a scientific discipline (Dietrich and Perron 2006). Biogeomorphologists continue to grapple with these issues but organic processes are at the very least considered to be locally significant, at the landform scale, and the collective influences of populations and whole communities that form ecosystems may be of regional and even global significance. For example, although microorganisms are individually small they are globally ubiquitous and can dominate entire ecosystems where other forms of life cannot survive. This includes deep ocean sediments, exposed rock surfaces, and dry desert soils. Organic processes have further driven periods of significant environmental change in the geological past, most notably the “great oxygenation event” about 2.4 billion years ago that gave rise to major global-scale changes in climate and geomorphic process regimes.

More recently, there have been sustained efforts to integrate ideas and concepts from ecology more fully with biogeomorphological theory. This is entirely necessary for a subject that straddles the boundary between the physical and life sciences. An important development here has been the emergence of the parallel ecological concept of “physical ecosystem engineering”—the idea that some organisms create and modify physical habitat resources for other species (Cuddington et al. 2007). This is proving important for biogeomorphology because it extends and highlights the relevance of biogeomorphological research for contemporary environmental issues such as ecosystem functioning and biodiversity conservation (see entry “Applied biogeomorphology”). Increasing collaboration between ecologists and geomorphologists offers exciting opportunities for biogeomorphology (and ecosystem engineering) through the generation of new larger-scale and longer-term datasets of populations and communities that can be used in biogeomorphological modeling. Efforts to incorporate broader geomorphological ideas and concepts, such as disturbance regimes, complexity, thresholds, nonlinearity, and self-organization, are also contributing to the theoretical development of...
the field. Links between life and geomorphology over successional and much longer evolutionary timescales are also beginning to be explored. As such, the state of biogeomorphology as a subdiscipline of geomorphology is healthy and productive, and rapidly developing.

Biogeomorphological research

Over the last 25 years biogeomorphology has received sustained research interest. Special issues of key geomorphology journals have been dedicated to the topic, including collections of papers spanning the entire subject and those focused more specifically on vegetation, ecogeomorphology, and zoogeomorphology (Viles and Naylor 2002; Butler and Sawyer 2012; Butler and Hupp 2013; Stoffel, Rice, and Turowski, 2013). This body of work not only demonstrates the incredible breadth of biogeomorphological research, but the vigorousness and increasing relevance of biogeomorphology as an integrated academic and applied field.

Central to biogeomorphology is the recognition that micro-organisms, plants, and animals influence exogenic geomorphological processes (weathering, erosion, transport, and deposition) and thereby contribute to the development of landforms in many ways (Naylor, Viles, and Carter 2002). A broad range of examples exists from different environments, including forested hillslopes, coastal wetlands, desert dune fields, glaciated mountains, the ocean floor, river floodplains, and building stone in towns and cities, to name just some of them (Figure 2). Animals that actively build landforms (called “bioconstructions”) include beavers (i.e., dams), termites (i.e., termitaria), and gophers (i.e., mima mounds). In coastal environments, bioconstructions include coral reefs and worm reefs (Figure 2a), which are particularly important for the biodiversity they support. Organisms also create landforms through the removal of rock and sediment, via processes of “bioweathering” and “bioerosion.” Micro-organisms (including bacteria, algae, and fungi) coat most rock surfaces forming biofilms, and are directly involved in the sculpting of rock through chemical and mechanical means (Figure 2b). These processes, alongside weathering of rock under soils and vegetation, can be very efficient on limestone terrain, where “biokarst” is a term sometimes used to describe a distinctive suite of biogenic landforms. In rivers and streams plants are involved in passive landform development, such as the formation of tufa barrages and log jams, and on land vegetation is actively involved in the weathering of bedrock, through the destructive action of roots, and erosion by the displacement of soil during tree-throw.

Importantly, the activities of biota alter the efficacy of co-occurring geomorphological processes. In this way some seemingly small impacts can have wider-reaching geomorphological (and ecological) consequences (Table 1). By building dams, for example, beavers alter river flows, sediment dynamics, and channel morphology. They also create new habitat (ponds and meadows) and alter in-stream conditions for other species. On land, a whole host of organisms influence the development and movement of soil at scales beyond their immediate impact. For example, populations of digging and burrowing animals such as earthworms, badgers, ants, and termites mix, move, and mound soil (called “bioturbation”). By loosening and breaking up the surface, these and other organisms make sediment available for subsequent entrainment and transport by wind and water, contributing to erosion at the hillslope scale (Figure 2c). In arid and semi-arid scrublands and deserts, disturbance of the soil by animals affects vegetation patterns and ecosystem health by redistributing nutrients.
and moisture. Animals such as crayfish and fishes also move and mix sediment in rivers as well as on the ocean floor, just as burrowing and digging animals do on land. Stream vegetation (“macrophytes”) slows down water and can encourage sediment deposition; dead woody material is also very important in river systems, as it affects flow velocity, channel shape, and flood regimes. On rock, microbial bioweathering and bioerosion create simple soils and release vital nutrients for epilithic plants, which is a particularly important process in primary succession (Figure 2d). They also alter rock properties such as roughness and strength, thereby affecting resistance to subsequent breakdown as well as the types and abundance of other organisms that can grow there. At the coast, for example, microscopic cyanobacteria and algae actively bore into rock alongside a whole host of animals including piddocks and urchins. These organisms alter surface topography and the availability of physical habitat niches, such as holes, crevices, and pools, which are important for other species (Figure 2e). The influence of rock type on the activity of these bioeroders (which are typically more common in softer and calcareous rocks) is an example of geological control on the occurrence and rates of biogeomorphic processes. This recognition – that the strength of association between organisms, landforms, and landscapes will vary across space – is an important one, largely dictated by climatic as well as lithological and edaphic factors.

A different type of biogeomorphological interaction is “bioprotection” or “biostabilization” – when organisms actively or passively reduce weathering and erosion. Coral reefs, saltmarshes, and mangroves provide excellent examples of this, as they buffer storm waves. In this way, these features are not only examples of bioconstruction but they have additional consequences for erosion, the morphological evolution of coastlines, and the protection of people that live along the coast. Vegetation can also have a protective role in the terrestrial and built environment. This includes some lichens that shield rock and stone surfaces from deteriorative agents (rain, salts, thermal fluctuations, and pollutants), cushion plants that stabilize rocky debris on mountainous slopes (Figure 2f), and trees,

which can be particularly good stabilizers of soil and slopes via the mechanical reinforcement of roots (Figure 2g). In drylands, where sediment is particularly susceptible to wind deflation due to a lack of cohesive moisture, vegetation acts as a stabilizing agent by binding the surface (reducing “erodibility”) and limiting the erosive power of wind and water (reducing “erosivity”). These influences can drive the spatial and temporal dynamics of entire landscapes, such as the mobility of vegetated dune fields in response to short- and long-term environmental change (Figure 2h). Even micro-organisms contribute to the stability of desert soils, forming biological soil crusts (“biocrusts”) that are more resistant to erosion than the loose soil underneath. Microbial biocrusts and thicker “biorinds” also form through the weathering and geochemical transformation of rock, particularly in harsh environments like deserts.

Ecologically, trophic interactions (between different levels of a food chain) often have important geomorphic consequences. A simple case would be the removal of stabilizing grasses by grazing cattle, which exposes agricultural soils to agents of erosion, or grazing mollusks on rocky shores that feed on microbial biofilms and actively scrape away layers of rock in the process (another form of bioerosion). More complicated examples occur where the actions of one or a few species cause a cascade of impacts throughout the landscape, sometimes called a “trophic cascade” by ecologists. A famous example of this is the reintroduction of gray wolves (Canis lupus) to Yellowstone National Park, USA, in the mid-1990s after being largely eradicated in the 1920s. After reintroduction, the wolves altered the numbers and feeding behavior of elk, enabling trees such as aspen and willow to reestablish where they had been previously excluded by grazing. As more vegetation established, soil erosion from
valleysides was reduced and floodplains and river channels were stabilized, and their morphology altered. This new vegetated landscape provided habitat for a range of other species, including rabbits, bears, and beavers, which themselves have zoogeomorphic impacts. At the community level of enquiry then, where interactions between species become especially relevant for geomorphology, the value of ecological understanding for biogeomorphology is clear. Equally, knowledge of the ways in which the physical environment responds to organisms and ecological processes (i.e., biogeomorphology) has very clear implications for biodiversity and ecosystem function, by constraining physical disturbance regimes and habitat heterogeneity that ultimately feed-back to ecology.

Importantly, rather than occurring in isolation, these types of interactions are often multiple and involve complex feedbacks (Figure 1). In any location many examples of biogeomorphological processes are likely to be found, even if one may be dominant at a particular point in time. On a hillslope, for example, some species are involved in sediment production and transport, some in trapping and consolidating that sediment, whereas others will have a relatively benign geomorphic role. One major future challenge for biogeomorphology, therefore, is to fully understand the whole spectrum of co-occurring influences of species that make up the unique flora and fauna in any particular location. This requires studies to look beyond the one-way geomorphological impacts of single or a few species, to investigate biogeomorphological processes, feedbacks, and their outcomes at larger spatial scales and over longer temporal scales than have typically been studied so far. This is difficult, both conceptually and practically, as it requires collaboration between geomorphologists and ecologists who may ultimately be interested in different things occurring at different scales. Nevertheless, significant progress has already been made here and, as new methods and techniques are established, this will no doubt prove as fruitful as it is necessary for the development of biogeomorphology as a field of research.

**Applied biogeomorphology**

One aspect of biogeomorphology that has rapidly evolved in the last ten years or so is what might be called “applied biogeomorphology”. Just as its parent discipline of geomorphology has gained much from its application to “real-world” problems, biogeomorphological research is also proving a valuable source of understanding and guidance for practitioners and policymakers. Managing the environment in the face of a rapidly changing world dominated by people necessarily requires holistic thinking; biogeomorphology offers one possible framework for this. The portfolio of applied biogeomorphological research is rapidly expanding and covers a diverse range of different problems across many different environments and scales. The restoration and maintenance of vegetated river channels and floodplains, for example, is widely seen as the key to healthy, functional, and resilient fluvial landscapes. Here, understanding of the complex interactions between hydrology, erosion, sediment transport, vegetation, and stream fauna is increasingly applied in efforts to alleviate flood risk, reduce erosion, and conserve biodiversity.

Other examples of applied biogeomorphological research include the reintroduction of native burrowing mammals to improve the health of degraded dryland soils, using tree rings to reconstruct and date past environmental change (“dendrogeomorphology”), examining the roles of microbes and lower plants in the deterioration of built cultural heritage, predicting the response of vegetated landscapes to...
changes in the concentration of atmospheric carbon dioxide, carbon sequestration via enhanced microbial weathering of rock, the response of coral reefs to ocean acidification, and sustainable farming practices to manage soil erosion. The utility of biogeomorphology extends even to other planets, where Earth analogues are proving useful in the search for evidence of life on Mars.

Back on Earth, the use of biological structures and processes to manage environmental problems is sometimes called “ecological engineering” (distinct from ecosystem engineering as previously described). In practice, many examples of this involve facilitating or enhancing the bioprotective roles of some species and biogeomorphic systems. In low-lying coastal areas of Europe, for example, where it is increasingly impractical to use expensive “hard” defenses to protect coasts from rising sea levels, allowing vegetated wetlands to form is becoming a favored option. Other examples include afforestation to manage soil erosion and building artificial log jams to slow down flood flows in rivers. An important aspect of this kind of approach to engineering is that it has the capacity to support biodiversity conservation at the same time, by creating new habitat. Indeed, applied biogeomorphology in general sits very well within the current paradigm of valuation and provision of “ecosystem services” – those goods and services that humans gain from healthy, functional, and therefore resilient ecosystems, many of which are underpinned by biogeomorphological interactions.

With all this in mind, biogeomorphology shows great promise for contributing to the understanding and management of major environmental problems that currently dominate earth system science. This includes climate change, pollution, land degradation, and biodiversity loss. As a holistic field of study, biogeomorphology remains rich in potential and opportunity for cross-cutting, integrative, and pioneering environmental research of real applied value.

Geosciences have experienced a large boom through the development and application of absolute dating techniques. In the 1950s, when radiocarbon dating was first implemented, absolute dating techniques favored a paradigm change in our understanding of Earth surface processes and their dynamics. All of a sudden, geomorphic features and processes could be dated exactly, such that the frequency and magnitude of processes could be studied and quantified in more detail and with a temporal perspective. This led to a better understanding of the relationship between processes and climate, environmental changes and human evolution.

Biological techniques have since been used extensively to gather valuable information about past geomorphic activity (Schneuwly-Bollschweiler, Stoffel, and Rudolf-Miklau 2012). These techniques have in common that they are based on the autotrophic conditions of organisms – such as trees, lichens, or coral – which force them to capture energy to live in a specific environment. These organisms thereby form direct witnesses of environmental changes that are taking place in their biotope and will thus record any change in environmental conditions or geomorphic process activity. As a consequence, they can be used for the absolute dating of features and processes based on the growth rate or growth anomaly of the recording organism. This entry briefly summarizes the current state of knowledge with respect to biological dating procedures and focuses on the application of these techniques in the analysis of geomorphic processes. It reviews the scientific basis of each proxy and discusses its utility and applicability.

Dating geomorphic processes with tree rings

Dendrochronology is the science dealing with the analysis and dating of growth patterns in trees and focuses on species living in temperate zones where rings are formed annually. Abrupt changes in precipitation and temperature regimes drive the meristematic activity of plants in these environments, and thus lead to the production of bands of cells during some parts of the year and no activity during others. The tree-ring patterns visible on cross-sections therefore result from the alternation of growing seasons (typically in spring and summer) and dormant seasons (normally in autumn and winter).

Tree growth and ring formation are influenced by internal (e.g., genetics, age) and external (e.g., moisture, temperature, light) factors. This fact has been used since the 1930s to attribute changes in ring widths or wood density to changing climatic conditions (e.g., precipitation, temperature). In addition, trees have been shown to record a large array of other environmental factors, such as the impact and mechanical disturbance induced by geomorphic process activity (e.g., rockfalls, debris flows, floods, snow avalanches, or erosion processes, just to name a few). Material transported by these processes can...
injure trees (Figure 1), tilt their stems, break their crowns or branches, bury stem bases, and/or expose tree roots. Mechanical disturbances are typically recorded in the tree-ring series, therefore allowing the dating of past geomorphic activity with annual and sometimes even seasonal precision. The approach, called dendrogeomorphology, represents one of the most valuable and precise natural archives for the reconstruction and understanding of geomorphic processes and usually covers the last several hundred years (Stoffel et al. 2010).

The methodological basis of dendrogeomorphology has been described by the process–event–response concept (Shroder 1980). Shroder defines the process as any geomorphic agent, such as a debris flow, snow avalanche, or rockfall, whereas the event is a specific disturbance that a geomorphic process can impact on a tree, such as an injury. The response represents the tree’s reaction to the disturbance; this is the evidence which can be used to date the occurrence of past events (see Figure 1). The following paragraphs describe the main responses of trees to geomorphic processes and form a summary of Stoffel et al. (2010).

One of the most common mechanical disturbances in trees is stem wounds. Impacting rocks and debris can partially remove the bark and destroy the meristematic cambium tissue. Trees react upon this disturbance by compartmentalizing the wounded surface to minimize rot and decay. Tree-ring research uses scars and related features to date the occurrence of past geomorphic events with up to seasonal resolution. After cambial damage, some conifers will form tangential rows of traumatic resin duct (TRD). In broadleaved trees, cambial injuries will typically result in anatomical changes such as reduced vessel sizes.

Tilted trees can be found at places where geomorphic events exert a sudden, unidirectional pressure on the stem (e.g., deposition of material by a debris flow), but also where there has been destabilization of the root plate system by landslides or soil erosion. Trees will respond to tilting with the formation of reaction wood, which can be dated macroscopically through the occurrence of eccentric growth rings in the stem.
Sudden growth suppressions can be seen in trees with crown decapitation or in partially buried trees. In the first case, the crown or branch losses will result in a sudden decrease of photosynthetic activity, and consequently in the growth rate. In the case of stem burial, the sediment deposited around the tree will prevent water and/or nutrient supply to the roots, which in turn will lead to a decrease in growth rates. Exposed roots – mainly reflecting sudden or continuous erosion processes – are characterized by noticeable changes in wood anatomy, and can thus be used as well to infer past geomorphic changes.

Geomorphic activity can also eliminate trees in areas affected by intense processes. Survivor trees tend to benefit from less competition and more light, nutrients, and water availability, so that they will show increased growth rates, yet not always immediately after an event. In addition, new plants may germinate on bare surfaces, so that the minimum age of newly germinating plants can be used to estimate the age of new landforms.

Pioneering studies in dendrogeomorphology date back to the 1960s, and focused mainly on soil erosion and floods. The use of tree-ring records has since been expanded considerably to include a large range of processes and to contribute to a better understanding of spatiotemporal patterns of mass movement activity. Stoffel et al. (2010) provide a state-of-the-art overview with illustrative examples showing how tree rings have helped to extend chronologies of processes and to determine climatic and environmental controls of process activity.

**Lichenometry**

Lichenometry is a biological dating technique using lichen growth to assess the age of exposed rock surfaces, based on a presumed specific rate of increase in the radial size of lichen over time. Measuring the diameter of the largest lichen of a species on a rock surface can thus be used to determine the amount of time a rock has been exposed. The method has been applied typically to estimate the minimum age of monuments, but also for the absolute dating of geomorphic deposits. Lichenometry has been used most frequently to date glacial deposits in tundra environments, but has also focused on the analysis of lake level changes, paleofloods, rockfalls, and snow cover persistence.

The approach is based on the principle that lichen growth – an association between an algae and a fungus – represents a site- and species-dependent process (Innes 1985). General growth rates at a specific site are determined using lichen sizes on objects of known age which are then compared to sizes of lichen growing on objects of unknown age. Lichenometry therefore is a very useful and efficient technique (i) when it comes to the analysis of processes beyond the upper limit of forests, and/or (ii) to complement dendrogeomorphic studies suffering from a limited number of old, disturbed trees.

Control points of the reference chronology typically include anthropogenic surfaces such as monuments, buildings, or cemetery headstones. Natural surfaces – dated with tree rings or historical sources – have been used in the past as well (Figure 2a). Because its ecotone covers different geographical environments, and as it can live under severe climatic conditions, *Rhizocarpon* is generally considered the most valuable species in lichenometry (Figure 2b). This species is characterized by its yellow–greenish color, a short thallus with angular areoles, and the easily recognizable circular shape. Traditional measurements of lichens were carried out with a millimetric feeler, which has been replaced more recently by photographic techniques. As a result of asynchrony between lichen sizes within the same geomorphic feature, Beschel (1950)
Figure 2  (a) The age of the different generations of debris-flow deposits can be dated by means of tree-ring analysis. (b) *Rhizocarpon geographicum* growing on a gneissic boulder transported by a flash flood in the Spanish Central System. postulated in his pioneering paper that only the largest, first-colonizing specimens should be measured on a specific geomorphic feature. In his work, he explored glacier extension and recent retreat in the European Alps by measuring the size of *Rhizocarpon* sp.
Different procedures have since been suggested to measure lichens in the field, such as the average value of largest individuals growing on a specific surface. More recently, a somewhat different statistical procedure has been suggested where the size distribution, including generalized extreme value (GEV) distribution, is assessed using a Bayesian hierarchical value model (Schneuwly-Bollscheiwer, Stoffel, and Rudolf-Miklau 2012).

Coral dating

Corals are marine invertebrates belonging to the class of Anthozoa of the phylum Cnidaria. They typically live in compact colonies of many identical individual polyps. Corals include the important reef builders that inhabit tropical oceans; these reef builders secrete calcium carbonate to form a hard skeleton (Figure 2c). The corals inhabiting shallow subtropical seas are autotrophic individuals which are adding seasonal layers composed primarily of hard calcium carbonate shells. Similar to trees, corals are very sensitive recorders of environmental changes and their growth will depend chiefly on nutrient availability and on small changes in temperature, rainfall, and water clarity. As a consequence, coral growth can be used as a valuable paleoenvironmental recorder of temperature change in tropical and subtropical oceans, changes in atmospheric circulation, pollution, and the occurrence of large floods. Changes in band density are thereby used to identify and date growth-limiting factors and to interpret changes in coral environments (Le Tissier et al. 1994). Sampling is somewhat more complex than in dendrochronology and lichenometry as it involves the drilling of skeleton calcium cores. Sample preparation consists in the cutting of thick slices from cores and their embedding in resin. The relative dating procedure of corals consists in a visual counting of individual growth bands, whereas the absolute age of corals can be obtained if density variations of annual bands are combined with chemical parameters. Changes in the \(^{18}\text{O}/^{16}\text{O}\) ratio have been used to provide a record of temperature and precipitation changes during the growing season of corals, so as to determine large-scale climatic patterns related to the El Niño Southern Oscillation (ENSO; Rimbu et al. 2003). Large amounts of sediments have been demonstrated to significantly alter the light absorption of certain algae so that the nutrient availability for corals is affected, which in turn has a negative impact on the development of coral structures, which thus allows the detection and precise dating of past, intense paleofloods (Deschamps et al. 2012).

Challenges, applicability, and limitations of biological dating techniques

This contribution has shed light on the potential of biological techniques for the absolute dating of geomorphic and/or climatic events over periods of several centuries and for different physiogeographical environments. The widespread applicability of biological techniques and the high sensitivity of the recorder organisms to environmental changes have improved our understanding of various environmental processes and changes, with previously unequalled spatial and temporal resolution. Table 1 and Figure 3 summarize the main characteristics of the three biological proxies presented here and highlight the main potential and some limitations of these different approaches.

Over the course of the past few decades, the breadth of application of these techniques as well as a multitude of methodological improvements

have clearly expanded the fields and areas for which biological dating can be used. It can thus be expected that more and more precise data will be gathered soon on various geomorphic processes and in areas which have been studied only poorly so far. The main challenge of present-day applications of biological dating techniques may thus reside in a better understanding of the detailed response of different species to environmental changes and in adding complementary analytical techniques (such as trace elements or stable isotopes) to infer the climatic characteristics of these environmental changes.

References

“Biome” is a unit of biological classification. It refers to large areas with similar vegetation, primarily defined by its physiognomy (particularly its structure, as in herbaceous, shrub, or tree, its leaf type, and its spacing of the largest plants) and to a lesser extent by its associated animals (although the addition of animals was meant to differentiate the biome concept from the vegetation classification of “formation”; see Phytosociology). In size it is the most extensive and in concept the most general within the planetary biosphere (although some systems place it lower than an ecorezone, which would be a biome in other systems). Examples, individually covered elsewhere in this encyclopedia, include extensive areas of broadleaf evergreen trees (tropical rainforest) and herbaceous graminoids and forbs (grasslands). However, the specification of individual biomes, their numbers, and their borders, are a matter of choices made, as with any classification system. Most work on biomes is limited to the terrestrial realm, but the classification of aquatic and marine biomes is ongoing (see Ocean biogeography and Stream ecosystems), although some are being defined as ecoregions (e.g., www.worldwildlife.org/biomes).

The difference in the identification and number of biomes is a matter of splitting or lumping. The most highly differentiated system was that of Whittaker (1975), who listed 36 biome types, including aquatic biomes. The more conservative are in the range of seven terrestrial biomes.

The minimal number of biomes is likely the six defined by the University of California Museum of Paleontology (www.ucmp.berkeley.edu/exhibits/biomes/index.php): Freshwater, Marine, Desert, Forest, Grassland, and Tundra. A number of hierarchical systems have been developed that subdivide biomes into ecoregions or ecosystems. The World Wildlife Fund for Nature (WWF) system is a useful representation of the biome concept (Figure 1; Olson et al. 2001). Its 14 major terrestrial divisions are as follows.

- Tropical and subtropical moist broadleaf forests
- Tropical and subtropical dry broadleaf forests
- Tropical and subtropical coniferous forests
- Temperate broadleaf and mixed forests
- Temperate coniferous forests
- Boreal forests/taiga
- Tropical and subtropical grasslands, savannas, and shrublands
- Temperate grasslands, savannas, and shrublands
- Flooded grasslands and savannas
- Montane grasslands and shrublands
- Tundra
- Mediterranean forests, woodlands, and scrub or sclerophyll forests
- Deserts and xeric shrublands
- Mangrove

The boundaries between biomes are also uncertain because the change from one type of vegetation to another is often a transition in dominance, not an abrupt switch. These transitions, or ecotones, are important biogeographical features and are discussed elsewhere in this encyclopedia.
Biomes are often used as a basis for inferring relations or processes in global biogeography. For example, global patterns of net primary productivity are reported for biomes based on samples within one particular definition; in more informative instances, the range is also given.

Overall, the foremost use of the biome concept is in teaching the basic relations of climate and biogeography. The common approach is to describe the physiognomic types as adaptations to maximize net primary productivity given the climate. For example, the boreal forest has needle-leaf evergreen trees because the evergreen condition maximized productivity in the short growing season while the needle leaf can survive the winters; conversely, tropical rainforests have evergreen trees given that photosynthesis continues year-round, but are broadleaved because such leaves are more efficient at capturing energy while not constrained to survive a season of low temperatures (or water); and between, mid-latitude forests are broadleaved and deciduous where the growing season is long enough that the time and energy spent in producing new leaves in the spring is compensated for by having the more efficient broad leaves for the rest of the season, from which reserves are withdrawn and which are dropped before being killed by
cold. Similar narratives work for a gradient of precipitation. This presentation is usually complemented by noting that the biome limit in the direction of greater resource (equator-ward for the boreal and mid-latitude forests) is more due to competition than to a milder climate (i.e., more resources for productivity). The low-resource abiotic/high-resource biotic limit for the biomes narrative is being modified to emphasize multispecies interactions in all cases, and to recognize the role of microbes.

A recent addition to the biome concept is the microbiome (see Microbial biogeography). While the ubiquity of microbes has long been recognized, the ability to differentiate them through new genomic technology has allowed new classifications and differentiation of this part of the biosphere. While the spatial extents seem small, the tiny size, large numbers, and high diversity (estimates have the number of microbial cells in the human body outnumbering the number of human cells 10:1 and the number of microbial genes outnumbering human genes 100:1; http://commonfund.nih.gov/hmp/overview) mean that microbes could have a biogeography as rich and diverse as all the macrobes on the planet.

Yet another addition to the biome concept is the anthropogenic biome. Ellis and Ramankutty (2008) identified 18 anthropogenic biomes ranging in extent and intensity of use from remote rangelands to urban areas, with only 25% of the terrestrial surface and 10% of terrestrial net primary productivity in nonanthropogenic biomes of forest, sparse tree, and barren land. From these nonanthropogenic biomes to urban biomes, they described gradients in land use and land cover, net primary productivity, carbon emissions, reactive nitrogen, and native and introduced biodiversity. One conclusion is the need to more closely examine human-dominated landscapes (see Urban biogeography and Agricultural environments).

The biome concept is being reinvigorated beyond a teaching tool by the developments in anthropic and microbial biogeography. As these new ideas become common in textbooks in biogeography, the biome concept will be strengthened for the field.

Biopolitics

Claudio Minca

Wageningen University, Netherlands

The notion of biopolitics and the “biopolitical turn” are at the core of many contemporary debates in the social sciences and the humanities, including human geography. Incorporating the concepts of both life and politics, biopolitics is seen to underlie discussions from the global mobility of migrants and refugees to the “war on terror,” from questions concerning biosecurity to questions of public health and the welfare state, from the pervasive tendency to establish new states of exception and emergency regimes, to the battle over new forms of population management. Crucially, biopolitics also facilitates broader debates over the “politics of life” concerning family values, abortion, and euthanasia, as well as reconceptualizations of the human body associated with the emergence of new biotechnologies and biomedical interventions.

Among political scientists, there exist positions supporting a positivist interpretation of these intersections of medicine, life sciences, technoscience, and politics. These readings, fundamentally based on the belief in the possibility of understanding political behavior via biology, are, however, contrasted by a growing body of critical literature that has questioned the basic assumptions and also the effects of considering society and politics in biological terms. In this sense, the critical, poststructuralist literature often proposes “negative” interpretations of biopolitics, viewing it as a modern form of sovereign power to be resisted for its violence and penetration into people’s lives. At the same time, some within this trend of critical thinking advance different forms of “affirmative biopolitics,” where the biopolitical is recognized as an alternative domain of empowerment and a different kind of politics to be embraced.

Despite often being characterized by distinctive disciplinary approaches to the politicization of life, works informed by critical readings of biopolitics share some common key stances across the board. First, they acknowledge the need to reflect on the role of science in forging “the social” from the nineteenth century onward, while at the same time they dismiss the assumption that culture and society can be explained merely in biological terms. They also recognize the crucial relevance of biopolitics in determining contemporary political subjectivities, a reason why they find the positivist approach to (bio)politics untenable and fundamentally deterministic. Second, most of them identify Michel Foucault as the initiator of the contemporary academic interest in biopolitics and of the putative biopolitical turn in the social sciences and the humanities. They also recognize the impact of most recent reinterpretations of biopolitics on the part of Italian philosopher Giorgio Agamben, although sometimes in rather critical terms. Third, they tend to remark on the role played by the Bush doctrine in determining new biopolitical interventions based on biometrics and biosecurity in reaction to the terrorist attacks of 9/11. Finally, they often take into consideration new conceptualizations of the body and of what “the human” is in relation to the emergence of biotechnologies. In this context, geography has largely incorporated biopolitics as a critical form of analytics and has accordingly...
entirely rejected the positivist interpretations proposed by those political scientists relying on the life science model of investigation of the real.

**Bio-geopolitical roots**

A crucial aspect of the definition of biopolitics is that concerning the origins of the term and how these may have affected its present use. Diverse genealogical reconstructions are offered by different fields and in relation to the various national academic contexts. However, a degree of consensus exists that these origins must be traced back to manifestations of biopower inaugurated by the secularized modern state from the nineteenth century onward. Eugenics, for example, is identified as an important and widely diffused form of implementation of such biopower and governance during the past century. This was an approach to life and politics that would tragically feed into the genocidal thanatopolitics exercised by the most biopolitical of all regimes realized, Hitler’s Third Reich.

It has been suggested that the term “biopolitics” was coined by political scientist Rudolf Kjellén (who, perhaps not incidentally, also coined the term “geopolitics”) in the second decade of the twentieth century, in line with the Lebenphilosophie tradition, the life philosophy that has had such an important influence on the German culture of modernity (see Lemke 2010). Other reconstructions, while acknowledging this first use of the term, however, maintain that the origin of “biopolitical thinking” may be traced back to the positivist attempts on the part of nineteenth-century French life scientists to identify prescriptive interpretations of social and political behavior in order to implement policies capable of improving the quality of the body politic. Contemporary Italian political philosophers (see, among others, Esposito 2008), for example, suggest that the deterministic view at the origin of the positivistic approach to biopolitics was already outlined in an embryonic form in the concept of biocratie (biocracy) adopted by August Comte in the 1850s. Biocracy refers to the form of government required to realize a society where a purely biological understanding of life would coincide with social, cultural, and political life. The term “biocracy” reappeared at the very beginning of the 1900s in the writings of hygienist Edward Toulouse, where pedagogy, psychiatry, and mental hygiene were assigned a fundamental role in forging and improving the social body. In the same positivist lineage, biopolitics was also explicitly theorized by Marley Roberts in his 1938 *Bio-politics: An Essay in the Physiology, Pathology and Politics of the Social and Somatic Organism*, an attempt to propose pathology as a key political technology in identifying and governing “normality.”

From the 1960s onward, a growing stream of positivist research on biopolitics in English-speaking academia consolidated around two broadly defined research trajectories, social Darwinism and ethology, both largely based on a purely technical and biological reading of the political (see Esposito 2008). Biopolitics was presented once again, especially using neurology, pharmacology, and molecular biology, with the objective of explaining human nature and political behavior. A parallel trend of biopolitics was registered in France in about the same period. Despite the French roots of positivism and social Darwinism, this trend appeared as more inclined to incorporate humanistic pedagogic interpretations of human nature in the face of dominant capitalism in shaping the social and exploiting the human body. Two exemplary cases of this approach are considered to be Aaron Starobinski’s *La biopolitique: Essai d’interprétation de l’histoire de l’humanité et des civilisations* (Biopolitics: An Essay on the History of
Humanity and Civilization) and Edgar Morin’s *Introduction a la politique dell’homme* (Introduction to a Politics of Man). In the meanwhile, positivist research lines have continued to be developed in the French- and English-speaking traditions, but they have been fundamentally ignored by the work of human geographers and by most debates on biopolitics in the social sciences and the humanities.

Italian philosophers Giorgio Agamben and Giorgio Cavalletti also identify a presumed geographical origin of the term “biopolitics,” implicitly recognized in a trajectory originating from Kjellén and the geographer Frederic Ratzel. The Ratzelian concept of population as a geographical spatial calculative political technology is indeed seen by Cavalletti as typical of the modern organic state, which sees the “geo” and the “bio” as co-implicated in its attempt to politicize living/vital spatialities. This interpretive line is also endorsed by sociologist Thomas Lemke, who claims that the concept of biopolitics emerges from Kjellén’s organicist idea of the state as a “living form” (*Lebensform*). Furthermore, philosopher Roberto Esposito suggests that this process of the naturalization of politics in Kjellén’s historical-cultural framework must be seen in parallel to the influential work of Baron Jakob von Uexküll, who in 1920 put forth the idea that the German state’s vital demands and potential pathology should be compared to the body’s anatomy and physiology.

Kjellén’s belief in the state as a living organism had an impact on many social scientists and life scientists of his time. One of them was the geographer Karl Haushofer, whose elaboration of the same approach suited what were clearly racist applications, in line with the spatial ideology of the Nazi *Lebensraum* (living/vital space). Haushofer played a prominent role in shaping the *Geopolitik* agenda and in founding the popular journal *Zeitschrift für Geopolitik* in 1924, where a 1933 article stated that the “natural science” of the state involves both biopolitics (the historical development) and geopolitics (the spatial development) of the state. This organicist state would soon become a purely racial state under Hitler’s rule, guided as it was by the objective of forging a new German Man together with a biologically homogeneous national community. Hitler’s biocracy was the first state to be mainly organized around the task of eliminating pathological human presences from the state’s organic body in space. The biopolitical and the geographical as understood by the Nazi radical ideologues thus united as one and the same, fused in the millennial horizon of the Third Reich. How these lines of positivist research on biopolitics intersected and influenced each other and how their legacy persists in the work of positivist social scientists today remains to be investigated in detail.

As already spelled out earlier, Foucault is commonly identified as the founding father of present-day critical debates on biopolitics. According to Campbell and Sitze (2013), mainstream anglophone critical social theory, in attempting to develop a theory capable of exploring both “life” and “politics,” has largely relied on Foucault’s pathbreaking work in the 1970s. Starting from his first writing of “bio-politics” in the 1976 essay “Right of Death and Power over Life” (Foucault 2013), Foucault’s analysis of the effects of the new “politics of life” in modern society is essential in reflecting on the biopolitical in geography and on the related biopolitical spatial regimes centered around population government. For Foucault, in fact, a whole system of surveillance, hierarchies, inspections, bookkeeping, and reports was established at the end of the seventeenth century and during the course of the eighteenth century. He identified the system as the emerging of a new technology of power, a “biopolitics.”
In the humanities and the social sciences today, many acknowledge Agamben’s writings (1998) to be among the most significant contributions to a reformulation of Foucauldian biopolitics, and to have brought biopolitics to the frontline of philosophical discussions. While Agamben identifies the enactments of sovereign power with the production of biopolitical regime and of “bare life” in modern politics, a number of further developments in biopolitical thought have taken the debate to different shores. This array of interventions, well beyond the field of philosophy, engage directly or indirectly with the Foucauldian take on the biopolitical. One example is the rather controversial appropriation of his work by Michael Hardt and Antonio Negri in *Empire* (2000), where they envisage a new stage of capitalism – a biocapitalism characterized by the coming together of economy and politics, (bio)creativity, and the body. Other equally important interventions critically reread Foucault (and often also Agamben) in light of recent technological and political developments, proposing new interpretations of contemporary biopower. These include, among many others, the work of Bruno Latour on the social and political role of life sciences, Jacques Rancière on policy and biopolitics, Donna Haraway on the postmodern body, Paul Rabinow on the new forms of anthropos, Nikolas Rose (2006) on “the politics of life itself,” and Achille Mbembe on the production of necropolitics. The most recent translations of Roberto Esposito’s essays on the biopolitical paradigm of immunity have also been incorporated in international debates preoccupied with new forms of governance of life. The result of these and many other similar interventions is what some identify as a biopolitical turn in diverse fields including, but not limited to, geography, political science, anthropology, and sociology.

**Geography and the biopolitical**

After decades of influence of Foucault’s work combined with the other scholarly contributions mentioned earlier, human geography “turned” biopolitical, especially starting from the 2000s. On the one hand, the discipline has seen profound theoretical work done in relation to the politics of life. Agamben’s work has been subjected to in-depth geographical readings, while present-day “vital geographies,” ethics, and the “value of life” and death have become topics of prime concern. Reflections are also made, for example, with regards to the ethico-aesthetics of life and bioethics in Félix Guattari, and with reference to Jacques Derrida’s speculations on “the beast and the sovereign,” while in other cases bare life is analyzed according to gendered biopolitics and its spatial projections. On the other hand, in an effort to understand how past and current geographical practices may imply a biopolitical dimension, and what the implications of these practices may be, geographers mostly incorporate biopolitics as a form of analytics in examining manifestations of biopower and their spatial representations and practices (for a recent review of geographers’ work on biopolitics, see Minca 2015).

For some, geography’s biopolitical turn has opened the door to historical investigations on the relationship between the “bio” and the “geo.” Two routes have been pursued in this respect: one focused on the Nazi bio-geopolitical technologies, largely influenced by Agamben’s work; the other, perhaps much more significant in terms of its impact on the discipline, focused on the biopolitics of colonialism and its post-colonial consequences. Several empirical studies have detailed postcolonial legacies and some of their biopolitical effects in relation to the “colonial present,” including the consequences of the new technologically driven ways of
waging war and, for instance, the biopolitics of “food provisioning” in colonial and postcolonial contexts.

Other major contemporary topics, especially in political geography, have also been examined in a biopolitical framework. Key areas of investigation are the new geographies of biosecurity, the “war on terror,” as well as the interventions in government of people’s (im)mobilities. Both conceptual and empirical work thus deal with the interrelated proliferation of spaces of exception, carceral geographies, new forms of bordering and border management, and relevant ideas of hospitality and/or encampment. The questions of sovereign exception and bare life are often evoked in these studies, while the specific issues include migration control, detention, airport biometrics, and the management of refugees, asylum-seekers, and stateless individuals.

In this vein, camp studies in geography have investigated sites ranging from Guantanamo to Auschwitz, to Khmer Rouge Cambodia, to the present-day camps in Lebanon and Palestine. Many of these studies draw directly or indirectly, and sometimes rather critically, on Agamben’s speculations on the camp as a biopolitical space of exception. Meanwhile, vast and rich material available on domicile citizenship, biological citizenship, and even postcitizenship has emerged recently in geographical fora. These redefinitions of the principles of citizenship and of the right to mobility have been part of the broader interdisciplinary efforts to understand the biopolitical regimes imposed on the growing masses of people fleeing situations of danger and emergency.

Other closely related research clusters around population governance and the shaping of the body politic. For one, the changing welfare state and the neoliberal state’s biopolitical operations have prompted timely scholarly interventions. Emphasis is placed on the following aspects: the state’s medical and family “care and management”; affect in biopolitics linked to the effects of neoliberal forms of biocapitalism and of global interventions against real or presumed terrorist threats; the calculative rationalities of state institutions that traditionally underpinned the constitution of specific “population regimes”; the workings of governmentality according to the new readings of Foucault; the management of emergency and its accompanying spatial strategies and conceptualizations of the individual body. Research on the effects of neoliberalism has furthermore interrogated “laboring bodies” and liberal “care” as expressed by biological and financial citizenship. In a similar context, global health and biosecurity have gained much attention, with the biopolitical understandings of public health, disease, and epidemic management playing an important role. These are complemented by work related to the state mentioned earlier. An equally crucial theme for geographers’ biopolitical analyses concerns the spaces of humanitarian intervention in relation to broader geopolitical scenarios and imaginations.

Finally, the even broader “politics of life” has entered debates in geography, largely based on reinterpretations of the Foucauldian/Agambenian legacy while incorporating the work of other scholars. This approach covers the realms of the more-than-human geographies and animal geographies, as well as biopolitical readings of major environmental issues, thus inaugurating a brave new field of investigation for nature geographies. Some work in geography has, for example, offered a biopolitical perspective on past and contemporary policies of “rewilding” nature. Animal subjectivity is analyzed in relation to livestock breeding. In conservation biology, biopolitics also inspires research and reflection on environmental risk and safety, and the realization of “biopolitical environmental citizens.” The new ecologies of global capitalism
bringing up questions of resilience, sustainable development, and climate change have also been studied through biopolitical lenses. Discussions expand into considering the Anthropocene and necropolitics. All these represent the rich heterogeneity of interventions enlivening today’s key geographical fora. In light of rapid biotechnological change and of the expansion of geopolitical interventionism on a global scale, the biopolitical turn seems to have a growing and enduring impact on the discipline.

Further reading

The concept of biopower is no longer new to geography and other fields in the humanities and social sciences. The precise intellectual origins of this term are difficult to identify and the ideas that it encapsulate have not remained static. However, it has been the work of the poststructural social theorist Michel Foucault that has spurred the adoption and popularization of this concept as an important tool for the analysis of a variety of social spaces, right from colonial policies to present-day slaughterhouses. Foucault’s (2008, 138) elaboration of biopower as the power “to foster life or disallow it to the point of death” has formed the basis of a substantial corpus of empirical and theoretical scholarship that has used, interrogated, and modified this concept for the examination of the complexities of flows of power in contemporary society. The significance of Foucault’s work on biopower for its subsequent interpretations and applications in the social sciences and humanities thus makes familiarity with his elucidation of the concept essential.

The power over life

Foucault, at the most basic level, was concerned with the subtle and diverse ways in which power functions in society and penetrates all layers of social interaction. His signature contribution was to theorize forms and mechanisms of power that are not repressive or obviously negative and harmful. Foucault develops these ideas on power through the examination of historical texts on the nature of state rule, judicial systems, sexuality, town planning, and economic theory in Europe, offering a schema that distinguishes between sovereign and non-sovereign forms of power.

Foucault introduces the term “biopower” in the first volume of History of Sexuality (2008) where he describes changes in mechanisms of state rule in eighteenth-century Western Europe and develops an expanded understanding of the forms and functioning of power. Traditionally, power is associated with sovereignty – of a monarch, a political group, a class, a caste, a gender, maybe even a species – and therefore, with repression and dominion. This kind of sovereign power is focused on “deduction and death,” and is founded on a “right of seizure: of things, time, bodies, and ultimately life itself” (Foucault 2008, 89, 136).

Until around the end of the sixteenth century, Foucault observes, state rule was largely based on the monarch’s right to take the lives of subjects – or the corollary – to let them live. The principal objective of rule was to protect the interests of the sovereign. Such rule used mainly negative or deductive mechanisms of power such as rules, taxes, and punishments, and was often enacted by force. In this period, it was not uncommon to see public displays of violent punishment, especially directed at those who threatened the sovereign.

In the seventeenth and eighteenth centuries, Foucault notes that texts on state rule indicate a shift in modes of rule. Instead of rule based on the threat of death and violence, this period sees a transition to nonrepressive
mechanisms of rule that were focused on regulating and fostering life. Foucault uses the umbrella term “biopower” – the “power over life” (2008, 139) – to refer to these. In his telling, biopower is a positive form of power that is aimed at “generating forces, making them grow, and ordering them, rather than … impeding them, making them submit, or destroying them” (Foucault 2008, 136). To Foucault, biopower does not replace sovereign power; rather sovereignty, discipline, and biopower are a triad of distinct but copresent forms of power that imbue social relations in the contemporary world.

Biopower, as theorized by Foucault, is exercised along two principal axes: an anatamopolitical axis that targets individuals through mechanisms of discipline to make them well-functioning and suitable members of society, and a biopolitical axis that targets the characteristics of populations and collectives in efforts to enhance overall welfare and security. These two axes come together as biopower which seeks to regulate populations and reduce the randomness inherent in life processes in order to achieve a hypothetical optimal stability. Biopower is thus simultaneously individualizing (through its disciplinary mechanisms) as well as totalizing (through its biopolitical mechanisms).

Foucault further writes that biopower is associated with pastoral rationalities and practices of care and flourishing which are aimed at managing life and life processes at the level of the population or some other kind of grouping. Biopolitical mechanisms try to shape life so as to suit certain ends, and when life is not considered valuable or suitable, it is merely “let die.” The exercise of biopower involves decentralization (Gordon 1991). Biopower is not wielded by just one authority, but operates through and at multiple layers of society, at microscopic levels and through unexpected actors, including families, nonprofit organizations, hospitals, private companies, and the academia. Biopower is dispersed; it is wielded at many levels, through many rationalities, and through many creative techniques; this complicates the task of identifying individuals (or specific social groups) as sources or sites of power, or as heroes or villains.

Foucault develops these observations on biopower in the History of Sexuality (2008), lectures at the Collège de France (2009), and various interviews. While he does not use the exact term “biopower” very often, his works on governmentality and pastoral power are recognized as building on and taking forward the conceptualization of biopower and non-sovereign modalities of power more broadly (Dean 2010). In this extensive corpus, which has been taken forward by scholars from a range of disciplines, it is possible to identify four themes that are central to the understanding of biopower: population, governmentality, the welfare–violence nexus, and subjectification.

**Population**

The idea of population lies at the heart of Foucauldian theorization of biopower. Biopower functions to enhance the wellbeing and fostering of the subject-objects of power at the scale of the population or collective. In other words, biopower is exercised in the name of the wellbeing of all, in the name of the “health, prosperity and happiness of the population” (Dean 2010, 27). Biopolitical interventions might work on and through individuals, but it is the population that is the main target – the main subject-object – of biopolitical power. In the context of biopower, the population is not merely a collection of individuals; it is an entity in and of itself, which has meaning, value, and significance beyond what can be attributed to the
individuals that constitute it. While Foucault’s initial use of the term “population” was tied to territory and the nation-state, it has since been expanded by social theorists Paul Rabinow and Nikolas Rose (2006) with the use of the term “biosocial collectivity” to signify human groups that are tied together through links such as gender, race, or other forms of shared identity. Biosocial collectivity has also been used by geographers to refer to groupings that include nonhuman life, whether nonhuman animals or biodiversity as a whole (Holloway et al. 2009; Srinivasan 2014).

Governmentality

Governmentality refers to a way of thinking and acting that is critical to the exercise of biopower. Governmentality incorporates the belief that the regulation and management of the population and its various traits and processes “is not only necessary but also possible” (Dean 2010, 44). In his work on governmentality and security, Foucault shows that in contrast to sovereign power mechanisms that lay down totalitarian laws or prohibitions and attempt to suppress or forbid undesirable activities, biopower works alongside and makes use of existing biological and socioeconomic rhythms and patterns in the population that is the subject-object of power (Foucault 2009). Here, management is achieved by permitting certain levels of unwanted phenomena in a population but keeping them below what would adversely impact the population as a whole. It is this “ordering” of life forces (2008, 136) that Foucault refers to as governmentality. Governmentality enhances the efficiency and subtlety of power by using the very subject-object of power and its rhythms as aids for its functioning.

The work of other scholars, such as Dean (2010), has contributed to the elaboration of the meaning and scope of the idea of governmentality. It is now widely acknowledged that governmentality can be seen in a range of social domains, whether colonialism, international development, or environmentalism (Agrawal 2005; Li 2007). This literature explains that while government is a calculated, goal-directed activity, the norms and ends of regulation are taken for granted; the main concern of government is the means, the how of regulation, which is understood as a matter for technical investigation rather than normative reflection. A certain utopianism marks governmentality in that any failure to achieve the objectives of government does not lead to the disruption of the goals, mentalities, and techniques of government, but instead often leads to calls to reinforce and strengthen the same governmental interventions (Foucault 1977).

Governmental processes are also enmeshed with the production of particular truths, norms, and knowledges which enable power to be exercised without enforcement and threat. In particular, the production of statistics and the circumscription of the population which is the object of intervention have been observed as being key to the exercise of governmental power (Agrawal 2005; Foucault 2009; Holloway et al. 2009). Governmentality thus goes alongside the emergence and deployment of “truths” and “norms” – and the production of formal knowledge bodies which are indispensable for the efficient exercise of power (Gordon 1991). Most importantly, the governmentality literature suggests that any analysis of power must necessarily consider “how we govern … [and the] techniques and other means employed” in the process of government (Dean 2010, 18, 27). This attention to the specific technologies and rationalities of power is a particularly important and distinctive feature of the analytical toolkit offered by biopower.
Welfare and violence

Another vital characteristic of biopower is the intertwining of discourses and practices of harm and care, or as Gordon (1991, 12) puts it, in the exercise of biopower, “welfare is conjoined to exploitation.” Foucault explains that biopower’s focus on the good life, care, and wellbeing does not mean that violence and killing are removed from the equation. What alters is the justification. In the context of state rule in eighteenth-century Western Europe, Foucault observes that while the violent rule typical of sovereign power was validated in the name of the sovereign, biopolitical technologies were explained as necessary for the wellbeing of the population, as on “behalf of the existence of everyone … in the name of life necessity” (2008, 136). In other words, the entanglement of welfare and violence in biopower can be understood in terms of trade-offs between individuals and populations: biopower intervenes harmfully on and governs individuals in the name of universal wellbeing. As Dean (2010, 170) points out, an example of this entanglement can be seen in China’s one-child policy, which targets “imprudent parents and their potential offspring.”

In doing this, biopower treats individuals as not only expendable and of lesser importance but also entities to be managed and intervened upon so that they contribute to collective development and wellbeing (Srinivasan 2014). This means that under biopolitical regimes, the ethical and political significance of individuals is reduced; individuals instead become “the instrument, relay, or condition for obtaining something at the level of the population” (Foucault 2009, 42). In fact, biopower often functions so that those who “resist the regulation of the population” are excluded and subject to techniques of repression such as “exile, death and punishment” (Foucault 2009, 44).

Subjectification

The notion of subjectification or self-governance is key to Foucauldian scholarship on biopolitical and governmental power. Subjectification underlies the functioning of biopolitical power, that is, it is the motor of biopower. Subjectification refers to the process by which individual entities internalize various truth discourses about individual and population/collective wellbeing, and self-govern, that is, work upon themselves, in accordance with these discourses. For instance, in History of Sexuality, Foucault describes how norms on sexual behaviors work so as to encourage a particular form of stable family life. These stable families in turn were necessary for the smooth functioning of society as a whole. Biopower therefore works through the internalization of norms, by inculcating subjectivities (or elements of subjectivities) rather than through the external imposition of rules that dictate dos and don’ts (Rabinow and Rose 2006).

The impacts of self-governance are not always positive for the individual and could even be detrimental to their wellbeing. However, subjectification, that is, the internalization of certain norms, has the effect that the outcomes and consequences of self-governance for the individual are not explicitly evaluated. Subjectification thus enhances the efficiency of the operation of power by making acceptable and incontestable even negative impacts of self-governance and by reducing the need for externally imposed interventions. Whereas sovereign power is exercised through force and imposition, biopolitical power is exercised by means of norms and discourses of care and flourishing that make individuals self-governing subjects. Therefore, techniques of biopower, being underpinned by subjectification, even if not strictly harmless in their impacts, are more subtle and less likely to invite resistance in comparison with techniques.
of sovereign power that depend upon external force and domination.

**Biopower: applications and debates**

Biopower and the related concept of governmentality have been used in geography and the wider social sciences to examine a range of topics and theoretical concerns. This includes analyses of neoliberal policies and programs, contemporary geopolitics, food security, urban ecologies, ethical consumption, developments in biomedicine, food production, colonialism, development practice, and environmental regulation, to name a few domains in which the biopolitical frame has been usefully applied to understand the complex manners in which human life is and has been managed in the present and recent past.

The concept of biopower was originally developed for the analysis of power in human relationships, and the rich vein of scholarship that has taken forward its theorization has also focused principally on the human domain. However, recent years have seen increasing application of the biopolitical schema for more-than-human inquiry; that is, the examination of human–environment and human–animal relations. This literature takes as its starting point the focus of the biopolitical framework on the ambiguities of efforts to foster and regulate both human and nonhuman life (Agrawal 2005; Demeritt 2001), and demonstrates its relevance to a variety of more-than-human domains, from spaces of care such as animal welfare (Srinivasan 2013) and biodiversity conservation (Srinivasan 2014; Chrulew 2011) to spaces of exploitation such as livestock agriculture (Holloway et al. 2009). In much of this literature, the intertwining of harm and care in human interactions with nonhuman life-forms appears as a central issue for critical reflection.

While this body of work has offered crucial insights regarding the play of biopower in human–animal/environment interactions, questions have been raised about the limits of the biopolitical framework when it comes to understanding and analyzing more-than-human spaces. This has particularly been in respect to the processes of normalization, subject-formation, and self-regulation that are understood as driving biopower in intrahuman relations, but that are less plausible in human–nonhuman relations (Demeritt 2001). In addressing this problem, geographers have put forward and elaborated on the concepts of relational (Holloway et al. 2009) and agential subjectification (Srinivasan 2013, 2014), wherein subjectification is seen in those humans who act for, or on behalf of, animals. The writings have therefore been productive in theoretically developing biopower as an analytical tool by highlighting the different sites and relational manners in which subjectification can take place.

The concept of biopower has sparked much theoretical debate over the years. One significant line of argument has been around the twin flavors of harm and care running through Foucault’s work on biopower which have led various scholars to interpret biopolitics as either affirmative (Rabinow and Rose 2006) or harmful (Agamben 1998). For example, Rabinow and Rose (2006) argue that when biopolitics is scaled down to the molecular and genetic levels, its manifestations as self-management through gene therapy or prenatal testing do not have the same pernicious implications as biopolitics in the form of eugenics does. By contrast, Giorgio Agamben (1998) associates biopolitics with racism, oppression, and exclusionary violence. Others, such as Roberto Esposito (2008), present a view of biopolitics as double-edged and marked by
an immunitary logic in that various activities directed at fostering particular forms of life can also cause various kinds of harm to the same or other forms of life. Yet others have argued that the harmful aspects of biopower are embedded in its future-orientated elements in that current wellbeing and interests are sacrificed for the sake of the future (Hannah 2011).

The rich and wide-ranging corpus of scholarship on biopower in geography and the broader humanities and social sciences speaks to the value and relevance of this concept as an analytical tool. There is a multiplicity of empirical domains within which this concept has been deployed and of manners in which it has been theorized and reworked. However, a key theme that cuts across these diverse applications relates to the importance of questioning what is considered to be normal–natural–right and of attending to the subtle and creative flows of power in unexpected and surprising social spaces. It is this insight carried by the framework of biopower that has and will continue to stimulate social science and geographical engagement with it.

Bioprospecting and biopiracy

Benjamin D. Neimark
Lancaster University, UK

History of natural products drug discovery

Bioprospecting is defined as the collection, research, and commercialization of biodiversity for new medicines and other useful natural products (perfumes, cosmetics, agro-chemicals, and functional foods). Although generally thought of as a modern practice, the discovery of natural products is part of a millennia-long quest for medicines. Evidence of this can be observed in ancient texts, including the Chinese Materia Medica, the Vedas, or the Brahmamic of Hinduism, and many influential Arabic medical works (Sneader 2005).

In Europe, imperial and colonial projects of economic botany helped to establish global botanical gardens where collections of valuable herbaria and details of their medical uses were housed and used for new discoveries. The reported use by Indians in Quito, Peru, of cinchona bark (Cinchona officinalis L.) as a medicinal decoction for shivering and cold spells led European scientists in the early 1700s to adopt the use of quinine as a treatment for malaria. Another important discovery from this period included the ipecacuanha root (Cephaelis ipecacuanha), which was used to treat amoebic dysentery.

Centuries later, drug discovery was a major focus of the US government when seeking treatment for wounded soldiers during World War II. Government research immediately began to collaborate with a number of large pharmaceutical companies, such as Abbott, Pfizer, Merck, and Squibb, for the commercial production of penicillin. The large-scale research cooperation opened a gateway for the US National Institutes of Health (NIH) to promote joint public/private funding for enhanced treatment from natural products.

Bioprospecting and regulation

Contemporary bioprospecting was introduced to the conservation and development community at the 1992 Earth Summit at Rio as a model of sustainable development intervention. Proponents held that the discovery of natural drug products could provide the incentive, and more importantly the finance, for the conservation of biodiversity hotspots or ecosystems most at risk of extinction. Two of the largest multi-collaborative bioprospecting projects that evolved out of this period and debuted in 1991 were the bilateral contract between Costa Rica’s National Institute of Biodiversity (INBio) and the large pharmaceutical firm Merck and Co., and the US federally funded International Cooperative Biodiversity Groups (ICBG) program (Neimark and Tilghman 2014, 247–248).

Posed as “win–win,” these large projects were structured in a way to enable efficient high-quality research while allowing for the return of commercial benefits to both source-country laboratories and local communities. On
the research side, bioprospecting projects were meant to facilitate scientific and technology transfer between global pharmaceutical firms and source-country public and private laboratories. On the conservation and development end, international environmental organizations built relationships with rural resource users and traditional healers in attempts to deliver sustainable development in areas where the natural resources and traditional knowledge were sourced.

Yet, in contrast to previous research on natural products, which generally used targeted searches for specific plants believed to have medicinal qualities, these new projects boasted a much broader geographic scope of plant collection. In fact, bioprospectors were now spanning the globe to ensure the delivery of bioprospecting samples (plants, insects, and micro- and marine organisms) in bulk quantities.

One reason for the increased scale of collecting was the advanced technology now accessible to the industry. The adoption of user-friendly robotics and high-throughput screeners provided researchers with opportunities to run hundreds of thousands of samples per day against a particular disease target (e.g., cancer or HIV). Following this, computerized databases allowed for immediate analysis of the laborious and multistep process of elucidation and isolation. To take full advantage of these technologies, however, it was essential to collect in quantities unforeseen in the past. Major pharmaceutical firms were lured in with the reassurance that for meager investment and relatively little risk they could amass desired libraries of samples to test without leaving their laboratories.

Nevertheless, the emergence of bioprospecting brought about a host of ethical concerns surrounding the exploitation of source-country participants’ knowledge and worries regarding the ecological impacts of collection. In an attempt to placate concerns, a regulatory framework was set up to provide a structure for return benefits back to the countries where the material and knowledge was collected.

Open for signature at the first Rio Earth Summit in 1992 and ratified a year later, the Convention of Biological Diversity (CBD) was for many a significant step forward, calling for an equitable exchange of benefits in return for the facilitation of access to the country’s biodiversity. Articles 1, 8(j), and 15 of the CBD were especially important in this regard. The CBD stated that signatory countries now owned all biodiversity within its territorial boundaries, with the understanding that it had to make all attempts to facilitate access for research and/or commercial interests. This reversed the earlier Stockholm agreement in 1972, which stated that biodiversity was the natural patrimony of all humankind, and thus, a global resource (Svarstad 2005). There was some trepidation by scientists that countries might become too overprotective of their resources, but most agree that the CBD was a major step forward in providing signatory countries the incentive to conserve resources through the commercialization of their biodiversity.

In order for the CBD to work in practice, bioprospectors and source-country governments had to agree on Access and Benefit-Sharing agreements (ABS)—a requirement that was finally ratified in 2010 by the Conference of Parties at the Nagoya Protocol. Although ABSs usually differed in structure, many shared the same mutually agreed upon terms, including (i) outlining how benefits were to be distributed, (ii) confirmation that details of informed consent were granted prior to collection, and (iii) goals for biodiversity conservation. Monetary and nonmonetary benefits from bioprospecting were usually delivered in the form of milestone or royalty payments, access or licensing fees, and technology transfer of equipment, materials, and/or trainings (Ten Kate and Laird 1999).
Due to the lengthy time necessary for discovery, small-scale sustainable development projects were constructed at the local level.

Biopiracy and resistance

Right from the beginning, however, the optimism surrounding bioprospecting was quickly met with well-organized resistance. Many held that the practice was essentially biopiracy, or the systematic theft of traditional knowledge and nature. First coined by the Canadian activist group Rural Advancement Foundation International (RAFI), biopiracy was used by the Indian scholar-activist Vandana Shiva (1997) in her book of the same name. The thrust of the critique coalesced around whether rural inhabitants received fair compensation for the natural resources and associated traditional knowledge used in the drug discovery research. The resources and knowledge used by locals for medicinal purposes had been discovered, it was argued, through countless years of “trial and error.” Many of the more vocal critiques claimed that given the history of exploitation of the global south leading back to precolonial times, any form of research and/or commercialization of biodiversity under the banner of bioprospecting was biopiracy (ETC Group 2004). Resistance grew to the point that the Maya–ICBG project operating in Chiapas, Mexico, was eventually discontinued (Rosenthal 2006), followed by other projects operating in Peru, Nigeria, and Indonesia, that were encountering problems due to disagreements from participating indigenous groups. These events sent shockwaves across the bioprospecting community, ultimately leading some scientists to question the ethics of the practice and their participation within it.

Although opposition to bioprospecting manifested from larger anti-globalization and indigenous rights movements, many of the critiques can also be traced back to the 1970s–1980s surrounding the collecting and commercializing of agricultural crops for the newly emerging biotechnology industry (Neimark and Tilghman 2014, 278–279). The galvanizing issue was the World Trade Organizations’ agreements on trade related aspects of intellectual property rights (TRIPS) and the contentious debate over intellectual property rights (IPRs). The TRIPS agreement was meant to provide a way of facilitating patents on discoveries of nature for life science and agribusiness multinationals and universal IPR standards that are enforceable through trade protocols. The logic was that patents would incentivize research and discovery within a globalized marketplace, thereby opening the door for ownership of novel discoveries. TRIPS essentially codified the application of western IPR law in developing countries. Yet, many argued that this trade agreement weighed heavily in favor of multinationals who had the financial resources and the political power to guarantee patents without any recognition of the original knowledge leading to the discovery, running counter to the spirit of the CBD and, in particular, the protection of indigenous people’s intellectual property.

A second major critique of bioprospecting concerned the fairness of the ABS agreements themselves. Many began to question whether these agreements could even be equitable, given that they were negotiated between high-powered lawyers representing large pharmaceutical companies and rural resource users with very little experience in negotiating such deals. One landmark case included the ABS agreements surrounding the Hoodia gordonii – a small cactus that grows in desert regions of southern Africa used by the San people to stave off hunger. The first license agreement was made through a scientific agreement with the South African-based...
Council for Scientific and Industrial Research (CSIR) and a joint-venture between Pfizer and a UK-based Phytopharm. Once in place, the agreement was challenged because it was signed without the consent of the San. A subsequent ABS, which included the San, was also contested on the basis that the group did not have proper legal representation at the signing (Wynberg 2010). The rights to commercialize the plant were subsequently sold to the giant multinational Unilever for the development of a functional food using the plant, but the company eventually dropped efforts due to health and sourcing concerns.

Another noteworthy case of drug discovery surrounds the commercialization of the rosy periwinkle (*Catharanthus roseus*). Commonly perceived as the quintessential case study of global biopiracy, the story of the periwinkle is quite a bit more complicated. The periwinkle is a pantropical plant that is generally agreed upon by botanists to be indigenous to Madagascar. Research on the periwinkle by Eli Lilly conducted in the late 1950s focused on the use of the plant as oral insulin for the treatment of diabetes. This work followed published and anecdotal accounts of its use as a bush tea to regulate sugar levels in Caribbean and Filipino communities. After extensive research, the periwinkle was serendipitously found to have a number of tiny vinca alkaloids, which were useful as an anti-cancer treatment of non-Hodgkin lymphomas and childhood leukemia. The original source material for the research, however, was collected from multiple sources, including from India and Jamaica, not Madagascar (Irving Johnson, personal communication). Lilly did, eventually, source periwinkle from plantations in southern Madagascar, but the country did not receive any royalties from the sale of the drugs, which some estimates put close to 400 million before the expiry of the patent. The periwinkle case leads one to question what claims Madagascar can make to benefits when the original source material or medicinal knowledge leading to the discovery was not collected on the island.

Many issues surrounding the landmark case of hoodia and the rosy periwinkle can be attributed to the complex political, biophysical, and geographical challenges of bioprospecting. First, much of the biodiversity desired for drug discovery are collected in tropical and subtropical ecosystems that are very far removed from the large-scale advanced research facilities in the global north. The biological/technical resource imbalance raises a number of proprietary issues concerning the collected material and knowledge. For example, one major issue surrounding the practice is that it is extremely difficult to trace collected material housed in botanical repositories and laboratories years after it was collected. As Bronwyn Parry (2004) notes, the increasing ability to “re-mine” this material through subcontracted rental agreements to third parties raises questions about the accountability and transparency of the original scientific agreements.

Second, the range of collected natural resources used for commercialization sometimes spans political borders and/or different communities’ customary boundaries and, as such, may not be covered by benefit-sharing protocols or afforded protection of intellectual property rights. Furthermore, many benefit-sharing laws are complex and outdated and source countries have not been able to keep up with appropriate regulations to deal with the emergent technologies of bioprospecting and biotechnology. Yet, maybe the most damaging effect of not having specific bioprospecting laws is the inability of source-country governments to hold bioprospectors accountable for the misappropriation of benefits. In the end, even with laws in place, keeping bioprospectors accountable is
extremely challenging for source countries due to the largely secretive nature of drug discovery and the lack of transparency of the research agreements.

Finally, laws governing biodiversity programs and associated benefit-sharing agreements are sometimes complex and difficult to understand. The potential for problems thus exists between parties who understand the terms of the agreements and those who do not. These misunderstandings may extend into mistrust among government institutions and may develop into over-strict policies causing unnecessary restrictions even for host-country scientists to access material for basic research. Many questions also remain as to the real value of biogenetic resources and traditional knowledge, which remains difficult to calculate in economic terms and, as such, there are gross miscalculations and expectations as to the benefits that can be gained from bioprospecting.

Due to these complex issues coupled with the onset of new technologies, major pharmaceutical firms have, on the whole, for some time now been moving away from bioprospecting and shutting down their natural products divisions. Instead, the industry has made a strategic shift toward the use of libraries of computer derived generated compounds—a process called combinatorial chemistry or “combichem.” The advantage of combichem is that it enables molecules to be “tailored” to fit the desired target. This method promises to shorten the time and lessen the financial burden in bringing home the blockbuster drug. Many arguments in favor of synthetic drug development notwithstanding, the pharmaceutical industry’s output under combinatorial chemistry has not lived up to expectations, just as the industry has not lived up to expectations. This lack of output has caused some in the industry to rethink the important role that natural products may still play in drug discovery.

In fact, to write off bioprospecting would be to misunderstand the practice. Private biotechnology firms and laboratories who continue to collect natural products have diversified their approach. Beyond just researching drug discovery, bioprospectors are putting their energy and resources into an array of natural products, including industrial biofuels, agrochemicals, functional foods, cosmeceuticals, and nutraceuticals. This also parallels shifts to collect natural products from nontraditional sites, including unexplored extreme environments (called extremophiles), or plant, animal, or microorganisms that thrive in extreme biophysical or geochemical environments, such as deep-ocean thermal vents or alkaline and saline pools.

Another major trend in the industry comprises developing technologies of synthetic biology and biomimicry, and the emerging work on re-engineering life forms using models based on nature. Recent discoveries of the first synthetic genome mapping may actually revive some programs which use natural compounds as a model precursor for new drug discoveries. As synthetic biology and biomimicry research expand, however, a new wave of social resistance seems to be growing as well. Although many of the environments, practices, technologies, and laws have transformed the practice of bioprospecting over the years, resistance remains strong and the schism remains between practice and critics’ calls for more distributive and procedural justice.

Further reading

Biosecurity, broadly meaning making life safe, has been framed by a series of events and colored by its application within various domains. The term rose to prominence at the turn of the century following a period of three decades in which a raft of newly emerging infectious diseases (EIDs) that crossed from nonhuman animals to people (so called zoonotic diseases) had come to the attention of Western states. They included AIDS (acquired immune deficiency syndrome), avian and swine influenzas, Marburg, West Nile, Ebola, and others. As a term it gained prominence and took on a militarized set of meanings as part of a post-9/11 zeal to make the Global North as secure as possible. Following the “paradigmatic” SARS (severe acute respiratory syndrome) events of 2003 wherein global health systems seemingly contained a possible zoonosis, biosecurity became a matter of ensuring preparedness and organization in the face of emerging infectious diseases. Meanwhile, biosecurity also started to apply to human-made threats, including bioterrorist activities and the inadvertent production of hazards within research laboratories. Last and by no means least, various animal diseases and food scares meant that biosecurity often became associated with threats to farming and food security.

With these and other events in mind, we can highlight four domains of biosecurity: emerging infectious disease; bioterrorism; the cutting edge of life sciences; and food safety (Collier and Lakoff 2008). Each is largely focused upon microbial threats in a mobile world of rapid environmental and sociopolitical change, with the deliberate manipulation and/or dispersal of mutable microbes, the inadvertent release of laboratory-based organisms, and the vulnerabilities of a mass food production system as core concerns. Fears provoked include epidemics and pandemics, epizootics, crop diseases, food-borne illnesses, threats to vital systems, and the “perfect storms” that are generated through intersystem failures that may include promiscuous and exuberant microbial life as one of a number of triggers. A fifth domain in which biosecurity has been invoked would include the more macrobiotic realm of invasive plants and animals, a domain that together with microbial diseases of trees draw in broader fears over national landscapes and ecological security.

A geography of biosecurity may well approximate to the following: a concern with public health, terrorism, and laboratory science dominates in the United States, while Europeans have been particularly concerned with food-sector vulnerability to disease, and Australians have been most active in the area of preventing the incursion of invasive species (see Alien and native species). Within Asia and Africa, concern has often focused on the threats to livelihoods posed by the diseases themselves as well as what some might see as the disproportionate responses of Western-based interests in reducing the emergence of those diseases (especially when other more mundane diseases remain a major threat). There are also important sectoral differences in emphasis, with national and international public health bodies like the World Health Organization (WHO) advocating pandemic preparedness and capacity building, while veterinary
and animal health organizations advance disease prevention and eradication of threats (often as a means to conform to international trading rules) and development and food organizations have vacillated between a concern to modernize production systems and the safeguarding of economies and livelihoods.

Despite this seeming variety, there is frequently a broad sense that biosecurity expresses a (human) will to exert power over life, a power that is exercised through increased border activity, disease surveillance, and interventions in living processes (Braun 2007). As we will see, this sense of human domination over nonhuman life may be a part of the problem. In order to explore why, we can focus on four key elements of biosecurity and in doing so tease out the spatial tensions that make biosecurity always far from being a straightforward exercise in control.

First, the generic issue of security, second, the relationship of security and liberalism or neoliberalism, third and fourth a pathogen-based and an anticipatory approach to danger.

First, the term “security” refers to a wide range of activities that together can instil a sense of safety and assurance as well as prevention of harm (see Security). The term may usefully be distinguished from defense. If the latter is about stopping a known enemy, security often indicates an altogether broader set of practices and states of feeling or affect. Security, in this sense, is not simply a matter of containment or shoring up existing (nation-state) boundaries (see Borders, boundaries, and borderlands). Rather, security is more constructive, and may involve building new borders within and beyond the nation-state, acting to prevent and pre-empt danger, and shaping the environment through constant activity. Security involves regulating or modulating known dangers (or risks, see Environmental risk analysis) as well as preparing for unknown though perhaps inevitable events, and possibly actively intervening in or even pre-empting dangers (like, for example, manipulating a virus in the laboratory in order to produce a highly infective strain for which, possibly, vaccines or other pharmaceuticals can be developed ahead of a viral evolution in the wild). If defense was largely a state-led exercise in preventing attack, security is more intrusive, drawing in a wide range of actors and institutions. In its call for continuous vigilance it inhabits everyday activities, affects (see Affect), and processes and even colonizes the future.

Second, securing life only really makes sense when we understand how life itself comes to be defined in liberal economies that are founded on economic expansion, exchange, and circulation. It is in these kinds of society that life comes to be defined as a set of calculable traits, which are amenable to some limited manipulation. The French philosopher Michel Foucault identified the rise of liberalism and security with the rise of biopolitics, wherein, to be brief, governance by population (more accurately depicted as a risk pool that enables calculative inscription) is continually challenged and enabled by the very relations and circulations that make it “thrive” (Foucault 2004). A population is made up of and is continually affected by the expanding space of circulations within which it exists. Indeed, circulation becomes the paradigmatic space for biopolitics, and its regulation a major preoccupation. Briefly put, expanding economic activity opens up new risks and dangers (through for example increased trade introducing new kinds of vectors for disease), and therefore its continuance depends on technologies of sorting, categorizing, and, importantly, allowing some things and people to circulate while detaining others. As an example, plague stones, dating from the sixteenth to the nineteenth century in rural England, are a material mark of the technologies of circulation. These stones, with a saucer shaped
hollow filled with vinegar, were placed at the edge of a village and allowed coinage to circulate even when a settlement was under quarantine as a result of plague, cholera, or other infectious disease. This filtering of movement at borders is similar in kind to what happens at airports, seaports, farm entrances, abattoirs, and so on, as circulation is encouraged under conditions of observation, surveillance, and regulation. Indeed, most borders and associated technologies are not there to stop circulation – they encourage certain kinds of movement albeit under altered and policed circumstances. They are infrastructures that foster circulation in ways that are deemed to be economically and politically favorable.

This logic of selective movement is underpinned by what many authors see as a contemporary reinvestment in liberal or neoliberal approaches to governance (see Neoliberalism). This is the attempt to shift the burden of security and responsibility (as well as cost) of keeping life safe onto nonstate actors, and/or the state-sponsored encouragement of new markets in security. In the biosecurity arena, this is more often than not interpreted as both a privatization of the state armature (Cooper 2008) and a move to private responsibility for risk reduction and cost sharing of both risk prevention and post-event amelioration. This broadening of security activity coincides, Cooper notes, with attempts to increase exceptional state powers in conditions of emergency. Moreover, the whole exercise is underpinned by claims of radical uncertainty and emergence which are used, she argues, to justify increased vigilance on the part of citizens and to defend emergency powers, as well as to sanction the diversion of public funds into market-led security measures. This is a contested area – for some the extension of vigilance to broad sections of society at the same time as a reinvestment in emergency powers and a marketization of security is a peculiarly neoliberal settlement wherein sovereignty reemerges as a key source of power. For others, conceding that life cannot be controlled from a central site suggests a possibility for other kinds of organization and alternative forms of politics. This is an empirical as well as theoretical issue. Indeed, the exact interplay of emergence, uncertainty, borderings, surveillance, detention, and the freedom to move and to expand is handled in a variety of ways which require further analysis. How these play out, and how freedom and security are balanced or otherwise, is a key question for contemporary governance (Lentzos and Rose 2009).

If freedom and security already start to suggest biosecurity’s spatial tensions, these are overlain in some sectors by a pathogen-based and an anticipatory approach to infectious disease and risk. Here, biosecurity equates to a desire to pursue not just the freedom to move but also a freedom from disease. As such, the spaces of circulation that Foucault emphasized are in tension with territorial expressions (like zoning) and inside/outside dichotomies. The result is a tendency to understand biosecurity as a matter of constructing and then protecting a system of spaces wherein pathogens are to be kept out. So, for example, biosecurity in many states is concerned with the incursion of infectious diseases and their impact on people, domestic and wild animals, and plants. This geography of incursion is often played out across nation-state territories or more latterly (and in poorer or more uneven states) disease-free zones, such that a trading body or zone can submit the necessary paperwork to the World Trade Organization (WTO) via the World Organization for Animal Health (OIE – Office International des Epizooties) in order to verify their disease-free status, or conversely use WTO sanitary and phytosanitary agreements to refuse trade in food stuffs where there is significant evidence of disease risk. The end result is a spatial segregation
BIOSECURITY

between the virtuous (often the Global North) and the unruly (often the Global South with the exception of the capital- and pharmaceutically intensive disease-free zones).

This drive for pathogen freedom in the name of circulation and trade is amplified by an anticipatory ethos that exists within public health, animal health, regulatory, scientific research, and food retail organizations. Here a need to protect organizational reputation drives efforts to reduce disease risk by adopting disease-free practices. This precaution is amplified by an anticipation of retrospection or an approach to a future which may well involve being called to account for the actions that were or were not taken to reduce disease risk. Anticipation of known and unknown threats exerts pressure on producers, retailers, and regulators, who either assert their sanitary agency over the living processes they organize or specify contracts and legal responsibilities such that, should the worst happen, guilt cannot be linked to the actions of the institution or organization. The result of this pathogen-focused anticipatory landscape is a territorial interpretation of biosecurity with a networked performance of distributed accountability.

A problem with this sanitary and territorialized version of biosecurity is that life is seemingly made safe while disabling the very processes that may make life possible or even flourish. A problem may be that too much attention is focused on halting the transmission of pathogens and not enough is placed on the life conditions of those living behind the wall (Hinchliffe et al. 2013). The neurosis and bare life that exist under so-called conditions of hypersecurity may in fact produce ill health themselves, and/or an overconfidence that allows for massive amplification of risk (in a similar vein to at-risk landscapes sheltering behind always imperfect flood barriers).

As this last point suggests, the four elements of securitization, liberalism, pathogen-based and anticipatory approaches to infectious disease and risk can combine in rather uncertain ways. The resulting mix of logics and tensions makes biosecurity an always ongoing compromise between economic surplus, surplus life, and the requirement to make life safe. In the food sector for example, biosecurity takes its lead from retailers and food regulation services, which tend to accentuate consumer safety through a model of hygiene and uniform public health. The result is a contractual-based and vertically integrated supply chain that (at least in theory) performs risk aversion through disease-free technique (see Vertical integration). Yet, it may not be the lack of or need for more human control over life that is the problem. It is the very affirmation of agency and the assumption of abundant capacities of deliberate human action, coupled with biosocial issues like infectious disease, which are the cause for concern. Instead of trying to separate human lives from pathogens, it may be more beneficial to learn to recognize the limits of human agency and to adapt living to what are always dense entanglements of human, nonhuman, and microbiological beings.

In the biosecurity literature, at least as it applies to public health and animal and plant life, this shift of attention to adequate responses has tended to take the form of a counternarrative whereby various ways of living with threats are opened up for debate. So instead of policing life in terms of borders between health and disease, an alternative proposes the question of what would it mean to partially abandon strict bordering and invest instead in living pathological lives. One source for this proposition came from accounts of the history of foot and mouth disease (FMD). In the twentieth century, FMD became a disease to be eradicated in the name of global trade, rather than something that previously
farmers and their animals had learned to tolerate (Woods 2004). The cost of this purification of stock became apparent in the United Kingdom in 2001–2002 when the disease re-emerged in an ill-prepared country and herd. Separately, disease ecologists have also argued that the inevitability of disease re-emergence suggests the need for a program of developing resilience rather than eradication (Waage and Mumford 2008) (see Urban resilience). In anthropology and geography, works on establishing “common cause” (Farmer 2004) or more recent attempts to think through “common sense” (Hinchliffe 2015), as well as work with lay understandings of disease and health (Enticott 2008), can open up a new space for making life safe. This involves a shift in the object of concern from pathogens to pathogenicity or health, with Farmer’s radical and clinically informed work on health and justice acting as a rallying point. Rather than eradicating pathogens, the aims should be to build health such that pathogenicity is reduced. “Living with” in this sense becomes a matter of working alongside others, and crucially with those who appreciate the complexities of health and illness, the entanglements of pathological life, and, in doing so shifts the debate from securing territories (be they national states, food premises, or bodies) towards building better health-care systems, reducing inequality and vulnerability, and stemming environmental and socioecological degradation. Some of this is about redirecting investment to basic health care, some of it is about recognizing and valuing the skills that exist within food and farming systems. The latter may risk a return to the logic and politics of which Cooper warns, vesting new powers and responsibilities in nonstate and sometimes reluctant actors as a means to displace accountability and costs, all under the auspices of an ontology (emergence) that has its own noninnocent history. While these risks are evident, the alternative proposition of working alongside people and microbes is also made in the face of a tendency to simplify life and living in the name of disease risk as well as to render those who know most about the complexities and nuances of human, animal, and plant health, its multidimensional characteristics, redundant in highly capitalized but deskilled food and health landscapes. Recent work, for example, highlights the need to arrest a tendency to oversimplify the food chain and downgrade agricultural, research, and surveillance roles within the food, farming, and health sectors. Indeed, the sources for making life safe may well be found in the maintenance of the craftwork that is involved in patching together healthy lives. Safe life depends upon a transdisciplinary assemblage of expertise, from farmers to slaughterhouse workers, from vets to virologists, from local authority health officers to wildlife volunteers and professionals. These people, who work with bodies and environments on a daily basis, and through their craft and nonhuman alignments know the complexities of health (as always more than the absence of disease), need not be imagined as exemplary neoliberal subjects, nor as integrated and so simplified by a coherent health infrastructure. They are instead, the spokespeople, the human—nonhuman collectives that make safe life possible.

Definition and history

Biotechnology was defined in the 1992 Convention on Biological Diversity as “any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use” (FAO 2002).

This definition potentially covers many techniques now used frequently in agriculture, food production, and health care, including animal husbandry, selective plant breeding for the development of commercially valued traits, vegetative propagation (i.e., cloning) of plants, and the production of antibiotics. Yet, a conventional understanding of the term restricts the meaning of biotechnology to the manipulation – or use – of genetic material from living organisms. Current activity covered by this definition builds on work undertaken in the 1950s when the structure of DNA was identified in 1953, and research in the 1960s that identified the proteins responsible for cutting DNA. By the 1970s it was possible to manipulate and transfer genetic material between species and by 1983 it was possible to create genetically modified (GM) crops (Bridge, McManus, and Marsden 2003; Stone 2010). DNA thus became recombinant DNA (rDNA) and opened up possibilities for new activity in a number of fields. The first commercially grown GM crop was tobacco, grown in China, in 1988 (Stone 2010). Since that time, GM crops of cotton, maize, canola, and soybean, amongst other plants, have been grown in a number of countries, mainly because these plants are commercially valuable and can be modified to tolerate herbicides (particularly glyphosate-based weed killers) and to resist insects (Stone 2010). In 2013, 175.2 million hectares of biotech crops were grown globally, up from 170 million hectares in 2012, and continuing the phenomenal increases in take-up rates since commercialization of GM crops began in 1996 in western countries (James 2013).

While many commentators refer to the history of human intervention and manipulation of natural systems as being of at least ten thousand years duration, the rise of modern biotechnology is generally agreed to have occurred in the mid-1970s. This is partly related to technical breakthroughs in science, as just summarized, but was necessarily accompanied by changes in the socioeconomic domains, notably the decision by the US Supreme Court in 1980 that life forms are patentable. Since that time, biotechnology has developed rapidly in many different fields. Mosier and Ladisch (2009, 27) highlight its impact – “new biotechnology has replaced, to some extent, traditional plant and animal breeding methods with tools that enable cloning and the directed insertion of genes from one species or genetic donor into another.” In summary, the technology has come so far already that only resistance by organized and highly funded groups, such as the thoroughbred breeding and racing industry, has prevented an even greater spread of biotechnology applications.

The history of biotechnology is often traced to the beginning of agriculture in about 10,000 BCE.
and the development of brewing techniques by the Sumerians and Babylonians, the Egyptians making unleavened bread, and copper smelting in Spain by the Romans over 2000 years ago (Bridge, McManus, and Marsden 2003). Yet, biotechnology is also aligned with the notion of “progress” as “universal, a historical claim that genomic technology and transgenic crops represent ‘progress for humanity’” (Bridge, McManus, and Marsden 2003, 165). In the past this may have been sufficient justification for the development of biotechnology but changing understanding of the relationships between humans and other parts of nature has led to the questioning of conventional notions of progress. This requires the generation of new forms of justification of biotechnology to secure funding, regulatory approval, and public/consumer support for what is produced by biotechnologists.

Justification for the development and application of biotechnology varies over time, depending on the location, and is influenced by the sector in which it is proposed for application. The most common justifications relate to population, particularly at the global scale. Borém and Fritsche-Neto (2014, 1) emphasize the “continuous growth” in global population, the rural to urban migration, and the requirement that “all current food production systems must either double in productivity until 2050 or risk failing to meet the growing demand for food.” They raise the specter of Malthusian mass starvation but offer the hope of scientists who “seek more efficient food production methods,” of which “cultivar development from plant genetic breeding is considered one of the most important and has been responsible for more than half of the increases in crop yields over the last century” (Borém and Fritsche-Neto 2014, 1). This justification is rejected by a number of geographers and rural sociologists, including Dibden, Gibbs, and Cocklin (2013, 61) who argue that “food security is evoked primarily with reference to developing countries” and “is supported by other emotive and guilt-provoking terms such as ‘world hunger’ which are likely to resonate with ethically minded consumers and citizens.” They argue that food security “provides a new discursive pivot for the debate about agricultural biotechnology, enabling issues surrounding GMOs (genetically modified organisms) to be transposed to a different spatial arena (the Third World) and a higher moral plane” (Dibden, Gibbs, and Cocklin 2013, 61).

Procedures and applications

As many commentators have recognized, discussing biotechnology means engaging with the diversity of procedures that fall under this label, and the uses of these procedures. This diversity extends to specific areas within biotechnology, such as the use of recombinant DNA, or rDNA, which includes different methodologies that vary in their risks and benefits. It also varies between fields such as agricultural biotechnology and microbiological technology, particularly in the type of organisms that are modified. While this may seem to be fragmentation, the engineering of genes brings together many academic disciplines. Geography is not directly involved in the production of biotechnology or genetic engineering but has provided important contributions to the understanding of this technology in terms of its origins, application, and impacts in local areas and at wider social scales. The engineering of genes requires an understanding of four basic concepts, which McHughen (2008, 37) identified as the foundation of genetics. These are:

1. all organisms are made of cells and cell products;
2 each cell in an organism contains the same set of genes;
3 the genome contains all the genetic information necessary make an entire organism;
4 all organisms share the same genetic language.

McHughen (2008, 37) identified the last of these concepts as being “the key concept” for genetic engineering because it “allows a gene from any one organism or species to be read and understood when transferred to another.” While this understanding enabled biotechnologists to progress rapidly with the development of new products and life forms, opposition to biotechnology has also been very high. The concerns about biotechnology date to at least the 1970s, when scientists began experimenting with animal cells and animal viruses. Importantly, this concern came from among the scientists themselves, rather than a homogenous science community supporting the development of biotechnology, with prominent scientists publishing letters in *Science* and in *Nature* that, in effect, advocated a moratorium on biotechnological development until issues such as biohazards of recombinant DNA had been evaluated (Barnum 1998). The second Alisomar Conference on Recombinant DNA Molecules in February 1975 produced safety guidelines for biotechnology, but getting agreement on these guidelines was difficult. The guidelines were published in *Science* on June 6, 1975, thereby fueling a debate that continued for about four years (Barnum 1998), and arguably longer, as evidenced by the ongoing controversies around biotechnology and newer technologies such as nanotechnology, and by the accompanying increase in the production and sale of organic, GMO-free produce.

David (2008) identifies nanotechnology and biotechnology as being ultra-controversies, that is, the absence of discrete issues but the “bundling” of many issues into one controversy and highly polarized political positions in relation to the debates. McHughen (2008) highlights the importance of retaining distinctions such as red biotechnology (medical) and green biotechnology for agriculture (see later) and argues that the position of opponents to biotechnology is inconsistent. In this view, similar processes cannot be advocated in some situations but not others – “condemning one use of a ‘forbidden’ technology must condemn all uses” (McHughen 2008, 40). He compares the use of biotechnology to create new food products (which some people oppose, but he argues for the life-saving aspects of food) with the creation of medical products from rDNA that are not available in a natural form.

The issue of genetic engineering is, however, more complicated because not only are individuals able to argue about the benefits and concerns of different types of biotechnology in different contexts (for example, human health benefits of biomedical research as opposed to increasing agricultural productivity), but there are also many different perspectives based on numerous variables. Degeling, Irvine, and Kerridge (2014) investigated various faith-based perspectives on biotechnology and identified similarities between them around animal respect and animal pain, but noted differences in that some religions gave a strong mandate to biotechnology research if it resulted in reducing human pain. The importance of faith-based perceptions is an area of interest to some geographers who are concerned about the discursive construction, performative practices, and social implications of biotechnology.

Geographers have been involved in understanding perceptions relating to the introduction of new technology, including advocating caution about comparing different technologies, without thinking critically about their basis, use, and
possible implications (MacNaghten, Kearns, and Wynne 2005). Geographers have also provided the scientific and socioeconomic context for many different technologies, including biotechnology (MacNaghten 2008). This is possible because these technologies engage with many of the subjects of geography, including ideas of naturalness, environmental change, and how people adapt to their surroundings to meet their needs. Geographers have also been interested in the role of sciences in changing the world, but recognizing that this change begins with imagining and not with the “application” of pure science (MacNaghten 2008). Social and ethical dimensions of science are not limited to application but arise with “the aims and purposes underlying the production of scientific knowledge” (MacNaghten 2008, 109).

This recognition was part of the challenge facing Bridge, McManus, and Marsden (2003), who attempted to move geographical perspectives on biotechnology away from simply mapping the location of biotechnology installations. Even so, it is worth considering the importance of venture capital and the concentration of biotechnology in particular locations. The initial success in developing human insulin in the late 1970s, being the first recombinant biotechnology product approved by the US Food and Drug Administration in 1978, was dependent on the availability of venture capital (Mosier and Ladisch 2009). The risks of failure were high but the potential financial rewards were also very high. This was particularly the case in pharmaceuticals (red biotechnology), where it was relatively easy to estimate the market value of a particular product and to calculate the financial risks in developing this product, although being able to estimate the value of biotechnology companies offering the promise of future success based solely on intangible assets such as intellectual property is challenging.

It usually takes many years of investing in an expensive industry before financial returns are forthcoming, with considerable risk that there will be no returns. Schneider (2009) estimated that the average timespan for red biotechnology to progress from initial development to the market is 10–12 years. The red biotechnology sector attracted more venture capital than did other applications of biotechnology. Today, the red biotechnology sector is far larger than other biotechnology industries and is concentrated in the USA and Europe. Green biotechnology is second, while some commentators see the potential of white (industrial) biotechnology to grow rapidly as the third largest application of biotechnology development, based on a shorter (3–5 year) development phase and on the fact that there are less regulatory requirements than in other more established biotechnology sectors (Schneider 2009).

In contrast to the concentration of medical biotechnology in the developed countries, the location of biotechnology crops is diverse, with 27 countries in 2013 planting such crops, but only eight of these countries are in the developed world, with 19 being developing countries. The top five countries for biotechnology crops, in terms of area planted, are the USA, Brazil, Argentina, India, and Canada (James 2013). While the USA is by far the country with the biggest land area devoted to biotech crops, the total land area devoted to these crops in the 19 developing countries exceeds that of the eight developed countries, a scenario that emerged in 2012 largely due to the rate of uptake in Brazil (James 2013). Importantly for the future growth of biotechnology crops, biotech cotton is grown in China and three African countries (South Africa, Sudan, and Burkino Faso) grow biotechnology cotton, while maize and soybeans are also grown in South Africa (James 2013).
Importantly, however, the locations of the companies involved in pharmaceutical and agricultural biotechnology is skewed towards the developed world, with seven of the top ten biotechnology companies by market capitalization being based in the USA. This crude statistic also masks uneven distribution within the USA, with three of the five largest biotechnology centers being located in California (Los Angeles/Orange County, San Francisco Bay Area, and San Diego) (Statista 2014).

Not only are the locations of biotechnology industries and application varied, there is also significant concern about the costs and benefits of bioscience. These are also unevenly distributed, as biotechnological application exists within multiple systems and flows of capital, knowledge, and power. There are particular concerns about biopiracy (the alleged theft of genetic material, often from biodiversity rich developing countries by scientific and pharmaceutical organizations based in wealthier countries) for the creation of profit. Additional concerns about biotechnology identified by Mellon (2008) include global resentment of American technical hegemony, corporations controlling the food system, the industrialization of agriculture, the blurring of university–corporate boundaries, and the opportunity cost of investing in biotechnology research, which she believes results in other technologies being underfunded.

Bridge, McManus, and Marsden (2003, 166–167) observed that “a defining characteristic of contemporary biotechnology is that its applications are widespread and ubiquitous.” These authors meant both in its geographical distribution and its application in different economic sectors. Bridge, McManus, and Marsden (2003) claimed that the diversity of applications fell into three main economic arenas in which biotechnology was then becoming significant; namely "plant/crop breeding, animal husbandry, and medical research.” In 2005, the 12th European Biotechnology Congress used four colors to identify biotechnological applications. These were white (industrial), red (pharmaceutical), green (food and feed), and blue (environment). DaSilva (2004) developed a ten-color schema that included red (health, medical, diagnostics), blue (aqua, coastal and marine) and dark (bioterrorism, biowarfare, biocrimes, anticrop warfare). This schema varies from the six-color classification (https://www.elsevier.com/life-sciences/biotechnology), which has red (medicine), white (industrial), green (agriculture), blue (marine and aquatic processes), black (research related to bioterrorism), and grey (environmental, including both biodiversity maintenance and contaminants removal). While there is sometimes slippage and overlap between these color classifications, within these classifications the application of biotechnology to plants and crops includes the genetic manipulation of seeds, tissues or plant cells to make them more desirable. This is achieved by modifying traits such as the size, growth rate, and resistance to herbicides and pests for particular plants. In plants intended for human consumption, other characteristics such as color, texture, and taste may also be genetically manipulated. This has resulted “in the spread of genetically modified (GM) crops, which has occurred with little controversy in some areas and with fierce controversy elsewhere” (Stone 2010, 381). Geographers are interested in the mapping and spread of such crops, and in the variations in responses to the introduction of GM crops across time and space.

In terms of industry size, the most important areas for the application of biotechnology are in the pharmaceutical (red) and green (agriculture and food) sectors. The remainder of this entry looks at these two sectors and identifies the key developments, major issues, and possible future directions for biotechnology development and
application, including potential implications. It is important to note that in practice there are overlaps between these sectors, and other sectors of biotechnology development, as demonstrated through the development of transgenic pigs, which have been developed for both food supply and biomedical research because of the similarities between pig and human anatomy and physiology.

Pharmaceuticals (red biotechnology)

The development of pharmaceuticals, especially cures to life-threatening diseases, is a major component of biotechnology development. The so-called red biotechnology has been at the forefront of biotechnology investment and research development, sometimes leading to the commercial development of new products because the market demand for life-saving drugs is high. One link between red and green biotechnology is the use of certain breeds of animals, whether it be for food production or for testing the effects of particular diseases and drugs.

The creation of chimeras (animals with both human and other cells, usually primate) for medical testing is controversial. Degeling, Irvine, and Kerridge (2014) note the contrast between responses to these chimeras and the relative lack of controversy around transplanting of pig heart valves into humans. The concerns can be summarized as being the welfare of the participants, the integrity of natural processes, and the wider social implications of this research. While this research may provide knowledge and possibly cures on long-term degenerative diseases, the above concerns have slowed the rate of biotechnological development in the western world. The regulation of biotechnology to address these sorts of issues, whether they be based in scientific research or be founded on public perceptions, is important in the rate and manner of biotechnological development in medical and pharmaceutical research.

One chimera that has developed rapidly in recent years is the transgenic pig. The pig has many advantages over other animals for use in biomedical research, including early sexual maturity, favorable short generation time, multiple offspring, is similar to humans in being omnivorous, has a digestive rate and efficiency similar to that of humans, and the feasibility of efficient and precise genetic modification (Wolf et al. 2014). The rapid increase, and the projected increase, in human medical conditions such as various forms of diabetes (often related to lifestyles in developed countries, but expanding rapidly into the wealthier developing countries) is a concern for governments and health authorities. The funding of research to address this issue includes the creation of research animals, such as transgenic pigs. Technological development means that it is now possible to create transgenic pigs to address specific issues within diabetes research and to target other degenerative diseases that impact on human quality of life. The long-term goal of much of this research is to develop xenotransplantation, that is, the surgical transfer of cells, tissues, or whole organs from an organism of one species to an organism of a different species, with the intention of regeneration of the recipient. In the case of diabetes biomedical research, the development of an entire pancreas in a transgenic pig which could then be harvested and transplanted into a human is within the bounds of possibility. This raises ethical concerns about the integrity of human life and about the ability to create new forms of life, and about the transfer of infectious diseases from one species to another. At present interspecies transfer of disease involves ingestion, physical contact or a vector of some kind (for example, wind), but the potential to accelerate interspecies disease transfer is a concern for some
critics of medical biotechnology, especially if it becomes widespread and beyond the confines of the most secure laboratories.

Agriculture and food (green biotechnology)

In the area of agriculture, the application of biotechnology can be subdivided into animal and crop industries. The development of genetically engineered animals (otherwise known as transgenic animals), where a particular gene is directly transferred into an animal (unlike traditional breeding where the transfer has been indirect, or cloning which seeks to reproduce the exact genes of a highly desired animal), is a huge business. Perhaps the most famous example of genetically engineering an animal is in the field of medical rather than agricultural research, where Harvard University scientists developed OncoMouse®️, which was a mouse that had a gene which made it susceptible to cancer, and therefore ideal for use in medical research. This was controversial but has been overtaken by developments in other areas of research and commercialization of biotechnological modification of animals.

In 1992 the biotechnology company GenPharm produced a bull, initially by injecting cells with a human gene coding for lactoferrin (which is important in preventing bacterial growth) into the embryo of a cross between two Dutch breeds of cattle. The creation of Herman the Bull was extremely controversial because he was the first transgenic bovine but, even more importantly, he contained human DNA. He sired offspring that could produce milk containing lactoferrin, which is normally absent in cow’s milk but is present in the milk of women and in formula, but it was not commercially viable at the time. Following the controversial experiment in The Netherlands, the offspring of Herman the Bull were slaughtered, while Herman was euthanized at the age of thirteen (suffering from arthritis, unrelated to the genetic engineering) and is now an exhibit at Naturalis, the National Museum of Natural History in Leiden.

The genetic engineering of animals can be undertaken for multiple reasons, including increased productivity. It is possible, however, to enhance perceived attributes, such as the ability to grow faster, produce more meat, and so on, using conventional breeding techniques, or by the application of feed supplements, and so on. Where genetic engineering is unique, and hence potentially lucrative, is the ability to target particular issues, such as lactoferrin in milk in the example of Herman the Bull. Another example of such targeting is the development by researchers at the University of Guelph of the Enviropig, which is a swine that has been genetically modified by the inclusion of an E. Coli bacteria and mouse DNA to a Yorkshire pig embryo so that the pig’s urine and feces contain about 65% less phosphorus than that of other pigs. This characteristic is a boon for the genetic engineering industry, as it enables the industry to showcase the environmental benefits of reduced phosphorus entering water bodies and generating eutrophication, which leads to algal blooms and catastrophic loss of fish and other marine life. The Enviropig research program was shut down in 2012 when funding was cut, meaning that it did not become the first genetically modified food animal to be approved in the world. While the Canadian government had approved the development of the pig, no government in the world had approved the inclusion of genetically modified animals for human consumption (Pollack 2012). Despite closing down the program, and slaughtering the small herd of pigs, the semen from the pigs has been frozen and potentially can be used in the
future by a company willing to commercially
develop the product (Pollack 2012). Critics call
the pig “Frankenswine” and argue that:

the common disconnect between science and
reality is represented perfectly by the ridiculous,
and yet threateningly real GM Enviropig™
project. Enviropig™ is the grotesque realization
of early scientific aspirations and laboratory
accidents. Born of scientific curiosity, hubris
and a complete misunderstanding of the real
world, a GM pig with less phosphorous in its
feces is being proposed as a solution to water
pollution caused by run-off from factory farms.
(Sharratt 2010)

The concern among critics is that the develop-
ment of the genetically modified pig would not
have reduced the total environmental pollution
but would have enabled hog farmers in Canada
(and the midwestern United States) to increase
their stocking rates because the limiting factor
of environmental restrictions on the permitted
level of phosphorus pollution would have been
alleviated. This, in turn, would have enabled
the perpetuation of intensive factory farming,
at higher stocking rates than previously. Envi-
ropig is an excellent example of the challenges
of commercialization of biotechnology, even
though it is scientifically demonstrated to work,
of the controversies around public acceptance of
biotechnology (particularly in animal-based food
for human consumption), of the importance of
regulation in promoting or stifling biotechnol-
y, of the arguments used by biotechnology
advocates to support their activities, and of
the links between issues such as biotechnology
development and related issues such as ani-
mal welfare. This last point is consistent with
David’s (2008) labelling of biotechnology as an
ultra-issue, where there is a bundling of con-
cerns rather than a focus on an individual issue.
For opponents of biotechnology, this so-called
“bundling” is logical, as in the case of Enviropig
where the connections between genetically
modified swine, increased stocking rates, animal
welfare, alternative solutions to environmental
management, and the risk to human health are
seen as parts of a single issue.

The termination of the Enviropig research
program certainly does not mean the end of
transgenic pigs, even allowing for the freezing
of sperm for later use. According to Bou et al.
(2014, 679), “transgenic pig holds great promise
in the fields of agriculture and biomedicine.
Currently, at least 65 kinds of transgenic pigs
were derived for research in porcine meat qual-
ity, growth and disease control, human disease
model, xenotransplantation, pharmaceutics
and the fundamental biology.” Importantly,
the “normal” pig becomes the “wild type” of
genetic material in this study, highlighting the
perspective of these scientists towards the control
of nature.

The other sector for the agricultural appli-
cation of biotechnology is in the development
of genetically modified crops. Biotechnology’s
major contribution to the crop industry, to date,
has been the ability to produce glyphosate-
resistant (GR) crops. As Green (2012, 1323)
obsved, this “was a scientific breakthrough that
helped to revolutionize weed management and
provided much of the impetus to restructure the
seed business.” Glyphosate works by blocking an
enzyme that is required in the process of pho-
tosynthesis. Using biotechnology, scientists have
created plants that “produce an alternate enzyme
that is not affected by glyphosate” (Thieman and
Palladino 2004, 144), in other words, a transgenic
crop that allows farmer to spray weeds without
the danger of killing the economically desirable
plants, which was a problem with some previous
herbicides. Glyphosate was “a relatively inex-
pensive and effective herbicide with an excellent
environmental profile” (Green 2012, 1324).
The timing of this scientific breakthrough was also important because weeds were becoming resistant to many herbicides that were in use at the time. Green (2012, 1323) adds that the timing also involved an increase in farm size while the number of farm workers was decreasing and “weed management was becoming too complicated, time consuming and costly for the new agricultural systems.” The use of biotechnology to create GR crops “made weed management easy, efficient, economical and environmentally compatible – exactly what growers wanted” (Green 2012, 1323).

Some crops were particularly suited to biotechnology, with soybeans being a prime example. By 2005, 87% of the total US soybean acreage comprised genetically engineered soybeans (McHughen 2008). Another crop that is suited to the application of biotechnology is cotton, which in the same year saw genetically engineering cotton account for 79% of the US cotton acreage (McHughen 2008). Thieman and Palladino (2004, 144) in advocating biotechnology observe how the social and environmental relations around agriculture have changed as a result of biotechnology – “before the advent of resistant crops, US cotton farmers spent $300 million per year on harsh chemicals to spray their fields (This total does not include the human factor of laboring in the sun to weed between the cotton plants, which is now unnecessary!).”

These examples highlight the justifications for biotechnology. They also demonstrate the role of biotechnology within a political economy of agriculture, which includes the ongoing replacement of human labor by machinery or other technological approaches (such as the application of biotechnology to remove the need for weeding). While corn, soybeans, and cotton were early crops in which genetic engineering was applied (all became commercially available in the late 1990s), more recent applications of glyphosate resistance include alfalfa (2007) and sugar beet (2008) (Green 2012).

The application of biotechnology to various crops has influenced the construction of productivist and post-productivist agricultural landscapes (Wilson, 2007). The application of biotechnology enables proponents to increase agricultural production whilst claiming environmentally beneficial outcomes. In this sense, Marsden (2008, 192) argued that genetic modification technologies are globally becoming an integral part of a changing agroindustrial paradigm, by “providing palliatives to the technical problems of large-scale capital-intensive producers, such that they can continue to effectively supply the concentrated downstream sectors with relatively cheap and bulk agricultural inputs.” The application of biotechnology enables the use of herbicides and pesticides, thus increasing outputs while potentially reducing labor costs and, thereby, making some agricultural systems more “productivist” than previously was the case.

Biotechnology adoption is, however, uneven “both spatially, and in terms of its application in different parts of the food chain” (Marsden 2008, 193), and productivist, post-productivist, and super-productivist models can coexist (Wilson 2007). This places farmers in a difficult position regarding the adoption of genetically modified organisms (GM or GMO). They may be “caught between the promptings of industry to adopt new technology, protest groups opposed to GM, and consumer wariness in relation to GM foods” (McDonagh 2014, 5). The pressures vary between locations and specific situations. Recognizing that biotechnology is both a discursive and physical insertion into existing agricultural and food production/consumption systems also means that “very different conceptions of sustainable rural futures are possible” (McDonagh 2014, 4).
The production/consumption relations surrounding the application of biotechnology in agriculture extend beyond herbicide resistance and labor-saving practices. In summary, the benefits include B1 crops (crops inserted with a gene from a South American tree frog to resist fungal growth and insect damage), the development of soy cooking oils with reduced saturated fat (which is important in promoting healthy eating and addressing growing concerns about obesity), and the ability to delay fruit and vegetables from ripening to enable shipping and longer freshness – the now defunct Flavr Savr™ Tomato that was introduced in 1994 being a prime example of application in this area. This application was designed to ensure that the tomatoes reached markets out of season, where supply was low and they could be sold at a premium. Biotechnology, therefore, influences the form of food consumption in locations that may be far from the initial biotechnological application in agricultural settings.

Biotechnology futures

The future of biotechnology is open to speculation. Diola and Fritsche-Neto (2014, 155) believe that “the development of genetic maps with markers of easy attainment and of large-scale, highly reproducible, co-dominant and specific to linkage groups, is highly desirable for their application in plant breeding.” These genetic maps form the basis for genetic engineering experiments, which are increasingly moving beyond agriculture to feed a starving world, or pharmaceuticals to save human lives. Two areas of development are particularly important to note. First, the creation of transgenic animals for nonhuman consumption (i.e., leisure and entertainment, human companionship, and so on) is now underway with the commercial release of the GloFish. This is the first transgenic animal available to the public; it has resulted from the insertion of protein from jellyfish that enables the zebra fish (a native of rivers in India and Bangladesh, but sold as a pet in developed countries for many years) to develop enhanced fluorescence. The GloFish were first available in Taiwan, followed soon afterwards by the USA (except in California). The importance of regulation is highlighted by the fact that these small tropical fish are not for human consumption, and are therefore not threatening to the human food supply.

The second area of biotechnology development that indicates future possibilities is the genetic engineering of marmosets (a small monkey, originally from South America) that resulted in a transgene being passed to the offspring of the modified animals (Cyanoski 2009). This development has significant implications for medical research, in that, to date, the usual animal used for experimentation when research is at an advanced stage is the Rhesus macaque (a taller monkey, originally from Asia). Scientists in Kawasaki injected viral vectors with green fluorescent protein (GFP) into 91 marmoset embryos, eighty of which were to surrogate mothers resulting in five offspring, all “of which expressed the glowing transgene in some features at some point during development” (Cyanoski 2009, 492). The next step was to use artificial insemination to produce glowing second-generation marmosets. This action is controversial for a number of reasons, including the creation of transgenic animals that are produced specifically for scientific experiments (similar to transgenic mice) but particularly because primates are close to humans both in their phylogenetic composition and on the sociozoological scale, where nonhuman primates and companion animals are positioned at the top of this scale (Olsson and Sandøe 2010).
The phylogenetic proximity between humans and marmosets is advantageous for medical research, but raises issues about the potential for human genetic engineering.

**Conclusion**

Human geographers are interested in biotechnology for many reasons as indicated here, although as Greenhough (2011) noted, there has been little crossover between geographies of health and geographies of bioscience. Foremost among the reasons is the way in which the “human” in human geography is understood. As Nash (2005) observed, we increasingly understand what it means to be human in ways that are informed by genetics and biotechnology. This includes understanding the history of not just an individual, but whole races and the processes of migration through the mapping of the human genome diversity project (Nash 2005). It also includes future-oriented implications, such as the establishment of biobanks or genetic database projects that can map out genetics and make it available for the application of biotechnology to overcome diseases and weaknesses, or to develop “improved” characteristics in individuals.

Biotechnology has advanced rapidly in recent years, both in scientific development and in commercial application. There is a well-established industry that is promoting the further development of biotechnology, including the important issue of regulation. The scientific development of biotechnology has advanced well beyond the point at which regulation is the only means that distinguishes between the possible and the desirable, based on benefits and risks. Any weakening of regulation will enhance the commercial viability of a number of scientifically developed projects that are currently not commercially viable, but this is not the same as protecting societies, the environment, and animal welfare. The future of biotechnology is intricately bound up in the regulation of these processes, their outputs, and implications.

The importance of the body for human geography may seem at first obvious. Bodies are everywhere in scholarship, popular culture, and everyday lived space. The term “body” is in the title or keywords of growing numbers of articles and books in geography and in the social sciences more generally, particularly since the 1990s (Longhurst and Johnston 2014). The meanings ascribed to the body, bodies, and embodiment vary significantly from one subfield to another and they have changed over time, affecting how geographic research is conducted, the questions posed, and the conclusions asserted. The shifts in understanding of bodies have not of course occurred in a straightforward, chronological march toward greater understanding. Rather, geographers have combined different ways of understanding the body in recent decades, in many cases developing complementarities between longer-standing approaches to bodies with contemporary social concerns and theoretical orientations.

Feminist geography, sexuality studies, queer geographies, and critical race scholarship have been especially important contributors to understanding differences between bodies (Nast and Pile 1998). These subfields have explored the power/knowledge relations associated with diverse embodiments and the theoretical implications of attending to, from, and with difference as it articulates bodies. They challenge the historically masculinist unmarked norms of the discipline and oppose the denial and distancing of the body, and the body/mind dualism, in classical geographic research. This work explores bodies as arenas through which social hierarchies are produced, reproduced, and contested and it takes seriously the scale of the body as a window onto power relations.

Early human geography assumed a classical Western philosophical notion of the human body, implicitly conceptualizing the human body as the common-sensical equivalent of an individual, universalizable person’s physical existence. In recent decades, scholars have increasingly challenged the assumption that bodies can be viewed as taken-for-granted sites of experience, and put forward analyses that question the ethico-political status of particular bodies, the limits and boundaries of individual and collective bodies, the dynamics of diverse embodied relations, and the relations of power that connect and divide raced, gendered, sexed, (dis)abled, and human/nonhuman bodies.

Human geography is deeply engaged in exploring how, why, where, and for whom specific individual and collective bodies and embodiments matter. The extraordinary interest in “the body” as a basis for a wide range of theoretical inquiries has affected most of the discipline’s subfields. Bodies figure as critical entry points for feminist research, sexuality studies, and critical race scholarship, social and cultural geographies, economic and political subfields, as well as themes in the margins of political ecology and population geography. Bodies, embodiment, and biopolitics now figure in research on topics as wide-ranging as care labor, migration, water governance, elderly people’s care, medical tourism, art, geopolitics, and warfare.
Feminist and critical geographers have contributed to conceptualizing and re-conceptualizing bodies and embodiment in virtually every theoretical register. For heuristic purposes, their interventions can be organized along the following five lines, all of which overlap and feed into one another in various ways: (i) phenomenological, living, sensing bodies, inspired by humanistic geography; (ii) laboring bodies, engaged from Marxist and socialist-feminist standpoints; (iii) disciplined and governed bodies, approached through poststructural insights; (iv) bodies of difference, cross-cut by gender, race, sexuality, and dis/ability, and informed by feminist, critical race, queer, and postcolonial theories; and (v) vital bodies, new materialist bodies, more-than-human bodies, and affective bodies, linked to a recuperation of bodies as alive with potential.

**Phenomenological, humanistic bodies**

In the 1970s, humanistic geographers paid renewed attention to bodies. They explored, for example, the ways in which bodies and places make each other and the meanings of an embodied sense of place. Their view of the body moved away from conceptions of bodies as units of human–environment relations. Rather, the bodies of humanistic geography were – and indeed are – sensorial, emotional, and perceptive. For phenomenological philosophers, the body was the fabric into which geographic processes were woven, and it was the primary instrument of perception and therefore comprehension. Humanistic geographers invoked the “body-subject” in the 1970s as an alternative to behavioralist views of bodies as objects. They argued that in order to develop more comprehensive spatial knowledge, geographers needed to examine spaces as felt and perceived first and foremost through the immediate experience of the body from which abstract ideas develop. The phenomenological humanists understood humans to think only after our bodily experiences and they proposed that therefore all knowledge is embodied and should be recognized as such.

From this perspective, it is what the researcher’s body can touch, smell, taste, hear, and see that are the elements of human experience from which thought and analysis can follow. This lens on the body retains the longstanding binary of mind/body, and simply turns it on its head. Now, rather than privileging the observing mind as the origin point of knowledge production, scholars were encouraged to prioritize the sensing body. Attending to the bodies’ experiences in and with a place or a landscape could open up fresh ways of knowing those places that were not reducible to behavior. Phenomenological bodies were valorized for their capacities to sensorially interact with places. Embodied experiences and place-making were understood to take shape in tandem with one another.

Early humanistic geography placed people as feeling subjects at the center of analysis and it understood embodied experiences as central to the human experience of space and place; however, power was not a major concern for these scholars. Their sensing body tended to be one that was abstractable without reference to its location in political economy, discursive fields, or body politics of any kind. The differences across experiences of embodiment were not of particular interest to phenomenologists. Contemporary scholars of embodiment, however, have re-invoked phenomenology alongside feminist theories of performativity as important elements for the construction of a renewed, practice-oriented humanism (Simonsen 2013).

**Laboring bodies**
Marxist conceptions of the body have been especially important for thinking about the politics of labor albeit that capitalist processes tend to be understood as largely disembodied. From this perspective, labor is a form of mediation, a metabolic exchange, between the human body and its environment; as commodities are produced, the labor power of bodies is appropriated and surplus value is accumulated. The laboring body is exhausted by its exploitation in the labor process and its alienation from the means of production. A vast, rich literature examines laboring bodies, and the ways in which they are regulated, as keys to understanding the ways in which geographies of capitalist production and accumulation are socially and spatially organized (Harvey 1998) and how different forms of capitalism, including merchant, industrial, and post-Fordist forms, rely on different forms of embodied labor exploitation.

The body is also a key scale of analysis for geographers who study gentrification and its links to homelessness. Historical materialist work along these lines shows that homelessness takes shape through the interlinked scales of the body, public–private distinctions, the city, and the global economy. Homeless bodies are rendered undeserving poor whose lack of property ownership is both their fault and cause for their eviction from public space. As “urban renewal” programs displace low-income populations, they marginalize the bodies of low-income people. Bodies are evicted from public space both literally and representationally. Homelessness makes it difficult to care for one’s own or one’s family’s bodies. When the challenges mount of washing, feeding, and relieving one’s body in practice, homeless people face an uphill battle for social acceptance in the public sphere.

Feminist geographers added to critical political economic research with attention to gendered body spaces as structured by socially constructed gender roles within families, households, workplaces, cities, and suburbs. They first illustrated these gendered sociospatial divisions along the lines of male versus female bodies, although the body itself was not a major focus of investigation. In research on work places, they also showed how “public” and “private” spheres rely upon and produce one another through bodies. They argued that the marginalization of women’s bodies in public spaces and formal politics, and the coding of personal and private spheres as feminized, are central to the persistence of male dominance in politics and the public sphere and that bodies interact in gendered patterns that reproduce male dominance in the workplace (McDowell 2009). They found that gender divisions of paid and unpaid labor, and the devaluation of women’s work relative to men’s in both domestic and wage-earning spheres, shapes everything from global labor markets to immigration patterns and local economies.

Disciplined and governed bodies

Poststructuralist, particularly Foucauldian, scholarship has also influenced geographic understandings of bodies. Foucault placed the body and biopolitics front and center in his work. He saw the body as subjected to meticulous forms of state discipline and documented surveillance as deployed first and foremost on the body. Through objectification, classification, and enumeration, bodies are made into subjects and populations. Medical and punitive knowledge systems and technologies slot bodies into categories and types as technologies of rule. He shows how premodern public executions made a spectacle of the criminal body’s suffering and death, while the modern state exercises its power through modes of power that are interiorized by
subjects directed at their own bodies. The modern state shifts away from the body and corporeal punishment towards a preference for indirect control over bodies through governmentality.

Foucault also put forward the concept of biopower as a way of understanding how human populations are regulated and imagined. He saw biopower as integral to the growth of industrial capitalism in that capitalism relied upon the organized insertion of bodies into production relations. The ideal laboring body was produced in order to maximize its exploitation for the sake of production and to be docile for the sake of labor control. In this view, the forces of the body are managed for the sake of efficiency and productivity. He saw bodies as reflective of history and the history of capitalism as destructive of the body.

Poststructural research examines the continually produced, contested, and destroyed sets of ideas and practices that make and unmake bodies. It does not seek an originary experience in embodiment. Rather, it asks how bodies are politically produced as normal/other or civilized/barbaric and how specific ways of knowing the body (e.g., medicalized, laboring, criminalized) can shed light on the machinations of power in a particular place and time. It decenters the universal human subject and thereby encourages attention to the politics of representing, managing, and knowing bodies. Prior to poststructural attention to the body, and often in conversation with it, feminists with critical race sensibilities have produced extensive scholarship about bodies (Federici 2004).

Bodies of difference

For feminist geography, the body is at the crux of analysis. It is alternately a site of struggle, a text that is read and can be re-scripted, and the basis of experience and knowledge. When feminists introduced gender to human geography, their work demonstrated the importance of gendered and sexed bodies in the making of all sociospatial relations (Nast and Pile 1998). In early feminist geography, the body was a relatively straightforward second-wave Western feminist vision: biological sex differences existed in male and female bodies, while gendered inequalities were socially constructed and tied to sexed bodies in tandem with norms of masculinity and femininity.

Research informed by feminist theory has also explored the body as a starting point for analysis. In addition to seeing bodies as socialized and socially constructed, studies have explored the materiality of embodied experiences, grounded in flesh and blood. They have analyzed the difference that it makes to live in and from pregnant bodies, “fat bodies,” disabled bodies, and bodies undergoing weight loss (Moss and Dyck 2003; Longhurst and Johnston 2014). This research challenges the universality of Cartesian body spaces and allowed for thinking through the body to understand the making of other geographies.

Tracing the specific ways that feminist geographers have approached bodies is therefore illustrative of multiple itineraries provoked by feminist interventions in human geography more generally. Research in human geography increasingly blends strands of these theoretical schools of thought and postcolonial and antiracist work has made key contributions to geographies of bodies. It reveals the deep histories and contemporary persistence of extreme and everyday forms of violence directed at black bodies (McKittrick 2000) and charts representational and epistemic violence tied to the discursive racialization of bodies. This work illustrates black bodies’ disproportionate subjection to slavery, imprisonment, and poverty.
Colonial narratives represented black bodies as more closely affiliated with nature in distinction to white bodies’ association with knowledge and the capacity to transcend the body through reason. Critical race scholars have analyzed “whiteness” as it attaches to, and is deployed via, privileged bodies. Recent antiracist research has turned a critical eye on the power of whiteness as it is produced through embodied relations. This work examines and exposes the power inequalities tied to emplaced racial hierarchies as they emerge in old and new forms. It shows how the unmarked norms of whiteness shape structures, policies, and knowledge in racialized terms that attach to bodies. Racialized power relations emit from myths about bodies as well as through bodily comportment, intersecting with multiple sociospatial hierarchies of belonging, entitlement, and power that also take embodied forms.

Much postcolonial critique can be read as warnings about how not to read or write the body. It invites geographers to think about aspects of bodies that are untranslatable because of their difference and their submersion in official historical transcripts. The subaltern subject is both discursively produced as devalued and othered, as well as a point from which to rethink Western assumptions about being, meaning, and voice. Recent theoretical research has returned to an examination of the materiality of phenotype in terms of its inescapable embodiment. Here the body is both a productive force and produced by its interactions with other bodies, embedded in histories both conscious and unconscious. Power relations surface in and on bodies and simultaneously shape the emergence and itineraries of bodies themselves. Bodies are contested terrain and malleable to some degree and people can recast aspects of the ways their bodies are read. Studies of mixed race women have highlighted the indeterminacy of bodies and the power of performativity in making embodied meanings and identities.

Sexuality is also embodied and queer theorists have made important contributions to understanding bodies and space. Scholars of sexuality and space have unpacked the heteronormative geographies at the base of much research and they have provided alternative theorizations of space and place that take seriously the standpoints of gay, lesbian, bisexual, and transgendered people. For example, they have shown that the domestic space discussed in second-wave liberal feminism was not only a patriarchal space, but also a heteronormative one underpinned by prescriptive heterosexuality. They have shown how lesbian, gay, bisexual, and transgender (LGBT) “public” and “private” spaces differ from heteronormative usages of these spaces and categories, both in terms of homophobic exclusions from various “publics” and reworkings of “private” not only as domestic but also in conjunction with sexual identities. They have studied the specificities of LGBT spatial practices to show how sexuality, for example, affects migration aspirations and embodied experiences of borders. For scholars of sexuality and space, bodies are crucial for thinking through not just power and difference, but also desire, affiliation, and identity. The transgender body, when understood as transformed in order for the person to change what s/he felt was the “wrong” body so s/he can live in a body that aligns with his/her sexed/gendered self, requires thinking about embodiment as irreducible to the dualisms of nature–culture, bios–technos, and sex–gender.

Every one of geography’s foundational concepts has been reconsidered with attention to difference. Different bodies – gendered, raced, and sexed – encounter and make places unequally through practices of spatial inclusion, exclusion, integration, management, control, travel, habitation, and claims-making, practices...
that are directed at bodies and that are encountered and challenged through bodies. Space itself is produced through embodied social relations of difference that take specific forms over time, whether researchers are tracing racialized residential segregation, women's bodies in the street or at night, HIV/AIDS activism, access to health care, embodied consequences of economic crises, or the highly unequal effects of war. The injustice of counting some bodies, and therefore some lives, more than others has galvanized tremendous oppositional activism. “Black Lives Matter” has emerged as a key rallying phrase for activists organizing in opposition to recent deaths of unarmed African American men at the hands of police. These are struggles, like the struggles of indigenous women in Canada to bring attention to the many murdered and disappeared women from First Nations communities, and like the struggles of feminist activists in Ciudad Juárez to make visible the femicide in their midst, to reassert the value of these different bodies as human lives.

Post-poststructural bodies

There are new theoretical languages to talk about bodies and embodiment. Renewed materialisms have reminded scholars that bodies – as matter – “talk” through actions including breathing, eating, reproducing, bleeding, ailing, and dying. In geography, such dimensions of bodily expression and experience have tended to be overlooked in research originating from disembodied observation and analysis. But when bodies re-enter the conversation the terms of dialogue shift. Some bodies’ pleasures, pain, illness, injury, and death are heard more than others. Antiracist and postcolonial geography have added the narratives of previously unrecorded voices and explored the ways that recuperating these bodies reconfigures the ways researchers understand historical agents and the dynamics of political economy.

Rather than starting with individual bodies as a focus, some important research attends to the relationships that arise when multiple bodies congregate together in a place. Studies have asked what results from many bodies coming together (Saldhana 2008) tracing the aggregate characteristics of groups of bodies to begin to explore how human bodies stick together not only in crowds, but also in neighborhoods, regions, cities, and nations. This work is decidedly relational in its approach to bodies, concentrating on how bodies affect each other as collective forces, energies, directions. The goal is less to understand the interiority or limits of individual bodies and more to examine bodies as always influenced by the other bodies they encounter. Bodies that come together in alliance for a cause may generate collective political power enriched through physical contact.

The “affective turn” in social and cultural geography has also prompted fresh questions about how we understand what influences bodies and what bodies can do. In particular, it asks what affects – rather than what causes, determines, structures, or produces – bodies, thereby enabling attention to the social reverberations of, for example, fear of violence or anxiety about economic futures. Bodies are affected not only by their material surroundings, the health care that is available to them, the food they consume, or the protections they lack or enjoy, but also (and in specifically socially located ways) by the tenor of public discourse, for example, of state-circulated scare tactics or widespread anxiety about economic decline.

Defining bodies in terms of affect makes capacities of bodies emergent rather than innate. It shifts attention from what a body is to what a body can do and what a body can become, thus
emphasizing the understanding of individual bodies as processes, always open, contingent, vital, and filled with potential. In this work, a body can be anything ranging from an animal to a mind, an idea, a linguistic corpus, or a social collectivity.

Geography has also returned to humanistic and phenomenological philosophical roots with some new twists. Building on these traditions, posthumanist philosophy is opening up a host of exciting questions for thinking about how bodies figure in human geography. First, it allows for the possibility that individual bodies may be sites where multiple selves reside or as complex compositions of multiple other bodies. Second, it asks where bodily boundaries might be drawn beyond the limit of the skin, and how bodies can be understood relationally, as lives are lived. Posthuman geographers are working to think beyond the body as the core, the interior, or the scale “closest in” of human being, and seeing it instead as a force in dynamic tension with nature and more-than-human bodies. In this growing collection of work, the human body is just one among many assemblages that have power to make and remake the planet, and our bodies are compositions of shifting interconnections, unbound and unhinged (Simonsen 2013).

Borders, boundaries, and borderlands

David Newman
Ben-Gurion University of the Negev, Israel

Geographers have traditionally viewed boundaries as lying at the very heart of their discipline. Since geography is concerned with the study of areal and spatial differentiation, the existence of territorial boundaries is taken as normative in the sense that the compartmentalization of social, economic, and cultural spaces assumes the presence of lines that separate these spaces from each other. The geographic literature in general, and the political geographic literature in particular, is replete with the study of boundaries as a category, building on numerous boundary case studies. While the bulk of this literature has focused on the international dimension of boundaries, the existence and functions of administrative, municipal, planning, and other forms of localized boundaries have also been studied. Nonetheless, it is the international boundary that has traditionally been seen as the most distinct of geographic demarcators, separating the sovereign state from its neighbor and, as such, determining the nature of the political and economic development on either side of the boundary (Newman 2006).

Political geographers have traditionally differentiated between the concepts of borders, boundaries, and frontiers. The border is a political concept, which identifies the territorial limits of the state and beyond where movement is limited to those with the necessary permits and documents. The boundary is a looser term, which signifies the territorial margins of the state, reflecting other social and ethnic characteristics of the population on either side. Recent literature has tended to downplay any significant difference in the use of these two concepts. The frontier is a zone, rather than single line, and signifies the area on each side of a border or boundary within which human activity is impacted by the presence of the border. This impact may change significantly depending on whether the border is “open” or “closed,” or whether it is a border between friendly countries or those at war with each other. Frontiers, also known in the recent literature as “borderlands” or “transition zones,” are those areas straddling both sides of the boundary where peoples from both sides can interact as part of the border opening process, and where, over long periods of time, ethnic and political hybridity may emerge.

Prior to the 1960s, political geographers focused on a descriptive analysis and categorization of international borders and the processes through which such borders have been delimited and demarcated. It was common for scholars to typologize the different types of border, based on the way in which they had been demarcated, during a period of major reterritorialization that took place, particularly in Europe, after each of the world wars (Jones 1959; Rankin and Schofield 2004). The classic border typology that appeared in many of the introductory political geography texts was that of Richard Hartshorne. Borrowing terms from fluvial geomorphology, he classified boundaries as antecedent, subsequent, and superimposed, the last describing the many colonial boundaries that had been drawn up by European powers in their division.
of territories in Africa, Asia, and the Middle East (Hartshorne 1936).

As with political geography and geopolitics in general, the period immediately following World War II lacked any significant border analysis, notable exceptions being Pound’s work on natural boundary ideologies (Pounds 1951) or Julian Minghi’s seminal overview of global boundaries and their categorizations in the *Annals of the Association of American Geographers* in the early 1960s (Minghi 1963).

The renaissance of border studies was spurred on by the globalization narratives of the late 1980s and 1990s (Ohmae 1990; Newman and Paasi 1998; Paasi 1998), which posited a “borderless” world as a result of structural cross-border processes such as the emergence of cyberspace and the global flow of capital, along with the historical and political contingencies of the fall of the East–West divide, along with the collapse of the Berlin Wall, the expansion of the European Union, and the removal of intra-European borders between the member states. While recognizing the impact of such processes on the function and significance of contemporary borders, scholars rejected the notion of a borderless, de-compartmentalized world, and began to meet across the disciplinary boundaries to examine the border phenomenon in greater depth and to provide a counter narrative to the idealized borderless world scenario. This collaboration included a deeper understanding of border management, power relations at the border, vertical, cultural, and social borders, invisible and perceived borders, and the spaces around the border that created borderlands, zones of transition, and spaces of hybridity.

Emerging initially as a counter narrative to the globalization theses of a “borderless world,” border studies have become transformed into a distinct subdiscipline within the world of political geography in its own right (Brunet-Jailly 2005; Kolossov 2005; Paasi 2005), drawing together scholars from diverse disciplines beyond the limited scope of geographers and political scientists. This has become evident in a growing number of research networks, conferences and workshops, and publications. These include ABS (Association of Borderland Studies), IBRU (International Boundaries Research Unit), BRIT (Border Regions in Transition Network), ABORNE (African Borders Research Network), all of which hold annual conferences and workshops. In addition to an exponential growth of border-related papers that have been published in both political geography and geopolitics, the *Journal of Borderland Studies* has emerged as an important outlet for such research in recent years, moving from a case-study oriented approach to a higher number of theoretical and conceptual contributions. Major research funding projects have, during the past decade, focused on border related topics, recent examples including the European funded research consortia, such as the FP5 EUBorder Conf and the FP7 EUROBORDERscapes, the Canadian funded Borders in Globalization (BIG) project, and the Finnish Academy funded RELATE Centre of Excellence for the study of Bordering, Identities, and Transnationalization.

A disproportionate amount of recent research has focused on case studies, especially those which describe the processes through which previously closed borders have opened and across which residents of one side undertake their journey of discovery to meet the other side. The subject of cross-border regions has been the focus of intensive discussion, especially throughout the expanding spatial sphere of the European Union. The process through which borders have opened and become more porous has been accompanied by a growing interest in the reclosing of borders, which has accompanied the securitization discourses of the post-9/11
era and a return to a renewed focus on border control, management, and surveillance.

There has not been the creation of a single border theory as such, bringing together different types and scales of border, but there has been a cross-disciplinary discussion (itself an interesting example of the ways in which borders are negotiated and crossed within the academic world and through which both scholars and practitioners with different experiences meet each other in cross-disciplinary transition zones) of a common glossary of terms of relevance to all types of border scholars (Newman 2006, 2011). These, as will be discussed in the remainder of this entry, bring together borders as a functional and dynamic process, boundary producing practices discussed within critical geopolitics in the 1990s, and the process of bordering as aptly coined by one of the leading border theorists, Henk van Houtum, from the University of Nijmegen, rather than simply as a physical and unchanging spatial outcome of a political or social process (van Houtum 2005). The common use of terms, albeit in different contexts, such as demarcation and delimitation of borders, the management and control of borders, power relations, the ways in which borders are represented, and border zones as spaces as contrasted with borders as lines, have been found to constitute common terms of interest to the growing diversity of border scholars.

Themes in contemporary border studies

Opening and closing of borders: parallel discourse

As the nature of the territory–state discourse has changed in recent years, so too has the role and function of boundaries. The end of the nation–state brought with it a parallel argument relating to the disappearance of boundaries. The impact of economic globalization, the dissemination of information and knowledge through cyberspace, and the firing of ballistic missiles over long distances paying scant regard to the physical existence or location of borders have greatly reduced the significance of boundaries in their traditional function of constituting barriers to the movement of people, weapons, goods, or ideas. The opening of borders was contingent upon the structural changes of globalization in such areas as the free flow of global capital, the cross–border cyberspaces that enabled information and communication to bypass the traditional border barrier controls, along with the political and historical changes, such as the fall of the iron curtain on the one hand and the removal of internal borders within the ever-expanding European Union on the other.

Notwithstanding, a brief glance at the map of the world shows that, despite the discourse of new world orders, the basic territorial compartmentalization of the globe remains strongly based on the existing pattern of sovereign states. Reterritorialization (as contrasted with the problematic notion of deterritorialization) continues to impact the world political map, even if the functions and significances of the borders – not least the disappearance of many of the physical and visible elements of the border fence – are constantly changing. The opening of borders and the easing of cross-border physical movement in some places have brought about new suprastate and intrastate geopolitical interactions, in many cases ignoring the state altogether. But while some boundaries were opened up to movement and became more permeable, many countries have created new fences of separation in an attempt to strengthen their own senses of identity and control mechanisms, not least in areas of continued ethnic or national conflict. In short, the processes affecting borders and boundaries in the contemporary world are geographically
differentiated, opening in some places, closing in others, contingent upon the constant dynamics of political and geopolitical change.

Nowhere is this process more apparent today than in parts of the Middle East where, in addition to unresolved problems of territorial demarcation for an independent Palestinian State, much of the region has been thrown into turmoil through the emergence of the Islamic State, which controls territories beyond the boundaries that emerged almost a hundred years ago following the dissolution of the Ottoman Empire, the Sykes–Picot arrangements, and the imposition of boundaries by the European powers.

Following the events of 9/11 and the emergence of global terror and violence, there has been a move toward the resealing and reclosing of borders as a means through which states prevent “alien” and “illegal” elements from crossing into the territories and the space of the homeland. This securitization discourse is itself a counter-narrative of the open border and has been, to a limited extent, shunned by critical scholars who see the border opening process as an idealized position that reflects the “good” as contrasted with the closed and the controlled as the “bad.” Notwithstanding, the number of closed and sealed borders as reflected in the large number of new fences and walls that have been constructed by states during the past decade as a means of preventing terrorism and violence from crossing the border is of major significance. This has become even more marked in the immediate aftermath of the mass flows of refugees and migrants escaping the ravages of war and famine in the Middle East (especially Syria) and Africa, and the inability of the European Union to deal with the humanitarian problem that has emerged. New fences have been constructed, but unlike those of previous eras, they are proving to be largely ineffective in providing barriers to the mass flow of people seeking to cross the borders at all costs. In one respect, new borders are more sophisticated in terms of the highly sophisticated surveillance and control techniques, well beyond the limited capabilities of a border guard, at a specific location along the border (such as in the US or Israel and its neighbors), while in other areas (such as the outer frontiers of the EU along the Schengen line), governments are unable to deal with the sudden mass movement of refugees, again reflecting the contrasting dynamics of contemporary border management.

The use of the securitization narrative has also been manipulated by those states that desire to prevent the continued transboundary movement of illegal immigrants from poorer countries seeking employment and life improvement opportunities. While in the past states could deal with the cross-border movement of migrants, remote from the public eye and the mass media, in whatever way they chose, such is no longer the case. Human rights groups, border ethics, and a wider focus on multiculturalism have prevented states from undertaking the sort of anti-immigrant actions that were common in the past for as long as the reason for crossing borders was to seek life improvement opportunities. The use of the securitization discourse by departments of homeland security, appealing to the base instincts of the public by highlighting the physical threat from terrorism and violence if the border remains uncontrolled, has proven to be a powerful means to enforce greater surveillance and more stringent controls over those who desire to cross borders from one side to the other.

The contemporary study of borders and boundaries reflects ongoing political practice of states and lobby groups, negotiating between two parallel border narratives: that of the borderless world, which brings about the opening and
eventual removal of borders, as contrasted with that of securitization, which brings about the closing and rescaling of borders (Newman 2015). This is not a binary distinction as each has its backers, a powerful economic lobby promoting unrestricted movement of people, goods, and capital, and a powerful securitization lobby promoting a return to stringent border control and management techniques. Both are considered important for the state as they seek to promote economic transactions and flows and to reduce the security threats (real or perceived) from the emergence of global violence and fundamentalist ideologies. There is not therefore a return to the previous notions of closed boundaries protecting the homeland population from the neighboring state, but an attempt to reshape the function of borders as barriers to threats that are themselves part of the way in which globalization has impacted and enabled the dissemination of knowledge – including knowledge that assists terrorism and violence – across borders.

In the North American example, NAFTA (Northern American Free Trade Agreement) and related economic agencies promote global trade and commerce and endeavor to create porous borders for the flow of people, labor, goods, and capital, as contrasted with the role of the US Department of Homeland Security, which endeavors to retain as tight control of borders as possible. In the eyes of Homeland Security, workers crossing the border are perceived as potential terrorist threats unless and until proven otherwise and this perception often enables governments to control the flow of labor migration under the guise of securitization – a discourse more acceptable to public opinion for justifying the stringent and, in some cases, less than ethical means used by border guards and security agents to prevent people from crossing the border from the “out” territory to the “in” territory.

Border diversity and scale

Borders may have common functions but they are diverse in nature. This point is as relevant to the spatial scale of those borders that impact our daily lives as it is to the non-geographic societal borders, the vertical constructs, through which society is compartmentalized and ordered. Equally, borders do not have to be visible to be effective. The perceived borders, the lines in the imagination, which prevent us from crossing from one place or one group into another, do not require the physical dimensions of fences and walls in order for them to impact upon our daily life patterns.

The decreasing significance of territorial borders between some states has served to highlight the increased importance of spatial borders at other spatial scales of analysis, which may affect our lives in a more powerful way than do the lines that separate one state in the international system from its neighbor. The analysis of scale in border studies is of major significance. We reside within urban, municipal, and other functional spaces, which impact our daily life patterns to a much greater extent than does the occasional crossing of the border between states. The provision of public services, the payment of property taxes, the registration of our children to schools or to health providers are but a few of the major life activities that are contingent upon the arbitrary demarcation of local borders by planners, bureaucrats, and municipal officials. Once demarcated, they can be difficult to change even if the dynamics of life change the nature of the urban segregation and stratification process much more speedily than the relatively slow, albeit sudden, changing of state borders. The establishment of municipal boundary commissions, with the object of resynchronizing urban and municipal boundaries in line with residential change and metropolitan expansion, is accompanied by much political intervention and spatial
engineering and gerrymandering. The determination of electoral districts or constituencies by redrawing borders is perhaps the most blatant of all boundary demarcation exercises, reflecting spatial change on the one hand and engineering political change on the other.

Most of us live within a highly fragmented set of spatial and social compartments. Society is too complex for all of the local borders to correspond with each other. Some borders, such as those that contain the municipalities to which people pay taxes or the school districts within which they are allowed to register their children for education, are more apparent than others. People are aware of many of the borders that determine their lives only on the few occasions when they are in need of them – a police or a fire district – and when these do not correspond with the other local borders with which they are familiar, they become unable to function with the same efficiency and certainty that they do in other spheres. Thus local borders are only of importance when the life function they demarcate is necessary; however, the fact that they play no significance in people’s daily lives for most of the time does not mean that they do not exist or that they do not play a role in the way in which society is spatially compartmentalized or socially ordered.

While such borders are mostly invisible to the eye and are not reflected in walls, fences, or security guards, their impact is of major significance. Most of the world’s population have never crossed an international border and do not possess the documentation to do so. Such is not only the case of the less developed world. When, in the 2000s, as a result of increased fear within North America from the flow of terror across the country’s borders, US citizens were obliged to have passports instead of relying solely on driving licenses to cross the border to Mexico or to Canada, it emerged that no more than 15% of the country’s citizens had ever taken out a passport or moved beyond the lines separating the United States from any other country in the international system. The most significant border crossing for much of the US population is that which separates the internal states from each other within the federal system of states, which may have different rates of local taxation, laws relating to liquor, or highway speed limits. These borders are geographical in nature – they significantly impact daily life patterns, but are vastly different in the ways that they are managed and controlled as contrasted with the borders that separate the United States from its neighboring countries.

The study of scale differences is also of importance in terms of the borders that separate one individual from the other – the self-spaces that we create, or are created for us, around the body, and in our relations with our neighbors. This entry does not address this scale of border analysis, other than to remark that a deeper understanding of personal spaces also requires another layer of understanding how such borders are created (demarcated) and what mechanisms are used (border control and management) to defend such personal spaces from the intrusion of others, while allowing loved or trusted ones to enter the space of the self.

A second form of border diversity is concerned with the vertical and societal borders, not all of which are spatial or geographical although their dispersion throughout space may have major geographical implications. Many socioeconomic or cultural groups cross borders in terms of a single fixed territorial location and their boundaries as such are movable or to be found in multiple locations at one and the same time. The emergence of a cross-disciplinary interest in borders has highlighted the common functional concerns with the way that borders are demarcated and controlled, no less in the way that people are compartmentalized within social or cultural categories than they are within
geographical districts. The hegemony with which geographers traditionally understood the concept of borders as being an essential spatial concept has been replaced by an understanding that borders create order in a complex world not only between geographic spaces, but also between cultural, social, religious, and economic groups, all of which contribute to the notion of societal compartmentalization. Each has its own border, its own processes of demarcation and delimitation, means of effectively controlling and managing the border, and its crossing points. Crossing from one territory into another may be relatively easy with the problems encountered by people attempting to cross from one cultural or religious group into another and the ways in which they negotiate, through documents, customs, or even linguistic skills (the ultimate sealed border for one who does not speak the requisite language) to move beyond the border.

The division of society into cultural, religious, and economic groups, to name but a few of the more major categories, is about borders and compartments. Notions of demarcation, delimitation, crossing borders, and border management are as much part of the discourse of sociologists, political scientists, anthropologists, and economists as they are of geographers. The functional terminologies discussed in this review are common to all forms and types of border, be they geographical or cultural, visible or invisible, local or global. The crossing of disciplinary borders creates a cross-border community of ideas, which is at the core of the recent renaissance of border studies within the social sciences.

The third form of border diversity is concerned with the tangibility or invisibility of boundaries. Borders can be perceived as much as they are visible or tangible. Within urban environments, specific neighborhoods and their assumed cultural characteristics are as much about image as they are about reality. Residents do not cross beyond certain self-perceived limits, a major transportation artery, or a major road junction, assuming the people on the “other” side to be different – in terms of racial characteristics, income levels, or ethnic diversity. The imagined borders of the urban landscape are as much about the creation of borders and self-imposed prophecies as they are about the ways in which they may reflect already existing realities and difference. In this context, Stephen Graham has discussed the role of urban dividing lines and their scalar connection to wider spaces and processes (Graham 2010). The perception of borders can be much harder to change than the physical removal of boundaries. With this knowledge many groups who are in positions of power (see next section), and are able to determine the constant formation and reformation of urban landscapes for their own political or economic ends, are able to manipulate the ways in which space remains segregated, or undergoes new processes of segregation, through the demarcation of municipal boundaries and/or the manipulation of the housing market within both the public and private spheres.

Power relations at the border

A major theme within all areas of border studies concerns the nature of power relations (Newman 2003). Power relations are as relevant in terms of those who undertake the processes of demarcation and delimitation as they are of those (often the same power elites) who determine the ways in which borders are managed and controlled. The decision to “open” or “close” borders is a political decision reflecting power interests as is the decision to relocate the control of borders away from the physical location of the border – in the middle of airport terminals in a foreign country or behind the faceless desk of a visa bureaucrat half way around the
BORDERS, BOUNDARIES, AND BORDERLANDS

world. Power thus determines the changing geographical location of the border and the border guard, aided and abetted by technology that intensifies border surveillance and management rather than contribute to the weakening of the barrier functions of borders. This management is in sharp contrast to the role of technology that was highlighted in the globalization debates of the 1980s and 1990s and that assumed a direct correlation between technology and the opening of borders as part of a uni-directional process.

The very existence of borders is essentially a function of political power. All borders are politically and socially constructed. They may result from military conquest, cultural hegemony, or from bilateral agreements, depending on the extent to which power is asymmetrical and borders are either imposed by one powerful side or agreed upon by two or more sides. The demarcation of many state boundaries has been superimposed as a result of victory in times of war. Their delimitation has not taken account of the requirements (legitimate or otherwise) of the vanquished side, not least in situations where warfare has focused around contested claims for valuable natural resources within the borderland or the inclusion of ethnic groups as part of the national entity. The construction of borders may signify identity, but is more significant in the determination of citizenship. This situation also raises many critical questions concerning the ethics of border construction, superimposition, and management that have been addressed by scholars in recent years (Williams 2003; van Houtum and Boedeltje 2009).

There is no such thing as a “natural boundary” in the sense that the physical topography determines the course and the location of the boundary. But where it is convenient for the power elites to make use of natural features and where it does not conflict with their political objectives, states will use them. The use of natural features would have been common in pre-technological historical periods of reduced mobility and access from one region to another. As such, the initial location of boundaries affected the development and consolidation of state territories over time. But where states have undergone processes of reterritorialization, especially through the past century, the natural features are only used by power hegemonies to determine the course of the boundary where it serves other political purposes. In many cases, natural features, such as the location of mineral deposits or the flow of riparian waters, are precisely the factors determining their inclusion by the power elites within their own territories. In the past, such factors were often the catalysts for territorial conflict.

In situations where ethnic majorities and minorities are split across boundaries and constitute spatial minorities in neighboring states, the formal determination of citizenship is contingent upon boundaries, even where this conflicts with critical issues of national identity. The superimposition of borders upon ethnic landscapes is a function of asymmetrical power relations. The long straight geometric lines so common throughout Africa and, until recently, in much of the Middle East are the most blatant example of the use of power to superimpose borders upon a landscape. This demarcation may have resulted in the division of homogeneous ethnic territories between neighboring states, reducing relatively large ethnic groups to minority status in neighboring political entities. Probably the most significant twentieth-century example of such division resulting from a process of re-bordering is that of the Kurds. The post-World War I victorious powers, seeking to re-compartmentalize the territories that had been under the control of the Ottoman Empire, and according to the realpolitik interests of the period, drew lines in the heart of the Kurdish territory, fragmenting the region between Iran, Iraq, and Turkey, with smaller
residuals in both the Soviet Union and Syria and leaving them as ethnic minorities within those neighboring states. One hundred years after the demarcation of Middle Eastern boundaries along the principles of the Sykes–Picot agreement, with the upsurge in internal discord, the Arab “spring,” and the rise in the power of the Islamic State, the artificially constructed borders of this region are falling away. The contemporary turbulent events in the Middle East have resulted, once again, in attempts to redraw borders and enable the Kurds to establish their own independent political territories.

The same can be said for Germans during the period of the division of Germany or Palestinians following the partition of Palestine in 1948–1949. In both cases a single ethnic group was split beyond the boundaries imposed as a result of political conflict. While their cultural identity remains unchanged, their separate citizenship is determined by the border regime. Instead of constituting a majority ethnic group as part of a “nation” state, they remain ethnic (and in some cases persecuted) minorities in neighboring states, where the borders are rigidly controlled in an attempt to prevent cross-border alliances against the existing state regimes.

Control is exercised as an absolute concept throughout state territory as far as the border. This claim contrasts with normative geographical theory in many areas of economic and social development, which emphasizes distance decay as a major explanatory factor for geographical and spatial differentiation. Notions of sovereignty do not, on paper, comply with the concept of core and periphery, where the process is stronger in one place than in another. The border is the ultimate delimiter in that it separates absolute control from zero control across a relatively small geographic space. It is this function of borders that has been challenged more than any other by globalization and that may yet serve to change the essential power relations at and beyond the border.

Border superimposition has also resulted in the opposite phenomenon, namely, the inclusion of multiple ethnic groups within a single political territory, resulting in competition for power and control and, in many cases in Africa and more recently the Middle East, civil strife and warfare, ethnic expulsion, and genocide. For a continent that has had to come to terms with the violent legacy of border superimposition in regions where territorial behavior for thousands of years was not based around fixed territories with lines that could not be crossed, contemporary westernized notions of borderless worlds are as much a superimposition of political hegemonies as was the imposition of the borders in the first place. The major difference between the two periods is that it was the Western powers, external to the region, who determined the territorial map one hundred years ago, while today it is the local power elites who determine the ways in which territorial power is to be distributed.

The same powers that determine the criteria for border demarcation also determine the ways in which borders are to be managed, especially regarding who and what can cross the border from one side to the other and under what conditions. The necessary documentation in the form of passports, visas, and other forms of identity documents and permits is a powerful form of border control that enables state agencies to permit or prevent people or goods (lacking the necessary customs fees) from freely crossing in a world of fixed territories. As border smuggling has become more sophisticated and as people cross national and other borders in cyberspace without physically moving from one place to another, so too the forms of surveillance and control have become more advanced and technologically sophisticated, as reflected in a major growth in the field of research on
border surveillance, often funded by respective departments of homeland security who seek ways in which to make borders more difficult to cross and even hermetically sealed in some places. The location of the border control point has moved partly away from the border itself to places where control can be exercised at a distance—such as the checking of passports in airports many thousands of miles away from the country to where entry is sought or to an office in Washington that collects surveillance data of movement across the US–Mexico border within seconds and relays these data back to the local control centers.

As borders were initially transformed from closed (sealed) to open and porous (or vice versa) it was initially assumed that this transformation reflected a transfer of power from one elite to another, as governments with different perspectives on global geopolitics wrested power one from the other. But in retrospect, it is the same power elites who, having determined what was in their political and economic interests at a time of border construction, are able to adapt with the changing global realities and to modify their policies vis-à-vis border management as a world of flows, movement, and networks serves their interests in the same way as did a previous world of closed compartments. It is essentially another way in which power is institutionalized within existing bureaucracies and governmental elites enabling power to be maintained even in the face of volatile global and regional transformation.

Borderlands and cross-border zones

Borders have become associated with the notion of the borderland, the functional space within which development is impacted by the existence of the border or the boundary in close proximity. A borderland is defined as a region in close proximity to a political border, within which development diverges from what would have been expected under normal planning models. Such spaces are not symmetrical on each side of the border and functions may extend more on one side of the border than the other, contingent upon both the nature of the border itself, and the government policies and investment within the border zone. In cases of cross-border tensions and animosities, where borders remain largely closed to the movement of people and goods from one side to the other, such policies can vary from extensive investment and development as a means of ensuring a bolstered presence along the border or a lack of resources in a region that is considered potentially at risk of conflict and potential destruction.

The literature has used different terminologies to describe cross-border spaces, including political frontiers, borderlands, cross-border regions, and border zones. The common point about all of these terms is that they focus on an area or space as contrasted with a single line. The extent of contact or meeting across the border line determines the extent to which the border functions as a barrier to movement or as a place where meeting takes place and, in some cases, where cultural and social hybridity is created. Cross-border spaces are particularly effective in regions where a process of border opening is taking place and where the initial cross-border contacts can take place at grassroots levels of mundane daily activities such as food provision, tourism, and commerce.

As borders in many parts of the world have become increasingly porous, the borderland has become transformed into a zone of transition where peoples and cultures, previously separated from each other, come into contact and create a place of meeting. Cultural transition between two distinct peoples or cultures may take place. In some cases there may even be cultural hybridity as the previous distance decay between state
cores and peripheries is replaced with a transition from one culture to another. The European Union in particular has created transboundary or cross-border regions within the borderlands as a means of easing the border opening process and creating places of meeting and familiarity where there had previously been places of separation and ignorance of what takes place on the “other” side. These policies have eased the eventual border opening or erasure as new countries become members of the EU, enabling free movement from one state territory to another.

Cyberspace and satellite communications have contributed a great deal to the reduction of cross-border animosities, as they depict the cross-border “other” as encountering the same daily life activities and problems. Such depictions may contrast with the governmentally constructed images of the cross-border “other” as constituting a threat from which the national self has to be protected through the construction of walls and fences and through stringent processes of border management. Cyberspace and globalization have contributed to a rethinking of the border phenomenon as borders that cannot be crossed on the ground have effectively been crossed on the internet and have removed the sense of threat and fear that traditionally emanated from the other side of the border.

Equally, the crossing of borders in cyberspace, has also brought about situations in which threat can be disseminated across boundaries that were previously closed. This is especially true of the dissemination of national ideologies, strengthening the role of diaspora groups and their attachment to their former “homelands,” even for those who are already second and third generations removed from their ancestral homelands. Such is also the case with the spread of global terror during the past fifteen years. The cross-border dissemination of messages, slogans, and information encouraging violence and anti-state behavior is enabled precisely through the use and manipulation of globalization technologies as state boundaries are no longer effective in preventing such flows of information from taking place. Thus, local populations are encouraged to take part in such activities (such as British citizens who were involved in the 7/7 bombings in London), rather than focusing on migrants who have physically crossed the border and have traditionally been perceived as the instigators of internal instability.

The existence of border regions in which the border can be crossed as part of normal life also highlights the changing understanding of cross-border difference. Much recent research in the field of border studies has focused on the changing mechanics and dynamics of the border crossing process. A misconception concerning the opening and crossing of borders was that as borders open, so difference is gradually erased and disappears. But the numerous narratives that accompany cross-border experiences strengthen, rather than diminish, the notion of difference on two sides of a border – in terms of the price of goods, the nature of the cuisine, the politeness (or rudeness) of the people, the language spoken, and so on. But the opening of the border enables such difference to be enjoyed and celebrated rather than constituting the underlying reason for threat. It strengthens the notion of the border as a line of cultural division or separation, but one that exists within a multicultural world where the previous binaries of “self” and “other” are to be shared and enjoyed, rather than feared out of a lack of knowledge and invisibility put in place by a sealed and impenetrable border. Difference that has existed across the border for hundreds of years will not disappear overnight as borders become easier to cross, but as borders become more porous and people cross them on a regular basis, difference no longer necessarily constitutes threat.
The celebration of difference within cross-border regions has also added a new dimension to the growing interest in border tourism. Both closed and open borders are a magnet for interested tourists. They are as eager to see and be photographed at the DMZ (demilitarized zone) in Korea or the points of transit between Israel and the West Bank as they are to experience different cultures and customs on each side of the border. Checkpoint Charlie in Berlin has become a major attraction for tourists, as have the few remaining border relics left by governments at former borders and around which new informal tourism commerce has emerged. There is a great potential for further border tourism and governments are eager to cash in on this new border phenomenon – at places of conflict as at places of peace.

Border representations and images

Much of the recent literature on geopolitics in general, and border studies in particular, has discussed the ways in which borders are represented in a variety of images, ranging from traditional sources such as cartography and paintings to additional media such as film, literature, caricatures, graffiti on walls, on the web, in Microsoft and other cyber products, and even poetry (Dell’Agnese and Amilhat-Szary 2015).

Images and representations of borders often reflect grassroots understandings of the impact and significance of borders. Maps and cartography were used in the past to create hegemonic views of the territorial configurations of state territories and the notion of the “correct” border in the eyes of the political elites and in the process of territorial socialization, especially in situations of territorial conflict between countries. Many caricatures of borders reflect the construction of walls and fences, rather than their removal, indicating the visual impact that such borders have on the public at large. The inability to move or communicate across borders is a theme often highlighted in films, as too the difficulties encountered when trying to cross closed or sealed borders. Smuggling across borders, illegal migration, or the crossing of the border from a dangerous to a safe space (including that of fugitives) are other common themes replayed in different geographical and political situations. Literature often focuses on the nature of difference expected to be encountered on either side of a closed border or, alternately, the discovery that perceived differences are not as threatening as originally thought when border crossings do take place. This topic offers much scope for future research and understanding of the significance of borders as they impact daily lives of both individuals and nations.

A Border Poem

Paul Muldoon (2001)

Boundary Commission

Your remember that village where the border ran down the middle of the street with the butcher and the baker in different states?

Today he remarked how a shower of rain had stopped so cleanly across Golightly’s Lane, it might have been a shower of glass that had toppled over.

He stood there, for ages, to wonder which side, if any, he should be on.

Boreal forest ecosystems

E.A. Johnson
Y.E. Martin
University of Calgary, Canada

The boreal forest is circumpolar (Figure 1) with two continuous parts, one in North America and the other in Eurasia. The two parts have similar tree genera and physiognomy. A few genera of both gymnosperms and angiosperms are common throughout the boreal (Table 1). Only a few tree species are strictly boreal and none are circumpolar. In species richness Asia has the most species, Europe the least, and North America is intermediate. The conifer physiognomy gives the boreal its distinctive characteristics. The orthotropic, monopodial trunks and plagiotropic branches help the trees shed snow because of their shape and flexible branches. The display of the needles along the tree trunk and around the branches is conducive to light capture at lower sun angles and the evergreen needles allow longer growing seasons and nutrient conservation.

The boreal flora is believed to be descended from mid- and late tertiary mountain forests. The flora and vegetation were established by the late Pliocene. The Pleistocene saw at least eight glacial–interglacial periods. In North America, only two possible boreal areas were not repeatedly covered by continental glaciation. However, there are several cryptic glacial refugia proposed based on genomic information. Genomics has advanced our understanding of possible centers in which populations survived glaciaation and spread. In both North America and Europe, populations closer to the furthest advance of the glaciers have been the most successful in the present boreal forest (e.g., Provan and Bennett 2008). Consequently, plants and animals had to migrate south as the ice advanced and then reinvaded during interglacials. Most of the boreal species survived quite a distance south of where they exist today.

One of the important findings of paleoecology has been how easily and often ecosystems can be reassembled. This is particularly true of the boreal ecosystems which have been repeatedly removed and reassembled from various surviving areas. The conclusion of Davis in 1979 still holds: interglacials were not long enough for plants and animals to have reached the extent of their ranges in which they could have survived, ecosystems throughout interglacials were constantly being invaded by new species, and modern species evolved in the biotic and abiotic instabilities of the Pleistocene. Therefore the boreal forest we see today is a melange of histories and conditions.

Until the middle of the last century the boreal was known best around its southern edges. Access further north was by water in summer and dog team in winter. There were and still are large areas without roads although planes, particularly small float planes, have made access better. The southern boreal was the site of optimistic settlement for agriculture from the end of the 1800s into the 1920s (Johnson and Miyanishi 2012). This settlement caused serious forest fragmentation and forest clearance caused wildfires which spread into nonagricultural lands. Thus, the southern edge of the boreal, although often
seen as natural, has an imprint of past land use. Scientific studies beyond observation and plant and animal collections only began in the 1930s, and from the 1950s to the 1990s the scientific research was primarily devoted to forestry and community ecology. In the 1980s, global climate model studies showed that higher northern latitudes would experience the most climate
Table 1  Boreal forest dominant trees: examples of “Rassendreise” (circles of species), series of allopatric (replacing) “species,” which perhaps are in many cases nothing but slightly differentiated geographical races.

warming. Further, the boreal forest accounts for one-third of the global carbon. This has resulted in a large number of carbon studies by individual researchers and large programs, for example, NASA-BOREAS.

The boreal has been aptly called a snow forest, but the zonation of vegetation is not related to winter hardiness. The boreal’s northern border is tundra while its southern borders can be semidesert, steppes, grassland, and conifer-deciduous forests. In North America the southern boundary of the boreal in the west is determined by the modal position of the arctic air mass in winter (Pielke and Vidale 1995). Support for this idea can be found in a physical model of heat and moisture limitation on reproduction of different vegetation types (e.g., Arris and Eagleson 1994). In eastern North America the boundary between the boreal and the deciduous forest is a transition zone of conifers and northern hardwoods. The northern boundary of the boreal has been attributed to the summer position of the arctic front but also to the interaction with the vegetated terrain (Bonan, Chapin, and Thompson 1995).

The boreal terrain in North America is largely glacial and mostly flat with incomplete drainage, slow moving waters, and numerous lakes and peatlands. The glacial deposits cover metamorphic and igneous rock on the Precambrian Shield. The southern edge of the Shield is covered by sedimentary rocks. The interior of Alaska has an assortment of terranes of metamorphic and sedimentary bedrock. The interior of Alaska was not completely glaciated but was affected by periglacial processes. These glacial processes explain most of the landscape forms and hydrological properties. Substrate can be divided roughly into till sediment deposed directly by the glacial ice, glaciofluvial, glaciolacustrine, and diamicton (poorly sorted and stratified material of glacial origin of a mixture of processes). Hydrological budgets usually depend on topographically defined watersheds which have
BOREAL FOREST ECOSYSTEMS

developed in landscapes that have not had long enough to come into approximate geomorphic and tectonic equilibrium. Also, the development of extensive peatlands in the last 3000 or 4000 years further disrupted the drainage systems. Surface and groundwater interact, creating complicated patterns so that groundwater does not always follow the surface topography. Buttle (2006) suggests three ways that the landscape template affects stream flow: typology defines the relative importance of vertical and lateral flow of water, topography defines the hydraulic gradient in a watershed, and topology defines the drainage network connectivity.

Overall, the water budget of boreal landscapes depends on the seasonal distribution of precipitation and evapotranspiration, the storage capacity of landscape units, permafrost, and the length of the season the water is not frozen. The boreal landscape is a series of hillslopes (uplands) and valleys in which some of these valleys will not have permanent streams. Many valleys and hillslopes have very little gradient and often are covered by peatlands (see below). The depth of the bedrock, glacial material, and peat will determine storage capacity and the spatial arrangement of the hydrological system. The runoff is further determined by a fill and spill system (Spence and Woo 2003) in which surface and subsurface water flows to the next downslope hydrological unit only after its storage capacity is filled. One can now see the importance of the landscape and seasonal distribution of precipitation and evapotranspiration. Table 2 gives a hierarchical arrangement of controlling factors showing how precipitation and potential evapotranspiration influence other factors. In years when \( P > PET \) the fill and spill connects runoff between hillslopes, valleys, and peatlands. But in times when \( P < PET \), hillslopes, valleys, and peatlands will be disconnected and runoff will be controlled by local gradients and storage. Permafrost reduces runoff by reducing the storage capacity, and in areas of incomplete coverage of permafrost the spatial differences in heat budgets play an important part in the distribution of permafrost in peatlands (e.g., peat plateaus) and hillslopes (fine textured soils on north facing slopes).

The spatial distribution of vegetation composition can be best understood by using environmental gradients once the time since disturbance has been removed. The moisture-nutrient gradients have proven to be the most important, followed by heat budgets. The latter is particularly true for those locations with upland permafrost. Moisture-nutrient gradients are most important because all landscapes consist of hillslopes which connect ridgelines and valleys even in the relatively low relief of most boreal regions. Consequently, since water runs downhill, the flow lines on hillslopes create, all else being equal, moisture gradients from drier ridges to wetter valleys. Nutrients are also carried in solution down these slopes. Figure 2 gives an example of the upland gradients in the south-central boreal forests of North America.

Peatlands are one of the distinctive features on both uplands and lowlands in the boreal. They come in many forms and the classification is sometimes confused because of different terms for the same feature. The principal environmental gradients are determined by the source of the input water and its mineral composition. Ombrotrophic peatlands, for example, bogs, are isolated from the mineral-rich ground and surface water. They get their mineral elements from precipitation. At the other extreme are minerotrophic peatlands, for example, fens and marshes, which are connected to mineral-rich ground and surface waters. Ombrotrophic peatlands are usually dominated by sphagnum and fens by feather moss (Amblystegiaceae family).

Swamps are forested usually by black spruce (\textit{Picea mariana}) in North America. Paludification is common in the boreal. Paludified peatlands have increased the water table and allow peat to expand onto the uplands. Continuous and discontinuous permafrost produce a series of distinctive peat features: pulsas, peat plateaus, and polygonal peat plateaus. In North America permafrost peatland features seem to be related to the annual –1°C isotherm, suggesting a heat budget reason (Vitt, Halsey, and Zoltai 1994).

Hugh Raup pointed out in his 1940 \textit{Botanical Reviews} articles of the boreal that the idea of succession developed in temperate grasslands and deciduous forests did not work well in the boreal forest. It seemed, when using the traditional idea of succession, that most of the boreal forests were still early successional. The missing ingredient was an understanding of natural disturbances, mainly insect outbreaks and wildfires caused by lightning. Traditional upland boreal succession considered disturbance as either rare or a result of humans. When disturbance did
Figure 2  General gradient of moisture and nutrients on glaciofluvial and till hillslopes. BOREAL FOREST ECOSYSTEMS

occur, succession resulted first in the invasion of herbs and shrubs, then fast-growing, shade intolerant trees (e.g., aspen (*Populus tremuloides*), jack pine (*Pinus banksiana*), and black spruce), followed by more slow-growing, shade tolerant trees such as white spruce (*Picea glauca*). The last stage was believed to be self-replacing. This is somewhat of a cartoon version of succession but gives the essence. Early studies of disturbance gave a descriptive chronology of the stages of recovery. Gradually, ecologists like Raup began to question and determine the disturbance frequency (or its inverse the return times). This led to a very important change in viewpoint, allowing disturbance to be seen not as an accident, but as a process that accounted for the survivorship distribution of the forested landscape. The disturbances were the result of both physical and biotic processes. Consequently, the connection of the disturbance process to the ecological processes became necessary. With this new viewpoint the changes in the boreal forest could be understood in a more in-depth manner. This new viewpoint also revealed more clearly the unrealistic assumptions made in the principal method used in determining traditional succession – the chronosequence (Johnson and Miyanishi 2008).

Incorporating disturbance requires that more detail of how a specific disturbance and ecological processes are connected to each other. One way of showing this is to start with wildfire and population dynamics of trees. Boreal fires are large size and high intensity (>4000 kWm\(^{-1}\) of fire front). Fires of these high intensities are crown fires, that is, fires burning on the ground and in the tree canopy. Wildfires are the result of forest structure and weather/climate. The forest structure creates a large amount of fine canopy fuels accessible by moderate flame height in surface fires. This is a result of canopies that do not overlap, with needles and leaves that are relatively small and thus are borne on small branches along the length of the branch and most of the trunk. The weather/climate role is in creating hot dry weather as a result of persistent positive mid-tropospheric anomaly (blocking high-pressure systems) caused by upstream negative anomalies usually over an ocean. Wildfires kill most of the trees by consuming the needles, leaves, and small branches, killing the trunk cambium and/or collapsing xylem. Thus, the fire creates an open environment with no surviving canopy trees.

Fire also consumes the forest floor organic F and H layers by smoldering combustion, leaving the mineral soil or a thin H layer exposed. This exposed surface has a good water budget for germinating seeds and is relatively free of competition from herbs and shrubs. Dispersal of seeds onto this surface depends on the season of the fire and how mature the seeds are in the cones at the time of the fire. In the case of serotinous cones, for example, on jack pine and black spruce, season is not important because the trees contain approximately 5 years of viable seeds in their closed cones. In non-serotinous, non-sprouting trees, for example, white spruce, the later the season of the fire the more likely the seed will survive and disperse because the seeds are already viable and the cones are still wet enough to reduce the heat flux into the cone from the fire (Michaletz et al. 2013). After germination or sprouting, as in the case of aspen, trees are either fast-growing and shade intolerant species or slow-growing and more shade tolerant species. Both of these tree types establish at the same time immediately after the fire, but their different growth rates give the impression of different ages by their different heights. This was the basis of much of the early observations of succession. Once trees are large enough to compete with each other the mortality rate increases, particularly among the smaller and
more shade-tolerant individuals. Wildfires may, of course, occur during this time, which will kill all or most of the trees. The fire frequency distribution has an average frequency of approximately 150 to 200 years, much less than the maximum age boreal trees can survive. The result is that the cohort that established immediately after the fire has a low probably of reaching old age before another fire. The cohorts that established after the immediate post-fire cohort have high mortality rates, very slow growth rates, and, excluding large openings (see below) in the canopy, have little chance of reaching the canopy and producing cones before the next fire.

Spruce budworm (*Choristoneura fumiferana*, Clem) is the most widespread endemic defoliating insect on spruce and fir in the North American boreal forest. They have widespread outbreaks every 25 to 40 years and are as important as wildfire in the eastern North American boreal forest. This disturbance is interesting in that it shows not only interaction between host and nonhost trees on the forest composition but also interactions between the budworm and its natural predators (Cook, Nealis, and Regniere 2007). Mature white spruce and balsam fir (*Abies balsamifera*) are preferred hosts of spruce budworm but black spruce can also be seriously affected. The outbreaks can be slow and diffuse or occur rapidly and synchronously over large areas. The twentieth century outbreaks have been large and synchronous compared to the nineteenth-century outbreaks. Suggested explanations for this have been natural changes in fire frequency and changes in land use, particularly in the eastern and southern boreal forest. The composition of the forest at the time of the outbreak plays an important role in future dynamics. To understand this we must remember that each species has different individual growth rates and that each species’ age distribution consists of different age (not size) classes which are (birth) cohorts. Cohorts, even for the same species, have different recruitment and mortality schedules, particularly for cohorts that developed in the open as opposed to those that developed under canopies. Shade tolerant species are able to grow slowly under canopies and, when a large enough opening occurs, can grow into the canopy. However, the opening must be large enough for adequate light and heat budget. The latter is quite important in the boreal forest where canopy openings can be “cold holes” and fill up with snow that melts slowly in the spring. Also, the individual must not be too old or have been damaged (e.g., by browsing) in which case they may not be able to change their growth rate to grow into the canopy. Canopies dominated by balsam fir are the most susceptible to beetles. Understory balsam fir cohorts often have seedlings that vary in age from the current year up to decades old. When the beetles kill the canopy trees some of these seedlings will grow to form a new canopy. This can occur even with partially killed canopies. Thus, balsam fir can regenerate its canopy from a “seedling” bank in its understory. Although black spruce is not as susceptible to spruce budworm as balsam fir, it can still suffer considerable damage. Its dynamics after spruce budworm-caused canopy removal involves both understory seedlings as in balsam fir but also layering. Both black spruce and balsam fir stands can also be susceptible to wildfire. Pine stands, however, are not susceptible to spruce budworm.

Industrial forestry occurs mostly in the southern parts of the boreal forest on productive sites. Starting in the 1950s in North America, sustainable forestry involved change from saw timber to both saw timber and pulp wood. In the 1980s with understanding of forest dynamics, the role of natural disturbances, wildlife ecology, biogeochemistry, and other ecosystem processes, forestry adopted a strategy of using natural
disturbances as a model to be mimicked in forest operations (Burton et al. 2003).

We now come to the elephant in the room. What is going to happen in the boreal forest if increased warming by CO₂ and other greenhouse gases continues to rise; or even more moderately, what happens in roughly 100 years if the present level of 400 ppm CO₂ stays the same? Just saying it will get warmer and wetter or drier does not tell us how the boreal ecosystems will respond.

First, we know from the past that the boreal forest has changed and rearranged its composition at the scale of hundreds to thousands of years. We also know that the landscape has been glaciated and re-invaded by organisms many times and that even in the last 12 000 years the postglacial environment has changed due to erosion and weathering in which organisms have played a significant role. Also, in the last several thousand years, green and brown mosses have created extensive peatlands, storing massive amounts of carbon and changing the hydrology. Finally, in the thousand or so years since deglaciation the megafauna that once inhabited the boreal forest and had major effects on the vegetation went extinct.

Second, we know from satellites that the boreal spring growing season has lengthened from 1982 to 2011 by one day per decade and that the amplitude of the annual CO₂ cycle increased significantly (Graven et al. 2013).

Third, the lengthening of the summer warm season will lead to the southern edge of the boreal forest being replaced by more southern ecosystems, for example, grasslands and deciduous forests. These forests often have lower carbon sequestration than the present boreal forest.

Fourth, large areas in the northern part of the boreal forest next to the tundra are developing a shrub-tundra instead of woodland or forest.

Fifth, it is not possible at present to evaluate the genetic changes that will occur to allow adaptation of animals and plants to the rapid rate of climate change. Most species’ predicted range shifts are based on the assumption that plants dispersing into new areas are already adapted (i.e., they follow the climate) and that previous local environmental adaptations will not hinder their adaptation to the new area. What we still lack is an understanding of the pattern of genetic variation and the importance of strong local natural selection and gene flow which may or may not allow plants to grow or survive rapid climate change. Davis and Shaw (2001) pointed out that plants at the southern edge of the boreal forest will generally not find pre-adapted populations further south which can move north.

These and many other effects will continue to emerge as a result of global warming. One thing is certain: in many of our lifetimes we will observe the rearrangement of the boreal forest yet again but with the forcings much faster than has happened in the last million years. Unlike ecosystems further south, the boreal forest does not have a lot of agriculture, industrial and social infrastructure, or populations to be disrupted. However, the human populations of the boreal forest are largely indigenous and have in the last few centuries been badly affected by western civilization.

Branch plant economy

Nicholas A. Phelps
University College London, UK

The branch plant or branch factory syndrome became fully apparent after World War II as the United Kingdom attempted to steer “new” mobile industry to old industrial regions, though those terms were not to enter the economic geography, regional economics, and regional studies literature until some time later. The managers of the industrial estates developed to attract new industry to the assisted areas were clearly aware of some of the frailties of the new industrial ensembles being created. Far from embodying new industrial districts of the sort memorably described by the economist Alfred Marshall and that had been associated with the rise of the United Kingdom as an industrial nation, they were seen in a large number of studies to have contributed to the assembly of random assortments of enterprises and industries and, as a result, the further economic decline of old industrial regions.

The branch plant/branch factory syndrome became academic theoretical shorthand for what in reality is a set of constantly shifting characteristics of individual productive investments, deserving of constant empirical reappraisal by scholars and practitioners. These characteristics, in turn, are related to evolving wider intra- and interfirm divisions of labor in and between national economies. The term “branch plant economy” grew out of a specific time and specific places, and an associated intellectual and academic theoretical context in which anxieties over the “deindustrialization” of national economies were very apparent. As such, we might question its value as a potentially rather static simplification of the reality and variety of regional economic development prospects – a simplification that is overly imbued with a sense of the territoriality of the production of specifically manufactured items in urban and regional economies experiencing long-term decline. However, the core concerns associated with its use also have been apparent in developing countries (notably in Latin America) concerned with dependent development. It is a concept that also appears to be salient to the organization of the production of services. Some of the insights associated with it may yet have their day even in the BRIC (Brazil, Russia, India, and China) countries, given their seemingly inexorable rise in economic terms. In this entry it is argued that, despite its very particular geohistorical origins, the branch plant economy concept retains a relevance for some localities and industries today and will continue to do so in the future.

If the branch plant economy is an (economic) geographical concept with significant question marks hanging over it in some respects, one purpose of this entry is to explore the continued salience of the term and, perhaps more importantly, associated insights and policy concerns. This entry begins by outlining the origins of the term and its key features as enumerated in many empirical studies and theoretical interpretations. It then explores its relevance outside the geohistorical context in which it arose. It is argued that it can still resonate with the experiences of people and institutions in many urban and regional economies hosting the branches of domestic companies and the subsidiaries of,
and contract manufacturers for, multinational companies. Following the example of literature on processes of agglomeration or clustering, the branch plant economy can usefully be updated and re-evaluated in light of changing circumstances. Here some of the key challenges involve questions of the time period over which productive investments contribute to urban and regional development, and the changing balance between intra- and interfirm divisions of labor and their ramifications for territorial economic development. The challenge theoretically – as Massey (1984) laid out some time ago – is to analyze territorial economic development in terms of the contributions of both place-bound and place-transcending economic processes.

The branch plant economy

The earliest insights regarding the branch plant economy emerged very early within the history of postwar “regional policy” in the United Kingdom. The UK government had experimented as early as the 1930s with regional policy in the form of major new industrial estates in which to house new industry in old industrial regions – for example, Trafford Park (Manchester), Team Valley (Gateshead), and Treforest (South Wales). Regional policy became more concerted after World War II, with the broad thrust of the influential 1940 Royal Commission on the Distribution of Industry (“Barlow Report”), enshrined in a later Act of Parliament. New towns and new industrial estates were developed in an attempt to deconcentrate and decentralize population and economic activity from London. Restrictions on factory development in London were combined with generous incentives for “mobile” or “footloose” industry to relocate to older industrial regions (Phelps 2009). While public policy focused on the location of manufacturing industry and its potential contribution to the United Kingdom’s regional problem, the same approach was taken somewhat later with respect to service sector “factories” – so-called back office functions. Indeed, the national government itself pioneered office decentralization to cities and regions with weak job creation, leaving a legacy in which a reliance of some local economies on public sector jobs was argued to crowd out the private sector. In the southeast of England, the Location of Offices Bureau played a significant role in steering new and expanded office development out of central London. These back offices were the service sector equivalents of branch plants, but they were only to become a more significant element of the branch plant economies in the United Kingdom, and to some extent overseas, by the 1990s, as discussed below.

These various branch facilities were sought partly because of the major direct employment contributions they made to local economies. In the case of labor-intensive manufacturing and service operations, such branches might employ several thousand people at one site. However, partly as a result of the restrictions placed on and incentives available to such “mobile” or “footloose” factories, much productive investment was in effect artificially split away from the main operations of primarily UK companies – hence the name “branch factory” or “plant.” After this time, as overseas (primarily, though not exclusively, United States) investors began to expand in greater numbers into the UK economy, the reference of the term would be extended from branch factories of multiplant domestic companies to encapsulate the overseas subsidiaries of multinational companies. This brought an appreciation of the problems of remote or external control of investment, resulting in the growth potential of branch factories being effectively attributed to decisions made...
by parent companies headquartered elsewhere, often overseas (Firn 1975).

Managers of postwar industrial estates rapidly had become aware that those footloose industries that had been attracted were diverse, to the point of having no commonalities and few local linkages with each other. The logic of regional policy was to diversify urban and regional economies in light of the perceived weaknesses of overspecialization. Yet, far from promoting the creation of new Marshallian industrial districts, these industrial estates were proving to be diverse collections of industries that were unrelated both to each other and to the existing industrial structure of the urban and regional economies in which they were situated (Phelps 2009).

Empirical studies of the branch plant economy

By the end of the 1970s, the largely empirical literature could be summarized as having centered on several propositions or suspicions regarding the potential shortcomings of the branch plant economies.

- The weak linkages, both forward and especially backward, of branch plants into the local economy. While some linkage “adjustment” was thought likely to take place as branch factories adapted to their new host economies, local backward linkages remained limited due to intermediate inputs being sourced from elsewhere within the parent company (Phelps 1993).

- Branch plants provided mainly routine, low-paid jobs. Branch factories were regarded as engaged in “screwdriver” assembly, in which mass production principles involving the minute division of labor were exploited to the extreme in order to manufacture standardized products at scale. The employment opportunities required minimal skills or even were associated with the active deskilling of workforces, leading to lower levels of remuneration. Part of the question regarding pay also centered on the fuller incorporation of women into the labor markets of older industrial region economies, for the first time on a massive scale (Massey 1984).

- Branch factories were a source of unstable employment. The dependence of branch factories on incentives triggered the idea that they were only marginal investments from the outset, rarely profitable on their own terms, and more than likely providing short-term additional production capacity. Some investors gained a reputation for being serial relocators farming available incentives, leading to the suspicion of branch factories being grant “snatchers” rather than the desired “stickers” likely to produce longer-term employment stability.

- By definition, branch factories were shorn of certain corporate functions, thereby contributing to a gradual denudation of the occupational profiles of their host regional economies. Branch factories certainly lacked conception functions such as research and development (R&D), but also other corporate functions or white-collar occupations such as management, sales, and marketing (Firn 1975). This created a “truncated” occupational structure in older industrial host region economies, with head office functions concentrated elsewhere in national urban systems.

- Branch plants were considered typically to be involved with the production of mature/standardized products, using old process technology and techniques. The common assumption was that they were manufacturing products at the end of the life cycle, using tried-and-tested process
technology requiring little in the way of supporting innovative activity. The product cycle (Vernon 1966) was a key theory used to explain the decentralization of production within metropolitan regions, from Rust Belt to Sun Belt states within the United States, and from London and the southeast of England to the older industrial regions in the United Kingdom. The growth of external control, via the acquisition of indigenous enterprise in some urban and regional economies, represented one route through which rationalization and technological asset-stripping further denuded the innovative capacity of older industrial regions.

Much of this empirical evidence was based on a quite limited and specific set of older industrial region contexts, notably Wales, Scotland, and the northeast and northwest of England in the United Kingdom, and the cities of the industrial Midwest of the United States. In the United Kingdom, these regional economies diversified their industrial complexion considerably over the twentieth century, yet continued to face economic decline notwithstanding their successes in attracting mobile investment, trumpeted by development agencies.

In fact, the evidence relating to each of these five characteristics of the branch plant economy tended to be quite mixed, of course, partly for reasons discussed below. Thus, notwithstanding these generalizations about the branch factory syndrome, most empirical studies comparing the performance and characteristics of branch factories and indigenous companies indicate that the former perform better. While branch plants generally continue to display weaker backward linkages with their local host economies than companies indigenous to the localities concerned, they also were found to have recorded higher rates of product and process innovation than indigenous firms, and were quite often found to offer better employment conditions and pay.

Thus, in certain respects, the branch plant economy thesis presents an apparent paradox. This paradox doubtless partly reflects an implicit tendency to compare branch factories to some idealized or romanticized version of a locally rooted and responsible indigenous business: a misplaced comparison. Yet, neither can it be assumed – as has been the case in much academic and policy literature – that mobile or foreign investment and the multinational enterprises (MNEs) that generate it inevitably contribute strongly to territorial economic development. Multilocal and multinational enterprises and their branch factories bring scarce capital and resources to a region, but it is not inevitable that these will spill over to other companies in the host economy.

As noted above, discussion of the branch plant economy in the United Kingdom is closely bound up with the objectives and results of regional policy. Designed to ameliorate one regional problem (diagnosed as a pattern of localized overspecialization in one or a very limited set of industries), this policy contributed substantially to a new regional problem. As an inquiry by the Regional Studies Association succinctly described: “The spatial-functional separation of activities within large corporations has led to a new territorial division of labour, apparent at both inter- and intranational scales. In the UK context, regional uneven development based on industrial specialization by sectors (e.g. coal, steel, textiles) has been supplanted to a large degree by regional differentiation based upon specialization by corporate functions (e.g. management, R&D, component manufacture assembly-line production)” (Regional Studies Association 1983, 46–47, original emphasis).
If this was a pattern that had emerged very clearly within the United Kingdom, in other advanced nations experiencing deindustrialization, and in some developing countries by the end of the 1970s, the question was how to explain it. It is to the theoretical interpretation of these empirical characteristics of the branch plant economy that this entry now turns.

Theory and the branch plant economy

By the end of the 1970s the concept of the branch plant economy existed in the Anglo-American literature as a collection of empirical studies, informed notably by behavioral theories of the firm and very loosely by the rapidly consolidating theory of the vertically integrated, hierarchically organized modern MNE (e.g., Buckley and Casson 1976) as it had emerged to that point. By the early 1980s, the term had gained currency (see, for example, Watts 1981), with many of these empirical insights being drawn together by analytical syntheses within the political economy tradition.

In the United Kingdom, these included the work of academics involved with the Conference of Socialist Economists, and drew heavily upon French regulation theory (e.g., Dunford, Geddes, and Perrons 1981). Elsewhere, these features of the branch plant economy proved a focal point for scholarship relating them to the broader political economy of relations of dependency in the international economy. In Europe, German development economists Fröbel, Heinrichs, and Kreye (1981) emphasized in *The New International Division of Labour* how highly selective forms of industrialization in developing countries were linked to processes of deindustrialization in Europe through a new imperialism orchestrated by MNEs, not states.

The idea of dependent development had gained an audience among scholars commenting on the developing world. Here very similar empirical findings were emerging with respect to the dependent development associated with the enclave forms of industrialization brought by foreign participation in national economies. Much of this literature developed in the Latin American setting (Cardoso and Faletto 1969), where there were long-standing concerns over foreign participation in industry. While enclave forms of production in a range of agricultural, extractive, and manufacturing sectors raised the production possibilities of home nations, they appeared to contribute little to stimulating the domestic economies of host nations. The various linkages of industry enclaves were primarily internationally oriented: while labor was a local input, the bulk of other inputs to production was imported.

There were some notable strengths to this literature. One was the consideration of “fiscal linkages” (Weisskoff and Wolff 1977); this was absent from discussions of the branch plant economy (and has tended to remain absent from recent discussion of processes of industrial clustering in economic geography). Some of this literature might also be regarded as proto-evolutionary economic geography in its approach to the examination of enclave forms of industrialization (Weisskoff and Wolff 1977). Finally, Cardoso and Faletto (1969) underscored how enclave forms of production in Latin America had their roots not just in the economic organization of production but also in the social and political bases of nations. Indeed, in this respect there was a measure of cross-fertilization, as some of the Latin American literature, and its associated concepts of dependency and the enclave, was brought into the Anglo-American literature.

As these ideas began to be applied more broadly, however, they also were exposed to important lines of critique from those concerned primarily with the developing world.
BRANCH PLANT ECONOMY

(Lall 1975). Some aspects of the critique offered by Lall, concerning the difficulty of establishing an adequate definition of dependence and its causes – notably in terms of the extent and nature of the role played by foreign enterprise in host economies – would be underlined by the rapid industrialization emerging in the newly industrializing, export-oriented, “tiger” economies of East and Southeast Asia.

Early attempts to theorize uneven development, linking understanding of regional problems to broader processes in capitalism, suffered from a failure to acknowledge how local institutions can exert agency to effect positive change, with a tendency to extrapolate from one or two possibly unusual trends of the time. These approaches were later adapted to discuss the emergence of semiperipheries in the international economy (e.g., Hong Kong and Singapore), with a greater concern for a variety of possible outcomes associated with changes in the division of labor coming to the fore with the development of global commodity chain (GCC) and global production network (GPN) approaches.

Perhaps the most notable of these theoretical contributions was Doreen Massey’s Spatial Divisions of Labour, which synthesized many of these theoretical elements with empirical findings in the United Kingdom. Massey’s treatment contrasted a “locationally concentrated” spatial division of labor associated with the United Kingdom’s industrial past, in which localities contained the entire division of labor associated with producing a commodity, with the new spatial divisions of labor of the branch plant economies that these regions had become. This spatial division of labor was the result of branch plants being part of “cloning” or “part-process” spatial structures associated with multiplant and multinational enterprises. Importantly, Massey’s analysis demonstrated that the incorporation of these older industrial regions into these new spatial divisions of labor presented a far more difficult and intractable new regional problem than that of the industrial specialization associated with the locationally concentrated spatial structures produced through the Industrial Revolution.

More than simply elaborating the structural underpinnings of local and regional economic development as derived from an analysis of changing corporate organization and strategy during the twentieth century, Massey sought to integrate corporate strategy and division of labor with the changing class and gender composition of labor markets in different localities. Famously, her treatment conceptualized rounds of productive investment as overlain on one another over time, with each round of investment representing a particular element in the spatial division of labor. She was signaling the emergence of a relational geographical approach, in which a sense of the peculiarities of places and place-bound processes was retained, but integrated with an appreciation of how localities are penetrated and woven together by social relations extending across national and international space. Her work also sparked a renewed interest in the economic fortunes of places, in the guise of “locality studies,” in which the commentators struggled to tease out structural change from locally contingent and locally causal sources of economic change.

Branch factories and the evolving division of labor

The branch factory syndrome proved something of a lightning rod for academic research in economic geography and urban and regional economics in the 1970s and early 1980s. It resonated with the broader political, policy, and academic climate of the time, which was skeptical of, if not
openly hostile to, the activities of multinational corporations. Much has changed since, however, not least the political, policy, and academic commentary on the value of foreign direct investment (FDI). This raises significant questions regarding the ability of this literature to address contemporary circumstances.

There have been, and remain, possibilities for injecting a degree of dynamism and contingency into the branch plant economy literature, revolving significantly around the evolving divisions of labor in society. Intra-corporate divisions of labor continue to be refined, in ways that require greater incorporation of insights from international business rather than simply geography or urban and regional economics. Intercorporate divisions of labor have evolved significantly in recent decades, producing paradigmatic approaches in the guise of GCCs (Gereffi 1999), global value chains (GVCs) (UNCTAD 2013), and GPNs (Henderson et al. 2002). These often have been rather quick to jettison any focus on arguably the key actor in such chains or networks – the firm. Thus an important opportunity remains to integrate insights from the branch plant economy literature with those from the GCC, GVC, and GPN approaches.

**Post-Fordism, factory upgrading, and the branch factory syndrome**

The earliest revisions of the branch plant economy came with a desire to consider the implications of industrial restructuring facing Western economies with the demise of Fordism. “Post-Fordist” patterns of industrial restructuring, variously presented as flexible specialization, flexible production, or flexible accumulation, involved the fragmentation of consumption, the vertical and horizontal disintegration of production, and the increased salience of time-based competition (Schoenberger 1997). These were considered to offer possibilities for resynthesizing the division of labor, for bringing back home investment that had offshored to low-cost locations, and for upgrading branch factories in the older industrial regions of the United Kingdom and the United States. This was inspired by observations in the so-called Third Italy, where an apparent decline of the “mass collective worker” had been supplanted by smaller-scale, craft-based, high-value, export-oriented production in “new industrial districts.”

While subject to considerable critique at the time (Gertler 1988), this broad-based “flexibility thesis” nevertheless presented grounds to revisit the concept of the branch plant economy. One current of thought held that many of the positive features of this brave new world of post-Fordist production flexibility, and its associated potential for the development of workforce skills, were unlikely to take root in older industrial regions. Others, however, sought to explore the implications of flexible production for branch plant economies in terms of upgrading possibilities for branch factories, previously shorn of particular functions and parts of the occupational hierarchy, into “performance” plants, which were becoming regionally embedded through the development of greater local linkages and their acquisition of significant nonmanufacturing functions such as R&D and sales (Phelps 1993).

Despite a measure of optimism at the time, born of the theoretical possibilities for such upgrading, empirical evidence for such upgrading in older industrial regions stubbornly refused to emerge consistently or strongly. What these academics had been eager to observe in branch plant economies might simply have been cosmetic: the effect of the loss of the worst branch factories from regional economies in the late 1970s and early 1980s, leaving a stock of factories that were among the most successful, technologically sophisticated, functionally integrated
and, possibly, locally embedded (Phelps 1993). Indeed, factories continued to become, if anything, more disembedded in many of these older industrial region contexts, as the full effects of corporate restructuring and regional integration agreements were realized. Patterns of input and final product sourcing became markedly more simplified and internationalized, as major corporations sought to fashion international interfirm divisions of labor with preferred suppliers and clients.

Examples of individual factories upgrading have been sparse across those older industrial regions in which a branch plant economy had taken root. Elsewhere, in the newly industrializing world, the prospects for economic development from the branches and subsidiaries of multiplant firms and MNEs are more mixed, and include examples where local economic development outcomes have been more positive to date. At least this is the tenor of much of the recent literature on GVCs, GCCs, and GPNs, which have focused primarily on interfirm divisions of labor.

### GCCs, GVCs, and GPNs and interfirm divisions of labor

The branch plant economy was intimately associated with theories of the large multiplant, multinational company as these had developed by the 1970s and 1980s. The theory developed by this time responded to the growth of these corporations and their typical organizational forms, as they had emerged during much of the twentieth century from a very limited set of origin countries, notably the United States. It presented a picture of the MNE as a vertically integrated entity, with an ever-growing internal division of labor. The essence of the MNE was conceptualized as a desire to exploit its competitive advantage across national borders through internalization. At that time, the transaction costs of dealing at arm’s length with third-party contract suppliers were considered significantly higher than those involved with direct overseas production (often in the form of what would come to be considered branch factories). Hierarchical ownership and internalization was thus the preferred means of coordinating production across national borders, with a view to minimizing the transaction costs associated with serving international markets (Buckley and Casson 1976).

With the onset of greater international economic integration, reflecting the creation, widening, and deepening of regional economic integration agreements and subsequently increased physical and virtual accessibility (underwritten by very rapid developments in transportation and information and communications technologies (ICTs)), this portrait of the MNE had become increasingly outdated. The United Nations Conference on Trade and Development (UNCTAD) first began to highlight these developments, as embodying the emergence of complex integration strategies of MNEs that contrasted with the stand-alone and simple integration strategies evident for much of the twentieth century (UNCTAD 1994). Since this time, MNEs have further outsourced final assembly and intermediate input production, seeking out a wider range of “offshore” locations from which to source inputs and/or finished products. Indeed, some MNEs (notably retail corporations) have been “born” global, operating without their own factories, but sourcing finished products from contract manufacturers to serve final markets. The MNE has thus become something of an arm’s-length coordinator of a network of operations, both its own and, increasingly, those of third-party contract producers. Indeed, some MNEs now barely coordinate such supply chains or networks, beyond a full package supplier or contract manager — often a major MNE itself — that assumes responsibility for (and
the transaction costs associated with coordinating the bulk of such networks. Thus, rather than a vertically integrated hierarchy concerned with internalization across borders, the generalized picture of the MNE that had emerged at the start of the twenty-first century resembled the imperial trading companies of the first global economy of the eighteenth to the late nineteenth century.

These developments have called forth influential theoretical approaches that seek to address, primarily, the greater elaboration of intercorporate divisions of labor. GCC and GVC analysis, emphasizing the governance structures of the production chains orchestrated by MNEs, distinguishes between producer- and buyer-driven chains. Focusing on the emergence of new clusters of production derived significantly from the expansion of retail MNEs and retail brands overseas (e.g., Gereffi 1999), these approaches are attuned to the often limited prospects for developing countries (Gibbon and Ponte 2005; Humphrey and Schmitz 2002). They also have emerged to strongly inform international policy agendas (UNCTAD 2013) and development practice. A GPN approach has emerged in geography in parallel to GCC/GVC analysis, with similar concerns but focusing less on firms than on networks of relations among both firms and a variety of other agents (Henderson et al. 2002).

The increased outsourcing of intermediate inputs may raise the prospects for the greater elaboration of the local social division of labor and linkages locally surrounding branch factories in many settings and many industries; processes of vertical disintegration of production centered on branch plants may result in the relevant intermediate inputs being supplied locally by suppliers. Indeed, empirical studies within the GCC, GVC, and GPN perspectives have drawn attention to the emergence of significant new clusters of economic activity centered on FDI. Such studies, implicitly and sometimes explicitly, are framed in contrast to the earlier literature on the branch factory syndrome, enclaves, and dependent development.

While these developments have affected manufacturing and service MNEs alike, service MNEs have emerged and internationalized remarkably quickly through these twin processes of outsourcing and offshoring. The emergence of brand name producers without factories has exposed localities to the vagaries of MNEs that – given the very low sunk costs associated with overseas production – are able to, and often do, switch production locations. Production switching is not new, though doubtless it is a greater threat when factories are operated by third-party subcontractors. Experiences across developing countries indicate that the incorporation of localities into GCCs, GVCs, and GPNs has not produced uniformly positive economic development effects. Notably, the governance structures associated with these chains and networks of activities can preclude the development of vital knowledge of consumer tastes among indigenous businesses (Humphrey and Schmitz 2002). In short, the branch factory syndrome and enclave forms of production still have considerable relevance for manufacturing activities coordinated by some retail MNEs. This is particularly the case on the African continent, where features of the branch plant economy in sectors such as clothing and textiles have often been a product of the specific provisions of trade agreements (Gibbon and Ponte 2005).

The rapid growth and internationalization of service MNEs also is evident with respect to those intermediate service inputs previously supplied in-house as part of vertically integrated manufacturing and service MNEs, but which now are outsourced. The rapid growth of employment in telemediated sales and back-office “call centers,” in localities within developed and developing countries,
BRANCH PLANT ECONOMY

has raised the same concerns registered in the branch plant economy literature: low wages and unstable employment. Some indication of the volatility of the jobs and economic development contributions made by such footloose service branch factory investments is signaled by the manner in which outsourced intermediate service inputs also rapidly have been moved offshore – to the point that the two terms are often conflated. One local economy’s loss can be another’s gain, as major new business process outsourcing (BPO) hubs have emerged in developing countries such as India and the Philippines. In India, some of the activities performed have local economic development potential (in terms of the value added) matching those in developed country settings (Dossani and Kenney 2007). The same may not be said of the presence of these activities in the Philippines to date. The build-up of BPO factories in the Philippines extends to second-tier cities where the replication of the branch factory syndrome is evident, despite some evidence of strategies of engagement between local governments and the private sector which may lead to qualitatively better local economic development outcomes in the longer term (Kleibert 2014).

Their orientation to interfirm divisions of labor means that GCC, GVC, and GPN perspectives are well attuned to the present drift of corporate organizational changes. As valuable as this emphasis is, elaborated interfirm divisions of labor nevertheless coevolve with shifting intrafirm divisions of labor, to which this entry now turns.

Intra-corporate divisions of labor: the “fine slicing” of value chains

Notwithstanding the greater development of interfirm divisions of labor, a hallmark of the MNE as it developed through much of the twentieth century has been the continued evolution of the intrafirm divisions of labor. The hierarchical organization of MNEs now coexists with, and complements, elaborated and geographically extended interfirm networks.

Indeed, in many respects the elaboration of interfirm divisions of labor described above – especially those associated with the outsourcing of intermediate service inputs – derived in the first instance from an increasing greater division of labor within MNEs, producing activities that have come to be defined as “noncore.” Yet, within those core manufacturing and service activities not yet subject to outsourcing, the division of labor within MNEs has continued to expand. International business scholarship has maintained a focus on the firm, seeking to inject a measure of evolutionary thinking into an understanding of the MNE as a heterarchy, rather than just a hierarchy, composed of a diverse group of local subsidiaries connected with one another and the parent organization. A major focus of international business research thus has been the evolving roles and capabilities of MNE subsidiaries. One implication is that heterarchical parent company organizational forms lessen the intractability of the regional problem raised by Massey (1984). Certainly, the variety of evolving roles and capabilities possessed by individual branch or subsidiary operations of MNEs have important implications for territorial economic development, but these have barely been explored by economic geographers.

There is a mutually reinforcing relationship between the more substantive and immediate nature of international economic integration, driven by a host of regulatory changes and information and communications technologies, and the internal organization of MNEs: “the more profound sense of uncertainty now said to be facing corporations is arguably leading
to greater experimentation within corporations and their subsidiaries, but also as corporations and their subsidiaries seek to experiment with the institutions that make up their external environments … ” (Cantwell, Dunning, and Lundan 2010, 571). One important aspect of such experimentation within the MNE has been the “fine slicing” of value chains (Rugman, Verbeke, and Yuan 2010), a process in which increasing division of labor results in the establishment of ever-more-specialized remits within functions (such as administration and R&D) commonly treated as indivisible. Strategies of fine slicing exploit the specialized capabilities of individual branch factories or subsidiaries in the context of local sources of technology and competitive advantage, as well as parent company, home country-derived ownership advantages overseas. This includes greater specialization within individual functions such as R&D, for example, with regional R&D centers not merely adapting products to local markets but also assuming more specialized roles for the parent organization as a whole – in some instances globally linked across time zones. These developments potentially offer economic development gains to host economies, but they also imply problems of considerable complexity for public policy seeking to secure such economic development. Notable in this respect is the difficulty of “picking winners” deserving of local institutional support in aid of upgrading.

In short, “processes of globalization … have allowed these firms to leverage greater competitive advantage from the differences between locations. This has resulted in MNEs generating heterogeneity in their own internationally networked operations. It has also meant that countries … have also learnt the benefits of generating differentiated sources of comparative advantage” (Papanastassiou and Pearce 2009, 1). An evolutionary perspective on the MNE and its internal divisions of labor (as these manifest themselves at the level of individual subsidiaries) has taken the international business literature towards a greater analysis of firm–host economy institutional interactions, including at the subnational scale. It is here that the international business literature comes closest to examining the “strategic coupling” emphasized in the GPN approach, where aspects of the older branch plant economy literature still have much to add to contemporary theoretical approaches.

The branch plant economy today

While the branch plant economy, or branch factory syndrome, became apparent in the economic decline across much of the United Kingdom and the deindustrialization of some parts of the United States, in an increasingly internationally integrated economy it retains great relevance to a wider set of countries and regions, including some that are growing in the aggregate and others that have shown signs of growth.

History and the branch plant economy

The emergence of the branch plant economy was produced by policy designed to obviate the cyclical expansion and decline of urban and regional economies that had specialized in a limited number of industries. Yet, ironically, the notion of the branch plant economy has shown a certain cyclicality of its own. Many of the same policy concerns surrounding the purpose and efficacy of the incentivizing and attraction or recruitment of inward investment, first raised in connection with the term “branch plant economy,” remain highly salient in fast-growing economies today.

This is apparent in the attraction of old and new industries alike. Extractive industries continue to be associated with enclave forms of economic
BRANCH PLANT ECONOMY

development. These have been subject to the long-term fluctuations in commodity prices made famous in long wave theory. However, new industries such as semiconductor device manufacturers, sought after as valuable industries around which to transform the skill bases of branch plant economies such as Wales, Scotland, and the northeast of England, also have been subject to intense cyclicality in international prices – for items that in many respects are commodity inputs to a wide array of modern products. It is little surprise, then, that such cyclicality has forced these national and regional economies to pay a high price for their temporary participation in high-technology industries.

Away from those industries, old and new, that are subject to commodity-like medium- to long-term price movements, branch plant economies may be subject to a degree of short-term cyclicality. There are a number of quite closely interrelated aspects to this short-term cyclicality of investment into certain city and regional economies. As time to market has become an important aspect of competition in recent decades (Schoenberger 1997), productive investments as a whole are subject to greater generalized uncertainty than in the past. Some of this uncertainty seems likely to affect even rapidly industrializing economies at some point, as in China, where there is intense competition for FDI despite the relatively strong bargaining position held by host urban and regional economies, given China’s huge domestic market.

For example, a series of cities across China find their economies significantly linked to the fortunes of a single MNE, Taiwanese Foxconn, whose own fortunes are linked to the market success of the branded products it chiefly manufactures under contract. The economic fortunes of China’s economy as a whole, as well as those of these cities, are linked staggeringly closely to this one company. Foxconn employs over 1 million people in China, in factory compounds ranging in size from 20,000 to 400,000 employees (Ngai and Chan 2012). This monopoly contract manufacturer contributes considerably to local economic development across China – at least in terms of direct and indirect job creation, but it is worth remembering that the branch plant syndrome in the United Kingdom also was closely associated with subsidiaries of US companies with similarly seemingly unassailable positions. Moreover, the Chinese cities competing vigorously to attract Foxconn factories offer generous incentives packages and “customized spaces” familiar in the West, and even bespoke company town extensions, to the point where many of the public policy dilemmas surrounding spatial competition for capital in the West are likely to be reproduced.

Singer (the sewing machine manufacturer) opened its Clydebank factory in Scotland as one of the first US investments in the United Kingdom, operating there for nearly a century. Such longevity, or anything remotely approaching it, is well and truly a thing of the past, however. Some urban and regional economies are populated by large numbers of factories associated with mature or standardized products – whose duration there is potentially limited to the span of one stage of these products’ life cycles. Empirical evidence suggests that it is actually quite hard for urban and regional economies to progress to developing new products. Instead, branch plants, and by extension their host local economies, are subjected to repeated competition as they seek to be the place to produce the next product allocated from a parent company. As such, one key empirical characteristic of the branch plant economy – the stability of employment – remains an important question for academics and policymakers. Moreover, the “financialization” of the production of many goods and services has further reduced the time
necessary to amortize productive investments, or the spatial fixity of capital. Companies have themselves sought to reduce the risks associated with long-term exposure to particular production locations. Moreover, local and national governments may inadvertently compound this because the incentives and customized spaces they offer to investors offset a firm’s sunk costs.

Ownership and the branch plant economy

The rapid regional and international economic integration since the 1980s has prompted the thought that ownership may be of little relevance to the question of how to effect local and national economic development. The international economy orchestrated by MNEs has become markedly more polycentric, with a growing array of origins and destinations of FDI and all that this implies for both the characteristics of the associated subsidiary or branch operations and the opportunities for developing countries (UNCTAD 1999). Though the 1999 UNCTAD report warned against this, this increasing polycentricity has been reflected, until very recently, in an over-optimistic assessment of the regional benefits of MNEs and their FDI. After all, the branch plant economy literature was imbued with the characteristics of FDI of Western origin, derived particularly from American MNEs as the dominant agents of international economic integration at the time. These were, in the main, vertically integrated Fordist manufacturing and service companies, enjoying at their height monopoly shares of national markets. Yet the United States was beginning to be overtaken by new sources of FDI from Japan, Germany, South Korea, and Taiwan, and more recently the BRIC countries. While Japanese MNEs have been slower to internationalize R&D and innovative activity, anecdotal evidence suggests they take a longer-term view of the development of subsidiaries and surrounding supply bases. The Korean chaebol (meaning a large family-owned business conglomerate), on the other hand, expanded rather more rashly overseas, triggering a series of high-profile tournaments for their investments but also, by the same token, high-profile failed and aborted ventures. Thus, persistent differences in the character and processes of FDI, associated with different home country origins of FDI, may produce rather different outcomes for territorial economic development than implied in the original branch plant economy discussion.

To set against this, the geographical origin of FDI and technological leadership in different industries has tended to shift more rapidly in the past decades than during almost all of the twentieth century. This creates an additional potential source of the sorts of instability in employment facing urban and regional economies discussed above. It also embodies a new, more complex geography to the branch plant economy, bringing into existence a large and almost totally unexplored research agenda centered on reappraising the term. As Iammarino and McCann (2012, 246) note, “... the intra-firm connection and inter-firm relationships which constitute the essence of multinationals represent simultaneously both complementary and inter-dependent ways of allocating and organizing resources and assets across national borders, thereby contributing at the same time to the growth and change of both the firm and the external world.”

This has made it increasingly difficult to disentangle endogenous from exogenous forms of urban and regional economic development, as the branch plant economy and dependency literatures sought to do. These changes in the origins and destinations of FDI, undermining ambitious generalizations regarding the impacts of MNEs and their FDI, vindicate the essentially empirical character of the branch plant economy.
literature; the benefits of MNEs and FDI remain to be demonstrated empirically, even at the level of the individual companies and investments involved.

The modernized dependency of the offshore enclave economy

Noted earlier in this entry was the cross-fertilization between scholarship on the branch plant economy and that on dependency and enclave forms of industrialization. The term “enclave” has continued to have a currency in recent years in the area and development studies and international relations literature, in a way that the term “branch plant” has not. To this extent it can be suggested that both sets of literature will continue to have a relevance to economic geography. The term “enclave economy” arose largely in connection with developing country economies dependent on natural resource exploitation and consequently on the resource-seeking FDI of MNEs. The notion of the enclave has been heavily criticized as an adequate depiction of the potential for territorial economic development – even that centered on those extractive industries most commonly associated with the time-limited urbanization and industrialization in enclaves. Nevertheless, its main features remain apparent in extractive industries and are a source of some concern.

The concept of the enclave economy has been somewhat overlooked, precisely because of its association with extractive industries and their geographical specificities. But it is remarkable that there has been so little elaboration of the term “enclave” in connection with secondary and tertiary economic activities, notwithstanding what Weisskoff and Wolff (1977) described as the potential for modernized *dependencia*. Just as for the formation of branch plant economies in the United Kingdom, economic development policy undoubtedly has played a role in the widespread emergence of modern forms of enclave industrialization. Special economic zones of various types are used extensively as vehicles for industrialization in East Asia and elsewhere. Territorial concessions appear to have re-emerged as part of developmental states’ extra-territorial management of the offshore movement of both domestic and foreign MNEs. Meanwhile, the overwhelming drift towards a liberalization of national law and policy regulating FDI, coupled with a drift towards the upholding of MNEs’ rights (when compared to their obligations) in international arenas arbitrating on legal disputes, has created asymmetry in relations between governments and MNEs. It has also manifested itself in the widespread promotion of economic enclaves of various sorts offering special concessions to MNEs.

Such modern-day enclaves, associated with dependent development, can be observed in an increasingly wide range of industries. Thus there is ample evidence of a growing “offshore” economy in the form of exclusive tourist resorts, export processing zones (EPZs), offshore finance centers, and secure BPO operations, shaped by a variety of concessionary agreements actively authored by nation-states and even city and regional governments (Palan 1998). In light of these developments, in different industries with potentially different local economic development implications flowing from potentially qualitatively different forms of enclave, it is strange that the academic literature has not produced the sorts of classifications or taxonomies of enclaves associated with the literature on agglomeration and clustering.

Questions remain over the longer-term economic sustainability of urban and regional economies centered on such enclaves of economic activity. Indeed, the critical questions are
very much those raised by the branch plant economy literature – whether the economic benefits really accrue primarily to MNEs and their national home economies rather than to local host economies. It is conceivable that powerful new processes of cumulative causation and urbanization may be set in train around industrialization in these enclave zones. However, it seems fair to argue that, for the majority of such cases, such narrow industrialization will fail to produce broader-based urbanization and economic development.

Conclusion

As a term with analytical value, the “branch plant economy” could be regarded as one produced from particular vantage points at a particular time and place. Yet, as this entry has tried to highlight, the branch plant economy and the branch factory syndrome remain likely to resonate with academic and policy audiences in other times and places, including today. A term that emerged in the deindustrializing United Kingdom and the United States during the 1960s and 1970s retains some salience to regions and nations less favored by the sorts of interfirm divisions of labor that now characterize GCCs, GVCs, and GPNs. Indeed, studying the effects of FDI in new host locations, including successfully industrialized developmental states, may provide empirical ammunition with which to selectively reapply, develop, and modify insights from the branch plant economy literature.

The term is certainly in need of recasting and reanalyzing. The intra- and interfirm divisions of labor to which the phenomenon is connected have continued to evolve in ways that require further conceptual analysis of the consequences for urban and regional economies. The question arises as to whether there are new spatial divisions of labor that can now be identified, alongside the cloning and part-process formats noted some time ago by Massey (1984), and whether an understanding of the evolution of MNE subsidiary roles and capabilities can shed light on the potential for sustainable territorial economic development to be fashioned from erstwhile tendencies towards the branch factory syndrome. Furthermore, the question is whether qualitatively different types of enclave can be elaborated (as has been done for industrial agglomerations and clusters over the past several decades) in order to explain the realistic potential to fashion clusters from erstwhile enclaves.

Any such analysis of the changing character of branch plant economies will have to draw on interdisciplinary insights from development studies, from political economy perspectives on industrial restructuring within GCCs, GVCs, and GPNs, and from international business and management perspectives on the parent–subsidiary relationship and subsidiary roles. The challenge is to adequately link the macropolitical economy perspectives offered by the likes of GCC, GVC, and GPN approaches with empirical findings, via relatively parsimonious meso-level concepts or theories. It is in this way that the prospects for territorial economic development can be understood as a recursive combination of the unique place-bound properties of cities and regions and the structures and processes common to global capitalism.

Brands and branding

Andy Pike
Newcastle University, UK

Caribbean cuisine, Latin American coffee, Danish furniture, Thai silks, Catalan design, Broadway theater, Hunter Valley wines, London insurance … Where branded goods and services commodities are from and the places with which they are associated are integral to their meaning and value. Raising such issues encourages reflection upon how we understand and explain the geographies of economy. Internationalization, even globalization, is complicating the picture. Brand owners, managers, marketers, buyers, and authorities are grappling with questions of origin(s), provenance, and authenticity. Yet, longstanding research, fixated with the “country of origin” effect on consumer behavior, has failed to develop ways of thinking about the geographies of brands and branding that extend beyond this national frame.

In the transition from a producer- to a consumer-dominated economy, society, culture, ecology, and polity, the brands and branding of goods and services commodities have proliferated in dramatic fashion. This rapid ascendancy has led some to claim the emergence of a “brand society” wherein brands are “the most ubiquitous and pervasive cultural form” and are “rapidly becoming one of the most powerful of the phenomena transforming the way we manage organizations and live our lives” (Kornberger 2010, xi, xii, 23).

Addressing the relatively neglected geographies of brands and branding, this entry defines what is meant by brands and branding, explains how they are geographical, introduces the idea of geographical associations, and emphasizes the roles of actors – producers, circulators, consumers, and regulators – in spatial circuits of meaning and value. Origination explains the geographical associations constructed by actors related in spatial circuits in their attempts to cohere and stabilize meaning and value in goods and services brands and their branding in particular spatial and temporal market contexts. Examples of origination are discussed, from branded clothing and telemediated services.

Answering the call to “get behind the veil, the fetishism of the market and the commodity, in order to tell the full story of social reproduction” (Harvey 1990, 422), origination offers a means of lifting the “mystical veils” (Greenberg 2008, 31) woven around branded goods and services commodities by actors’ increasingly sophisticated activities. Their strategies, techniques, and practices seek carefully to create, manage, rework, and sometimes obscure where goods are made and/or from where services are delivered, and the economic, social, political, cultural, and ecological conditions where and under which they are organized.

Defining the brand and branding

The rapid growth, evolving sophistication, and widespread use of the term “brand” has been accompanied by an outpouring of definitions from academic, business, consulting, and practitioner accounts. Such efforts have served to
BRANDS AND BRANDING

fragment rather than integrate understanding and explanation. No single or generally accepted model exists of the tangible (e.g., design, function, quality) and, of growing significance, the intangible (e.g., feel, look, style) attributes and characteristics of brands and their relative importance and relationships. An influential conception defines the brand as the characteristic kind or variety of a particular good or service (de Chernatony 2010). A more refined conceptualization utilizes the idea of “brand equity,” defined as the “set of assets (and liabilities) linked to a brand’s name and symbol that adds to (or subtracts from) the value provided by a product or service to a firm and/or to a firm’s customers” (Aaker 1996, 7). Brand equity is a function of the connected tangible and intangible assets of brand loyalty, awareness, perceived quality, associations, and other proprietary resources that together generate meaning and value through their creation, articulation, and enhancement by brand and branding actors (Table 1). The elements include associations (e.g., with particular people, periods, and places), identities (e.g., image, look, style), origins (e.g., where it is designed, made, connected with, or perceived to come from), qualities (e.g., feel, form, function), and values (e.g., efficiency, reliability, reputation). Actors comprise those involved in the production, circulation, consumption, and regulation of brands and branding (Table 2). Taking a social and spatial approach to brand equity addresses the critique of Aaker’s (1996) “managerial” approach with its focus upon corporate brand ownership and control by producers rather than consumers, its relative blindness to the social construction and consumption of brands, and its weakly developed understanding of the relations between meaning and value (Kornberger 2010, 35).

If the brand is the object, branding is the process of adding value to goods and services commodities by providing meaning. Branding ensures that goods and services are no longer defined only by their material basis and functionality but also by “symbolic powers and associations” (Kornberger 2010: 13). Branding suffers from the same proliferation of definitions and conceptualizations that complicate the task of defining the brand. Branding is the “manufacture of meaning” (Jackson, Russell, and Ward 2011, 59). It is what actors do meaningfully to articulate, enhance, and represent the facets and cues of the assets and liabilities in brands in ways that create value in specific market times and spaces. Branding attempts to engender consumer trust and goodwill through constructing distinctive associations in the brand – such as

authenticity, quality, and style — that directly and positively influence purchasing decisions (de Chernatony 2010). Relative to commodified or more generic goods and services, the object of the brand and the process of branding are utilized by actors seeking product/image and price differentiation.

The geographical in brands and branding

Despite their rapid emergence and reach, the geographies of brands and branding are under-researched and lack conceptualization and theorization, analytical and methodological approaches, and a cumulative and substantive body of empirical research (Pike 2015). Economic geography, for example, has “consistently undervalued brands as an area of study” and “many of our theories and accounts stop abruptly as the products leave the factory gates” (Power and Hauge 2008, 123, 139).

Brands and branding are geographical in at least three interrelated ways. First, when conceptualized as an identifiable kind of good or service commodity, the brand is constituted of characteristics imbued to varying degrees and in differing ways with spatial connections and connotations. As Dominic Power and Atle Hauge (2008, 138) argue, brands have an “inherent spatiality.” Facets of brand equity — such as loyalty, awareness, perceived quality, attributes, and associations — inextricably intertwine with spatially inflected considerations of who makes the good or delivers the service and from where, as well as their identities, histories, and sociospatial connotations. Industrialization and mass production in the late nineteenth century underpinned the commercial value and meaning of brands: “Through industrialization the production of many household items, such as soap, moved from local production to centralized factories. As the distance between buyer and supplier widened the communication of origin and quality became more important” (Lindemann 2010, 3). Branding is similarly entwined in geographical associations and contexts as actors attempt to articulate the attributes and characteristics in brands in meaningful and valuable ways. Such actors deploy the meaning-making of branding to identify, articulate, and represent signs and symbols that are inescapably associated with the spatial contexts and connotations of particular brands.

Second, brands and branding are geographical because they (re)produce geographical differentiation across space and time. Modifying Michael Watts’ (2005, 527) argument for the more thoroughly branded world of contemporary “cognitive-cultural capitalism” (Scott 2007, 1466): “The life of the [branded] commodity typically involves movement through space and time, during which it adds values and meanings of various forms. [Branded] Commodities are therefore pre-eminently geographical objects.”
Some see “global” brands and branding as placeless vehicles of globalization and homogenization that cross borders as a “global fluid” and are “super-territorial and super-organic, floating free” (Urry 2003, 60, 68). Qualifying this view are more spatially sensitive interpretations of heterogeneity, diversity, and variety in how brands and branding (re)produce geographical differentiation in a spiky and sticky world (Pike 2015). In these conceptions, branded commodities travel and communicate differing meanings and values across space and time. Particular brands and their branding find geographically differentiated kinds and degrees of commercial, social, cultural, ecological, and political meaning and value. In seeking to shape and respond to the particularities of different geographical and temporal market settings, branding practices may similarly be spatially attenuated and heterogeneous.

Third, brands and branding are geographical because of the close interrelationships between their inescapable and spatially differentiated geographies and “uneven geographical development” (Harvey 1990, 432). Accumulation underpins the role of brands within marketing strategies. The actors involved in brands and branding are compelled by the rationales of accumulation, competition, differentiation, and innovation to search for, create, exploit, and (re)produce economic and social disparities and inequalities over space and time. Brand owners are therefore compelled to construct, define, segment, and exploit profitable parts of goods and services commodity markets in particular spatial and temporal settings.

Brand actors invest substantial time, effort, and resources grappling with social and geographical differences, and specifically how these can be used and perpetuated to create and realize meaning and value in spatial circuits. Spatial manifestations of economic and social differences and inequalities fuel market construction and segmentation because “[w]ide disparities between rich and poor … bring into being more luxurious types of goods than would otherwise exist” (Molotch 2002, 682). Social stratification and hierarchy underpin the relentless search by elite groups for distinction through consumption, propelling the continuous refinement and construction of new desires and wants beyond needs. Brand and branding’s differentiation imperative compels actors actively to seek out, perpetuate, and (re)produce such inequalities, fostering social polarization.

Geographical associations in brands and branding

Having defined and established the geographical basis of brands and branding, the next step is better to understand how such geographies are conceived of and articulated. Geographical associations refer to the characteristic elements – material, symbolic, discursive, visual – of the identifiable branded commodity and branding process that connect and/or connote particular “geographical imaginaries” (Jackson 2002, 3). Geographical associations do not just materially tie brands and branding in fixed relationships to certain spaces and places, but are of different kinds, varying in their extents and natures over space and time (Pike 2015). Material geographical associations include specific spatial connections to authentic and traditional methods and particular places of brand production. Symbolic geographical associations imbue and insinuate spatial referents in brand logos as proprietary markers circulated to draw attention from potential consumers. Discursive geographical associations attempt to align brands with aspirational and desirable spaces and places through stories and narratives.
Visual geographical associations utilize “origin images … recalling to consumers a rich set of associations” to surround and imbue brands and infuse branding concepts and messages (Thakor and Kohli 1996, 33). Aural associations signify geographical connotations through meaningful music, songs, poetry, language, slang, accents, and dialects.

Actors deploy these geographical associations in brands and branding. In terms of economy, the characteristics invoked include quality, tradition, and reputation. Actors work these and other attributes into their brand and branding practices and elements through design, name, and labeling. Actors involved in the financial services brand Scottish Widows, for example, deliberately articulate the attributes of frugality, integrity, prudence, and trustworthiness that are geographically associated with the national territory of Scotland. These values, symbolized in the brand name and its advertising, are material in the functional financial products they sell to consumers.

Brand and branding actors exercise much care and selectivity in constructing geographical associations in branded goods and services commodities for certain market times and spaces. Guided by particular interpretations and judgments about particular market contexts, actors seek to capture and amplify certain attributes and qualities of branded commodities while discarding and hiding others. At one end, they play up certain desirable and valued meanings such as the heritage, quality, and reputation connoted by particular places. At the other, actors mask meaningful but less commercially valuable or even damaging elements. Diversity and variety in the different types, degrees, and characters of geographical associations afford brand and branding actors a rich and pliable palette. Brands and their branding are not simply insert content afresh, however, with the exception of entirely new market entrants.

Geographical associations encompass tensions and accommodations between relational and territorial, bounded and unbounded, fluid and fixed, territorializing and deterritorializing tendencies (Pike 2015). Advancing beyond the constraints of the nationally focused approach to “country of origin” dominant in the discipline of marketing (e.g., Bilkey and Nes 1982) to engage other geographical scales, geographical associations in brands and branding can be framed territorially at different spatial levels (Table 3). Actors try to construct geographical associations to delineated, even jurisdictional, spatial entities in establishing, representing, and regulating the connections and connotations of particular branded goods and services commodities. While it can be important, the national is not the only territorial scale at which geographical associations are framed and articulated by the actors involved. Geographical associations in brands and branding are scalar and territorial as well as relational and networked. Unbounded, fluid, and deterritorializing spaces and places, stretching through circuits and networks in and beyond clearly defined and delineated territories and spatial scales, also are evident in the geographical associations of brands and branding. Combining territorial and relational understandings, actors utilize brands and branding to create differentiated meaning and value. They borrow and attempt to transcend, hybridize, and mix the geographical associations of the territories and networks of specific spaces and particular places. Nebahat Tokatli (2013), for example, demonstrates how the modernization of the luxury fashion brand Gucci drew upon and articulated geographical associations based upon the look, style, and sensibility of the City of Los Angeles, California. This representation elided a set of disparate spatial connections.

and connotations: the American designer Tom Ford was from Austin, Texas, and worked in Paris, France; the brand is headquartered in Florence, Italy; and the Gucci branded clothing is manufactured in Italy and, increasingly, internationally.

Brands and branding in spatial circuits of meaning and value

The ways in which differentiated meaning and value are created, circulated, and valorized in spatial circuits can be explained through the agency of interrelated actors – producers, circulators, consumers, and regulators (Table 2) – seeking selectively to construct, cohere, and stabilize geographical associations in commodity brands and their branding in commercially valuable and meaningful ways, in particular spatial and temporal market settings. Brands and branding are integral to the dialectic between spaces and circuits of value and meaning as well as representations of the “economic” in markets. Together with branding, “the creation and promotion of brands are … pivotal in realising the surplus value embodied in commodities and so in helping assure the smooth flow of value and expansion of capital” (Hudson 2005, 76). Together, the object of the brand and the process of branding facilitate actors in their efforts to create and fix the geographical associations constituting brand meaning and value in spatial circuits. The brand provides a temporarily stable frame that is required because “particular objects need to maintain a degree of stability of meaning in order that they can perform as commodities and so enable markets to be (re)produced” (Hudson 2008, 430).

Brands and branding provide an object and a process for the efforts of actors to construct and stabilize what branded commodities mean and are worth in particular geographically situated market contexts and time periods. Meaning and value are inextricably related, and not simply reducible to the brand’s geographical associations. Any fixity and stability achieved by actors are always unstable and makeshift accomplishments. The restless and disruptive rationales of accumulation, competition, differentiation, innovation, changing consumer tastes, and so forth, constantly threaten to recast and rupture the meaning and value in a brand and its branding in specific market times and spaces. Acknowledging meaning and value creation beyond the point of production, Hugh Willmott (2010, 526)
argues that “there is often greater potential for generating surplus from intangibles like branding – even allowing for the vulnerability of brand equity to displacement by innovation, shifts in fashion or risk of its destruction by consumer activists.” Logics embedded in cognitive-cultural capitalism risk undermining the coherence and stability of brands and branding as devices for continued value flow and capital expansion in spatial circuits. Meaning and value are not simply fixed or given by brand owners, stamped or marked on the finished goods and services commodities as they leave the factory or are communicated from the office. Brands are economic, social, cultural, ecological, and political, making them inherently fluid, unstable, “socially negotiated” (Power and Hauge 2008, 130) and “fragile things” (Kornberger 2010, 53). Some are actively contested over space and time through market rivalry and consumer activist dissent. The evolving nature of space and place further ensure that the fixing, cohering, and stabilizing efforts of brand actors are only ever partial and temporary. While brand meaning and value can sometimes be enduring in particular times and spaces, the work of brand and branding actors is always unfinished and ongoing.

### Origination

Origination conceptualizes the ways in which actors – producers, circulators, consumers, and regulators interrelated in spatial circuits – attempt to construct geographical associations for goods and services commodities. These geographical associations are selected to connote, suggest, and/or appeal to particular spatial references as part of efforts to create, cohere, and stabilize meaning and value in specific brands and their branding in the specific settings of certain market times and spaces. At particular moments in spatial circuits, actors attempt to originate branded commodities, deploying strategies, frameworks, techniques, and practices of branding to articulate and communicate meaningful and valuable geographical associations. This produces, circulates, consumes, and regulates “geographical imaginaries” (Jackson 2002, 3) in diverse and varied ways. Such actors both constitute and are compelled by rationales of accumulation, competition, differentiation, and innovation that continually disrupt the spatial and temporal fixes of geographical associations, risking the collapse of the commercial coherence and competitiveness of their branded goods and services commodities. Given the differing interests of the actors involved, origination is a highly selective process. Particular geographical associations that provide branded commodities with certain kinds of meaning and value in specific market settings are highlighted and emphasized, while those that threaten to undermine meaning and value are suppressed.

Longstanding research in the discipline of marketing has demonstrated how product–country image and origin are often decisive in consumer decision-making. Such cues underpin the longstanding “country of origin” or “made in …” effect, evident in consumer views of the geographically differentiated capabilities and historical reputations of countries for particular goods and services (Bilkey and Nes 1982). While extended to encompass “country-of-origin of brand” (Phau and Prendergast 2000, 159), this work has remained focused on the national level (Pike 2015). Yet, this national framing has been disrupted by recent changes. First, for increasingly complex manufactures with multiple component parts and subsystems, it is no longer straightforward to assign a single and definitive national geographical origin to the finished branded good provided for sale in a particular market. Second, services have
risen in importance, facilitated by advances in information and communication technologies. Their relational nature and geographical reach have stretched economic activities across national contexts and complicated any assignment of their “country of origin.” Moreover, the growing significance of intangibles, for example design and styling, is blurring the distinction between branded manufacturing and services. Third, the “national” identifiers central to “country of origin” have been played down, reworked or even eradicated, as actors seek to obscure historical associations or dissociate brands from specific national territories in the context of globalization and efforts to reach beyond particular national markets. In the wake of these changes, a belated and growing recognition has emerged in marketing that origin is more than just “country of origin.”

Consequently, the origin category for the provenance of brands and branding has been opened up, extended and articulated by actors to reflect more closely – as well as in some cases obscure – which activities are undertaken, by whom, and where. Driven by brand owners’ differentiation strategies and regulatory standards, new forms of communication and labeling formats are emerging. “Designed by Apple in California. Assembled in China” (Apple) and “Designed by Kawada in Japan. Made in Thailand” (Nanoblocks) are two from an array of such originations (Pike 2015). These practices are grappling with the notion of multiple and connected – even “global” – origins for the particular production and service activities constitutive of specific brands. New markers of origin(s) are being used by actors to reference and represent the places of different functions, including assembly, design, delivery, engineering, component sourcing, and manufacture.

Origin has now fragmented and splintered. Analytically, branding actors in spatial circuits can be identified as working with at least 10 different categories of origination:

1. where the brand was originally born,
2. where the brand was innovated or thought up,
3. where the brand is designed and developed,
4. where the brand is tested and refined,
5. where the brand is headquartered (or indirectly where the brand owner is headquartered),
6. where the branded good or service is delivered or provided from (physical, virtual),
7. where the brand is made (manufactured and/or assembled),
8. where the brand is sold (wholesale or retail channels),
9. where the branded good or service is serviced or supported from (e.g., after-sales services, maintenance),
10. where the brand is recycled and/or disassembled.

Further, the order of importance of such forms of origination has shifted too. In the context of complex and internationalized global value chains, “there remain product categories where it pays marketers to ensure that superior expertise is still widely associated with a particular place” and “the power of brand trust is expected to override any doubts customers might have as a result of products being sourced from multiple countries. Consumers are more concerned about the country or place of design and quality oversight than the country or place of manufacture” (Quelch and Jocz 2012, 44).

Significantly for origination, the multiplicity and complexity in origin(s) and its geographies afford heightened degrees of flexibility for actors in (re)working the geographical associations of brands and branding. Depending upon specific connotations in particular geographical and temporal markets, a singular origin or plural origins can be less easily or obviously discernible and
the object of promotion or obscuration by the actors involved. The rise of online services in the digital era has further reinforced the flexibility of origins in virtual space. Situating origin(s) can still include the national scale, but this is only one spatial level amongst other territorial constructs that also need to be situated in tension and accommodation with understandings of relational networks.

**Origination in branded clothing and telemediated services**

The clothing industry has a long history of internationalization, and a geographically expansive division of labor marked by the enduring importance of brands and branding as well as provenance as manifestations and signs of meaning and value. Contemporary examples demonstrate how actors are originating their brands in particular ways. US-based American Apparel, for example, foregrounds “Made in Downtown LA” as integral to its business ethos and brand, and uses this origination to mark its products and retail outlets. The actors involved differentiate the brand in competition as “Sweatshop-Free” and vertically integrated, in contrast to the low-cost, vertically disintegrated and international subcontracted business models prevalent in the clothing industry. The brand is presented as an American-based “Industrial Revolution” with its key research and development, marketing, and manufacturing activities located in downtown Los Angeles. This narrative is articulated in the brand’s circulation and consumption in its retail outlets and on its website, which invites potential consumers to “Explore our Factory.” The actors involved in this branding have originated the good and service commodity in a nationally situated brand name (“American Apparel”) and articulated a “Made in …” claim that is located in a specific territory within a particular city and state – the downtown area of Los Angeles, California. Meaning and value are sought from geographical association with LA as a center of innovation, style, and buzz in global fashion circles. Origination illuminates the particular kinds and forms of geographical associations central to the brand’s identity and its branding activities.

Branding actors deploy geographical associations also in efforts to create and fix meaning and value in branded services. In telemediated services, the origination of where actual tasks are undertaken and services delivered from has become more complex. These emergent sociospatial divisions of labor therefore have begun to influence how branding actors originate their services, inflecting the spatial connections and references articulated in trying to construct meaning and value in market settings. The standardization and routinization of back-office service functions led to the development of contact or call centers, decentralized to economically lagging places with pools of abundant lower-wage, often women, workers. Competition and cost pressures encouraged outsourcing and the international offshoring of such contact centers, facilitated by advances in information and communication technologies. However, problems with quality, customer disquiet, and competition have led some UK service providers to return their contact center services to the company’s perceived home country. Such changes have influenced the articulation and circulation of the origination of the branded services. The bank NatWest, for example, used a recent advertising campaign to bolster its brand’s reputation for “Helpful Banking” by asking: “We have award-winning 24/7 UK call centres. Does your bank?” (emphasis added). Its branding actors explicitly seek to construct their services as higher quality and accessible because of their
BRANDS AND BRANDING

origination in “UK call centres.” This emphasis upon the United Kingdom is central to the meaning and value of the brand’s proposition vis-à-vis its competitors, who may still be offering services outsourced to external – and by implication lower quality – providers operating from outside the United Kingdom. NatWest is explicitly promoting the origination of its service delivery, connecting with consumers anxious to access services from the specific territory of the United Kingdom. This origination is being deployed, even though the telemadated means used to deliver actual services means they could be provided from virtually anywhere, and certainly beyond the United Kingdom.

Conclusions

Understanding how the meaning and value of branded goods and services commodities are entwined with where they are from, and the places with which they are associated, helps explain their geographies. Engaging the dramatic rise, importance, and pervasiveness of brands and branding in contemporary economy, society, culture, ecology, and polity, this entry seeks to focus more attention upon their relatively neglected geographies. It has defined brand and branding, explained why they are geographical, introduced geographical associations, and emphasized the agency of actors in spatial circuits of meaning and value. Origination is vital to understanding the geographical associations constructed by actors related in spatial circuits – producers, circulators, consumers, and regulators – in their efforts to fix meaning and value in spatial and temporal market settings. Connecting with geographical political and cultural economy, origination provides a means to address critical questions about how, why, where, and by whom goods and services brands are associated with specific and particular spaces and places.

Brazil: Associação dos Geógrafos Brasileiros (AGB) (Brazilian Geographers Association)

Founded: 1934
Location of headquarters: São Paulo
Website: www.agb.org.br
Membership: 6500 (as of December 31, 2013)
Chairman: Renato Emerson dos Santos
Contact: nacional@agb.org.br

Description and purpose

The structure of AGB is comprised of a national executive board and dozens of local branches distributed throughout the country (with elections every two years).

Its objectives are to: promote the development of geography by researching and disseminating geographic issues; encourage the study and teaching of geography, as well as propose measures for its improvement; participate in exchanges and collaborate with other Brazilian and international entities engaged in geographical research or subjects of reciprocal interest; examine decisions of the public or private sector that affect and involve geographical science, geographers and geographical education, and research institutions, and voice its opinion on the matter; convene geographers, geography teachers, students, and other interested parties for the defense and prestige of the profession; organize meetings, conferences, exhibitions, symposiums, courses and debates, and professional exchanges; and represent the thoughts of its members before government authorities and professional, cultural, and technical associations.

Journals or major publication series

- Anais dos Encontros Nacionais de Geógrafos e Congressos Brasileiros de Geógrafos (Annals of the National Geographers Meetings and Brazilian Geographers Congresses)

Current activities or projects

The Association sponsors the biannual National Geographers Meeting, and every ten years, the Brazilian Geographers Congress, with the most recent congress being held in Vitória, Espírito Santo in 2014. It also sponsors “Speak up Teacher,” a meeting held every four years to foster and disseminate articles related to the teaching of geography in school.

Active throughout Brazil, working groups linked to local branches address, on an ongoing basis, social issues, such as urban, rural, and environmental policies, among other topics.

Brief history

Founded in 1934, the association is a civil nonprofit organization. Over time, it has become a truly national organization with members throughout the country.

Until the mid-1970s, AGB was characterized as a researchers’ association. However, at the end of that decade, spurred by the growth of the Brazilian student movement, it changed its organizational perspective, which was reflected in the reformulation of its statutes. Since then, it has expanded as an association and is more closely tied to the fight for human rights and to
the political and democratic discussions taking place in Brazilian society.

AGB’s institutional history is linked to the history of geography and Brazilian geographical thought; there is a close relationship between geographical knowledge and Brazilian society. The local branches are responsible for the publication of several scientific journals, such as the *Paulista Geography Bulletin*, the oldest in circulation, the *Gaucho Geography Bulletin*, the *Fluminense Geography Bulletin*, and others. They are also responsible for organizing regional geography meetings.

Brazil: Sociedade Brasileira de Geografia (Brazilian Society of Geography)

Founded: 1945
Location of headquarters: Rio de Janeiro
Website: www.socbrasileiradegeografia.com.br/inicio.html
Membership: 600 (as of June 2, 2015)
President: William Paulo Maciel
Contact: sbgrj@socbrasileiradegeografia.com.br

Description and purpose

The Sociedade Brasileira de Geografia has the following goals: the study, discussion, research and scientific explorations of geography in its various branches, principles, relationships, discoveries, developments, and applications; and specialty study and knowledge of the facts and documents concerning the geography of Brazil.

Journals or major publication series

Current activities or projects

The organization does not undertake large projects or continuous activities. Its main activity is the maintenance of the journal, Revista Eletrônica da Sociedade Brasileira de Geografia, and the presentation of occasional short-term courses.

Brief history

The society was founded on February 25, 1883, as the Geographical Society of Rio de Janeiro. In 1945 it became the Brazilian Society of Geography. The creation of the society was inspired by the French model, characterized by the dissemination of scientific knowledge through the exchange of publications, participation in conferences, and exchange of correspondence with similar foreign entities, mainly European. However, its main goal was the organization of its national territory.

Submitted by Jan Monk
Buffers refer to spaces between objects or areas or within a specified distance of an object or place. They appear in a variety of contexts, including vector applications in geographic information systems (GIS), in which they are used to demarcate spaces within particular distances of features. It is frequently observed that many phenomena are limited by distance, and a buffer provides a simple way of mapping out this area. Plants and animals within a certain distance of a road may be affected by noise and runoff, and a buffer can identify those areas.

In political geography, urban planning, and conservation, buffers may be areas used to separate incompatible land uses or geographic entities.

In vector GIS, a buffer is a space defined by a user-specified distance from a point, line, or area feature. It is a common application widely implemented within GIS software, though the exact details and capabilities will vary from one software package to another. Depending on the software, it may be displayed as a graphic outline around the original feature or used to generate a new polygon dataset. A buffer around a single point will simply be a circle; those around lines and areas follow the shapes of these features, though they will be somewhat generalized. Multiple buffers may be generated at different distances from a feature, and some software may allow variable buffer distances to different features to be automatically generated based on an attribute field (or column in the attribute table). More important roads may therefore get a wider buffer than smaller roads. Overlapping buffers can generally be combined into one shape, and buffering inwards from an area’s boundary may also be possible, although it is not supported on all software. These operations are similar to dilation and erosion in mathematical morphology and image processing, with dilation generalizing a shape like a buffer to make it appear thicker and erosion doing the reverse; the latter might be approximated visually by inward buffers.

Figure 1 shows buffers of 500, 1000, and 1500 ft around the boundaries of George Washington Carver National Monument in Missouri. At farther distances the buffers become more generalized. Figure 2 shows buffers of the same size around the Monument’s Visitor Center. As this building is represented in GIS as a dimensionless point the buffers are concentric rings around the point. For clarity the buffers are shown on top of the Monument boundary. Figure 3 shows 500-, 1000-, and 1500-ft buffers around the Monument’s entrance road. At farther distances the buffer again becomes more generalized.

The GIS user must decide the distance a buffer will extend. Appropriate standards may exist for a particular application; for example, the US Federal Transit Administration uses $\frac{1}{4}$ mile (1250 ft, about 381 m) as an indicator for access to bus stops or public transit stations. In the field of road ecology, studies have been done to identify the relevant distance from roads at which particular

plants and animals will be affected by different highway phenomena.

In addition to displaying an area, buffers can also be used to select out other geographic features during GIS analysis operations such as “select-by-location” or “map overlay” operations. This type of operation includes selecting features by distance as one of the standard spatial relation types. In this case, vector objects within a user-specified distance of one or more features will be selected for further analysis or manipulation. This selection process works in a very similar way to buffers except that instead of generating a new object on the map the selection buffer is not seen.

Some important limitations exist. Buffers are usually based on straight-line or Euclidean distance in two dimensions only, and will therefore only approximate true distance in rough terrain. They also do not take into account the Earth’s curvature and so will provide accurate results only over small areas, though an inappropriate projection may also distort the distance value. GIS software may allow geodesic or spherical distances to be calculated and, if so, these are more accurate over larger areas. As with most
GIS applications, buffers create an absolute or Boolean space in which distance defines an area with sharp boundaries and no transition. This is represented by a typical GIS polygon in which a location is defined as either inside or outside, with no possibility of ambiguity or uncertainty. In the real world, there may be a gradual transition, as with a culture area or neighborhood unit. An additional difficulty with buffers is that they do not allow for uncertain or probabilistic distances. Geographic features may not have a fixed existence that can be precisely measured or verified. A probabilistic or fuzzy representation would be more appropriate in many applications.

A number of other GIS operations are similar to buffering. Thiessen or Voronoi polygons divide an area based on distance to the nearest seed point. These also use straight line distance but unlike buffers they partition an entire area into separate polygons that never overlap. They are also based only on vector points. A related application is visibility analysis or viewshed mapping, which identifies areas visible from one or more observation points based on a terrain surface such as a raster digital elevation model (DEM). The result is two polygon areas: those

Figure 2  Buffers around Visitor Center of George Washington Carver National Monument, Carthage, Missouri. 500 feet = 152 m. Data from National Park Service and U.S. Census Bureau.
BUFFERS

visible from a point and those not visible (or invisible) from that point. As with buffers, there is a Boolean border with no transition. They commonly have very irregular shapes with many discontinuous sections and so look very different from buffers. However, they could be used in a planning process to screen areas. This visibility does not take into account buildings, vegetation, haze, and often the curvature of the Earth. Observations points are vector points, though research has been done to accommodate linear or area-based viewsheds.

A different form of buffers can be generated using network distance, such as measured through a street network. These network buffers may be called service areas or service networks. Network analysis functions in GIS allow computation of network distance areas that show all streets within a user-specified distance of one or more origin points. Not all transport routes will permit the same speeds or costs, leading to uneven movement opportunities. These service areas therefore tend to be irregular, depending on the topology of the street network and the particular impedance function used (network distance, driving time, etc.) and how this relates to the links in the network. They may also have holes inside them in areas with few streets.

Figure 3 Buffers around entrance road of George Washington Carver National Monument, Carthage, Missouri. 500 feet = 152 m. Data from National Park Service and U.S. Census Bureau.
An application of buffering also appears in network analysis routing computations when the GIS software must connect an origin to a destination. These would be input by the user and must be within a certain distance or search tolerance of a network link. This tolerance will have a default value but will likely be adjustable by the user. The tolerance is effectively a buffer; locations within the buffer are reachable while those beyond it are not. This is especially important when the user manually places a point on a link with no width, or when geocoded addresses with a location offset from the street centerline are used.

Distance can be measured in raster GIS as well, again using straight line distance with cell resolution (size) to approximate an area within a distance of a specified cell or group of cells. Euclidean distance will be measured between cell centroids, so accuracy for a distance measurement is highly dependent on resolution. Cells within a particular distance of a cell or group of cells could be selected using a reclass function and would approximate a vector buffer. A spread function or cost distance can be used to take terrain, network, or other impedances into account by assigning each cell a friction factor. Accumulated impedance will be measured outwards from an origin cell or group of cells, approximating a network buffer. These will be displayed as a new raster surface. As with network analysis, the results will likely be irregular areas. Least-cost paths through the accumulated impedance surfaces can also be found, though these will more likely represent movement over different types of terrain or land cover than vehicle speeds through a network.

Buffers also appear in other geographical contexts, though in slightly different form. In political geography, a buffer refers to an area around or between jurisdictions that serves to separate them. In this case, a buffer exists between geographic entities, a different usage than that in the field of GIS. Demilitarized zones between hostile countries such as North and South Korea or the neutral zone that divides the island of Cyprus are examples; an independent buffer state that exists between two hostile countries, such as Mongolia between China and Russia, is another. The exact width, area, or shape of the buffer may be less important than its population, power, or ability to isolate jurisdictions.

In urban geography and planning, buffers can refer to areas both between and around particular land uses. This is particularly the case with Euclidean zoning (derived from the city of Euclid, Ohio). Incompatible land uses, such as industrial and residential, may be separated by a buffer zone or separator, whether of another land use (a use buffer) or open land (a landscaped buffer). As zoning codes commonly make use of a hierarchy of land uses, incompatibilities are defined as land uses from different levels that are adjacent or near each other. Such buffers could be based on adjacency and containment (no incompatible land uses in or touching a residential area) or by distance (none within 1000 ft of a home). Use buffers are written into the zoning code, while landscaping buffers are essentially a design feature of a property, such as vegetation to screen unattractive facilities and to provide a noise barrier. Buffers or buffer zones may also be legally enacted to limit protest activities or ensure access to public facilities such as abortion clinics.

Conservation planning also makes use of buffers as additional lands to protect a nature reserve, natural features, or water. Conservation buffers may be landscaped areas to protect a riparian corridor, vegetation planted around a farm to protect soil, a recreational greenway along a stream, a greenbelt around a city, a windbreak, a vegetative filter to trap pollutants running into streams, or similar kinds of features.
BUFFERS

large and small. Buffers may have different or multiple purposes, and may be developed into a network. GIS can be very useful for identifying potential buffer areas and their characteristics; however, this will likely be based on a different methodology than vector buffering based on distance. This notion of buffer fits within International Union for Conservation of Nature (IUCN) Protected Areas Categories V and VI, but unlike larger reserves and parks they will likely have no legal status except that under local zoning codes or land ownership laws. There is some potential for demilitarized zones to serve as nature refuges, so again multiple uses of the buffer concept may inadvertently coincide.

The built environment can be interpreted as the product of regional cultures and of economic and technological forces, and as the legacy of successive phases of historical development. It can also be seen as a significant influence on individual and social behaviors, and is widely recognized as simultaneously both outcome and shaper of political, cultural, and socioeconomic forces. There are many subdisciplinary approaches, each with a different perspective and emphasis. Table 1 outlines the principal approaches discussed here.

The emphasis on these various interpretations has differed a great deal from one disciplinary and subdisciplinary perspective to another. The traditional view of the built environment in geography and anthropology was exemplified by the “Berkeley School” of cultural geography and its chief exponent, Carl Sauer (1889–1975), and by the work of architectural theorist Amos Rapoport (1929–). Sauer and his followers were interested in understanding the material expressions of culture on regional landscapes. This led to the concept of cultural landscapes, a tangible outcome of the complex interactions between a human group – with its own distinctive cultural practices, preferences, values, and aspirations – and the natural environment of a region (Sauer 1964). The focus of such work, for several decades of the mid-to late-twentieth century, was the character of vernacular housing and of regional building types such as log cabins, churches, temples, farm buildings, and tobacco barns. Vernacular architecture was seen as a product of the needs, means, materials, traditions, culture, and natural order of local populations. The principal critique of such an approach is that it implicitly treats regional cultures as superorganic: overarching and independent forces in their own right.

A second traditional perspective on the built environment, morphogenesis, emphasizes its spatial framework as the outcome of broader historic influences. Morphogenesis refers to the processes that create and reshape the physical fabric of urban form. Over time, the morphology of settlements changes, not only as new fabric is added but also as existing fabric is modified (Whitehand 1992). Basic forms, consisting of house, plot, and street types of a given period, become hybridized as new buildings replace old, plots are amalgamated or subdivided, and street layouts are modified. Each successive phase of settlement growth is subject to the influence of different social, economic, and cultural forces, while the growth of every settlement is a twin process of outward extension and internal reorganization. Each phase adds new fabric in the form of accretions and replacements. Morphological patterns are based on two fundamental elements: the size and shape of plots of land, and the layout of streets. Both vary according to historical period, economics, and sociocultural ideals. For example, where there is a shortage of building land, or where as many buildings as possible have to be accommodated along a given frontage (as on a waterfront or around a market square), small, deep plots tend to result.
Elsewhere, the size and form of the plot tend to be determined by the predominant house type.

In disciplines such as architecture, history, political science, and sociology, the built environment has often been treated as fossilized social history: an expression of the economic and political power exerted at different times by various individuals, social groups, and governments; and a reflection of the prevailing spirit, or zeitgeist, of the time. Architectural history, in particular, has provided a large body of knowledge that is mostly descriptive and contextual, with a focus on the aesthetic response, in built form, to the broad sweep of history. Thus, for example, Renaissance and Baroque architecture reflects the literary and scientific humanism that displaced the reactionary medieval mysticism of previous centuries. It gave expression to reason, rationality, and idealism, striving for a sense of infinite space and for imposing grandeur. Built form of this sort was only possible on any scale where centralized, autocratic power was combined with significant economic resources, and so the result was often reduced to an extravagant symbolization of wealth, power, and destiny.

The initial aesthetic response to the radical changes of the industrial revolution of the nineteenth century was reactionary. In the face of turbulence and change, architects and their clients opted for the reassurance of neoclassical styles. In the second half of the nineteenth century, architects were still struggling to find an appropriate response to industrialization and to the challenges and opportunities presented by new technologies. Neoclassicism gave way to eclectic revivals and mutations of various historic styles before the Arts and Crafts movement, based on a romantic idealization of preindustrial crafts, emerged in England. The Arts and Crafts movement was at its height in Europe between

1880 and 1910; in the United States (where it was known as the Craftsman style) it peaked between 1910 and 1925 before giving way to another reactionary design impulse in the form of the Beaux Arts and the City Beautiful movement.

The first genuinely original aesthetic response to the industrial era was German Modernism: the Deutsche Werkstätten, the Dresdner Werkstätten, and the Debschitz School in Munich in the 1890s and early 1900s. These led to the establishment of the better-known Staatliches Bauhaus in 1919. As artists and designers grappled with the implications of the rush of technical sensations of the era — electric power, telecommunication, internal combustion engines, aviation, radio, photography, and cinematography — and the dislocations of economic change and modern warfare, the Bauhaus was at the heart of a broad movement of Modernism. Modern architecture gave particular expression to the technological and scientific underpinnings of the industrial era. Among the most influential practitioners in this context was Le Corbusier (1887–1965), who advocated apartment buildings as rationally designed “machines for living.”

The social-democratic radicalism of early twentieth century Modernism was lost by mid-century as Modernism became the principal language of high design, symbolic of progress and prosperity, and adopted in the form of an International Style by corporations worldwide. In the late twentieth century a new and rather eclectic aesthetic response, postmodernism, emerged as architects sought to reflect the globalized and consumption-oriented societies of the period. Meanwhile, Modern design has been widely reasserted but in a commodified form that revises the strict form-follows-function of Modernist architecture, producing pseudomodern buildings with basically regular, Modernist proportions embellished with functionless ornamentations.

This sort of perspective on the built environment reflects the distinction famously made by architectural historian Nikolaus Pevsner (1902–1983) between architecture and “mere building.” Yet of course there is much more “mere building” than there is “architecture.” In parallel with the aesthetic responses to changing societies have been changes in building technologies that have made for new kinds of buildings while making architecture the art of the possible. Iron girders, for example, made two- and three-story “fireproof” factories possible; steel framing was a precondition for the development of skyscrapers; while the low cost and ease of balloon framing with wooden studs helped to transform the suburban landscape of North America.

In many subdisciplines, the built environment has automatically been assigned the role of an independent variable, “explaining” everything from people’s perceptual acuity to their social networks and propensity to indulge in deviant behavior. A common suggestion is that the design and configuration of buildings and spaces sometimes create microenvironments that discourage “normal” patterns of social interaction and encourage deviant behavior of various kinds. A considerable amount of evidence has been accumulated in support of this idea. The inhibiting effects of high-rise and deck-access apartment dwellings on social interaction and child development, for example, have been documented in a number of different studies; and from these it is a short step to studies that point to the correlation between certain aspects of urban design and the incidence of particular aspects of deviancy. The best-known link between the built environment and deviant behavior relies on the concept of “defensible space” (Newman 1972). Much of the petty crime, vandalism, mugging, and burglary in modern housing developments, it is believed, is
related to an attenuation of community life and a withdrawal of local social controls caused by the inability of residents to identify with, or exert any control over, the space beyond their own front door. Defensible space is now an essential component in the praxis of urban design, endorsed by many law enforcement agencies as part of an international movement known as Crime Prevention Through Environmental Design (CPTED). Such an approach, as with all studies that treat the built environment as an independent variable, runs the risk of privileging built form over social process and falling into the trap of environmental determinism (built-form stimulus → human/social/cultural response).

There is, nevertheless, a good deal of evidence of the ways in which the “syntax” of built form relates to patterns of social encounters and relationships (Hillier and Hanson 1984). The built environment can be interpreted more subtly as a text: as a socially constructed phenomenon that expresses a distinctive mix of ideas and practices, of often oppositional social groups and political relationships. The built environment is heavily endowed with social meaning, but this meaning is rarely simple, straightforward, or unidimensional. There is an important distinction to be made, for example, between the intended meaning of architecture and the perceived meaning of the built environment as seen by others. David Harvey’s study (1979) of the Sacré-Coeur in Paris has demonstrated how the intended symbolism of the building – a reaffirmation of Monarchism in the wake of the Paris Commune – was for many years seen as a provocation to civil society, and is still interpreted by the predominantly republican population of Paris as a provocative rather than a unifying symbol.

Another critical point is that the social meaning of the built environment is not static. Thus powerful symbols and motifs from earlier periods are often borrowed in order to legitimize a new social order, as in the adoption of a selection of motifs from the classical revival in Europe by Jefferson and the founding fathers responsible for commissioning public and ceremonial architecture in Washington, DC. Buildings can legitimize a particular ideology or power system by providing a physical focus to which sentiments can be attached. The ideology of civics and the power of local government, for example, are symbolized in civic architecture. In similar fashion, metropolitan élites frequently use high-profile buildings and extensive regeneration projects as part of their brand identity in a competitive world economy.

On the other hand, the built environment can carry an unintentional symbolism. Quite ordinary settings can be powerfully symbolic because they are understood as being a particular kind of place. For example, as Donald Meinig (1924–) has observed, the stereotypical New England town is widely taken to represent not just a certain type of regional architecture but also a certain kind of community with distinctive values: family-centered, God-fearing, morally conscious, industrious, thrifty, and democratic. The commonplace landscape of California suburbia, meanwhile, is symbolic of a particular lifestyle for middle-class, nuclear families: individualistic, private, informal, and recreation- and consumption-oriented.

The formal literature on architectural symbolism distinguishes three facets of symbolic meaning: syntactical meaning, or the meaning that an element of the built environment acquires by virtue of its location in relation to other elements; pragmatic meaning, or the meaning that is understood in relation to the intentions of the architect, client, or social group at the time of building; and semantic meaning, or the meaning it acquires – intentionally or not – because of the idea or ideology that it represents. The semantic meaning of the built
environment can be an important component of people’s daily surroundings: powerful but stealthy backdrops that can naturalize and reinforce dominant political and economic structures as if they were simply given and inevitable. Laden with layers of semantic meaning, the everyday built environment amounts to a moral landscape that reaffirms dominant values.

These symbolic attributes are a reminder that the built environment is socially constructed as well as physically constructed. The production and consumption of the built environment can be seen not simply as a matter of supply and demand but also as a function of time- and place-specific social relations that involve a variety of key actors and institutions, including landowners, investors, financiers, developers, builders, design professionals, business and community leaders, government agencies, homeowner associations, and consumers. At the same time, it is clear that these relations among key agents and institutions need to be understood in terms of their linkages with the broader sweep of economic, social, cultural, and political change. These sets of relations represent “structures of building provision.”

Landowners stand at the beginning of the chain of events involved in urban development, and they influence morphogenesis directly through the size and spatial pattern of parcels of land that are sold to developers and through the conditions that they may impose on the nature of subsequent development. Speculators are an important category of landowners — especially the bigger players who not only rely on an ability to anticipate trends but also hope to influence or engineer change for their own benefit. They are an important component of the overall structure of building provision in big cities: “growth-machine” coalitions of local real estate, finance, and construction interests. This rentier class of landowners, developers, realtors, commercial bankers, and construction companies (along with auxiliary players in utility companies, engineering and technical subcontractors, retailers, chambers of commerce, lawyers, title insurance and trust companies, federal, state, and local agencies, transportation and utility companies, and local media) has a common interest in securing the preconditions for growth. This involves general support for the ideology of growth and consumption as well as direct tactical involvement in local politics around local government land-use regulation, and development policy. Many political leaders become members of growth-machine coalitions because local governments rely heavily on real estate taxes to fund infrastructure and essential services such as schools, police, and fire protection.

Within local structures of building provision, demand and supply are mediated by a whole spectrum of “exchange professionals” such as mortgage financiers, realtors, surveyors, market analysts, advertising agencies, appraisers, and property managers. Most important in terms of the physical attributes of the built environment are design professionals: architects, planners, urban designers, and landscape architects. As key arbiters of style, design professionals are in a powerful position to stimulate consumption merely by generating and/or endorsing changes in the nuances of building styles. Meanwhile, by virtue of the prestige and mystique socially accorded to creativity, design professionals add exchange value to the built environment through their decisions about design. As a result, design professionals have been charged with a “silent complicity” with the agendas of the politically and economically powerful in local growth machines. More generally, design professionals draw on their particular skills to translate social and cultural values into material form: they are amplifiers and rectifiers of intellectual, social, and cultural trends; at once both products
and carriers of the flux of ideas and power relationships in society. But because of the dominance of aesthetics in their professional ideology, most design professionals tend to see their work as abstracted from the people and places that it affects. The result is often a design determinism in which people are conceived of as beholders, not willed agents/actors.

The physical production of the built environment is an important component of the economic geography of many countries. In this context, the development industry has followed the trends of other producer and service industries, with mergers and acquisitions, vertical and horizontal integration, product diversification, the deployment of new technologies, just-in-time delivery, and niche marketing, resulting in a much greater market dominance of big, publicly traded companies with complex and sophisticated operations. In the United States there are tens of thousands of home builders, most of them tiny, but the biggest builders have been getting bigger, and taking up an increasing share of the market. In 1986, the market share of the 100 largest builders (in terms of new home sales) stood at 24%. In 2012, it was more than 40%, with the top 10 builders capturing more than 25% on their own.

Meanwhile, the progressive liberalization of international financial markets since the 1980s has constituted a global driver in big-city real estate construction. It has also led to the financialization of real estate – in the form, for example, of real estate investment trusts (REITs) and pension funds with large investments in the built environment. This has introduced far-reaching institutional changes in financial markets, increasing the role of financial actors and financial institutions in creating real estate credit and in operating domestic and international real estate development processes. At the same time, the organizational structure of real estate development has become more complex and more decentralized.

In particular, the design and construction of the built environment are increasingly influenced by corporate globalization. Enabled by digital and telecommunications technologies, by advanced international business services, and by the emergence of clients with transnational operations and a cosmopolitan sensibility, the portfolio of many architecture and construction firms has an international component. The scope of operations of many of the largest firms is now truly global, and some firms are transnational corporations in their own right: huge architecture and engineering (A&E) firms with multiple international offices covering several continents. Globalization has facilitated the spread of “traveling ideas” about real estate design and development that have contributed to homogenizing trends in built form. Property-led urban regeneration schemes are arguably the principal reason for the homogenizing appearance of many cities. The success of property-led redevelopment of the likes of Bilbao, Barcelona, London’s Docklands, and La Défense in Paris has led it to become the most influential of all traveling ideas, resulting in the serial reproduction of “designscapes”: ensembles of office buildings, retail space, condominium towers, cultural amenities, renovated spaces, landscaping, and street furniture that are different in the details of styling and finish but generically similar in concept and execution.

These trends in the production of the built environment are paralleled by trends in consumption. Global cultural shifts have come to place a premium on consumer experience, celebrity, and spectacle, and “place” has become increasingly commodified. In this context, developers understand that design – especially by “star” architects – can add significantly to exchange value. Policymakers have also
recognized the demand for quality in the built environment. A key part of providing a good business climate, for many cities, is the promotion of urban design and iconic architecture. Under the pressure of increased economic competitiveness, decision-makers increasingly look to flagship architecture to combine an imagery of economic regeneration and civic pride. While for centuries the quality of the built environment was an outcome of economic growth of cities, nowadays it is a prerequisite for the economic development of cities; and urban design has acquired a new role as an instrument of economic development.

From a structuralist perspective, the built environment is seen as part of the socioeconomic superstructure stemming from the dominant mode of production. As such it reflects the Zeitgeist of the prevailing system and serves, like other components of the superstructure, as one of the means through which the necessary conditions for the continuation of the system are reproduced. Investment in the built environment is seen as an important secondary circuit of capital and a potential component of the “spatial fix” of market crises.

David Harvey (1979) characterized the restless formation and reformation of the built environment as part of capitalism’s perpetual struggle to create a social and physical landscape “in its own image” and requisite to its own needs at a particular point in time. He nevertheless recognized the danger of thinking in terms of simple causal relationships, stressing the need for a flexible approach that allows urban development to exhibit a variety of forms within the dominant mode of production. As Edward Soja pointed out (1980), the spatial imprint of capitalism is not a smooth and automatic process in which the “needs” of capital are stamped, without resistance or constraint, onto the landscape. Rather, there is a “sociospatial dialectic” of significant reciprocal and recursive relationships among individuals, the built environment, and society. The built environment is thus, in Meinig’s words, “mold and mirror” of economy, culture, and society; it is both the product of, and the mediator between, social relations, and it is central to human geographies that are simultaneously contingent and conditioning, outcome and medium, product and premise.

Business improvement districts

Kevin Ward

University of Manchester, UK

Business improvement districts are public–private partnerships in which property and/or business owners in a defined geographic area elect to make a collective contribution to the maintenance, development, and marketing/promotion of their commercial district. This is done in the form of a self-agreed and self-imposed levy, or “tax,” which is a percentage of the annual business rates. Collected by local government in some countries and by central government in others, this tax is then given over to a business improvement district management committee consisting of paid officials and elected representatives of local businesses and, in some cases, local residents. It decides how to spend its budget, which in a city like New York ranges from US$500 000 for a business improvement district in Harlem to over $10 million for a business improvement district in midtown Manhattan.

The business improvement district (BID) program began in a small west Toronto shopping area. In the 1960s, local retailers in the Bloor West Village realized that voluntary contributions would be insufficient for them to deliver yearly revitalization strategies. After a series of meetings between local and provincial officials and local business representatives to discuss the establishment of a self-imposed levy, the city of Toronto passed By-law no. 170-70. The Ontario Municipal Board then approved the Bloor Jane Runnymede Business Improvement Area, the world’s first business improvement district. The city is now home to 77 business improvement districts and more than 300 exist across Canada.

The first US business improvement district was established in New Orleans in 1975. Since then the number of business improvement districts across the country has grown, as states have introduced enabling legislation. By the end of the twentieth century, just 25 years after they were first established in US cities and towns, there were over 400 in 42 states, with 64% in just five: California, New York, New Jersey, North Carolina, and Wisconsin (Mitchell 1999). According to Hochleutner (2003, 374), business improvement districts have changed “the way America governs its shopping districts, commercial areas, and downtowns.”

In the past 15 years, a number of other countries have introduced BID programs. These include Australia, Germany, Ireland, Japan, South Africa, the Netherlands, and the United Kingdom. This internationalization has increased the number of BID programs at play and the differences between them: for example, between the services they provide, the level of contribution by businesses, and the way in which the contribution is calculated, which varies, sometimes subtly and sometimes dramatically, from BID program to BID program. Likewise, there is a significant variety over space in the types of business that participate in its management, those who are levied, and those who are eligible to vote. In the United Kingdom, for instance, the contribution is compulsory for all business property occupiers within the area once the business improvement district is established, setting it apart from predecessors such as town center management schemes. In the United States, it is compulsory.
BUSINESS IMPROVEMENT DISTRICTS

for all property owners in a designated zone, although in some states churches and schools are exempt from the levy. In other countries, such as Australia, the contribution is not compulsory. The name “business improvement district,” furthermore, is not always used – so in Canada it is business improvement areas, in the Netherlands “bedrijven investeringszones” (business investment zones), and in Germany, neighborhood improvement districts. So while it is possible to write of a single BID program, there is actually a variety of similar, and contrasting, BID programs in existence and circulation.

Nevertheless, these differences should not mask a number of similarities in the different BID programs. There is significant overlap between what business improvement districts do in different cities around the world. Mallett (1994, 277) has argued that the US BID program was “concerned with cleanliness and aesthetics of public space, security, achieving the best mix of activities, transportation access, and portraying an image of the whole to potential consumers.” That is, US business improvement districts “understand that simple things – such as keeping sidewalks clean and safe – matter enormously to the urban quality of life” (MacDonald 1996). This is also the case for other countries’ BID programs. In some countries, BID programs augment services provided by local government. In others, their work occurs in the space left by the redrawing of government boundaries. So, in the United States, Mallett (1994, 284) has argued that “[B]usiness improvement districts are a response to the failure of local government to adequately maintain and manage spaces of the post-industrial city.”

More specifically, what business improvement districts do can be grouped into three types of activity. First are those that target physical infrastructure. Examples include capital improvements (e.g., lighting, street furniture, shrubbery, etc.), economic development (e.g., offering incentives to businesses to relocate or stay in the BID area), and maintenance (e.g., collecting rubbish, removing litter and graffiti, etc.). The second type of activity is those focused on promotional infrastructure. Examples include consumer marketing (e.g., organizing and advertising events, producing and distributing maps and newsletters) and policy advocacy (e.g., lobbying government and other stakeholders, liaising with other business improvement districts, etc.). The third type of activity is surveillance infrastructure: for example, enhancement of public space regulation (e.g., regulating traffic flow, discouraging on-sidewalk selling, moving along the homeless, etc.) and security (e.g., ambassadors, security guards, and the use of CCTV cameras).

It is possible to understand the presence of business improvement districts in a growing number of cities around the world in a number of ways. For some, they reflect a bottom-up uprising by capital, as local businesses voluntarily involve themselves in decisions over how to govern and use public space. Here, work seeks to evaluate the impact of business improvement districts against a number of criteria or “key performance indicators.” Concerns center on efficiency and the value the BID program adds in terms of economic development (Mitchell 1999). For others, the BID program reflects the growing role assigned to capital and its representatives in the governance of cities, as governments are restructured. This work raises concerns over the “right to the city” and to whom business improvement districts are accountable. It argues that the BID program is one of a number of examples that reflect the growing interweaving of market-based and state-based regulatory arrangements, the combined effects of which have profound implications for notions of spatial and social justice (Ward 2006).

Description and purpose

The Canadian Association of Geographers/Association Canadienne des Géographes is a national, bilingual (English and French), not-for-profit organization. It is the only national organization in Canada representing practicing geographers across the entire spectrum of the discipline. The association produces a peer-reviewed academic journal and an annual institutional directory. It also organizes academic conferences and regularly engages in communications with members and nonmembers about geographical issues. It plays a leadership role in connecting learned societies of relevance to geographers and in promoting geographic education in Canada.

Journals or major publication series

Current activities or projects

The association coordinates several conferences each year, one national and others in the regional divisions. Approximately 1000 delegates attend these meetings each year. The association facilitates other forms of communication among the Canadian geographic community including websites, a listserv with a reach to more than 2500 people, social media, and two newsletters. It also has responsibility for the Canadian National Committee for the International Geographical Union, has membership in both the Humanities and Social Science Federation of Canada and the Canadian Federation of Earth Sciences, and works with the Royal Canadian Geographical Society to strengthen geographic education in Canada.

Brief history

The concept for a Canadian association of geographers emerged, in part, out of the perceived value of geography in politics and international relations in the period during and following World War II and also out of a need to expand our understanding of and research on Canada’s north. The association was formed in 1951 when practicing geographers, both academic and nonacademic, were invited to attend an inaugural meeting at McGill University in Montreal.

Since 1951, the CAG has met annually as a national organization and regionally in smaller groups to achieve its mission which includes: dissemination of geographic research; promotion
of geographic education at all levels; recognition of geographic excellence; increased cooperation with other national and international geographic organizations; increased participation in national interdisciplinary organizations; and improved service to the membership.

Carceral geographies

Dominique Moran
University of Birmingham, UK

Carceral geographies are an emergent and vibrant field of geographical research concerned with the spaces and practices of detention and imprisonment, informed by much longer-standing academic engagements with incarceration, namely criminology, prison sociology, and critical legal studies, and in particular with these disciplines’ increasing concern for an understanding of carceral space. Carceral geographies sit at a nexus of various interrelated developments in geographical research: the immense influence of the engagement between Michel Foucault and questions of space, place, and geography; the prominence within contemporary critical human geography of the ideas of Giorgio Agamben about bare life and spaces of exception; the growing prominence of the work of Loïc Wacquant on hyperincarceration and the punitive turn in the United States and Western Europe; and the integration of these perspectives into human geography by scholars such as Ruth Wilson Gilmore and Jamie Peck. In parallel, the recent spatial turn within criminology and prison sociology draws on human geographical understandings of space and spatiality as multiplicitous and heterogeneous, lived and experienced. As a result, an increasingly interdisciplinary approach has emerged within the social sciences that has opened a space for the coalescence of work under the heading of carceral geographies. This coalescence occurs at a critical moment in contemporary penal practice in the Anglo-American context with the expansion of workfare and prisonfare policies, the criminalization of immigration, and the expansion of the carceral estate. Of particular note is that carceral geographies’ focus on the spaces and practices of confinement extends both to “mainstream” incarceration, that is, of individuals detained by the prevailing legal system, and to migrant detention, where irregular migrants and “refused” asylum seekers are detained, ostensibly pending decisions on admittance or repatriation. Taking an overview of the scholarship produced by geographers concerned with incarceration enables the notion of the “carceral” to be brought more clearly into view. Dynamically open to transdisciplinarity, carceral geographies are informed by and extend theoretical developments in human geography, but also, critically, interface with contemporary debates such as the ongoing discussion of the aim and purpose of imprisonment.

Three main areas of interest characterize the field, broadly conceived as the nature of carceral spaces and experiences within them, the spatial geographies of carceral systems, and the relationship between the carceral and an increasingly punitive state. Taking these in turn, it is clear that scholarship in these three areas offers new perspectives on imprisonment, and that ongoing research enables novel understandings of the experiences of carceral spaces to develop. First, in work on the nature and experience of (highly racialized, classed, and gendered) carceral spaces, theorizations of incarceration informed by Foucault are debated and contested. Human geographers have shown that rather than being rendered “docile,” prisoner resistance to omni-disciplinary control can be expressed
CARCERAL GEOGRAPHIES

by reclaiming culturally defined prison space, with prisoners exerting agency to make and remake spaces, both material and imagined. In some contexts prison space is also personalized, through display of objects and belongings, and it has been suggested that this spatial modification reflects the construction of the meaning of prison spaces. Geographers have explored individual and collective prisoner agency and identified ways in which prisoners consciously negotiate tactical spatial maneuvers to find solitude in crowded prison spaces. This scholarship highlights the nature of prisons as institutions in which those in control construct and exercise their power and those incarcerated tactically create their own spaces within those places and making them temporarily their own as they occupy and move through them.

Second, spatial geographies of incarceration have been inspired by concern for the impact of places of incarceration on the communities that host or surround them. Geographers have engaged with: spatial interdependencies between prisons and cities; the impacts of prison development in persistently poor rural places in the United States, questioning prison siting as a means of encouraging economic development; as well as studying the effects of geographies of punishment on experiences of incarceration. Considering forms of confinement that take place outside the prison “proper,” they have also explored the use of electronic monitoring as an extension of mainstream carceral environments, suggesting that confinement can be independent of physical restriction and arguing that forms of punishment that are not explicitly prison-based can be just as constraining, in a different sense, as traditional incarceration. A major contribution of this body of work is in its suggestion that the carceral is something more than merely the spaces in which individuals are confined; rather, the carceral is a social and psychological construction relevant both within and outside physical spaces of incarceration.

This understanding of the nature of the carceral informs the third strand of research, into the relationship between these spaces and practices of imprisonment and a punitive state, often referred to as the prison industrial complex. It has been suggested that “transcarceral” spaces form beyond prison walls and constitute reconfineinent. Others see the carceral as inscribed on the bodies of prisoners who feel stigmatized after their release from confinement. Geographers have discussed the relationship between prisons and the metropolis in the context of hyperincarceration in the aftermath of what Wacquant (2009) describes as a swing from the social to the penal management of poverty, particularly in the United States, with a punitive revamping of public policy tackling urban marginality through containment and establishing a single carceral continuum between the ghetto and the prison. Very recently, US scholars have drawn attention to specific facets of the relationship between the carceral and the state, with analyses of the political controversy over the counting of prisoners in the US Census – where prisoners are “counted” as residents of the prison where they are held rather than as residents of the places from which they have come, with the result that prison populations are used for political purposes (such as the allocation of federal funds) from which disenfranchised prisoners are generally excluded. Similarly, geographers have drawn attention to the use of US prisoner labor, lacking protection through workers’ rights or health and safety inspections, to conduct hazardous waste-processing activity in ways that both subsidize the costs of imprisonment and undercut private recycling companies.

Carceral geographies also contribute to theory building within human geography with recent work critiquing the under-theorization...
of mobility and power by advancing notions of forced, coerced, disciplined, or governmental mobility, drawing on research into the enforced movement of prisoners and migrant detainees. Significant contributions have also been made to literature on feminist geography and embodiment, and within historical and cultural geography, where there is a growing interest in examining conceptions of crime, regimes of punishment, and their corresponding spaces of corrections and confinement, incorporating a historical-spatial focus into the study of current and former correctional institutions and their wider social contexts. Carceral geographers have made significant contributions to antiracist geographies and have also attended to the experience of transgender individuals’ experience of incarceration.

Care work

Shirlena Huang  
*National University of Singapore*

Care work refers to any face-to-face, often hands-on, service that contributes to the physical, emotional, psychological, and cognitive maintenance and development of the individuals receiving the care. While it can be unpaid (especially when carried out by family members or friends), care work (or caring labor) more usually refers to occupations in which those providing the service, whether in homes or institutions, are paid employees but are nevertheless motivated (at least in part) by concern about the recipient’s welfare. Because care is socially constructed around imaginings of “good care” as a “natural” attribute of women, care work is epitomized in the feminized occupations of nursing and child, elder, or therapeutic care. Geographical discourses on care work(ers) have been bound up with debates around issues of difference and discrimination, as well as rights and responsibilities, and have most recently been examined within frameworks of ethics and social justice, across various spatial scales, from the body to locale-specific sites, to the transnational.

Gerontologists and child development scholars were among the earliest to study care, focusing primarily on the recipients of care. Feminists’ foray into the field of care research moved the focus to the nature of the work, those who performed care work, and its ties to gender and social inequality. Indeed, much of the research on the geographies of care and care work has been built on and strongly influenced by feminist and gendered analyses, which have drawn attention to the associations of care work with women, as well as to the power relations and gendered inequalities at the heart of its conceptualization and organization. While the initial focus was placed on unpaid care within the family (primarily of children and the elderly) and how its naturalization as women’s work affected women’s lives, more recent academic work has centered on the neoliberal shifts that have moved care to the market and commoditized care into the family; the cultural and economic undervaluation of care labor; the structural positioning of care workers (particularly along gender, ethnic, nationality, and skills dimensions) within local and global labor markets; and the transnationalization of care work and its implications for perpetuating structural inequalities as the demand for care workers in the Global North threatens the availability of care in countries of the Global South.

The feminization of care work has its origins in the industrial model of a male breadwinner whose family and home are cared for by a wife. Despite the rise of two-income households as women's opportunities for work in the paid labor force expanded, the family ideal of male breadwinner–female caregiver has persisted. With the thinning out of the welfare state, affluent societies have turned increasingly to commoditized care. As female citizens become unwilling to take on paid care work, given the unattractive pay for work that is demanding, often dirty, and sometimes demeaning (Huang, Thang, and Toyota 2012), the care vacuum in the home created by women's labor force participation has transitioned from one traditionally filled by local (often minority) women from lower
CARE WORK

socioeconomic classes to a sector dominated by migrant women from less well-off economies. The transnational transfer of caring labor from women in the Global North to migrant women from the Global South, who in turn depend on their fellow countrywomen to fill the care gap they have left behind, has created what has been described as “global care chains” for care workers (Hochschild 2000; Yeates 2009).

Feminists contend that, when commoditized, care work is undervalued first and foremost because “care enters the market as historically gendered and domesticated practices” (Green and Lawson 2011: 650). Work done by women – in particular that of mothering – is often deemed “natural” and to be done out of love and obligation; thus care work not only pays less than other jobs, but also pays less than other women’s jobs of similar skill levels that do not involve care (England, Budig, and Folbre 2002). Paula England and her colleagues (2002) forward three other reasons why care work suffers from a relative wage penalty. First, the low pay is supposedly made up for by the intrinsic fulfillment of the job, as it is assumed that those who undertake care work gain intrinsic satisfaction from altruism and a sense of “duty to care,” rather than money. Second, much of it is labor-intensive and hence not amenable to productivity-enhancing capital substitution. Third, people who need care are usually least able to afford it; because the social return is greater than the private return for care, the state will step in to provide this public good at a cheaper cost when the market undersupplies it. The discourses of devaluation mark all levels of care work; thus, even highly educated nannies from developed countries are relatively poorly paid, as are credentialed and skilled (migrant) nurses (Cox 2013; England and Henry 2013).

Those performing care work are subject not only to the ideological construction of the tasks as feminized, but also to cultural and class stereotypes by institutional structures, industry organizations, recruiters, employers, and care recipients. For migrant workers, gender commonly intersects with class, race/ethnicity, and nationality/migrancy as co-constitutive factors to construct a hierarchy of workers in the care labor market based on stereotypes which categorize individuals, groups, and classes as more/less appropriate care workers. For example, Filipinas are often placed in the top stratum as care workers in the global labor market because of their perceived intelligence and “natural” capacity for warmth and patience. Studies of migrant nurses reveal systematic patterns of discrimination as a result of structural inequalities and employers’ overt and covert practices (including pay differentials despite similar qualifications, and being assigned work or positions that do not match their skill sets, which results in deskilling and poorer promotion prospects) because of racist attitudes in their workplaces and host societies (e.g., Batnitzky and McDowell 2011; Huang, Thang, and Toyota 2012). Immigration policies often exacerbate these labor market inequalities by restricting migrants to particular categories of jobs, often for a limited time period, despite migrants’ skills, educational histories, and previous class positions in their home countries. In combination, these mechanisms redefine the class position of migrant care workers as they move across transnational space.

While feminist scholarship has challenged the association of care work with feminization and the reproductive sector, it has not gone far enough to challenge the care/economy dichotomy. Simply seeking a re-evaluation of the worth of care work does little to disrupt the binary; instead, it entrenches the categorical associations of women and care with domesticity (Green and Lawson 2011). Future work needs to relocate care squarely within the economy rather than as subordinate to it. Indeed, it is
now generally recognized that care work, rather than simply being “natural” for women, is a form of emotional labor that requires workers to produce managed performances that display specified emotions (verbally and nonverbally) to influence the emotional state of care recipients. Hence, while an affective component is seen as critical to good care, commoditized care means that care work can be performed without real care and, as such, is purely waged work. More recently, feminist geographers working on the transnational mobilities of care work have drawn on the ethic of care to contribute to postcolonial debates about the injustice of the Global North’s extraction of care workers (akin to resource extraction) from the Global South and threatening the availability of care in countries there. By drawing attention to the interdependence that shapes the lives of people and nations – and the amount of care work that undergirds societies – a care ethics perspective works to problematize and counter neoliberal notions of autonomy and its individualizing processes (Cox 2013; Raghuram, Madge, and Noxolo 2009). In pushing for considerations of collective wellbeing, a feminist ethics of care also highlights the need for equitable wages for paid care work.

Scholarship on care and care work in geography has grown rapidly after incipient efforts in the early 2000s. One clear indication of this healthy and evolving state of the research on the care sector is the burgeoning number of themed issues on care in geography(-related) journals in the last few years, including “Postcoloniality, Responsibility and Care” in Geoforum (2009); “The Ethics of Care” in Ethics, Policy & Environment (2010); “Care of the Body” in Social & Cultural Geography (2011); “Transnational Mobilities for Care” in Global Networks (2012); and “Gendered Spaces of Commoditised Care” in Social & Cultural Geography (2013). Geographers have been able to bring a unique perspective to the study of care work, particularly in its commoditized form. By seeing place as intersubjectively constructed, geographers trouble the problematic nature of the public/private boundary and provide insights into how the meanings of care and care work shift across different spatial contexts and scales, thereby challenging the identity of the spaces and the nature, extent, and form of caring relationships that take place within those spaces. Developing an ethics of care will require more research on care work in non-Western contexts, and from the perspective of care-sending countries. We also need a better understanding of how care – and hence care work – as a concept and practice is mediated as it moves across transnational spaces and is reshaped by social, cultural, economic, and political mechanisms. There is also much scope to further explore the role of men in care work. Our current understandings of what constitutes care and care work as essentially feminized limit how we understand what men do as constituting care; as feminist scholars have indicated, focusing only on women in care work reinforces that it is women’s work.

Caregiving

Andrew Power  
*University of Southampton, UK*

Caregiving refers to a range of interpersonal practices and emotions involved in supporting people. In contrast to other concepts such as help or assistance, caregiving is more deeply inscribed with a set of moral values that inform the quality and integrity of care that takes place within caregiving relationships. At the same time, it is a contested term, given its historical legacies with former practices that were anything but “caring.” It is thus a complex and dynamic concept, its meaning often depending on the trajectories of different actors involved across time and space.

Caregiving practices form a core part of the work carried out by a range of professionals including social worker, nurse, home help worker, occupational therapist, and personal assistant. In many cases, though, the terminology and values associated with care are receding from professional codes of practice. Previous experiences of “bad” care by health and social care users, particularly people with physical disabilities and mental health difficulties, have led to a disfavoring of the term. The future for caregiving is thus discussed further later in this entry.

Caregiving is also closely associated with the care work within the family. Caregivers typically provide a range of emotional and instrumental supports that enable people who may need support to continue to live in the community. Caregiving has been associated with the dual tasks of caring about and caring for a person, although these are not necessarily mutually inclusive. In the former case, caring about a person refers to being concerned for the wellbeing of another. It typically involves offering moral support and guidance and showing respect for the dignity of the person. In the latter case, caring for a person typically involves physical acts of support and personal assistance and/or actively supporting a person’s decision-making.

Caregiving for someone can involve assistance with instrumental activities of daily living (IADLs) – for example, transportation, housekeeping, meal preparation, shopping, home maintenance, and medication management – as well as activities of daily living (ADLs) – for example, bathing, toileting, eating, and personal hygiene. They may also be involved in formal service coordination and management (e.g., navigating formal health systems, linking individuals to services, and coordinating multiple services from different providers for persons with complex needs). This recognition of the distinct care roles by certain family members (over and above those deemed typical for family life) gave rise to the concept of “informal caregiver,” a distinct role to describe individuals who provide ongoing care and assistance, without pay, for family members and friends in need of support due to physical, cognitive, or mental conditions.

Women have been primarily involved in these care roles, to a certain extent because of the long-standing patriarchal assumptions of the nurturing and altruistic roles of women within families. The concept thus initially began to attract attention from feminist geographers from the 1980s in response to the ways in which women were arguably confronted with a social and moral duty or obligation to provide care,
referred to as “compulsory altruism” (Land and Rose 1985), which often led women to become involved in different “caring cycles” as various family members moved through the life course such as young children, disabled or sick relatives, and elderly parents.

This early work – and the coining of the term “informal caregiver” within the literature – also coincided with the broader context of social care policy in the 1980s, in particular the erosion of state-run institutions and care facilities. This period saw the emergence of community care, which was welcomed by many proponents of social care reform, as it was envisaged that care recipients would take up more active and valued roles in their neighborhoods. For policymakers though, it was envisioned that community care would mean care by the community rather than in the community. In other words, in many neoliberal countries that had led the way with deinstitutionalization, such as the United States, Canada, and the United Kingdom, the state arguably failed to provide the range of formal services to make independent living in the community a reality. Indeed, the development of “service dependent ghettos” and rising homelessness followed the first wave of deinstitutionalization in the 1980s in North America, leading to “landscapes of despair” within the urban environment (Dear and Wolch 1987). In this context, the locus of care shifted into a community-based asylum without walls for many people.

Given the unfolding processes of deinstitutionalization and the rise in community care, different care “contracts” began to be carved out in terms of how caregivers were being recognized across and within various countries. In response to the political debates concerning family caregivers at the time, Twigg (1989) developed a threefold typology that categorized carers variously as: resources, where family care was taken for granted and assumed; coworkers, where carers were seen as having co-responsibility alongside care professionals; and co-clients, where informal carers were seen as requiring support alongside the care recipient. In each case, Twigg argues, there are distinct differences in how carers are valued and supported, and in how their potential vulnerabilities are recognized. In practice, she acknowledges that no one model prevails, but rather each is found to varying degrees in the ways different government parties, professionals, service providers, as well as gatekeepers of public assistance, value family caregivers.

This ambiguity is evident at the comparative national scale. Work by Power (2010), for example, found distinct differences between the United Kingdom, the United States, and Ireland, in terms of how carers were categorized. In the United States there is less general acceptance of the need to support the caregiver. In comparison, in the United Kingdom there is more emphasis on caring for the carers, which includes an assessment of needs for the carer. Meanwhile, despite there being less literature on caregiving from the Global South, Kamundia (2012) notes that in Kenya mutual caring and support in the community are the norm, and it is often felt that there is no need for persons with mental health issues or disabilities to live physically and financially apart from their families. Community-based mental health-care services in Kenya are thus limited.

Given the gendered norms associated with nurturing and caring, it is primarily women who have taken up the mantle of providing care and assistance to those relocating from residential institutions to the community, as well as for the next generation of families whose children are transitioning into adult services. Despite the strong gendered lines according to which caregiving is drawn, however, geographers such as Aitken have also examined the awkward spaces of fathering within family life. Aitken (2012)
CAREGIVING unpacks the daily emotional practices that are negotiated, contested, and resisted between parents in different spaces, exploring the complex identity politics around “househusbands” and “Mr. Moms.” Rather than seeing the greater presence of male caregivers as leading to a mutual or shared care identity between men and women, he found that even the most active fathers tend to see their role as “helping out” their partners rather than taking the main responsibility for child care themselves. Others have found that men who are caring for people with complex needs are more likely to draw boundaries around the extent of intimate care they will or will not undertake. Also, male spouse carers are often more likely to accept domestic help, as it is often perceived as substituting for domestic labor previously provided by their wives.

Geographers have chronicled the complex and varied spatial aspects of caregiving: in the home, in the community, in public spaces, and within the complex array of in-between care-related places such as shelters, daycare centers, and group homes. More recently, geographers have also examined new geographies of care that are unfolding in shared spaces in the community such as libraries, museums, and cafes (Power 2013). Across all these spaces, geographers have been attuned to the embodied dimensions of care.

The home has received much attention from geographers, given the complex and evolving sociospatial relations between individuals and their homes. Milligan (2000) has examined the changing meaning of the home for family caregivers, particularly for those caring for frail older people. In this context, the home has now firmly become the preferred site of care. This has given rise to new care technologies, formal care workers, and other professionals increasingly entering the private sphere, thus blurring the boundaries between the public/institutional space and the private home space; it may be described as an institutionalization of the home. Other work has emphasized the careful controlling of noise and routines in the home that may arise from caregiving duties within the domestic sphere. These factors raise delicate moral and ethical questions for families involved in caregiving work.

Other geographic work examines how caregiving continues across public space in terms of the management of both the tasks and perceptions by members of the public. One example of this work focuses on the complex and ongoing interactions between parents of learning-disabled children and members of the public. Ryan (2005) points to the ongoing spatial coping strategies and interventions used by mothers to appease negative reactions to children who may not be able to conform to appropriate ways of behaving and using space. In this case, caregiving becomes more than physical supportive acts and involves complex relational practices and coping strategies. Carers are also often caught in the middle between promoting the independence of young adults with learning disabilities and being overprotective, which can manifest itself in the ongoing management of their spatial practices.

Caregiving has also been examined through the lens of social geographers who have scrutinized the spaces of care and welfare within the city (e.g., shelters, drop-in centers) and have examined the impacts of social care reform in urban settings. These supportive approaches to how vulnerable groups are managed on the ground are arguably downplayed by many mainstream (primarily US) accounts of urban injustice by geographers who have become largely fixated on the punitive accounts of injustice in the city – particularly within a context where the residual neoliberal welfare state rules. Indeed, injustice must coexist with and depend on these more supportive currents within urban space.
In this sense, caregiving at a very fundamental level thus allows the geographies of capitalist production to continue.

More recently, with the rising acceptance of independent living, the spaces of caregiving have increasingly become fragmented, and “place-less,” as people expect to live meaningful lives in the community. Geographers have examined the blurring of boundaries between social inclusion and social exclusion for persons with disabilities within the context of daycare center closures and greater expectations for former service users to take up valued lives in the community and to occupy positions in the open labor market, becoming effectively coerced into inclusion (Hall 2005). Thus, to feel part of the wider community a person with a disability may at times experience greater feelings of social exclusion while simultaneously being constrained from collective and interdependent forms of support (Hall 2005).

More generally, despite the increasing recognition of the level and types of caregiving across the family and community, the term has more recently lost favor, as stated earlier, particularly among the care professions such as social workers, personal assistants, occupational therapists, and clinicians. This is arguably a reaction to the criticism of the term by many groups of people who may require support, such as disabled adults (primarily those with physical disabilities) and persons with mental health issues, who prefer terms such as “help,” “assistance,” and “support.” This rejection of the term is largely a reaction to the way people were previously “cared for” by the state, in a way that was anything but caring and that often forced them into separate and institutional lives. In this sense, care became synonymous with dependency, being helpless, and being a subject of pity.

For this reason, the terms “care” and “caregiving” have become less visible within social-care policy discourse. Their place has been taken by an evolving lexicon of choice and control prioritizing autonomous decision-making and control over one’s own support. This shift has been led by a strong independent living movement in the United States, Canada, Sweden, and the United Kingdom, and has become a central policy agenda, referred to as personalization or self-directed support. What is unclear in this context of self-management and autonomy is how personalization and caregiving can cohere.

Paradoxically, despite the term losing favor among certain client groups such as disabled people, within contemporary social policy there has been a renewed focus on the privatization of caregiving and the increasing reliance on the family. With the rise of austerity politics within many neoliberal countries, which seek to reduce budget deficits in an attempt to allow markets to adjust during adverse economic conditions, policymakers have been increasingly looking toward individuals and families within the community to become more involved in local caregiving and volunteering work. Again, geographers have been centrally involved in debates in this remaking of the welfare state. This has manifested itself on the ground by restricted eligibility criteria for social care users and regional commissioning bodies (e.g., local authorities) providing support only for those in “critical” and “substantial” need. As a result, more individuals have to rely on the care and support of relatives, friends and neighbors, and local voluntary associations.

The neglect of caregiving within social policy has led some scholars like Marion Barnes to make renewed claims for an “ethic of care” to be reinstated within welfare and social policy (Barnes 2012). She draws on the work of Jean Tronto and other moral theorists to articulate six core principles of care: attentiveness, responsibility, competence, responsiveness, trust, and respect. Without an ethic of care at the core
of support policy, she argues, those in need of support can become susceptible to a more commodified, transaction-like, and potentially abusive relationship with support professionals. It is clear, therefore, that caregiving speaks to broader issues of social justice in the way we value and encourage human flourishing.

Geographers who have contributed to this debate over the contested understanding of caregiving include Sophie Bowlby, who has argued against seeing the term as inferring dependence but rather recognizing the interdependence inherent in all personal relationships. Bowlby’s work has questioned the assumption that the experiences of a caregiver are often presented as a dyadic relationship with a care receiver, and that this is a one-way relationship. This work has emphasized the interdependent and reciprocal nature of caregiving relationships. Bowlby proposes the concept of “caringscapes” to illustrate the multiple, interconnected care relationships across space, to help minimize understanding of caregiving as solely a dyadic relationship between carer and cared for (Bowlby et al. 2010).

In terms of future directions in theory and methodology, it is clear that growing numbers of older people will place greater demands on informal caregiving. On the supply side, delayed marriages, declining fertility rates, and evolving family structures (from extended intergenerational family units or traditional nuclear families to single-parent households or people living alone) mean that there are fewer family members to provide informal care. How families, voluntary organizations, the private sector, and the state will reconfigure care arrangements and renegotiate the care contract will be forced to evolve in new ways. As support budgets devolve down to the level of individuals and the privatization of care continues, it is also likely that, for professional caregivers, particularly personal assistants, caring will become an important issue, as many will likely see more precarious working conditions, zero-volume contracts, and rising transport costs exacerbated by having to call on separate clients across the community. Given this continually evolving landscape of care, and the resulting spaces and places which its different actors must access, occupy, shape, and use, geographers are well placed for examining how these issues will continue to play out.

Cartesian coordinate systems

Michael N. DeMers
New Mexico State University, USA

Cartesian coordinate systems are planar (flat, two dimensional) coordinate systems that define the location of any given point by a unique set of $x$- and $y$-coordinate pairs. These pairs can be placed on a one-dimensional line as in a number line or they can be placed on a two-dimensional (2-D) (Figure 1) or even a three-dimensional (3-D) plane. The plane may be real, representing, for example, the coordinates of a carpenter’s framing square used to prepare a piece of wood for cutting, or it may represent something more abstract such as geometric spaces in mathematics. A prominent geographic example of a 2-D geometric space is that produced by map projection, the cartographic process of converting spherical latitude and longitude coordinates of the Earth’s graticule into a flat representation.

Once the Earth’s geographic coordinates are projected it is often more important to locate objects on that projected map surface than it is on the globe itself. This is because it is more common to make measurements on small portions of the Earth than on the Earth as a whole. One advantage of using Cartesian coordinates is that calculating distances is much simpler – employing the distance equation rather than spherical geometry. The distance equation is simply a deconstruction of the Pythagorean theorem in which the hypotenuse of the right triangle is the distance in question and the values of $x$ and $y$ are represented by the differences between any two $x$-coordinates (longitudinal distances) and any two $y$-coordinates (latitudinal distances).

The Universal Transverse Mercator coordinate system

There are several classic cartographic examples of Cartesian coordinate systems. The first, the Universal Transverse Mercator (UTM) system was developed by the United States Army Corps of Engineers during the 1940s and currently employs the WGS84 (World Geodetic System 1984) reference ellipsoid. Although there are many other Cartesian coordinate systems in use around the world, the UTM is among the more universally accepted forms for cartography and geographic information systems (GIS) work.

The UTM system divides the Earth from 80°S and 84°N latitude into 60 numbered zones, each 6° of longitude wide (Figure 2). The beginning zone, zone 1, ranges from 180° to 174°W longitude and continues eastward to zone 60 where it ranges from 174°E to 180° longitude. When referencing a UTM coordinate system the band numbers are necessary because each of these 60 zones uses its own transverse Mercator projection designed to reduce the amount of distortion throughout the north–south oriented zone. The Transverse Mercator projection, unlike the Mercator projection, has its projection cylinder rotated 90° (west to east) and touches the Earth at each of the 60 central meridian longitudes. The zones are kept narrow and the scale factor of the central meridian is reduced to 0.9996, thus keeping the distortion amount for each zone to approximately 1 part in 1000.
Locating positions on the Earth using the UTM system begins by identifying the number of the zone in which the measurement is to be considered. To omit the need for negative numbers, the system measures distances in the north (called northings) and in the east (called eastings). For simplicity, all measurements of northings and eastings are in meters.

The starting point (origin) of each UTM zone is the intersection of the zone’s central meridian with the equator. To avoid dealing with negative numbers within any zone, the central meridian of each zone is set at 500 000 m East, written 500000Em. This is called the zone’s “false easting.” Thus, an object located at say 8743 m west of the central meridian would be \((500000 - 8743 = 491257)\) written 491257Em. Likewise, a reading 75 281 m east of the central meridian would be \((500000 + 75281 = 475281)\) written 475281Em. UTM eastings range from about 167 000 m to 833 000 m at the equator with the range narrowing towards the poles due to converging meridians. The use of the false origin results in easting values that are limited to six digits (Carnes 2007).

In the Northern Hemisphere northings are measured northward in meters from zero at the equator. The maximum “northing” value is about 9 300 000 m at latitude 84° N, the north end of the UTM zones. In the Southern Hemisphere northings decrease southward from 10 000 000 m at the Earth’s equator to about 1 000 000 m at 80° S latitude. In the UTM system northings one does not reference the lettered latitudinal zones but meters to a maximum of seven digits.

Because of the extreme distortion at the poles, a special coordinate system called the Universal Polar Stereographic (UPS) coordinate system, in conjunction with the UTM system, is used to locate coordinate positions on the Earth. Like the UTM coordinate system, the UPS system uses a metric-based grid on surfaces developed from conformal projections. Unlike the UTM system, it uses a stereographic projection. The UPS coordinates begin where the UTM system ends. In the north it begins at 84° N and continues to the pole at 90° N, while in the south it begins at 80° S and continues until it reaches the South Pole at 90° S. To make sure there are no gaps between the UTM and the UPS systems the UPS system also contains a 30-minute latitudinal overlap between the two systems.

At the polar portions of the Earth where all meridians converge, north and south lines also begin to converge. This results in confusion of exact north and south directions varying up to
Figure 2: Numbering system of the Universal Transverse Mercator coordinate system. Modified from http://en.wikipedia.org/wiki/File:Utm-zones.jpg.
CARTESIAN COORDINATE SYSTEMS

180° as the meridians approach the poles. To simplify things, the UPS grid north is set arbitrarily as the prime meridian.

Military Grid Reference System

A derivative of both the UTM and the UPS systems, the Military Grid Reference System (MGRS) is employed by NATO (North Atlantic Treaty Organization) military organizations for locating places on the Earth. Because it encompasses elements of both the UTM system and the UPS system, the MGRS covers the entire Earth. The significant difference is in the labeling method.

The MGRS grid reference is a point reference system that has three parts: a grid zone designator (GZD), a 100,000 m square identifier, and a numerical location in easting and northing meters. The grid zone designation includes one of the 60 numbered UTM zones, each of which is intersected by the latitudinal bands that have a lettering scheme that determines their relative latitudinal position (National Geospatial Intelligence n.d. (a)).

Each MGRS zone is divided into 20 of these latitudinal bands each 8° in latitude. For convenience, these bands are given corresponding letters starting with C at 80°S latitude and ending in X. The system omits the letters “I” and “O” because of their similar appearance to the numbers one and zero. To ensure that all land in the Northern Hemisphere is contained within the system, zone X is extended 4° to a total of 12°, thus explaining why the top and bottom of the zones are not at corresponding north and south latitudes. It is notable that zones A and B and zones Y and Z do not exist within the UTM system. That is because they are reserved for the Universal Polar Stereographic projection system employed for the north and south poles (National Geospatial Intelligence Agency n.d. (b)).

The MGRS then uses an alphanumeric system for designating the UTM or UPS coordinates. The MGRS designation comes in two parts; the first is the grid zone designation (first three characters) and the second is the 100,000 m square designation). Using the following example, 16RWC8071741305, you would get the following for the grid zone designation.

- “16” indicates UTM zone 16 (single-digit zones employ a zero before the digit).
- For polar regions (those outside the UTM coverage) the characters are omitted.
- “R” represents the 8° latitudinal zone with that letter designation (12° for zone X)
- If the area is outside the UTM, zone A is used to represent the Western Hemisphere near the South Pole and zone B to represent the Eastern Hemisphere. In the south, Y and Z are used.

For the 100,000 m square designation each UTM zone is divided into 100,000 meter squares resulting in UTM coordinates that will always be multiples of the 100,000 m. The designations are based on a column and row lettering scheme where the columns are A–Z, omitting I and O (as in the UTM system) and the rows are next ranging from A to V, omitting I and O. So for UTM zone 1 (near the equator) the columns would be A–H, zone 2 would be J–R (omitting O), zone 3 would have S–Z. The letters begin over again with A at zone 4 and continue on around the globe to the equator (Figure 3).

For row letter designations there are two alternative lettering schemes, MGRS-New (aka AA scheme) and MGRS-Old (aka AL scheme). In the MGRS-New scheme, based on the WGS84 and other modern datums, the letter for the first row just north of the equator is A in odd-numbered zones and F in even-numbered
zones. In the MGRS-Old scheme based on older datums, the row letters are shifted 10 steps alphabetically. Thus the letter for the first row would be L for odd-numbered zones and R for the even-numbered zones. The systems are unique in that, with only the exception of zone X, an identical position reported on MGRS-Old and one on MGRS-New would not be confused. So for the previous example value of 16RWC8071741305 the letter W indicates the 100,000 m column W and the 100,000 m row C.

The remaining portion of the designation, the numeric locator, indicates the position within a 100,000 m square and is designated as $n + n$ digits, where $n$ is 1, 2, 3, 4, or 5. So, for example, if one is using $n + n = 5 + 5$ then the first five digits indicate the easting in meters measured from the westernmost edge of the square and
CARTESIAN COORDINATE SYSTEMS

the last five digits would represent the northing measured in meters from the southernmost edge of the square. A $5 + 5$ designation is the most accurate, representing a resolution of 1 m. Thus a $4 + 4$ represents 10 m resolution squares, $3 + 3$ represents 100 m squares, $2 + 2$ represents 1 km squares, and finally $1 + 1$ indicates the coarsest resolution, at 10 km. The NATO standard for specifying coordinates is $4 + 4$. The previous example of 16RWC8071741305 is a $5 + 5$, or 1 m resolution, indicating an easting of 80 717 m and a northing of 41 305 m for 100 000 m square WC in zone 16R.

There are some specific rules regarding this designation that should be remembered. First, if you are in a specific grid zone and are communicating about that grid zone then specifying it is not necessary. The numeric specification is sufficient. If an area being specified is small, but it is located in the overlap of multiple 100 000 m square zones then the entire grid reference is used. Another rule is that all coordinates are read with the easting first and the northing second, or “read right up.” Finally, the current convention regarding an abbreviation of the MGRS to lower resolution or when converting UTM coordinates is not to round but rather to truncate the values.

The MGRS convention is different for the polar regions of the globe. For the southern portion, that region south of 80°S latitude, the Universal Polar Stereographic (south) projection is used rather than the UTM projection. The west semicircle creates a grid zone designated zone A while the east semicircle forms a separate grid zone designated B (Figure 4). Regions north of 84°N latitude employ the Universal Polar Stereographic (north) projection. The west semicircle is designated grid zone Y while the east is designated grid zone Z (Figure 5).

In polar regions, the lettering scheme for the Military Grid is also somewhat different. While the row letters remain the same in that they range from A to Z, omitting I and O, the columns use a smaller alphabet. Columns are lettered from A to Z but omit I, O, D, E, M, N, V, and W. They are arranged such that the rightmost column in grid zones A and Y employs column letter Z. The next column in grid zones B or Z begins with the column letter A. This system was devised to avoid confusion by guaranteeing that no UPS square would be adjacent to a UTM square that possessed the same identification.

State Plane Coordinate system

Within the United States there is a highly accurate Cartesian coordinate system, or rather a set of 124 zones, each with its own coordinate system, that together constitute the State Plane Coordinate (SPC) system. Each US state contains one or more state plane zones that typically follow county boundaries. There are a total of 125 zones – 110 in the conterminous United States, 10 in Alaska, and five in Hawaii. Puerto Rico and the US Virgin Islands each have one. The SPC is popular because it uses a simple coordinate system based on plane surveying techniques and is not linked to the geographic system of latitude and longitude. To accomplish this, the SPC ignores the curvature of the Earth thus making calculations of distance and area easy to perform. In addition, because it relies on plane surveying, the SPC is extremely accurate within each of the zones (errors less than 1 in 10 000). Because the accuracy does not extend beyond the zones, it is not as useful for regional or national mapping as UTM. Instead it tends to be used for mapping within state governments.

Of the 124 zones, most are based on either a transverse Mercator or a Lambert conformal conic map projection, the choice essentially determined by the shape and orientation of
the state and the zones. The orientation of the state (e.g., north-south versus east-west) typically employ zones that share that orientation. State SPC zones that are longer in the vertical (north-south direction) than in the horizontal (east-west direction) use the Transverse Mercator projection because of its property of maintaining accuracy in the north-south direction. Alternatively, state SPC zones that are oriented in the horizontal (east-west) direction typically employ the Lambert conformal conic projection because it tends to preserve accuracy in the east-west axis. The Alaskan panhandle whose orientation is neither vertical nor horizontal, but diagonal, employs an Oblique Mercator projection designed to minimize the combined error in both the vertical and the horizontal.

Developed in 1933 by the US Coast and Geodetic Survey under contract by the North Carolina Department of Transportation, its creation was to convert latitude and longitude coordinates into a user-friendly Cartesian coordinate system. At the time the system was based on the North American Datum of 1927 (NAD 27) and later converted to the more accurate NAD83. It is currently the
most widely used such system used for local and regional surveying and mapping in the United States (Doyle 2004). The system has been revised several times and its digital equivalent has resulted in considerable savings in GIS processing speeds. Because of the rapid increases in geographic database sizes, this characteristic has allowed the system to continue to be used in GIS despite improvements in computational efficiencies in the computers themselves.

Despite its continued use for regional mapping applications, the SPC system is not without its problems. The primary problem is that each zone uses a unique coordinate system making cross-zone work difficult. Examples would include regional studies that cross state lines or operations on metropolitan zones that include multiple zones. To perform such analyses requires that each zone’s coordinate system be converted to that of another – a procedure that is burdensome and adds to the possibility of introducing error. Today’s modern GIS software is capable of making such conversions with relative computational ease and with limited loss of accuracy.

United States National Grid

A Cartesian coordinate system designed at least in part to provide for improved interoperability for location-based services and other GIS operations throughout the United States is the United States National Grid (USNG) (FGDC 2001; Cavell 2005). Sharing many elements of other national grid systems, it was developed by the Federal Geographic Data Committee as part of their mandate to improve interoperability in GIS and to allow its easy integration with other national grid systems. It also very closely resembles the Military Grid Reference System (MGRS). In fact, when the WGS84 or NAD83 datum is used, the coordinates between the two are identical.

Another of the interoperability characteristics of the USNG is that its coordinates can easily be transferred to US Geological Survey topographic and similarly gridded maps using northings and eastings. These measurements are in meters making between-location distances easy to calculate. Numerical digits designating these distances vary in precision from kilometers (two digits for each coordinate) to meters (with five digits for each coordinate). The USNG uses a common system based on the USMG that permits the use of physical landmarks that allow users unfamiliar with the local area to use them.

Ordnance Survey National Grid reference system

While there are many other national grids, perhaps the best non-US system known is the Ordnance Survey National Grid reference system. As the name implies, the United Kingdom’s National Grid was developed by the Ordnance Survey as the British Grid System in 1919 and adopted for use on military maps. By 1927 the system had been replaced by the “Modified British System” which was well adapted for use in military operations.

Today’s UK National Grid breaks Great Britain into progressively smaller squares identified by letters and numbers, as seen in other grid systems. The largest of these squares is 500 km on a side. These squares are identified first by letters and then by numbers. The letters – the first of a two-letter system – range from A to Z, omitting I. However, Great Britain is only covered by four of the squares – those designated H, N, S, and T. Each 500 km square is further divided into 25 100 km squares. Letters, again ranging from A to Z, and omitting I, identify these smaller squares. This is the second letter of the two-letter system (Figure 6; Ordnance Survey n.d. (a)).

The smaller squares are themselves divided into smaller (10 km) grids, each of which is numbered starting at 0 in the southwest corner and moving east and north. A map reader can then identify a 10 km grid square by stating the two letters first and then the easting and northing grid numbers (e.g., SE 4 8). Finer resolution designations are made by estimating eastings and northings in 1/10-grid intervals, allowing the map reader to quote a location to an accuracy of 100 m on the ground.

The Ordnance Survey’s National Grid is based on the Transverse Mercator map projection. It covers all of Great Britain (Ordnance Survey n.d. (b)). Northern Ireland and the Republic of Ireland have their own National Grid system. Latitude-longitude coordinates for the true origin are located at 49°N latitude and 2°W longitude. Its false origin is just southwest of the Isles of Scilly, which was selected so that all the coordinates were positive (east of the origin at 00). As a result, 400 km are added to all eastings and 100 km subtracted from all northings. This
conforms to methods applied in other grid systems as well.

**Cartesian grid transformations**

Cartesian grids come in many forms and represent multiple projections. Because of this it is often necessary to alter the Euclidean geometry of such systems to account for differences in scale, adjustments of control points, rotation, and translation. Cases where such transformation come into play include rubber sheeting to allow co-locating identical objects digitized from two sets of unrectified imagery; projecting maps; digitizing maps either from a digitizer or using heads-up methods from a monitor; or printing and/or displaying a map using printer, plotter, or digital monitor coordinate spaces.

Although there are special modifications, the primary mechanism for making these transformations is the affine transformation. This is defined as “A geometric transformation that scales, rotates, skews, and/or translates images or coordinates between any two Euclidean spaces. It is commonly used in GIS to transform maps between coordinate systems. In an affine transformation, parallel lines remain parallel, the midpoint of a line segment remains a midpoint, and all points on a straight line remain on a straight line” (Wade and Sommer 2006). Affine transformation can translate (move), rotate, skew, scale, and skew coordinates (Figure 7). The affine transformation function is

\[
x' = Ax + By + C \quad \text{and} \quad y' = Dx + Ey + F
\]

where \(x\) and \(y\) are the input coordinates and \(x'\) and \(y'\) are the coordinates after transformation. The letters \(A, B, C, D, E,\) and \(F\) are determined by the control points of the source and destination control points and scale, skew, rotate, and translate the layer coordinates.

Coordinate distortions occur through input errors, map registration errors, lack of geodetic control, and many other causes. The process of rubber sheeting uses the basic transformational methods of scale, rotation, translation, and skew to adjust your data for improved accuracy. A major difference between rubber sheeting and transformation is that the distance features move
depends on their proximity to other objects. The process involves locking down locations that are not going to be moved and displacing those that need to be moved. Most often this is done using interpolation using temporary triangulated irregular networks.

One frequent transformation of Cartesian coordinates involves the conversion between map coordinates representing real Earth locations and those representing the map in the display space of the display device. One major difference that must be accounted for is that in normal Cartesian coordinate systems the origin is in the bottom left. In computer monitors, and other devices as well, the origin is on the upper right. As such, one additional transformational process that is required for this is called mirroring. The second major difference is that screen coordinates are recorded in pixels. The challenge then is to find a method to transform each point within the world rectangle to a point in the pixel rectangle and vice versa. Both of these transformations can be performed using affine transformation equations.

Further reading

Maps can help to understand the world around us. They do so in an effective and efficient way, because they can summarize, clarify, explain, and emphasize aspects of our environment. Maps have many functions. They support navigation and decision-making, they tell stories of the past or assist in planning the future. Maps offer insight into spatial patterns and relations among the mapped phenomena, and do this well because they symbolize and abstract the reality represented.

Early definitions of a map describe it as a conventional image, mostly to scale and on a plane, of concrete or abstract phenomena that can be located in space. In this definition, conventional refers to agreements like “forest is green, and water is blue.” The International Cartographic Association provided the following definition: “A representation or abstraction of geographic reality. A tool for presenting geographic information in a way that is visual, digital or tactile” (Board 1990). The definition used here is based on the description in the book “Nature of Maps” by Robinson and Petchenik (1976), who defined a map as “a graphic representation of the milieu.”

Maps appear in many different media. Most common are maps on paper or on-screen. The first can offer a broad overview, but are more difficult to update. On-screen maps are often interactive and can be easily updated, but are limited by size. Many map types exist. They are usually divided into topographic and thematic maps. Topographic or geographic maps portray the landscape as accurately as possible with the map scale in mind. They cover, for instance, land use, hydrography, transportation, settlements, administrative boundaries, relief, and geographic names (Figure 1a). Thematic maps show the distribution and characteristics of particular phenomenon supported by (selected) topography as a base map (Figure 1b).

Maps are designed following the cartographic visualization process. This process is guided by the saying “How do I say what to whom” (Koeman 1969 in Kraak 1998). “How” refers to cartographic methods and techniques, such as generalization, and the choice of a map type. “I” represents the map-maker. In the past this was the sole domain of the professional cartographer. With the rise of geographical information systems other professionals became involved in the map-making process. Today, developments of the Internet, web 2.0, and mobile devices also allow the nonprofessional, with the help of tools like Open Street Map and mash-up technology, to create maps about virtually anything. These developments have resulted in a tremendous increase in the amount of maps produced and used.

How we “Say” things in a map refers to the symbology and semantics that represent the data. “What” refers to the geographic data and its characteristics. “Whom” refers to the potential map user, the context of its use, and its purpose. In the past any map created by a cartographer was supposed to be good enough for its intended use. Today, this supply driven approach has changed into a more user centered, demand driven map-making process. This has extended the original “How do I say what to whom?”
Figure 1 Basic map types: (a) topographic or geographic maps (source Google Maps); (b) thematic map. Both maps represent the Estonian island of Saaremaa. The topographic map emphasizes the structure of the landscape and the thematic map shows the administrative division of the island.

with “And is it effective?” In other words, cartography has become very much interested in how its products perform. This usability includes the effectiveness, efficiency, and satisfaction of the map products (Nielsen 1994).

Maps are created for many purposes, including navigation, education, urban planning, and weather forecasts. In these applications they are used for presentation and exploration (MacEachren 1994a). In their presentation role maps are designed to inform users about spatial patterns and relations. This reflects the traditional cartographic approach. The cartographer starts with a known dataset and has to select an appropriate visualization technique. The emphasis is on map design, resulting in high quality graphics presenting facts. The objective of maps designed for presentation is to communicate the information they represent. However, communication will never be perfect, even when one applies all cartographic rules. This is because information is lost, or perhaps even gained, during the communication process. The first happens because the cartographer can decide to ignore some information and/or because the map reader might not understand everything depicted. The second happens when the cartographer explains the original information and/or when the map reader combines the map data with his/her own prior knowledge.

Nowadays data are available from a variety of sources. However, one is not always fully acquainted with the data. The data has to be explored to find out if it is indeed useful to assist in the problem-solving at hand. The exploration process is often a search for patterns and trends. As a result one might end up with different alternative views that might provide a hypothesis. The emphasis is on enabling “discoveries.” An exploratory mapping environment is usually on-screen and preferably highly interactive. The maps are directly linked to databases that can be queried during the process. The graphic displays are not necessarily only maps. The exploratory cartographic visualization process is strongly information technology driven and, as such, closely linked to visualization in other disciplines. Over the last two decades progress
has been stimulated by developments in other fields such as scientific visualization and information visualization. The first of these deals with the visualization of 3-D phenomena with an emphasis on realistic renderings. The second is defined as the communication of abstract data by the use of interactive visual interfaces. This has resulted in a situation where maps are used in interactive environments to stimulate and improve explanation, insight, discovery, and decision-making.

In both presentation and exploratory mode, maps may be used to answer all kinds of geographical questions. Questions are asked because the map reader has certain tasks in mind in relation to the data mapped. Examples of these tasks are to identify the name of the province with the highest population, locate the province with the lowest population, or to make comparisons. Comparisons may be spatial (local or regional variations), based on multiple attributes (observe differences or similarities between the spatial distribution of possibly population and land elevation). Temporal comparison is applied to detect change, such as the population development over the years. To execute these tasks an extensive and flexible functionality should be available that allows selections to be made at will, based on criteria related to the attribute, locational, and temporal component(s) of the data.

However, in all circumstances, the maps should be well designed to play their role. The next section discusses how to prepare the data for an effective design.

Cartographic data analysis

When creating a map a set of constraints that will influence its design has to be considered. Among these are the purpose of the map (which questions have to be answered by the map), user characteristics (age, experience, knowledge of mapped area or phenomena), the use environment (in the field, or online) and the data characteristics. Each of these factors will influence the choice of the scale, a map projection, the required accuracy, and the map interface, and even the content. However, the data characteristics have most impact on the choice of the symbology, because qualitative data cannot be expressed in the same way as quantitative data. This section discusses how to select the appropriate symbology based on the data characteristics.

Cartographic data analysis starts with the determination of the data’s measurement level to get an idea of its character. For instance, the variable “population” in the table in Figure 5 is quantitative in nature. To allow the map user to experience these amounts the symbols to be used should give the map user the impression of different amounts. This can be realized by selecting the correct visual variable. In Figure 4a a point symbol that varies in size has been applied. The visual effect of this selection works well because a change in size is readily perceived as a change in amount.

Based on their measurement level, spatiotemporal data can be grouped into four categories: nominal, ordinal, interval, and ratio. Today, spatiotemporal data can also be derived from nontraditional sources such as photographs, video, and sound clips as well as texts. Nominal data are defined by qualitatively different characteristics. Examples include land-use categories such as road, hamlet, and border, as in Figure 2a, or the different municipalities of Saaremaa as in Figure 1b. There is no rank order, nor are arithmetic operations possible on nominal data. Ordinal data can be ranked in terms of relative quality, such as high and low, as in Figure 2b. Exact differences cannot be expressed and arithmetic is not possible. An example is a road classification such as highway, major road, and
**CARTOGRAPHIC DESIGN**

secondary road. Interval data are quantitative data. Here differences in amounts are known; however, an absolute zero is not. Distance is the defining characteristic and arithmetic manipulations possible are addition and subtraction. Examples are temperature expressed in Celsius, as in Figure 2c. The ratio scale is also quantitative but is defined by proportions. Differences in amounts are known as well as an absolute zero point. All arithmetic manipulations are possible. Examples are the number of inhabitants of provinces (Figure 4a), or the percentage of native speakers. Figure 2e shows the relation between the measurement levels, their perceptual properties and the visual variables.

The next step is to convert the measured character of the data into symbols. This has to be done so that perceptual properties of the symbology allow the map reader to readily understand the character of the data (e.g., the measurement level). In the sample maps in Figure 8a the varying size of point symbols has be used to depict the

![Figure 2](image)

**Figure 2** Measurement levels and perceptual properties: (a) nominal, (b) ordinal, (c) interval, (d) ratio, (e) the relation between the measurement level, perceptual properties, and visual variables.
number of inhabitants. Besides point, lines and area symbols are used to represent the data. Text is often used as an additional option to transfer information. All symbols can be varied using six basic visual variables: size, value, grain/texture, color, orientation, and shape (Bertin 1967). Figure 2a links the perceptual properties of the different measurement levels to these variations in symbolization. For instance, it shows that color is useful to express differentiation but ineffective to express proportions or distance (quantities) or order. Size on the other hand is not suitable to express differentiation but works well to express order, distance, and proportion. The notion of color seems straightforward, and yet it is complex. Color as used by Bertin is also known as color hue (the dominant wavelength), while his variable value is also known as color value (white added to the hue). Additionally there is color saturation (black added to the hue).

Figure 3 presents how, in the context of a map, these variations work for point, line, and area symbols, as well as text. The far right of the figure displays how these variations and their perceptual properties can be linked to the measurement levels of the data, being proportional, distance, order, and differentiation.

If the symbols to which a visual variable has been applied are spontaneously perceived as

![Figure 3](image-url)

**Figure 3** The visual variables: left as applied to point, line, and area symbols and text; right in relation to their perceptual properties.
different the variable is differentiating. Figure 3 shows that shape, orientation, and color are differentiating. Figure 1b shows an example: color differentiates the individual municipalities of Saaremaa. A visual variable is ordered if spontaneously all symbols to which it has been applied can be placed in an unambiguous order. Examples are from dark to light, small to big, or from coarse to fine. In Figure 3 it can be seen that size, value, and texture are ordered while color, orientation, and shape are not. An example can be found in Figure 10a, displaying the population density of Estonia’s provinces. If spontaneously all symbols to which a visual variable has been applied can be placed in an unambiguous order, and an estimate of the distance between the symbols within the range can be made, it enables distance perception. As Figure 3 shows, this is true for size, value, and texture, but not for shape, orientation, and color. Examples are both Figure 4a and Figure 10a. A visual variable is proportional if the differences

Figure 4 The use (a) and misuse (b and c) of the visual variables: (a) size used to express the number of inhabitants per province; (b) color used to express the number of inhabitants per province; (c) shape used to express the number of inhabitants per province.
between the symbols to which it has been applied can be expressed in distinct amounts. Figure 3 shows this is only possible with size. Again, Figure 4a is an example.

At the far right of Figure 3 it can be seen that qualitative data (the nominal measurement level) link to shape, orientation, and color. Quantitative data (the ordinal, interval, and ratio measurement levels) link to size, value, and texture. It is important to note that ratio data can be split into absolute and relative data. Absolute quantities are observed, measured, or counted and relative quantities are calculated: densities, ratios, percentages, and averages. Size should be used for absolute ratio data (Figure 7a) and value for relative ratio data (Figure 10a). Often it is seen that value is also used for absolute ratio data (Figure 10c), but when the geographical units to which it is applied are not all of the same size the impression of the map will be wrong.

What if these guidelines are not applied? Figure 4 shows one correct map and two examples of how not to apply the visual variables. The population data to represent are quantitative data, which should be represented by symbols changing in size as is correctly done in Figure 4a. The question “Which province has most inhabitants?” can be immediately answered. Figure 4b and 4c illustrate that color and shape are not suitable. Getting an answer to the question is not easy, the information is somehow embedded in the map, and if the legend is studied well an answer can be found, but not efficiently (i.e., in a short time and correctly).

There is some debate whether the six variables as defined in 1967 by the French cartographer Bertin can cover all variations possible (MacEachren 1994b; Tyner 2010). This debate gains additional impetus from the fact that on-screen maps offer options not possible on paper, for which the six variables in Figure 4 were originally developed. Examples of new variables are transparency and focus. Transparency can be used to show multiple symbols/layers on top of each other to show direct relation between the topics (Figure 8d). Focus refers to the clarity of the symbol. Giving a symbol a fuzzy appearance can for instance be used to display uncertainty. Additionally symbols can blink or be highlighted to attract attention (Kraak and Ormeling 2011).
CARTOGRAPHIC DESIGN

It has to be realized that application of the above guidelines does not always result in clear maps. Especially when multiple topics are included in a map, they may become complex. This led Bertin to distinguish between “maps to see” and “maps to read.” Maps to see will give insight in the data in a single instant (Figure 4a). Maps to read have to be studied (Figure 8d). A map to see can often only be created based on a single variable (or component), and places constraints on how many variations can be applied on the symbols.

How to execute a cartographic data analysis? In the next paragraph, examples are given based on the data shown in Figure 5, which has a base map of the Estonian provinces and a table with some population statistics data from 2012.

Figure 6a represents a workflow to execute cartographic data analysis in this case. Figure 6b and 6c are elaborated examples for quantitative and

![Figure 6](image)

Figure 6 Cartographic data analysis in practice: (a) the principle; (b) an example with quantitative data; (c) an example with qualitative data.
CARTOGRAPHIC DESIGN

The first step is to establish what the dataset is about. In Figure 6b it is the population of Estonia’s provinces and in Figure 6c it is the regions of Estonia. Bertin refers to this as the invariant, which will appear as the title of the map. In Figure 6b the measurement level of the variable “population” has to be established. These variables, or subtopics, are defined by Bertin as components. It can be seen that “population” is made up of absolute numbers (quantitative data), which makes it a ratio level. In the flow diagram’s box “measurement level,” two other columns can be observed: length and range. For qualitative data, length represents the number of categories; for quantitative data, range represents the interval between the smallest and highest value. Both values will decide if the data have to be grouped or classified before mapping. In the example, the range is 8482–55 2927. The flow diagram also has a geographic component, which will be implicitly available in all maps. It refers to the number of geographic units for which one has data. In the examples the length of the geographic component is 15.

In the next box of the figure the measurement level is linked to a visual variable with the required perceptual properties. In this example the component “population” needs a visual variable with absolute proportional properties. This makes size the only suitable variable. In the resulting map, shown right of the flow diagram size is applied on point symbols. In Figure 10c the same process is repeated for a quantitative variable “region.” The analysis of this variable “region” follows the same path. The measurement level is nominal (qualitative). It needs a visual variable that can differentiate between the regions. Three options are available, orientation, shape, and color. The last variable has been selected and has been applied to the regions, as can be seen in the map in Figure 6c.

The outcome of the analysis, for example, measurement level, the number of components one intends to include, the need to use point, line or area symbols directs the choice of the thematic map type. This choice is also related to the elementary nature of the data, as being continuous or discrete. Continuous data (or “fields”) extend over space without interruptions and values are simply observations at sample points. Examples are heights or temperature. Discrete data are distinguishable for individual entities, such as administrative units like provinces or individual objects such as towns. For a detailed discussion on different thematic map types see Slocum et al. (2008).

Design

The cartographic data analysis suggests which visual variable to use for which component and what symbol set and map type. However, it does not tell us anything about the actual graphic design, which dictates the look of the map. The map in Figure 6b is very basic, not attractive, and as a result inefficient. All lines have the same weight, all polygons have same fill color. In Figure 7b, some colors have been used but not necessarily according to any plan. To create efficient and effective maps, how the map should look must be considered. The map layout, the choice of line width, the selection of colors and fonts, the hierarchical organization of the map content, must all be considered to create an attractive map. This is the actual map design process. Despite all information to visualize it is important to keep the map as simples as possible, and avoid what Tufte (1983) called “chart junk.” Examples are abundant colors, overuse of shading, fancy lines, and exotic fonts.

What is a good design? If one asked several professional cartographers to finish the
map in Figure 6b it is likely that ten excellent but different results would be given. This is because there are no fixed “rules” or “restrictions.” A background in white or dark blue, the proportional symbols as diamonds, squares or circles, fonts in Arial or Times, all can be acceptable. One of the first design actions would be to visually organize the data such that the most important information is observed first. This introduces the design principles of figure-ground, which makes the reader spontaneously follow a sequence from important to less important. Appropriate figure-ground can be achieved by applying visual hierarchy as illustrated in Figure 7. In this figure the left map has no hierarchy applied and in the right map the information has been ordered. Below, the base layer with Estonian provinces, followed by the text layer with names of the provinces. The next layer has the proportional point symbols representing the number of inhabitants, followed by map title and legend. At the top of the hierarchy is the highlighted symbol of Tartumaa.

Figure 8 gives four examples of different but correct designs. The map titles and legend have been left out on purpose. Figure 8a is the color version of Figure 7a. The figure ground principle is applied by using a light blue for the Estonia, dark blue for the proportional point symbols to make them stand out from the base map. Figure 8b has different colors, gray for the base map and orange for the proportional point symbols, which basic shape is now a square. Figure 8c is similar to Figure 8a, but with different colors and shading added to the proportional point symbols which creates a stronger visual hierarchy. The map in Figure 8d follows yet another approach. The base map is a choropleth map representing the provinces’ population density (relative ratio data). The visual variable value is used in a scale from light blue for low densities to dark blue for high
densities. On top the proportional point symbols representing the number of inhabitants (absolute ratio data). For the selection of a proper color scale see www.colorbrewer2.org. The point symbols have been made slightly transparent and allow the map layer below to be seen. This is especially useful for the province with the highest value where the symbol is covering the province almost completely.

Applying visual hierarchy alone is not enough. A few other design principles have to be adhered to as well. It is obvious that all map content has to be presented in a clear and unambiguous manner. The map should have a balanced design and have contrast to be able to distinguish the information content. A well-designed map is not overcrowded with symbols. This is especially applicable for on-screen maps, as they are presented on a relatively small space. These maps can be “empty,” as access to other information is available via a mouse click and can be acquired at will. With today’s options to bring together information from many different sources, it is often tempting to also show all these layers in a single map, which may result in a cluttered and incomprehensible map (Figure 9).

In Figure 10a a choropleth map displays the population density of Estonian provinces in four
classes based on the data in the table in Figure 5b. Several classification methods exist to decide on the distribution of the data over those four classes. In this example a nested means classification has been applied where the average of all observations (here 24) is first defined, followed by the calculation of the average of the range below and above the overall average, resulting the classes as show in Figure 10a. Each class has been given a color defined via colorbrewer2.org. Next to a legend the map has a title in the upper right of the map, and a scale bar in the lower left. A north arrow is usually added, but often omitted when the map is north oriented. A grid with longitude and latitude could also be added. The location of this so-called marginal information depends on the space around the map. The title is preferably positioned at the upper left, for example, where one normally starts to read a document; however, in this example space does not allow this due to the shape of the mapped area. Space limitations are often the reason why legends are missing when the map is presented on-screen. The scale of the map is always relevant, and as scale indicator a scale bar is preferred because it will scale with zooming. Reference to the year of production is often needed to determine how up-to-date the map is and information on the producer can reveal something about the credibility of the map.

In Figure 10b a wrong visual variable is applied. Not value, as correctly done in Figure 10a, but color instead. The effect is that an overview
Figure 10  Good and bad and wrong designs: (a) a well-designed choropleth map; (b) choropleth map with wrong visual variable applied; (c) choropleth map with wrong data; (d) choropleth map with overdone design.

of low and high densities is no longer visible. Figure 10c show a choropleth map design, but based on absolute ratio (the number of inhabitants). This is a common error that results in a wrong impression of the mapped phenomena. An example illustrates this: when two districts, one of which is small and the other very large, have the same population, they will get the same color value in the map, but the large district will attract most visual attention, giving it a dominance over the small, but population-wise equal, area. Compare this in Figure 10c and Figure 8a. Figure 10d is an example that contains “chart junk.” Shading has been applied to all individual map items, resulting in a strange stepped effect in the map. The map is also visually unbalanced because the marginal information is distributed more or less randomly.

Online maps have many advantages when it comes to dissemination of the information and the (visual) exploration of the data. Currently, several solutions exist that allow one to publish their own data online, and interactively share it with others. Examples are CartoDB (Figure 11) and GeoCommons. The user has some simple choices to display the maps and, although the design options are limited, they generally result in acceptable maps.
For the more advanced user exploratory environments, such as offered by the Estonian bureau of statistics (Figure 12), are available. These mapping environments have a much steeper learning curve. From a design perspective default settings are provided, but during the exploration many options are offered which do not necessarily end in well-designed maps. However, if one has an exploratory objective in mind these tools can be very helpful to find and understand spatial patterns and relations.

Cartographic modeling

C. Dana Tomlin
University of Pennsylvania, USA

Cartographic modeling is a set of methodological concepts, conventions, and capabilities intended to generalize and standardize the use of geographic information systems (GIS) for the interpretation of geospatial data. It is an application-independent methodology that attempts to address a wide variety of interpretive tasks in a clear, consistent, and comprehensive manner. To do so, it establishes a system of elementary components that can be combined with relative ease and great flexibility. These include components relating to data, data processing, and data processing control.

Data

The cartographic modeling methodology does not prescribe particular data formats, but it does assume that data are organized according to a certain general construct. This is a hierarchical construct at the base of which lies the “cartographic model.” In its most common form, a cartographic model is simply a body of data pertaining to a designated geographical locality or “study area.” All of the geospatial data representing a given study area are associated with “layers,” each of which can be envisioned as a map of a single site characteristic that varies over that area. Like a traditional map, a layer is a planimetric depiction of the area that characterizes every location within it. Unlike most traditional maps, however, a layer records only one characteristic for each of its locations. Thus, the variety of topographic and demographic characteristics that might well appear together on a traditional map would instead be presented by way of a separate layer for each.

Every layer is represented by a “title” in the form of a distinguishing string of text, and it is stored with “metadata” that indicate things about the layer itself: its source, publication date, orientation, resolution, the time period to which it refers, and so on. What a layer conveys about its study area, however, is represented as a set of one or more “zones.”

A zone is the set of all locations for which a particular geographical condition is recorded. On a layer entitled SoilType, for example, each zone might represent a particular type of soil. A layer of SoilDepthToBedrock, on the other hand, would probably include zones representing distances beneath the surface of the Earth. Zones are represented by text string “labels” such as PaxtonFineSandyLoam or FreetownMuck. These can be assigned arbitrarily as long as each is unique among those within its layer. More importantly, every zone is also associated with a numerical “value” that distinguishes the zone from others within the same layer. Like labels, values can be arbitrarily assigned; unlike labels, they can also be computed.

The use of numerical values (as opposed to colors or graphical symbols) to represent geographical conditions is one of the things that most distinguishes cartographic modeling from its nondigital antecedents. It is also one of the things that enable this methodology to take advantage of the precision, flexibility, and processing power of modern computation. Zonal values can be
CARTOGRAPHIC MODELING

recorded either as integers or real numbers, and they can relate to nominal, ordinal, interval, or ratio scales of measurement that are either linear or cyclical. A special “null” value can also be used to represent the absence of meaningful data.

The final component of data within a cartographic model is the set of (what have already been casually referred to but now must be more formally recognized as) “locations.” A location is that particular portion of a study area (or a cartographic model representing such an area, or a layer within such a model, or a zone within such a layer) that can be uniquely defined by a pair of geographical “coordinates.” A coordinate is a number indicating position along one of the two perpendicular dimensions. To the extent that this number is of finite precision, it actually represents an interval or range of positions along that dimension. Thus, each location can be envisioned as a finite, 2-D portion of a study area, layer, or zone. If the coordinates that define locations refer to perpendicular and similarly calibrated dimensions, then the area uniquely associated with each location will be square, and the overall pattern of locations will be a rectilinear grid of perpendicular and equally spaced “columns” and “rows.” Alternatively, a location can be regarded as a sample point at the precise position defined by its two coordinates, and locations can thus be redefined by resampling.

Though the manner in which locations are encoded need not affect the organization of a cartographic model, it can have a very significant effect on the manner in which they are processed. For that reason, it is useful to distinguish at least between “raster” and “vector” formats.

In raster format, locations are usually called “grid cells” or “pixels,” and each is often regarded as a discrete geometric entity. In vector format, however, the degree to which individual locations are recognized as such depends on whether the zones containing them are encoded as points, lines, or polygons. While a vector-encoded point feature may well be fully defined by a set of explicitly encoded locations, line and polygon features are not. Most of the locations along a line or within a polygon are never explicitly recorded; instead, they are only implicitly referenced by a (typically much smaller) set of explicitly encoded vertices.

The practical implications of this are apparent: encoding locations in a vector format is generally more efficient and flexible than doing so in a raster format. The conceptual implications are less apparent but perhaps even more important. Whereas vector encoding casts the world as a set of distinct geometric objects or “features,” raster encoding presents a world of conditions that vary over spatially continuous “fields.” The former records locations associated with each of set of conditions, while the latter records conditions associated with each of set of locations. While it is not at all difficult to reconcile these perspectives in terms of the way in which data are stored, the two are decidedly different in terms of the way in which data are processed.

Data processing

If the purpose of a cartographic model is to store a body of data, then the purpose of cartographic modeling is to interpret those data: to convert recorded facts of potential utility into recorded facts of actual utility and, thereby, transform data into information. This is generally a matter of making implicit qualities explicit by analyzing and/or synthesizing the existing layers of a cartographic model in order to generate new layers.

Along with data preparation and presentation, data interpretation is one of the major functions of any modern GIS. What distinguishes cartographic modeling is the manner in which it organizes such interpretive capabilities.
Fundamental to this organization is use of the layer as the primary unit by which data are not only stored but also processed. Cartographic modeling capabilities are presented as a small but highly integrated set of “operations,” each of which performs a relatively primitive task, but all of which do so by taking one or more existing layers as input and generating a single new layer as output. Since the output of any one operation can, therefore, potentially be used as input to any other, only a small set of these elementary operations is required to perform an open-ended variety of arbitrarily complex tasks. Just as primitive algebraic operations (such as addition, subtraction, multiplication, or division) can be combined to form much sophisticated mathematical functions, primitive cartographic modeling operations (such as the assignment of zonal values, the superimposition of layers, the measurement of size, the determination of distance and direction, the calculation of travel costs, the characterization of shapes, the computation of slope and aspect, the delineation of viewsheds, and the simulation of movement) can also be combined to form more sophisticated “procedures.”

Cartographic modeling operations are deliberately defined in terms that relate more to the structure than to the substance of the data to which they apply. Each is defined by describing its effect on a single typical location, understanding that all locations are being processed in the same manner and (conceptually at least) at the same time. This use of locations (rather than points, lines, or polygons) as elemental units of space results in a style of processing oriented more toward fields than features. It also promotes a location-centric or worm’s eye perspective on geospatial computation that is subtly yet significantly different from the map-wide or bird’s eye perspective more commonly employed. Consider, for example, an operation that “surrounds buildings with rings of increasing distance.” The same operation could be also described as one that “measures each location’s distance from the nearest building.” While those two descriptions are equivalent, the latter reflects a point of view that is oriented more towards the locations for which new values are about to be computed than the locations from which those values are about to be generated. For all of its simplicity, it is this worm’s eye perspective that establishes the conceptual foundation for a highly efficient and effective suite of cartographic modeling operations. The suite includes operations of three major types: “local,” “zonal,” and “focal.”

Local operations compute new values on a location-by-location basis. Each generates a new layer on which every location’s value is computed from the value(s) of that same location on one or more existing layers. While some of the local operations provide for the explicit assignment of new values, most call for their calculation by way of familiar mathematical functions. Local-Classification, for example, is an operation that might be used to assign user-specified scores to different types of soil. The resulting layer of scored soils might then be combined with layers representing other site suitability factors by using an operation called LocalMean.

Zonal operations compute new values on a zone-by-zone basis. Each generates a new layer on which every location’s value is computed from the value(s) of all locations on one existing layer that share its zonal value on another existing layer. Many of the zonal operations are directly analogous to local counterparts; they call for the explicit assignment of new values or their calculation by way of familiar functions. Zonal-Classification, and ZonalMean, for example, are operations that might be used to summarize site suitability scores within each of a set of towns.

Several of the zonal operations go beyond this kind of zone-wide summary to characterize each location’s existing value in relation to those of
the others within its zone. *ZonalRanking* is an operation that might be used to sort site suitability scores within each of a set of towns, for example, while *ZonalPercentile* might be used to set each location to a value indicating how much of its town has a lower score.

Focal operations compute new values on a neighborhood-by-neighborhood basis. A “neighborhood” in this context is the set of all locations that are situated at designated distances and/or directions from a given location, which is then referred to as the “focus” of that neighborhood. Those distances and directions may either be the same for all such foci or vary from one to another. Each of the focal operations generates a new layer on which every location’s value is computed from the values of neighboring locations on an existing layer, and there are focal equivalents to many of the local and zonal operations that summarize existing values. *FocalMean*, for example, is an operation that could be used to set each location to the mean of its nearby site suitability scores.

There are also focal counterparts to those zonal operations that characterize each location in terms of the relationship between its own existing value and those of the other locations being summarized. *FocalPercentile*, for example, might be used to set each location to a value indicating how much of its neighborhood has a lower suitability score.

A number of additional focal operations consider not only the value of each neighboring location but also (or instead) its distance and/or direction from the neighborhood focus. *FocalGradient*, for example, is an operation that might be used to calculate the rate at which site suitability scores change over space.

Focal operations vary as well according to the nature of the neighborhoods to which they are applied. “Local” neighborhoods include only those locations that lie adjacent to each neighborhood focus, while “lateral” neighborhoods extend that reach to encompass all neighboring locations lying at specified distances and/or directions. “Visible” neighborhoods limit what might otherwise be regarded as radial neighbors to those that lie within sight of each neighborhood focus, given an intervening landscape of visual obstructions. And “accessible” neighborhoods are defined in terms of distances that are measured not in units like meters or miles but in units like minutes, dollars, ergs, or levels of environmental impact. These are units that accumulate as a consequence of implied motion from each neighborhood focus and do so at rates that can vary according to conditions impeding that motion.

Given an ability to specify sequences of local, zonal, and/or focal operations that generate new layers from existing layers, it becomes possible to draw an important distinction between “actual” layers that are stored as data and “virtual” layers that are stored as procedures to be applied to actual data. In order to include such virtual layers in a cartographic model, the procedures involved must be recorded in a format that is not only legible to humans but also executable by machine—a language for data processing control.

**Data processing control**

The notation used to represent cartographic modeling data and data processing activity is not intended to replace the programming language employed in any given GIS. Rather, it is intended to relate to such languages in a manner that transcends their minor differences in order to focus on fundamental commonalities. It is a pseudocode that employs “statements” to represent individual operations and sequences of statements called “programs” to represent procedures. Statements are given in an imperative form.
much like that of conventional algebra but with greater use of words than symbolic characters. The formal syntax of this “map algebra” is more fully described elsewhere but is illustrated below with a typical example. Here, a new layer entitled *Summits* is generated from an existing layer entitled *Elevation* by applying a procedure that:

1. smooths a 3-D surface of topographic elevations,
2. calculates local deviations between the original and smoothed surfaces,
3. relates those deviations to a scale from 0 to 100,
4. identifies areas of high positive deviation as hills,
5. distinguishes each hill from the others,
6. determines the maximum elevation of each hill, and
7. isolates the location(s) situated at each hill’s maximum elevation.

Note that this notation refers to layers by their titles. Note, too, that this particular program refers to its input layer by way of a title (*Elevation*) that could either identify a specific layer that is currently available or instead represent a generic layer that has yet to be provided. A program that refers only to specific input layers can be regarded as a (virtual) layer itself. A program that refers only to generic input layers, however, acts more like an operation than a layer. This is an important distinction that effectively broadens the definition of a cartographic model to include what amount to nouns and verbs of up to four major types:

- standard operations stored as GIS-based functions,
- special operations stored as programs with generic inputs,
- actual layers stored as data, and
- virtual layers stored as programs with specific inputs.

**Development**

The cartographic modeling paradigm can be traced to manual techniques that were employed by landscape architect Warren Manning in the early 1900s and popularized by landscape architect Ian McHarg in the 1960s. Its digital antecedents start with SYMAP (Fisher 1966) and extend in a direct lineage to GRID (Sinton and Steinitz 1969), IMGRID (Sinton 1977), and MAP (Tomlin 1980). The term “cartographic modeling” was introduced in the late 1970s and the methodology was refined throughout the 1980s (Tomlin 1983, 1990).

Since then, cartographic modeling capabilities have been widely adopted and adapted. They remain primarily associated, however, with data that are encoded in raster format. Much of the reason for this relates to the simplicity and generality of that format – one in which all manner of geographical phenomena are represented by the same type of geospatial unit. When working with vector-encoded data, units defined
CARTOGRAPHIC MODELING

by points, lines, and polygons present a much greater challenge, particularly with respect to focal operations. This is a worthwhile challenge, however, and a challenge that can only be met by recognizing that the world outside is one of both fields and features.

As a rubric, History of Cartography has two distinct connotations: (i) the chronicle of technical and intellectual developments surrounding mapmaking and map use and (ii) the interdisciplinary endeavor that invokes historical context in studying both the map as a visual object and the societal impacts of cartographic technology and mapping activity. (It should not be confused with historical cartography, the mapping of past events by historians and historical geographers.) A third and equally pervasive connotation is the comprehensive History of Cartography initiated by J.B. Harley (1932–1991) and David Woodward (1942–2004) and published by the University of Chicago Press. Because the several volumes of the History reflect major divisions in map history, the series provides a convenient framework for much of this entry, which also identifies important English-language synopses and appropriately emphasizes developments since 1900, including dynamic maps and geospatial technology. This entry also examines academic activities, including conceptual frameworks, key individuals, and the institutional apparatus of map collections, exhibitions, conferences, and journals.

Encompassing geospatial technology, this entry demands a definition of map with two levels: the narrow, traditional sense of a graphic framework whereby symbols representing geographic features facilitate navigation, planning, and general understanding (Harley and Woodward 1987, xv–xvii) and the broader, more recent sense of topologically structured geographic information intended to support spatial analysis, graphic display, or both. The word cartography merits a similar disambiguation insofar as it encompasses not only the traditional focus on mapmaking but also the broader context of map use and mapping as a governmental, commercial, and intellectual endeavor.

Frameworks and chronologies

Systematic study of salient trends in map history involves the overlay of three factors: a classification scheme that recognizes the diverse ways in which maps are produced and used; a chronological schema akin to the eras or stages of development common to broad-brush historical narratives; and distinctive themes such as the impacts of technological innovations like printing and photography and political revolutions like the rise of the nation state. Science, technology, and state formation have precipitated distinctive changes in cartographic symbols and formats as well as in the social relations surrounding maps and mapping.

Modes of mapping practice

How maps are made and used, and to what ends, is arguably the most revealing basis for sorting cartographic artifacts into categories for historical analysis. Competing categorizations include map scale, which is both the lynchpin of cartographic theory and a key characteristic of any map. Even so, categories based on scale are too coarse and internally varied to sustain a broad range of meaningful interpretations and
conclusions. Similarly limited are categorizations based upon whether the mapmaker is a governmental or a private-sector entity, whether the map is circulated on paper or electronically, or whether replicated images were copied by hand, engraved on a copperplate or lithographic stone, or transferred photographically. Although the reproduction method leaves distinctive marks on the artifact, these differences in appearance are less socially and intellectually significant than differences among cartographic modes such as property mapping, marine charting, and geodetic surveying.

The concept of cartographic modes was introduced by Matthew Edney (1993) as a framework for studying the development of European cartography between 1500 and 1850, which includes the Age of Discovery and the rise of capitalism. His schema initially consisted of nine modes of cartographic practice, defined as “sets of cultural, social, and technological relations which define cartographic practices and which determine the character of cartographic information” (Edney 1993, 54). Although these modes overlap and interact, each has a typical range of map scales as well as distinctive forms, innovations, and user communities. Celestial mapping, with ties to astrology and astronomy, looks heavenward and has the smallest scales. Small-scale maps are also the most characteristic product of geographical mapping, which summarizes spatial knowledge for the entire world and its regional subdivisions. Geodetic mapping, which measures the size and shape of the planet, is a continental or global endeavor most conveniently depicted (if at all) on small-scale maps; even so, its most important products are the highly precise triangulation networks that provide a geometric framework for the large- or medium-scale maps generated by topographic mapping, which focuses on the representation of places and the Earth’s surface, and by urban mapping, a historically important endeavor focused on cities. Measurement is no less basic to property mapping, which promotes land ownership with large-scale representations, and boundary mapping, which delineates national territories and their provinces on medium- or small-scale maps. Marine charting, which produces small-scale maps of the seas and medium-scale maps of harbors, interfaces with topographic mapping along the coastline. Thematic mapping, which encompasses the broadest range of scales, typically exploits topographic maps and marine charts as spatial frameworks for plotting natural or social phenomena.

As Edney (1993, 59–64) observed, these modes represent a convergence of mapping practice around 1500 followed by a marked divergence before 1800. By the sixteenth century the collective emergence of mercantilism, printing, the commodification of land, and the modern territorial state had led to four distinct modes – charting, geodesy, small-scale chorography (place mapping), and large-scale topography – which by the early eighteenth century had amalgamated into a relatively amorphous “mathematical cosmography” inspired by the Scientific Enlightenment and exemplified by systematic and detailed national surveys like the mapping of France by the Cassini family. Fragmentation into the aforementioned modes by 1800 reflects the increased political, economic, and intellectual complexity of European society.

Edney’s schema also included four institutional endeavors that cut across multiple modes. Military cartography, for instance, employs geographical maps for strategic planning, topographic maps for tactical operations, and marine charts for naval activities. At local as well as provincial and national scales, administrative cartography intersects property mapping, thematic mapping, topographic mapping, and urban mapping. The map trade, which became map publishing after printing and engraving technologies vastly expanded the
cartographic marketplace in the sixteenth century, encompasses the commercial distribution of maps of all types, and map collecting by institutions and individuals brings together maps useful for military intelligence, general reference, and scholarly research. And in the twentieth century in particular, antiquarian dealers have touted rare and merely old maps as aesthetically attractive investments.

Technological advances in the twentieth century required two additional modes of cartographic practice: overhead imaging, whereby aircraft and satellite platforms and diverse imaging technologies vastly increased cartographic coverage and content, and dynamic cartography, whereby interactive and animated displays offer comparatively complete and often engaging displays of temporal or complex phenomena. In addition, academic cartography emerged as a distinct institutional endeavor focused on the systematic, scholarly study of not only the design and production of maps but also the cultural connotations and societal impacts of mapping activities.

**Historical approaches**

The scholarly study of map history has roots in the eighteenth century, but systematic treatments were largely lacking until Manuel Francisco de Barros e Sousa Santarém (1791–1855), the Portuguese scholar-diplomat believed to have coined the term cartography to describe the study of old maps, published his *Facsimile-Atlas* of early maps in 1841. Another milestone was *l’Atlas des monuments de la géographie*, published in 1879 by the French civil engineer Edmé-François Jomard (1777–1862), who assembled a collection of facsimiles to emphasize cartography’s close ties to progress in science and discovery. In turn, Jomard’s atlas was the source of several reproductions in the *Facsimile-Atlas to the Early History of Cartography, with Reproductions of the Most Important Maps Printed in the XV and XVI Centuries*, published in 1889 in Swedish and English by Adolf Eric Nordenskiöld (1832–1901), a Finnish natural scientist, arctic explorer, and map collector. Although many of Nordenskiöld’s images were necessarily reduced in size, the *Facsimile-Atlas* (1889) was a useful general reference for librarians, historians, and map collectors. Systematic cataloging of old maps fostered problematic notions of inevitable, ever increasing cartographic progress propelled by advances in mathematics and natural science, measuring techniques, and graphic reproduction.

Facsimile atlases were followed by narrative histories, such as Lloyd A. Brown’s *The Story of Maps*, published in 1949. A former map curator at the University of Michigan’s William L. Clements Library, Brown traced cartography’s evolution as a modern science from the ancient geographies of Strabo and Alexander the Great to the International Map of the World, a heroic multinational endeavor frustrated by two world wars, limited cooperation, and lack of a clear-cut need. Military strength and world peace, he argued, depended on reliable maps, and fully complete and reliable maps were impossible without peace and prosperity. Like most narrative histories, Brown’s *Story* put maps, geometric accuracy, and cartographic coverage at center stage and paid little attention to the complexity of maps as social and cultural texts.

Erwin Raisz offered a more schematic treatment in his 1938 textbook *General Cartography*. Raisz was a Harvard faculty member as well as an accomplished illustrator, widely recognized for his insightfully detailed physiographic diagrams. His calligraphic dexterity is readily apparent in elegantly hand-lettered timelines for Antiquity (300 BCE–300 CE) (Raisz 1938, 15), the Middle Ages (400–1400) (1938, 25), the
CARTOGRAPHY: HISTORY

Renaissance (1470–1700) (pp. 36–37), Modern Maps (1700–1930) (pp. 52–53), and the United States (1750–1930) (pp. 60–61). Most events are tagged with the name of a specific mapmaker; his Renaissance timeline includes separate columns for England and France; its Modern Maps counterpart assigns noteworthy developments to Italy–Spain–Latin America, France, Netherlands–Germany–Austria, Great Britain, and “Others,” whereas his United States timeline is divided equally between “Surveys, Official Maps” and “Private Cartography.” This emphasis on persons, national traditions, and technology is typical of the “internal histories” that arose in the late nineteenth century, when mapmakers began to enrich their manuals and textbooks with historical narratives of steady progress in overcoming diverse challenges.

J.B. Harley and David Woodward questioned the reliability of internal histories, which not only emphasize scientific progress, famous firsts, and intriguing artifacts, but also tend to ignore the influence on mapmakers and mapping institutions of intellectual and political movements. Harley was a historical geographer with Marxist leanings, whose careful examination of late eighteenth-century English county maps and detailed maps produced during the American Revolution aroused a critical appreciation of old maps as historical sources with limitations beyond the obvious consequences of imprecise instruments and sloppy fieldwork (Edney 2005b). Woodward was a historian of cartography whose research on map engraving and printing inspired a wider interest in how maps were circulated and used (Edney 2005a). In spring 1977 he persuaded Harley to forego plans for a four-volume history of mapping in North America and collaborate on a general history of cartography focused on the societal context within which maps were produced and consumed (Woodward 2001, 23–24). They planned to cover the period from prehistory through the end of World War I in four books, divided chronologically at 1470, 1660, and 1800 and totaling no more than a million words. Their hope of having all volumes in print by 1992, the 500th anniversary of Columbus’s widely celebrated voyage to North America, greatly underestimated the richness of map history as an academic endeavor.

A “big book” project

Their million-word estimate proved similarly naive insofar as the History of Cartography, when completed in the early 2020s, will be at least seven times as large, and take its place alongside monumental “big book” reference works like the Dictionary of American Regional English (1985–2012) and the Dictionary of Scientific Biography (1970–1990). From the beginning Harley and Woodward recognized that their project would require numerous collaborators, grant support, and a committed and competent publisher (Woodward 2001). The University of Chicago Press, with which Woodward had worked, filled the publishing role, and “the History Project” (as it came to be known) has drawn substantial support from the National Endowment for the Humanities, the National Science Foundation, and the University of Wisconsin–Madison, which added Woodward to its geography faculty in 1980.

Volume One, titled Cartography in Prehistoric, Ancient, and Medieval Europe and the Mediterranean, appeared in 1987. Its 21 chapters are largely interpretative narratives focused on a region, a time period, a type of map use, or perhaps all three, as exemplified by the title of chapter 12: “Maps in the Service of the State: Roman Cartography to the End of the Augustan Era.” Topics covered in various chapters include the measurement and calculation methods of the
Babylonians and Greeks, Ptolemy’s *Geography*, maps for urban planning and civil engineering in the early Roman Empire, Woodward’s recognition that medieval *mappaemundi* were symbolic representations of history rather than geometric representations of the planet, the development and use of *portolan* sailing charts in the fourteenth and fifteenth centuries, and an increased number and variety of maps overall.

In their preface, Harley and Woodward proclaimed a fundamentally new definition of *maps* as “graphic representations that facilitate a spatial understanding of things, concepts, conditions, processes, or events in the human world” (Harley and Woodward 1987, xvi), and in chapter one, “The Map and the Development of the History of Cartography,” Harley appealed for recognition of map history as a distinct scholarly pursuit devoted to questioning the map’s role in sociopolitical discourse. Eight other scholars contributed most of the essays, and the editors concluded with a call to fill gaps in the historical record, enhance understanding of the map’s emergence as a means of human communication with diverse geometric frameworks, and widen appreciation of the social context, including the map’s use as an intellectual weapon. In their view, a comprehensive reference work that got the facts right could stimulate critical scholarship as well as enlighten curious readers. To this end, Volume One set a standard for the thorough fact checking, careful editing, and accessible typographic design that permeates the series.

As their plans evolved, Harley and Woodward added a fifth volume to encompass the twentieth century. The series swelled to six volumes after they discovered numerous scholars who could collectively cover mapping by indigenous and non-Western societies. Though not part of the original four-volume plan, these topics became the focus of Volume Two, published as three separate books: *Cartography in the Traditional Islamic and South Asian Societies* (1992), *Cartography in the Traditional East and Southeast Asian Societies* (1994), and *Cartography in the Traditional African, American, Arctic, Australian, and Pacific Societies* (1998). Harley died in 1991, but Woodward continued the series, often with the support of associate or assistant editors.

When Volume Three, *Cartography in the European Renaissance*, was published in 2007, its 2334 pages, bound as a set of two large books, dwarfed Volume One’s 654 double-column, 21.59 × 27.94 cm (8.5 × 11 inch) pages, which had established the series’ internal design. Aware of the challenge posed by the explosion of mapping activity after 1650 and sharing the publisher’s concern about production costs – Volume Three overran its original budget of a million words by 30% – Woodward adopted an encyclopedic format for the remaining three volumes. This shift from a small number of relatively long narrative essays authored by comparatively few scholars to a much larger number of encyclopedia entries also acknowledged cartography’s increased complexity, allowed the participation of many more contributors, and afforded a workable strategy for controlling each volume’s length. Consistent with the series’ role as a reference work, the encyclopedic strategy and Woodward’s plan to share editorial responsibilities also promised to reduce production time.

CARTOGRAPHY: HISTORY

2021. Entry-term lists for these encyclopedic volumes reflect the systematic polling of broadly constituted boards of international advisors as well as hierarchically integrated conceptual clusters (HICCs) based on Edney’s modes of mapping practice and institutional endeavors, which were reworked into multiple levels so that important topics would not be overlooked.

Each volume’s HICCs reflect key developments in its respective era. For example, Volume Four details the impact on cartography of the flowering of science, technology, and rational philosophy in the eighteenth century, when mapping became an important instrument of scientific inquiry, especially in the natural sciences, and maps based on observation and measurement had become markedly less decorative than their Renaissance counterparts. In addition, the map was now a powerful device for organizing knowledge in a revealing, readily accessible way as well as a commonplace tool of governmental administration, including planning and maintaining public civil infrastructure. Military cartography faced a similar need for systematic mapping after the open battlefield replaced the prolonged siege of fortified cities as the primary strategy for confronting hostile rivals. No less important to Enlightenment cartography was an increased public consumption of maps fostered by an expanding middle class and related improvements in literacy and education. By 1800 maps were a distinct part of Europe’s visual culture.

The nineteenth century witnessed a strengthening of cartography’s relationships with measurement, mathematics, and statistics, readily apparent in the diverse and complex thematic maps that accompanied advances in the physical, biological, and social sciences and in medicine and public health, all of which used maps for exploratory analysis, hypothesis testing, and serendipitous discovery. Geodetic networks grounded in improved technologies for measuring angles and distances provided a framework for the mapping and demarcation of political boundaries and for the detailed topographic and hydrographic maps important to economic development and military defense. Mapping also supported the growth and densification of railway networks, particularly in Europe and North America, as well as mineral exploration and nascent efforts to inventory natural resources. By mid-century sparse networks of atmospheric observations had provided an empirical basis for understanding the development of storms and demonstrated the practicality of forecasting weather; by century’s end map-intensive operational meteorology had become an essential service of central governments. International cooperation in meteorology, geology, and geography fostered an appreciation of standardized measurements that culminated in the International Meridian Conference, which established the Greenwich meridian as the global standard for longitude in 1884 and provided a stable framework for the worldwide system of time zones, which continued to evolve in the following century.

Mapping’s close relationships to society and technology are particularly apparent in the emergence of a mass cartography promoted by lithography, photography, and industrialized map production, exemplified in turn by inexpensive reference atlases for the home, textbooks with abundant maps, and school atlases. Increased consumption of maps by government, business, and the public accompanied the growth of geographic and general literacy, which also benefited from improved access to public education and municipal libraries. By 1900, a fitful increase of maps in newspapers reflected a growing thirst for spatial information as well as advances in printing and engraving.
Twentieth-century developments

Technology and map use combined with state formation and global forces to make the twentieth century a distinctive and coherent period of map history. Overhead imaging emerged early in the century when the integration of photography and propeller-driven airplanes provided systematic aerial surveys for topographic mapping and related administrative and military endeavors. Satellite surveillance and the electronic capture and processing of overhead data, which followed in the 1960s, were part of a far-reaching electronic transition that included geographic information systems, global positioning systems, enhanced methods for measuring distances and angles and for reconciling measurement errors, and the computational power required for fly-by animation, LiDAR imaging, network adjustment in geodesy, advanced spatial statistics, and the numerical simulation of environmental processes (Foresman 1998).

Technologies that combined transport and mapping fostered new kinds of national territory. Maps were used to partition and control navigable airspace, extend terrestrial boundaries seaward, and divide the seabed on the continental shelf and beyond. The cartographic coastline provided an anchor for exclusive economic zones 200 nautical miles wide, which encroached on the high seas, created heretofore improbable neighbors like Japan and the United States, and precipitated litigation before the World Court when coastal neighbors could not agree on a common boundary. In addition, submarine mapping and space exploration produced remarkably detailed maps of the ocean floor, the Moon, Mars, and asteroids a few kilometers wide, which in turn revealed prominent features like seamounts (sub-marine volcanoes) and impact craters amenable to international naming conventions. As with the electronic gazetteers developed to support topographic mapping, computerized inventories of feature names provided a framework for applying new toponyms and resolving disputes.

Exploration and mapping of outer space and the seafloor continued the longstanding association of cartography and warfare, a synergy further underscored by weapons systems like the cruise missile and the unmanned aerial vehicle, or drone, which made air strikes both more precise and more likely, thereby undermining diplomacy while reducing (but hardly eliminating) civilian casualties. Military spending was a driving force, directly or indirectly, behind many developments in geospatial technology, which trickled down to civilian applications and reproduced a multitude of prohibitive cartographies (Monmonier 2010). Developments rooted in military research include GPS, digital terrain models, and high-interaction display software like Google Earth. These origins spawned debates, still ongoing, over whether geospatial technology can ever be value-neutral (e.g., Harley 1991).

Particularly noteworthy is GPS, originally devised to guide cruise missiles but used widely after 2000 for vehicle navigation and traffic-flow monitoring, land survey and environmental data collection, and tracking sex offenders, criminal defendants, Alzheimer’s patients, children, pets, and packages. An essential component of almost all wireless telephones, GPS supports instantaneous map displays of the user’s immediate surroundings and can compile extensive location histories, invisible to the user but archived indefinitely in the interest of national defense. Although the marked expansion of satellite surveillance after 1990 epitomizes the diverse impacts of mapping on society during the twentieth century, earlier cartographic activities with important influences on individuals and society at large include highway mapping, weather prediction, hypothetical environments proposed by planners and landscape architects, and video
entertainment for both mass audiences and individual users. Video games, which are inherently spatial if not blatantly cartographic, enhanced players’ hand-eye coordination and raised expectations among a new generation of map users.

The twentieth century also witnessed a markedly increased use of maps as tools of public administration, for diverse activities such as land-use zoning, hazard modeling and mitigation, real-property assessment, community policing, and the creation and adjustment of special districts for historic preservation, additional municipal services, and school attendance. Particularly significant is the redistricting software that raised partisan gerrymandering to new levels, first by promoting bizarre congressional districts in the remap following the 1990 Census and then by using shape geometry to craft equally effective but less visually inflammatory gerrymanders that undermined collaborative decision-making by giving one party a distinct advantage in the vast majority of districts. The inherent ambiguity of geospatial technology became apparent when interactive software that encouraged citizens to create alternative redistricting plans reinforced the questionable notion that single-member districts and first-past-the-post voting are essential for representative government (Monmonier 2001).

No less emblematic of twentieth-century cartography is the paradox of globalized practices and customized content. Global standardization reflected increased communication within distinct mapping communities such as national mapping agencies, commercial mapmakers, and academic cartography. Textbook authors codified symbolization strategies, and successful software developers, most notably Esri, introduced new terminology and a standardized aesthetics readily implemented by a swelling cohort of eager users no longer hamstrung by the tedious, error-prone tasks of pen-and-ink cartography and manual digitizing. New mapping communities arose along a spectrum stretching from the necessary uniformity of aeronautical charts and to the purposeful pursuit of novel advertising and tourist maps. In addition map projection software allowed a wider range of custom-tailored geometric frameworks, and a web cartography that empowered map users to be their own mapmakers precipitated widespread customization of geographic scope, map scale, and content. Because millions of these use-specific maps were printed on inexpensive ink-jet and laser printers, the predicted demise of the paper map was delayed if not circumvented.

Map history as an institutional endeavor

As an intellectual enterprise, the history of cartography is particularly indebted to the Russian historian Leo Bagrow (1881–1957), who built upon the facsimile atlases of Santarém, Jomard, and Nordenskiöld by establishing the journal *Imago Mundi* in Berlin in 1935. Its premier issue included several short notices, a bibliography of recent literature, and twelve articles – nine in German and three in English. Its subtitle, printed in both languages (“Jahrbuch der alten Kartographie/Yearbook of Old Cartography”), underscored a focus on pre-nineteenth-century maps. Bagrow had written on map history while working as a hydrographic surveyor in the Russian navy. In 1918, he emigrated to Germany and in 1945 he moved again, to Sweden, where he continued to edit the journal until his death in 1957 (Skelton 1959). Despite multiple publication gaps related to geopolitical turmoil and editorial turnover – no issues were published for 1936, 1938, 1940–1946, 1957–1958, 1961, 1973–1974 – an increase from one to two issues per year in 2004 underscored *Imago Mundi*’s role
J.B. Harley and Michael Blakemore highlighted *Imago Mundi*'s crucial role in a content analysis of its first 30 volumes. Most of the articles published between 1935 and 1978 examined readily available printed maps “published in relatively large numbers, on paper or similar transportable media, yet which were sufficiently old to be of historical importance” (Blakemore and Harley 1980). Less than 5% of the articles examined mapmaking after 1800, and 78% of the mapmakers were Europeans. In concluding that prior scholarship collectively underrepresented important activity after the “Age of Discovery,” they identified three overarching themes: a Darwinian paradigm that emphasized steady, progressive improvement, typically by hypothesizing distinct stages of development; an “old is beautiful” paradigm that underscored an antiquarian fascination with Renaissance maps, their decorative flourishes, and heroic mapmakers; and a nationalist paradigm that reflected convenient access to maps produced in the authors’ homelands. They concluded that the history of cartography was a fragmented discipline lacking coherence and balance.

Matthew Edney (2014), who tabulated both pages and articles, extended the analysis through 2010. In general, empirical studies dominated scholarship on map history throughout *Imago Mundi*'s first 75 years. Edney identified three primary approaches to map history, which he labeled traditional, internal, and sociocultural. Traditional approaches, including biographical and bibliographical essays and content analyses, were dominant until the early 1960s. Internal studies, which focused on map forms and their related technologies and procedures, were then preeminent in the journal until around 1985 when traditional approaches enjoyed a brief resurgence before losing ground to sociocultural studies after 1990. Geographical mapping has been the dominant mode throughout the period, accounting for 65% of all articles followed by marine charting at 15%. Although Renaissance cartography was the dominant chronological focus throughout the period, followed by Enlightenment cartography, “modern topics” (essentially the eighteenth and nineteenth centuries) emerged in the 1980s as a third theme. Overall, the twentieth century has fared no better than non-Western cartography, which accounts for only 10% of *Imago Mundi*'s content.

The sociocultural turn is synonymous with the rise of a “critical history of cartography,” a rubric too readily conflated with Marxist, structuralist, poststructuralist, postmodern, and other avowedly “theoretical” academic ideologies that sometimes read like conspiracy theories. Nonetheless, the sociocultural history of cartography is fundamentally critical in its focus on questioning the map’s creation and use in contexts that are intrinsically social, political, or cultural. This contextualized probing is inherently interdisciplinary as demonstrated by the active participation of art historians, literary theorists, social and political historians, and other humanists and social scientists at academic conferences on map history and in the pages of *Imago Mundi*.

As an intellectual discourse, the history of cartography relies not only on a refereed international journal but also on the synergy of face-to-face discussion at meetings like the International Conference on the History of Cartography (ICHHC), initiated at London in 1964 and held every two years since 1967. *Imago Mundi*, Inc., a registered charity in Britain, which appoints the journal’s editor and editorial board, oversees ICHCC. In 2011 a group of scholars associated with the charity formed the International Society for the History of the Map, which
CARTOGRAPHY: HISTORY

holds its own symposia and whose dues-paying members elect officers and are eligible for a reduced-rate subscription to the journal. The Commission on the History of Cartography, affiliated with the International Cartographic Association, also promotes map history. The Commission holds its own biennial symposia, a year out of sync with the ICHC and focusing on the nineteenth and twentieth centuries.

A third organization, the International Map Collectors Society serves map collectors, map dealers, and cartophiles in general by sponsoring an annual map fair in London and publishing the quarterly IMCoS Journal to which academic map historians often contribute. The symbiotic relationship between cartophiles and historians of cartography accounted for short-lived popular periodicals such as The Map Collector's Circle and The Map Collector, published in Britain 1963–1975 and 1977–1996, respectively, and Mercator's World, published in the United States between 1996 and 2003. The Portolan, published by the Washington Map Society since 1984, is a prominent example of a map history newsletter published by a state or local map society.

The intellectual apparatus of map history also includes specialized bibliographies of maps or mapmakers, such as Robert Karrow’s masterful 876-page Mapmakers of the Sixteenth Century and Their Maps: Bio-bibliographies of the Cartographers of Abraham Ortelius, 1570. Published in 1993 by the Newberry Library, Mapmakers exemplifies map history’s close ties to map collections at national, university, and endowed research libraries like the Newberry. Institutional map collections regularly sponsor themed exhibitions, and bibliographies and cartobibliographies advertise their holdings to historians and other empirical scholars.

Map history’s scholarly infrastructure also includes online map collections and directories. Most institutional map collections have a presence on the Internet, and many websites provide carefully researched descriptions as well as zoomable map viewers, which allow detailed inspection of symbols, labels, and text. Particularly prominent is the David Rumsey Map Collection (www.davidrumsey.com), a trove of high-resolution images scanned from the private holdings of a successful real estate investor. In 2009 Rumsey announced his plan to donate his entire collection of maps and digital images to Stanford University. Other valuable online resources are the Map History Gateway (www.maphistory.info), maintained by Tony Campbell, former map librarian at the British Library, and the International Directory of Researchers in Map History (www.maphistorydirectory.org), hosted by the Osher Map Library at the University of Southern Maine on behalf of Imago Mundi, Inc., which published nine editions of a printed directory between 1975 and 1998.

In sum, both cartography and map history have changed markedly during the twentieth century when overhead imaging and dynamic cartography emerged as distinct modes of mapping practice and both mapmaking and map use became more standardized globally, more customized to the preferences of individuals, and more crucial to science and government. In this vein the societal impact of mapping became more readily apparent not only in enhanced surveillance by the state but also in formal resistance through counter mapping. And by century’s end map history had moved beyond the antiquarian tastes of map collectors to become an interdisciplinary scholarly endeavor with strong ties to geography, librarianship, the humanities, and the history of science. The History of Cartography series exemplifies this intellectual
maturation in its concern for the societal context within which maps were produced and consumed.

and Map Use in 1900.” *Historical Geography*, 28: 157–178.

Case study approach

Susan W. Hardwick
University of Oregon, USA

The case study approach has been a popular and accepted research strategy in the social sciences for almost a century. Case study research is particularly useful for geographical research because it is a holistic, nuanced, and integrated approach. The case study approach is defined as the study of a single instance or a small number of instances of a particular phenomenon in order to explore the relationships and contextual influences on that phenomenon (Baxter 2010).

Sample research topics based on a case study approach that have been explored recently by geographers include studies of the incorporation experiences of immigrants in a particular place or context and research on race and whiteness; development; biotic change; participatory planning; and the impacts of climate change on a particular place.

Since focusing on a case study makes it possible for scholars to compile a detailed analysis about a selected place, process, or group, it is useful for doing both theoretical and empirical work. However, during the past three decades or so, and due to the important influences of feminist geographers (and other scholars in the field who are interested in developing or testing theory), research based on a case study approach has been increasingly popular among theoretical and qualitative researchers in the field.

There are three main types of case studies – exploratory, descriptive, and explanatory – although no exclusivity exists between each of these categories (Schell 1992). Some of the best case studies, in fact, are both exploratory and descriptive or descriptive and explanatory (such as William Whyte’s frequently cited 1940s study of street corner society). Exploratory case studies are often a beginning point, or a preliminary analysis, to be used to help develop a plan for conducting a more in-depth research project later on. A descriptive case study, on the other hand, is more often based on a preconceived theoretical and/or empirical framework that may need to be explored or developed in some depth prior to launching a larger project. In comparison, explanatory case studies are most often used for cause-and-effect geographical investigations.

Robert Stake identifies three other kinds of overarching case study categories useful for geographers (1995). These include intrinsic (when the researcher already has an interest in the case before it is studied); instrumental (when the case study is used to study and analyze more than what is obvious to the observer); and collective (when a small group of different case studies are analyzed and compared). Both human geographers and physical geographers have long favored the use of the collective case study approach (often referred to as a multisited analysis), because the study of people and processes in several different places provides the kind of detailed comparative data needed to test theory or for theory building and also for transferability to other places.

It is important to note that literally all types of case studies are multiperspective approaches. In other words, a case study researcher not only considers the voice and perspective of the actors in particular places but also observes and analyzes the context and the relationships and interactions between and among them (Tellis 1997).
CASE STUDY APPROACH

**Origin and evolution of the case study approach**

During the twentieth century, two widely respected academic programs – the Sociology Department at the University of Chicago and the Harvard Business School – developed, refined, and disseminated the use of the case study approach for scholarly work (at Chicago) and for classroom teaching (at Harvard) to scholars and educators in the United States and, ultimately, in many other parts of the world. Many urban and social geographers and scholars in other related fields in the social sciences have long respected and built upon the work of urban sociologists from the Chicago School. The intensive case study-based research they conducted and published on immigrant neighborhoods in Chicago is credited with pioneering the use of the case study approach for urban studies and, later, for a wide variety of other research specializations in human geography and beyond.

The work of Chicago sociologists such as Robert Park, Ernest Burgess, and Louis Wirth popularized the use of the case study approach for urban research, and their widely read publications also encouraged other researchers to emulate their use of a mix of quantitative and qualitative data sources. Most scholars credit the widespread adoption of this Chicago School approach as a positive contribution to the importance of what today is referred to as mixed-methods research. Others, however, are less enthusiastic about this overly positive view of the methodological contributions of urban scholars at Chicago. They argue that the widespread dissemination of their blended methodological approach all too often has resulted in a tendency for scholars to exaggerate the differences between the value of quantitative (“objective”) and qualitative (“subjective”) approaches, and that this division continues to devalue the importance of qualitative work today (see Pratt 1992).

In the 1950s, the follow up contributions of the founding faculty at the Harvard Business School added both impetus and importance to the value, integrity, and validity of the case study approach. During the development of this now prestigious program, early business faculty were surprised to discover a complete lack of appropriate textbooks or other materials needed for classes to be offered as a part of their innovative program. As a result, a core group of faculty thereafter decided to help fill this curricular gap by collecting a group of “real world” case studies of business practices and business practitioners to use as classroom texts. They began this process by conducting personal in-depth interviews in the field and then compiled detailed interview transcripts of their findings.

These interview-based “reports” then were used to develop “cases” that were structured around particular learning objectives and refined in the classroom prior to publication. These case studies were supplemented with a variety of other classroom materials that contained both quantitative and qualitative data. Although the case studies at Harvard were not designed for scholarly work, they nonetheless greatly furthered the importance of the use of a mixed-methods case study approach for guiding student inquiry and also helped validate the use of the case study approach as a legitimate academic tool.

**Rigor, validity, and objectivity of the case study approach**

As with other kinds of research and teaching frameworks, it is vitally important to construct a careful plan to guide and defend all case study-based projects. Otherwise, the internal and external reliability of the outcome of the
study is compromised. One way to enhance the validity of case study findings is to use multiple approaches and multiple data sources. To achieve this goal, geographers frequently depend on “triangulating” case study data sources and research methods by compiling and analyzing data, for example, from such sources as interviews, participant observation, census data, and survey questionnaires. This approach not only helps corroborate the findings of a project, but also adds rigor and validity to the outcome of the study.

A recent example of a geographic study based on a triangulated, multisited, case study approach is a comparative study of the migration flows, incorporation experiences, and spatial patterns of US-born residents of Toronto and Canadian-born residents in Atlanta, Georgia (see Hardwick and Smith 2012). The validity of this comparison of two urban case studies was enhanced by triangulating a suite of methods and data sources including the use of interviews, census data, and other government documents and participant observation. This multisited case study project of cross-border immigrants in two different urban areas (like the countless other research projects based on the case study approach that appear regularly in geography journals, book chapters, and conference papers each year) provides evidence of the ongoing popularity, value, and usefulness of case study-based research in the field in recent years.

**Research design, theory, and methods for case study research**

Case study approaches are useful for geographers who favor using both an inductive and a deductive research design. For clarity, a deductive case study-based research approach carefully develops the research questions and chooses the most relevant theoretical framework to use prior to launching the project’s data collection phase. This approach is quite different from the work of inductive scholars who allow their conclusions and theories to grow out of the discoveries that the data bring to the fore during the project. Geographers favor the use of either or both of these approaches – with positivist, quantitative scholars in the field usually preferring inductive approaches and geographers interested in the use of qualitative methods, grounded theory, and/or other kinds of theoretical frameworks more often favoring research based on deductive approaches.

That said, however, it is important to note that qualitative research in practice is rarely a purely deductive or purely inductive approach. Instead, it often is more of a cycle in the sense that theory stated up front as hypotheses or more loosely simply as possibilities (deductively) to study issues in the “real world” to gather information is then used to generate new concepts (theory) to explain what is observed (inductively) (Baxter 2010). The use of grounded theory is one helpful way to move through this cycle to create and form a detailed and in-depth understanding of the findings from a case study.

Regardless of the often vast chasm dividing these various diverse ways of working and thinking, it is essential for all case study researchers to first develop a well-thought-out research design before launching a project. Likewise, a carefully constructed list of the most appropriate research methods must be developed in advance of launching the project. As mentioned above, one of the many strengths of centering a research project on the use of one or more case studies, especially as compared to other approaches, is that data can (and should) be collected from multiple sources. This triangulation of data-collection strategies provides essential “multiple sources of evidence.” This approach
CASE STUDY APPROACH

not only helps confirm the validity and rigor of research findings, but also can be based on an overlapping set of quantitative and qualitative methods.

Most sources agree on the basic methods/data sources for a case study analysis. These include:

- documents,
- archival records,
- direct observation,
- participant observation,
- physical artifacts.

Data can be collected from one or more of these sources of information during the research process although case study research is likely to be taken more seriously by other scholars if more than one of them is used. Thus, case study scholars should use as many sources as are relevant to the goals of the study. The key is to use one or more of these methods for case study research to collect enough information to (i) document and analyze patterns revealed by the data; and (ii) be able to look for patterns or processes that give meaning to the case study as a whole.

In sum, Yin (1994) suggested three principles to guide the data collection process for case study research.

1. Use multiple sources.
2. Create a case study database.

Strengths and weaknesses of the case study approach

As discussed in this entry, the case study approach has remained an often criticized but viable research strategy since the early twentieth century when the Chicago School conducted case studies of local neighborhoods in the city. Despite this strong foundation, however, in most of the major social science textbooks, the case study approach was not discussed as a central or very important research approach until the mid- to late 1980s when qualitative research began to gain favor.

Because of the lack of support for the case study approach until recent decades, and despite the body of early work by the Chicago School that was based on the case study approach, many scholars continue to view case study-based research as exploratory at best and overly descriptive, narrow, and pedestrian at worst. This negative perception gained momentum among geographers during the discipline’s quantitative revolution in the 1960s when the testing of statistical data and the development of static generalizable research outcomes were favored. As a result, by the early 1970s, quantitative methods and statistical data resulting from survey research and government documents had become the norm with case study research used and discussed much less often. As a whole, the dominant perception at the time was that case studies completely lacked objectivity and rigor as a research approach (Rowley 2002, 16).

However, as discussed in earlier sections of this entry, it is possible for the case study approach to serve as a useful and reliable research method when executed with care. It also has a number of distinctive strengths. First, case studies are the most useful and effective way to gather and analyze detailed information about a particular place, group, or process. Second, case studies are more useful than other approaches when questions prefaced by “how” and “why” are being asked about a contemporary set of events over which the investigator has little or no control (Yin 1994, 9).

Third, another important argument in support of case study research is its usefulness for generating theory or for theory testing. This is one of
the most important strengths of this approach for qualitative scholars as compared to other research approaches because conducting research based on case studies allows theoretical propositions either to be stated before entering the field or, for scholars who prefer using ethnographic approaches or grounded theory, for theory generating later on.

Finally, since all case studies are multiperspectival, the voices of the powerless and often overlooked actors in particular places or groups are heard and considered along with the powerful people involved in the analysis.

Despite these many strengths, it is also important to note that the case study approach does not use sampling as a research strategy. However, with the careful development of a sound research design, strategic planning of the most appropriate research methods to use, and triangulation of data sources and methods, the rigor and validity of a study accomplished using the case study approach can be improved.

In sum, use of the case study approach has been criticized as lightweight, overly descriptive, and insufficiently rigorous since the quantitative revolution in the 1960s. Of greatest concern has been the lack of generalizability of research findings from this approach. However, in recent decades, the increased use of case study research by feminist geographers and other qualitative, theoretical scholars in the field has called attention to the increasing importance, significance, and usefulness of this approach for theory testing, theory building, and overall more nuanced outcomes.

**Conclusions**

As this entry has made clear, the use of a case study approach is an ideal choice when a detailed holistic investigation of a particular place, group, or process is needed. Case studies are especially useful for bringing out the viewpoints and voices of all participants in a study via a triangulation of multiple sources of data. Some case study projects only study one group or one site. Others are multisited analyses that involve analyzing more than one case for comparative purposes and greater transferability or findings.

There are many different kinds of case studies – but more than one category may be used at the same time if they are designed to achieve a common goal. Regardless of which category defines the type or types of case study framing a project, all of the different kinds of case studies are grounded in a multiperspective approach from beginning to end. This means that the researcher in this kind of project is interested in more than just an analysis of the voices of project participants. The interaction between and among actors is also important, as is the context of the place or group being studied. Along with the contextual interpretation of data from this kind of study, perhaps even more importantly, is the consistent way that case study projects call attention to the impacts, perceptions, and voices of the powerless as well as the powerful. Thus, ultimately, despite all the criticisms of the case study approach over the years, this multiperspectival quality ensures that case study analyses continues to be a valuable and timely research tool.

Cellular automata

Andrew Crooks
George Mason University, USA

Over the last few decades our understanding and modeling of geographical systems have changed from looking primarily at aggregate patterns to examining individuals, and from assuming equilibrium to looking for far-from equilibrium through the lens of complexity science. One way of exploring how aggregate patterns emerge from the bottom up (i.e., individuals) is through the use of cellular automata (CA) models. A CA model is an arrangement of individual automata, or a software representation of a self-contained entity, that is situated within a regular tessellated space, such as the rectangular grid shown in Figure 1. An individual cell represents a discrete spatial confine of the automata, and an individual automaton is understood as neighboring some other automata. Each automaton processes inputs such as the characteristics or “state” information (e.g., whether a cell is alive or dead) from its neighbors and itself, and then decides whether to change its own state (e.g., from dead or alive), in light of instructions programmed within itself. It is important to note that in traditional CA models, all cell states are transformed by the same set of rules. The neighborhoods may take on a number of different configurations: agglomerations of adjacent cells are defined by their distance from an individual automaton. Two standard neighborhood configurations are illustrated in Figure 1: the nine cell “Moore” neighborhood (which includes the cell in question and its eight surrounding neighbors) and the five cell “von Neumann” neighborhood (which includes the cell in question and its four surrounding neighbors) along with a variation of one of these, the extended $5 \times 5$ Moore neighborhood.

An important feature of CA is that the automaton’s location does not move; the automaton can only change its state. This is different from an agent-based model where mobility is often key (see Crooks and Heppenstall 2012 and Agent-based modeling). The position of the cells and their neighborhood relations remain fixed over time. Information is explicitly exchanged, or “spread” only through neighborhoods (i.e., a local diffusion process). This notion of neighborhoods fits well with one of the tenets of geography, that of “everything is related to everything else, but near things are more related to each other” (Tobler 1970). Additionally, traditional CA models only have one attribute; for example, a cell could be occupied or unoccupied, but the cell cannot contain multiple attributes such as building type or date built. However, over time, this assumption has been relaxed to create more expressive models (as is discussed further later).

To illustrate how CA models work, Conway’s Game of Life is used. This is a simple model that operates over a rectangular lattice with square cells. A cell has only one attribute and one of two states, either dead or alive. The rules of the model are remarkably simple: each cell checks the states of itself and its nine surrounding cells (i.e., Moore neighborhood) and, depending on the states of these cells, the cell will do one of three things. If the current cell state is alive and two cells in its neighborhood have a state that is alive, then the state of the cell remains in the
alive state, otherwise it dies. However, if the cell is currently dead, it will become alive if the state of three neighboring cells is alive. Lastly, the cell will die if it has fewer than two neighbors with a cell state of alive or if more than three neighbors are alive. Figure 2 shows these rules in action.

Specifically, Figure 2 shows how dead cells (white) become alive (black) depending on the number of alive cells around a specific cell in question. Some patterns are stationary or unchanging over time, such as the first four patterns on the left of each image where the same cells stay alive, while others oscillate, for example the three patterns on the right of each time slice. Others translate across the space, such as the “glider” in the bottom of each image, so named because the collection of live cells appears to slowly move across the grid. Such a model demonstrates that from simple, well-defined rules, more complex patterns can emerge and persist through space and time. In essence, each cell processes information from external sources and reacts to these sources based on rules. This notion will be revisited in the applications section of the entry. The key message is that depending on the transition rules and the current state of the cell, different complex patterns can emerge.

CA models have become a standard way of modeling of complex systems because they offer a way to model the idea of emergence, that of complex patterns emerging from simple and well-defined lower level interactions via well-specified rules. The attractiveness of using CA models relates to why there is a need to model more generally. Specifically, the fact that the world is infinitely complex and trying to model all of its behavior is impossible. Modeling allows researchers to unravel this complexity and examine key elements of a system that are of most interest, to test different ideas and theory, and to help understand and predict past and future events. CA models allow us to do just this within the environment of a computer. Once the model has been created, it can be run to see how the system evolves through the interaction of cells.

**Background**

The history of CA dates back to the beginning of computer history when Alan Turing demonstrated the idea that computers could “reproduce” themselves, but it was not until the 1950s and 1960s that the field became alive, so to speak. This earlier work relates to that of John von Neumann and the theory of self-reproducing automata, which described the conceptual principles of a machine that was able to self-replicate (similar to the Game of Life example above). Such work laid the foundation of CA models today. Interested readers wishing to know more about the foundations of CA are referred to Benenson and Torrens (2004) and Cioffi-Revilla (2014).

While the discussion above has highlighted how 2-D CA models work, CA models can also be developed in other dimensions, such as one and three dimensions. Initially, many CA were developed on a 1-D space. For a 1-D model, cells are arranged along a line where the right-hand side is joined to the left-hand side to avoid edge effects. Wolfram (2002) notes that for 1-D CA
models, only 32 different rules can be used with respect to cells changing their state. This is because there are only a finite number of dead and alive states for a cell and its two neighbors. For example, Figure 3 shows an implementation of Wolfram’s “rule 30” (Wilensky, 2002), where a specific pattern emerges from an initial seed cell in the middle of the image.

This rule states that a cell becomes alive (white in Figure 3) or dies (black) depending on the cells to the right and left of it. More specifically, the cell state at \( t+1 \) can be written as:

<table>
<thead>
<tr>
<th>Time (( t ))</th>
<th>Cell state</th>
</tr>
</thead>
<tbody>
<tr>
<td>( t = 0 )</td>
<td>AAA AAD ADA ADD</td>
</tr>
<tr>
<td>( t + 1 )</td>
<td>D D D A</td>
</tr>
<tr>
<td>( t = 0 )</td>
<td>DAA DAD DDA DDD</td>
</tr>
<tr>
<td>( t + 1 )</td>
<td>A A A D</td>
</tr>
</tbody>
</table>

where \( A \) is alive and \( D \) is dead. For example if the current cell is dead (\( D \)), and both its left and right neighbors are alive (\( A \)), the cell dies in the next iteration.

Such simple rules also form fractal patterns, in the sense that the patterns repeat themselves across many scales due to their growth rules reflecting successive applications of local neighborhood principles and, as such, make them attractive to geographers as self-similarity is seen in many geographical settings such as cities (see Batty and Longley 1994, and Fractal analysis). Moreover, 1-D CA models do not just generate interesting patterns but have been used to explore many social science questions, including the emergence of residential segregation or how new political actors and empires emerge over time (Axelrod 1995). However, to apply CA to these systems it must be assumed that each cell is an agent, and that all agents employ the same rules. Such models also assume that agents will not change their behavior and that their behavior is based on what has occurred in the previous iteration, which some authors question as being unrealistic of human systems (Miller and Page 2007).

Moving to a 2-D view could be considered more suitable to geographical questions given their spatiality. Specifically, how objects and spaces relate to one another can be explored, as CA allow for diffusion and interaction (Batty 2005). However, Wolfram (2002) notes that by adding additional dimensions there is no remarkable difference in the occurrence of complex phenomena. Several things change, however, by adding an extra dimension. First is the increased number of possible rule sets and

Figure 2  Example of cells changing state from dead (white) to alive (black) over time depending on the states of their neighboring cells.
the ability to have different neighborhoods (e.g., instead of just right and left in 1-D CA, allows the von Neumann and Moore neighborhoods). While the vast majority of 2-D CA models operate on a square lattice, CA models have been developed on hexagonal and triangular lattices (Cioffi-Revilla 2014). However, such delineation of space has not gained popularity within the geographical community. On the other hand, there are a growing number of models that use a Voronoi tessellation of space (Benenson and Torrens 2004). Such spatial partitions have been developed due to criticisms that geographical phenomena, such as urban growth, do not always fit the regular geometric partition of space of a square lattice. Unlike in the CA models introduced above, the form of the neighborhood and the number of neighbors varies between automata in the CA. For example, neighborhoods using Voronoi tessellations can be based on shared edges as shown in Figure 4: cell 258 has neighbors 261, 264, 266 and 274, while cell 266 only has one neighbor, that of 258.

CA models have also been developed in 3-D and are sometimes referred to as voxel automata. In such models, cells are organized into identical cubes or voxels, and the Moore and von Neumann neighborhoods are extended in the third dimension. The predominant area of application has been in computer graphics, such as the modeling of clouds in flight simulators. However, there are a number of 3-D CA models developed to explore geographical problems, such as the infiltration of water to that of river deposits (Karssenberg and De Jong 2005).

Applications of CA

CA models did not begin to feature much in the geographical literature until the 1990s. That is not to say that CA models were not being developed before that time. Some of the earliest models were developed in the 1960s and 1970s. For example, Chapin and Weiss (1968) developed a cell space model to explore urban growth in Greensboro, North Carolina. While not adopting the term CA, their model used a grid to represent the settlement, and the attractiveness of a cell to become urban was based on adjacency relationships. With a CA-like model that generated a movie of growth in the Detroit area, Tobler (1970) showed how land-use could be defined using a neighborhood and how land-use could change over time. Such models, along with others, showed how one could model socioeconomic processes at a fine scale.
Figure 4  Voronoi tessellations of space where each polygon has a different number of neighbors based on a shared edge.

The rapid growth in applications relates to two broad advances within the sciences more generally. Specifically, the evolution of complexity science and the digital revolution, when computing capacity and graphics became more accessible to researchers combined with the release of remotely sensed imaging (Batty 2005). The CA model regular lattice structure is analogous to the raster data structure from many remotely sensed images and allows a one-to-one mapping between cells within the CA model and remote sensing. An example is the DINAMICA model (Soares-Filho, Cerqueira, and Pennachin 2002), which was designed to simulate landscape dynamics in the Amazonian tropical forests: its cell transition rules are based on spatial data pertaining to soil types, vegetation, altitude, slope, distance to rivers or distance to roads; the
CELLULAR AUTOMATA

model uses this information to explore land-use and land-cover change.

Many consider the incorporation of spatial data into CA models of geographical systems important because this integration provided the ability to have cells that are related to actual geographic locations. This is of crucial importance with regard to modeling geographical systems, as everything within a city, region or country is connected to a place. Furthermore, it allowed modelers to think about how objects (i.e., cells) and their aggregations interact and change in space and time. For geographical information systems (GIS) users, it provided the ability to model the emergence of phenomena through individual interactions of features within a GIS over time and space. Moreover, some would consider this linkage highly appealing in the sense that while GIS provides us with the ability to monitor the world (i.e., land cover), it provides no mechanism to discover new decision-making frameworks, such as those that can be explored through a CA model by applying rules to cell states. Moreover, the use of spatial data within CA models also allows researchers to validate and calibrate their models. Several validation and calibration techniques exist; readers are referred to Pontius et al. (2008) for a detailed discussion of these techniques, as it is beyond the scope of this entry (see also Validity and verification).

The flexibility offered by CA has resulted in this technique being used across the spectrum of geography: from that of exploring the physical world to that of exploring the human world and anywhere in between. For example, representative applications of where CA models have been developed to explore social science issues include the emergence of political actors, segregation, social interaction, and traffic dynamics. In the physical arena, CA models have been developed to explore geomorphological processes, groundwater flow and the contamination of soils, earthquakes to that of the spread of diseases, and the spread of fires. Perhaps the largest area of applications within the geographical community is that of land-use change. CA models have been developed to explore deforestation due to pressure from farming to that of exploring the re-growth of forests (Soares-Filho, Cerqueira, and Pennachin 2002) to that of urban growth. The popularity of CA in this area is due to the fact that to truly understand and explore land-use change it is necessary to capture both temporal and spatial dynamics of such change, which is a movement away from past generations of models, which focused on equilibrium outcomes rather than on their dynamics and which assumed that land-use change processes were well behaved (Benenson and Torrens 2004).

With respect to geographical modeling, CA models represent a significant improvement on previous generations of simulation models: they are spatially implicit while contemporary models generally conceive of space in relative terms (e.g., spatial interaction and gravity models, econometric models, and location-allocation models). CA additionally treat individual entities or objects at a microspatial level and as temporally dynamic, embodying processes that do not imply any equilibrium end state, and reflect simulations based on local rules which generate development, one cell at a time, over many time periods, all of which capture notions from complexity science (Benenson and Torrens 2004). With respect to defining transition rules, multiple statistical and nonstatistical methods have been developed. For example, Clarke and Gaydos (1998) used a Monte Carlo method, while logistic regressions are favored by others such as Verburg et al. (2002), and nonstatistical methods for defining transition rules include artificial neural networks or particle swarm optimization (readers are referred to Liu and Feng (2012) for further discussion).
However, as with all modeling approaches, CA models have their weaknesses. One is their reliance on neighborhoods for the propagation of information, which inhibits action-at-a-distance from taking place and makes them unable to handle explicit spatial interaction between cells. Additionally, real-world neighborhoods come in many different shapes and sizes that may not map well onto the CA tessellation. Also, when modeling physical applications, care must be taken that the basic object being modeled is consistent with the physical processes involved. Another weakness of CA models, specifically in relation to geographical systems, is the inability of automata cells to move within the lattice in which they reside. It has been argued, for example that one can only go so far with representing urban development as fixed locations (Batty 2005). There is a need for mobile objects that can move between cells, for example, when dealing with mobile objects such as pedestrians, migrating households, or relocating firms. However, this limitation has been overcome using the cells just as locations in which the agents can move around and, more importantly, can communicate with other agents. For example, the FACS (free agents in a cellular space) models by Portugali (2000) show how important it is to consider mobility within the process of segregation.

As a result of these weaknesses, CA models applied to geographical systems rarely invoke the strict limits of CA outlined above. Researchers have adapted the formalism of CA to meet their simulation needs. For example, Clark and Gaydos (1998) relaxed the cell neighborhood assumption entirely, in that cells are chosen for development across the entire space without any constraints imposed by local neighbors. O’Sullivan and Torrens (2000) discuss adding several cell states to account for continuous change in land-use and demographic makeup, instead of purely discrete states (e.g., dead or alive). Another weakness of CA models is their homogenous state transition rules, which are applied to all cells in a way that limits modeling processes that vary over space and by individual, such as human behavior. While this is not an issue for many physical systems, it is an issue for systems where humans are involved.

Future research directions

In response to the various challenges faced in using CA, one area that is currently being investigated is the linkage of CA with agent-based models (ABM) (Heppenstall et al. 2012). In practice, CA and ABM have often been applied separately to explore a wide variety of urban phenomena, but they are increasingly joined. For example, CA models are commonly applied to represent possible land-used changes, while ABM are often applied to crowd dynamics and traffic simulation. However, models are increasingly being developed using a combination of CA and ABM techniques to overcome some of the weaknesses identified above and the distinction between them is increasingly blurred. For example, cells may be granted some degree of agency in their state descriptions and are simply reinterpreted as artificial agents and/or agents are imposed on top of a CA layer, while simulated agents are interpreted as responding to average cell conditions and are able to move location. This combination of CA and ABM results in the continuum between the two approaches narrowing and, as such, these models are better described as agent-based models operating in cellular space (CS) models rather than pure CA models (Batty 2005). By combining the two approaches, the entire range of action and interaction effects relevant to geographical systems can be accessed, for example, action-at-a-distance. Additionally, by granting
CA models some degree of behavior, decisions can be taken account of; for example, in a CA model, it might be assumed that a land cell will be converted from rural to urban if its surrounding cells are all urban. However, ABM allows the behavior of individual cells to be considered. For example, if the land cell owner does not desire to sell the land cell to a developer, the land will not be developed. This individual behavior is often missing in CA models of urban growth.

One approach that uses this combination is that of “geosimulation” (Benenson and Torrens 2004), which stresses the importance of studying space when seeking to understand our environment. These involve problems where nonfixed objects (e.g., people or cars) are located on fixed objects (features such as houses or roads) allowing for the simultaneous processing of immobile and mobile objects, at the same time directly accounting for spatial relationships between various types of urban and nonurban objects, revealing the emergence of spatial patterns at higher levels of urban hierarchy.

Summary

This entry has introduced CA models, presented its history with respect to geographical systems, discussed its application domains, and highlighted future directions of research. Readers wishing to explore the topic further are referred to Benenson and Torrens (2004), Batty (2005), and Wolfram (2002), whose books give further reviews of CA principles, models and their applications.

Census geography

Wardlow Friesen
University of Auckland, New Zealand

The term “census geography” is used to define broad issues of the implementation, analysis, and application of a census and related issues of its political, social, and economic implications. Comprehensive censuses are largely a phenomenon of the eighteenth century onward, but the history of census-taking goes much further back, probably to as long ago as 6000 years. The earliest censuses were taken for the purposes of military conscription, labor recruitment, and taxation, and were carried out in various early civilizations including China, Egypt, Babylonia, and Rome. A more recent census was the Domesday Book of 1086 in England and Wales, which involved the enumeration of each landowner according to the value of the land and livestock they held, for taxation purposes.

The “modern census” is said to have started with the 1749 census of Sweden, although a few earlier censuses had some modern attributes. The ideal modern census is complete, accurate, and simultaneous. Completeness involves an enumeration of the whole population. It also implies the collection of information on a range of variables for individuals and usually households. By the end of the nineteenth century most of the countries of Europe, as well as the countries of significant European settlement, had implemented modern censuses. Through the nineteenth and twentieth centuries some colonial powers initiated censuses in their colonies, and by the end of the twentieth century most nation-states had a census. International organizations are also involved in census-taking, with the United Nations recommending a standardized range of core variables; in many countries significant logistical input is provided by the United Nations Fund for Population Activities (UNFPA). In recent years, a number of countries, especially in Europe, have stopped taking full enumeration censuses in favor of other types of data collection, including censuses based on a sample of the population and population registration systems.

The functions of a modern census are rarely related to the earlier purposes of conscription and taxation, but rather are undertaken to promote the wellbeing of national populations. In some democracies based on universal suffrage and “one person one vote,” including the United States, Canada, and New Zealand, the census has a constitutional role in facilitating the drawing of equitable electoral boundaries. In virtually all countries, census functions include the provision of information for an understanding of the social, cultural, and economic characteristics of the population, as well as to facilitate the planning of systems of health, education, labor force, transport, and other services.

With the focus of contemporary censuses on the wellbeing of the population, demographic and socioeconomic analyses are central. Much demographic analysis of fertility, mortality, and migration is dependent on census data. In countries that have comprehensive birth and death registration systems, vital rates are partly based on compulsory registrations, but are still dependent on census data to establish base populations for the calculation of rates. In many less developed countries such registration systems
are absent or inaccurate, so determining rates of fertility and mortality are largely dependent on census analysis. A census also provides data on many contingent variables, which can be analyzed in conjunction with data on vital rates. The analysis of international migration, for example, is dependent on census data as well as other data such as arrival and departure data and immigration visa information. Besides detailed empirical studies, censuses tend to be the main source of data on migration outcomes, through the analysis of birthplace and ethnicity data in conjunction with other variables related to economic activity, occupation, income, housing tenure, and many other variables.

The determination of patterns and characteristics of internal migration is largely dependent on census data, except in those countries that have comprehensive population movement registers. Census questions about residence at a previous point in time provide at least a snapshot of internal movement. If a census does not ask a previous residence question, the residual method of migration analysis can be used, whereby changes in the age–sex structure of an area (combined with birth data and life tables) between censuses can be used to infer the age–sex characteristics of net migration.

Demographic information produced in censuses is particularly important for planning through population projections at national, regional, and local levels. These usually involve the incorporation of estimated undercounted populations and the use of assumptions based on past trends and forecasts of economic and other conditions in the future.

Population geographers and others are involved in a great range of socioeconomic analyses based on census data on educational achievement, occupation, income, housing tenure, ethnicity, gender, and migrant status, among other variables. Methods of analysis include descriptive cross-tabulation, correlation analysis, geospatial analysis, and the creation of multivariate indicators of wellbeing or deprivation.

Resources and services provided by governments are often allocated on the basis of population distribution and characteristics determined from a census. In some cases, like the United States, allocation has a legislative basis, while in others, this mechanism is less formal. Thus, if a population undercount occurs, resources may not be equitably distributed. Although most censuses aspire to 100% coverage of the population, there is no evidence that any census has ever achieved this goal, despite penalties for nonparticipation. Impediments to full enumeration include the suspicion of some, including undocumented migrants, that census data may be passed on to other government agencies; the rise of libertarian or anarchist movements averse to government in general; the difficulty of locating highly mobile or homeless people; and the reluctance of people to fill out a sometimes lengthy form.

Post-enumeration surveys in countries with effective census systems have typically shown undercounts in the range of 2–4% of the population; however, they also show that the undercount is age, gender, and ethnically selective, so undercounting among young males in minority ethnic populations may be three or four times that of other groups. In general, minorities in large cities are undercounted, as are indigenous groups. In the United States this has been a political issue after every census, since funding for education, health, and other services is dependent on census counts. In addition, the electoral representation of minorities is negatively impacted in many countries.

The late twentieth and early twenty-first centuries have seen the convergence of two arguably contradictory directions in census geography: the move away from comprehensive traditional
full enumeration censuses by some governments despite the development of new technologies that have much greater potential for improved and cost-effective census-taking and analysis.

In the latter part of the twentieth century, new technologies have allowed much more comprehensive processing and analysis of census data than had been possible earlier. Computerization has permitted a much greater range of variables to be collected and analyzed, and geographic information systems (GIS) have aided enumeration procedures, as well as spatial analysis and display. Most censuses through the twentieth century involved door-to-door enumeration, often involving at least two visits by enumerators to each household to ensure compliance, but in some countries e-censuses involving online enumeration are increasingly being adopted, usually resulting in significantly reduced costs.

Despite these new potentials, some authors have claimed that it is the twilight of the traditional census because of the high cost (especially of enumeration), privacy issues, declining response rates, and the need to obtain more timely and regular data, especially when some censuses are conducted only every 10 years (Coleman 2012). The primary alternative has been the analysis of databases based on population registration, sometimes combined with other administrative data. These have been in use for several decades in the countries of Scandinavia, which have adapted existing registration systems, and in Japan. These countries also have populations that are accustomed to registration and which largely accept this level of monitoring. Most of the other countries that have moved away from the traditional census are in Europe, with only a few elsewhere.

Kukutai, Thompson, and McMillan (2015) counter the twilight argument by pointing out that only 12 out of 241 countries (including territories) did not have a census of any sort in the 2010 round of censuses (this number includes censuses based on registration). Further, the great majority of the world’s countries have taken a full enumeration census in recent years, including some that had never taken a census before. The reasons for this include greater international support for census-taking and analysis, the reality that most countries do not have comprehensive systems of registration or extensive administrative data, a sense that the use of such systems would be even more intrusive than a confidential census, and the realization by politicians and planners that the collection of a comprehensive range of census variables is critical to future planning. Another complicating factor is that some variables are not collectable or are not usually collected in registration systems. These include ethnic self-identification, languages spoken, household and family composition, and variables relating to services such as mode of transport to work or school.

Even if the traditional census does not disappear, there is the possibility that its extent and quality may be compromised in some cases, with Canada being an example. At short notice, and apparently for political reasons, the compulsory long form of the 2011 Canadian census was abandoned in favor of a short form with a limited number of questions, supplemented by a voluntary National Household Survey (NHS). The response rate to the NHS was only 69%, causing academics, planners, and others dependent on census data to suggest that the resulting data are of limited use because of the skewed nature of the sample (Walton-Roberts et al. 2014).

These changes in census methodologies and their resulting data outcomes are a challenge not only for population geographers and others in terms of data analysis, but also for many in relation to their role as advocates for the ongoing collection of census and other data to allow for
CENSUS GEOGRAPHY

robust academic research and effective planning decisions.

Central business district

Peter O. Muller  
*University of Miami, USA*

The downtown central business district (CBD) of a city consists of its core concentration of largely nonresidential activities that is endowed with superior accessibility to the surrounding urban area it serves. Prior to the last third of the twentieth century, that reach was dominant throughout the metropolis. But over the past half-century, that tributary area has contracted to mainly encompass the central city as spatial restructuring has turned the American city (especially) inside out, forging a new polycentric urban form anchored to a suburban constellation of new metropolitan-level centers as well as the downsized CBD.

The origins of the central business district can be traced back at least as far as the agora that formed the nucleus of the ancient Greek city, which in turn evolved from the central activity cluster that probably marked urban settlements since they first appeared more than 5000 years ago. Nonetheless, formal CBDs did not emerge until the mid-nineteenth century, when innovations from the Industrial Revolution triggered the modern age of urbanization by unleashing a massive migration from rural areas into the newly forming manufacturing cities. Swiftly, the loosely organized networks of small preindustrial cities mutated into a national-scale urban system, connected by an expanding web of increasingly efficient railroads that linked raw material sources, producers, and markets. Internally, the transformation of the larger nodes of the new urban system was just as dramatic, particularly the spatial reorganization of its economic activities.

A key component of that restructuring was the expansion and differentiation of urban employment, enhancing the role of centrality in the nascent industrial city that facilitated the rapid emergence of the CBD after 1850 (Ward 1971: 85–102). The transportation-cost savings of a central location were most advantageous not to the operators of factories, but to the producers of commercial and service activities that accompanied the rise of the industrial urban economy. The latter outbid all other land uses in the competition to locate at the most accessible node where the city’s trolley (and, later, subway and commuter rail) lines converged, sorting themselves into increasingly specialized retail, warehouse, and financial districts. Administrative activities also grew alongside them, and by 1900 had evolved into modern office complexes as improved elevator technology enabled the proliferation of skyscrapers that added significantly to the available floor space for business when the CBD’s density approached its maximum.

During the first half of the twentieth century, CBDs dominated the metropolitan areas they centered. (The term “central business district” was coined in the 1920s by core-city civic leaders to assert the primacy of downtown as new highways began to spawn commercial centers in the suburbs.) But, by 1960, the steadily strengthening forces of decentralization, propelled by the automobile and new superhighway networks, were shaping the rise of an outer suburban city that surrounded an aging central city still dependent on its declining public transit systems. In short order, the CBD’s exclusive hold on region-wide centrality disappeared as accessibility became a
ubiquitous good – now almost any location on the metropolitan freeway network could easily access the entire urban area. By the 1970s, the metropolis was both turning inside out and spatially reorganizing as new metropolitan-level centers – edge cities – mushroomed in the suburban ring at major freeway intersections, and the monocentric urban form of the past gave way to a new polycentric metropolitan structure that has been maturing ever since.

The consequences of these changes for the CBD over the last half-century have been substantial. From the late 1950s into the 1980s, downtowns stagnated as the central cities entered a new (and still continuing) era of economic and population decline commensurate with their reduced role in the restructuring metropolis. But the core city’s civic leaders did not give up on the CBD, and by the 1990s a turnaround was underway. An important driver was the “back to the city” movement of young professionals, which emphasized downtown-area residential opportunities, especially the gentrification of CBD-bordering neighborhoods. At the same time, the livability of the city center was being enhanced in numerous ways, both to entertain its new residents and to attract visitors from the rest of the metropolis and beyond. The layout of the CBD now began to change as well, with the long-standing office–financial–hotel–retail complex (increasingly marked by reconstructed buildings) forming the core, surrounded by a revitalizing frame containing myriad parking facilities, new entertainment and convention districts, and expanding medical and government clusters (Hartshorn 1992: 337).

By the 2010s, this core-frame pattern had become established in several major central cities (leading the real estate and revitalization booms at mid-decade were the CBDs of Denver, Seattle, and Chicago). Yet still unclear was whether these successes amounted to a true renaissance of the city center or merely a temporary reversal in the long-term economic and demographic decline of the United States’ old metropolitan cores. Taking no chances, many CBDs vigorously continue their quest to reinvent themselves – in fact, these days the very term “central business district” has mostly been replaced by “downtown.” This movement has fascinated researchers across the broad spectrum of urban studies, and a sizable body of scholarly literature has accumulated since 2000 to document the rebirth of downtowns. Apart from significant work on such specific topics as gentrification and homelessness, however, the spatial generalization and theorization of downtown redevelopment remains a research frontier in its formative stage.

The most widely cited and comprehensive treatment of the subject continues to be Larry Ford’s (2003) America’s New Downtowns: Revitalization or Reinvention?, a classic study of landscape change, interpretation, and conceptualization based on meticulous fieldwork. Concluding that the old CBD has evolved into something more substantial than a “postmodern downtown of consumption and display” (the superficial label used by many researchers), it provides the foundation for a new urban geography of the city center, the cornerstone of which is Ford’s (2003, 308–310) composite model of downtown spatial organization. Incorporating the key features that mark post-1990 downtown expansion (new attractions to draw in people; restoration of local historic districts; residential growth; and transport innovations), the model consists of seven major elements: (i) the spatial form of downtown, especially its degree of linearity; (ii) theme districts (new entertainment facilities, cultural centers, sports venues); (iii) enhancement of physical amenities; (iv) new commercial-building “footprints” as walls and gates; (v) competition between private and public spaces; (vi) new residential and recreational
spaces to fill vacated commercial properties; and (vii) making downtown a family-oriented event center.

All of these elements continue to be vital for monitoring and understanding the processes that are transforming the heart of the old metropolitan core. During the decade since the composite model was first proposed, it became apparent that the forces of globalization constitute yet another element in the reshaping of downtown. An overriding impact of globalization on the metropolis has been the increasing fragmentation of people and activities within central cities and suburban rings. Thus transnational migration intensifies the diversity (and internal spatial differentiation) of the metropolitan social mosaic, while economic activities increasingly attuned to global networks localize in state-of-the-art business centers – especially in and around suburban edge cities. As this process unfolds, the implications for big-city CBDs are enormous. To date, most have demonstrated not only resiliency but also a commitment to compete for their share of the action, nurturing continuity when possible but always open to new opportunities to reinvent themselves.

Central place theory

Peter W. Daniels  
*University of Birmingham, UK*

One of the notable features of patterns of settlement or (for example) shopping districts within cities is a sense of regularity in their spacing and size. Smaller groups of shops or freestanding settlements are more numerous than larger shopping centers or settlements. Moreover, the larger entities are generally spaced farther apart than the smaller ones. During the early twentieth century such attributes in the spatial organization of places did not go unnoticed by a German geographer who was intrigued by settlement patterns he had observed in southern Germany. Walter Christaller (1966/1933) developed a theory concerning the size and distribution of what he termed “central places” (settlements). Central place theory seeks to account for how different types of settlements (differentiated by size and function) are located in geographical space.

To appreciate the value of central place theory, it is useful to consider the functions performed by settlements that can range in size from a very small group of homes with few people to many thousands of homes and millions of people alongside, for example, numerous business, administrative, and cultural activities and buildings. Settlements exist not only to support people’s needs for goods and services but also to provide goods and services for those nearby; each settlement has a market area and is centrally located within it; the reach of the settlement is determined by the number and different kinds of goods and services that it provides. Settlements supplying the most goods and services are described as higher-order centers, while those supplying the least are the lowest-order centers. It follows that, because the lowest-order centers possess a very limited range of functions, they will tend to be used by those who are nearest. Some of the functions located in the larger places will be more specialized and used less frequently, but these will command a much more extensive geographical market.

The purpose of central place theory is to provide a universal set of rules for explaining the location, hierarchy, role, and function of settlements in geographical space (Hsu 2012). It can be used to understand historical and contemporary patterns of settlement distribution. The starting point is a set of simplifying assumptions that can be used whenever and wherever the theory is put to the test. For the purpose of his theory, Christaller assumed that the pattern of settlements develops on a flat, limitless, and homogeneous surface (an isotropic plain); that populations are uniformly distributed across this surface; that resources are evenly distributed; that consumers of goods and services have the same income levels and purchasing power, and behave in the same way as consumers; that perfect competition exists between sellers who all seek to maximize their profits; that only one mode of transport exists which is equally easy to use in all directions; that the cost of transport uniformly increases with distance covered; and that the pull power of any one supplier of a good or service steadily declines as distance to a user increases.

Using these simplifying assumptions, Christaller introduced two concepts to translate their effects into settlement arranging. First, the concept of
Central Place Theory

Range is the maximum distance users of goods and services are prepared to travel to reach them. This distance varies according to the type and frequency of use of different types of goods and services but a point is reached at which the cost outweighs the need or benefit. The second concept, threshold, is the minimum number of users (or market) for a good or service that is required to make it viable. With the range and threshold varying according to the type, size, and specialization of a good or service, it becomes apparent that every good and service cannot exist everywhere across the isotropic plain. Consequently, central place theory posits that a hierarchical system of centers will emerge, with those at the base of the hierarchy closest together and offering a narrow range of frequently used functions (such as newsagents, village stores, and post offices) and centers at the top of the hierarchy providing a larger range of goods and services (as well as all the frequently used functions) that are reached from longer distances and less frequently, and are therefore dependent on a larger market (population). Examples include fashion stores, jewelers, department stores, photographic equipment suppliers, and car dealerships.

It remains to consider how these assumptions and key concepts shape the distribution of settlements. Christaller started with the assumption that each settlement offering the same order of goods and services will have the same circular market area delimited by the range and threshold. From an examination of the overlap of market areas for settlements at different levels in the hierarchy, Christaller concluded that the most efficient pattern for serving markets with minimum overlap would take the form of a triangular/hexagonal lattice. Three different settlement layouts were identified: the marketing ($k = 3$) principle, the transport/traffic ($k = 4$) principle, and the administrative ($k = 7$) principle (Figure 1). Take, for example, the $k = 4$ principle which involves the minimization of the length of roads connecting central places at levels of the hierarchy of settlements. The highest order center (1) has a market area that includes half of the market area of each of the six neighboring lower-order centers ($0.5 \times 6 = 3$). These lower-order centers are located on the sides of the hexagons around the higher-order settlements and this creates the most efficient transport network.

There are other ways in which the principles of central place theory can be used to account for the pattern of settlements. Rather than working downward from the highest-order central places, August Lösch (1954) started with a system of self-sufficient farms (lowest order) that were distributed regularly in a triangular-hexagonal pattern. From this smallest scale of economic activity, he worked upward, using mathematics to derive a number of central place systems that also included the three systems identified by Christaller. This analysis addressed Lösch’s concern that the three options derived by Christaller paid too much attention to location and not enough to how the pattern of centers would maximize the benefits to consumers rather than to the distributors of goods and services. To Lösch, his method created a distribution of settlements as an ideal consumer landscape where the requirement to travel for any good or service was minimized and profits were held level.

![Figure 1](image.png)
The assumptions used in central place theory for explaining patterns of settlement are actually difficult to replicate in the real world. Few landscapes are uniformly flat; physical features such as lakes, estuaries, and mountains distort transport routes and costs. Also, a population’s socioeconomic attributes are unlikely to be homogeneous; some households will have one or more cars, others will only have access to public transport; some households will have higher incomes than others. Finally, households can display behavior that does not necessarily conform to the principle that they will travel to the nearest appropriate center for a good or service. This tendency will also be influenced by real or perceived differences between centers in the quality, cost, or even experience of shopping. The role of location and cost of travel is therefore compromised by numerous other factors. Set against these limitations, the increasingly ubiquitous use of information and communications technology for online retailing, banking, or arranging home service deliveries (ranging from groceries to vehicle tire fitting) has dramatically changed the extent to which the assumptions of central place theory can be fulfilled.

This is not to suggest that central place theory is not useful. This was recognized very early on by the Nazis; they hired Christaller to develop a plan for repopulating the depopulated areas of Germany and Poland using the principles of central place theory (Barnes and Minca 2013). Many geographers, especially during the period 1950–1980, set out to validate the theory by examining real-world patterns of settlements (Berry 1967) or the distribution of retail centers within cities (Johnston 1966). Its principles have also been widely utilized for planning the location of public services such as hospitals or commercial shopping centers. The relative absence of central place theory in recent research does not reflect its demise; rather, it is probably the case that, since the 1990s onward, its tenets have been implicitly, rather than explicitly, utilized in activities such as planning for the location of new shopping centers, office parks, new towns, or new transport infrastructure. Some have recently suggested that it is time for the re-emergence of central place theory (Mulligan, Partridge, and Carruthers 2012).

Change detection, in the geospatial context, is broadly defined as the identification and characterization of the effects of natural and anthropogenic processes in a landscape. Examples of landscape change include conversion of agricultural land to residential areas, and shifting forest species composition due to climate change. Change detection is important in a wide range of applications, such as urban planning, wildlife habitat monitoring, and carbon flux estimation. It is difficult to imagine a natural resource or environment-focused application that does not depend, in some way, on knowledge of the changing composition of Earth’s landscapes.

Change detection can be accomplished with many types of geospatial data, including field measurements, land-cover/use maps, and various layers such as road networks, cadastral data, and elevation models. However, the most commonly used data type in change detection is imagery acquired from aerial, satellite, and in situ sensors. Advantages of imagery for change detection include the many sensor options available in: (i) spatial resolution (i.e., pixel size), from submeter to multiple kilometers, allowing for studies at different spatial scales of interest; (ii) temporal resolution, allowing for flexible revisit times based on the needs of the application; (iii) spectral resolution, with existing and planned sensors offering sensor bands in optical wavelengths suitable for varied terrestrial and marine applications; and (iv) radiometric resolution, with newer sensors such as Landsat 8 able to distinguish fine gradations in reflectance.

Landscape change results from a variety of activities and processes. A distinction is often made between changes in land cover, that is, the landscape element that is apparent to the viewer or sensor (e.g., forest or water) and land use, or human activities that affect the appearance of a landscape (e.g., agriculture or silviculture). However, change can occur in many forms. The causes of some changes may be readily apparent, such as the construction of a lumber mill in a formerly forested area. Other changes may have multiple or uncertain causes, such as a forest fire: Was the fire the result of a lightning strike or a poorly tended campfire? Since it may be difficult to determine whether a change is natural or anthropogenic, the characteristics of the change, as measured using the input data, are of primary importance.

An important determination affecting the accuracy of both the detection and the characterization of landscape changes, regardless of their causes, is whether they are discrete or continuous. A discrete change is one that results in a new land-cover label for an area. For example, in the construction of a housing development in a former crop field, the old label of “agriculture” or “row crop” could be replaced with “low density urban” or “house,” depending on the scale and thematic detail of the resulting map. In contrast, a continuous change is
one in which the thematic label assigned to an area is constant, but change nonetheless occurs. For example, as a forest ages the crowns of its trees may grow together, resulting in an increase in crown closure and a decrease in visibility of the understory or ground vegetation. The label “forest” would remain, but maps showing crown cover percentage as a thematic variable would require updating. Complicating factors in discriminating discrete from continuous change include the lack of temporally sufficient data to identify a continuous change, and, given enough time, a continuous change may cause a discrete change. For example, vegetation in a drying wetland may gradually be replaced by upland species, resulting in a discrete land-cover label change from “wetland” to “upland.” Annual imagery may be suitable for identifying and characterizing such a continuous change, but images acquired several years apart may be useful only for mapping the discrete change.

In a properly designed change detection study, the change identification and characterization goals are specified such that available data and methods used can support those goals. In a research environment often characterized by limited funding and short duration projects, one rarely has the ideal dataset to conduct a given change detection study. Thus, comprehensive planning must be undertaken to ensure that maximum utility is extracted from the resources that are available. Land-cover label definitions must be clearly specified so that ambiguity about what constitutes a change is minimized. The types of changes to be mapped, for example discrete versus continuous, must be described. The change-mapping goals must be appropriate for the quality and spatial, temporal, spectral, and radiometric resolutions of the input data. Finally, the methods used must be appropriate for the changes to be mapped.

Change detection and visualization methods

Many change detection techniques have been developed and studied since the mid-1970s (Singh 1989; Coppin et al., 2004; Lu et al., 2004; Jensen 2004). These techniques have been generally divided into two groups: preclassification change detection and postclassification change detection.

Within the preclassification change detection (pre-CCD) group, techniques are generally pixel-based, that is, operating on one image pixel at a time. These techniques analyze multitemporal images on a pixel-by-pixel basis and do not take into consideration spatial context of the surrounding pixel. Examples of pre-CCD pixel-based techniques include: (i) multidate composite image, (ii) image algebra, and (iii) transformation band.

Multidate composite image change detection combines images from two or more dates with the purpose of creating one multilayer, multidate image, and extracts any change information from the composite image. A common example of detecting changes with this technique is through the use of variation in pixel values for the different dates to transform the input image into change and no-change pixel groups.

Image algebra techniques use arithmetic operations on the spectral values, along with a threshold value to determine changed areas. Common examples of techniques within this category include: image differencing, image regression analysis, image ratioing, vegetation index differencing (e.g., Normalized Difference Vegetation Index, a measure of vegetative land cover), and change vector analysis. The majority of these techniques are easy to perform and understand. The most common pre-CCD technique used within this category is image differencing in which one date of imagery is
subtracted from another to produce a “difference image” that highlights pixels for which the spectral values have changed. The main difficulties with pre-CCD are that these techniques do not provide from–to class label information and they require the selection of a suitable pixel value threshold to detect changed areas. For example, in the image-ratioing change detection technique the ratio of the pixel values is first computed and then a threshold is applied to the ratio to discriminate change from no change.

Transformation band change detection refers to the use or manipulation of color or multispectral band transformations. The following are examples of techniques used within this category: principal component analysis (PCA), Kauth–Thomas transformation, Gramm–Schmidt (GS) process, color invariants, and chi-square transformations. The most commonly used techniques in this category are PCA and K–T because of their relative simplicity and wide availability in commercial remote sensing software. The main advantages of this pre-CCD category are the reduction of data redundancy between image spectral bands and the maximization of image information shown in derived components. These techniques suffer from limitations similar to those of image algebra methods.

Pre-CCD techniques are particularly useful for identifying changes rapidly and for determining the magnitude of changes through comparison of image pixel values over multiple dates. The main challenges with pre-CCD techniques are that the change detection results do not describe changes in a particular class (e.g., urban or forest) and the computed pixel differences can be affected by a range of factors including sensor calibration, atmospheric conditions, illumination and view angle, and groundwater and soil conditions.

Postclassification change detection (post-CCD) techniques can be grouped into two categories: pixel-based and object-based image analysis (OBIA). In general, these techniques use thematic classifications of the input images produced using a classification technique (e.g., supervised or unsupervised classification). Once the images are classified, the class labels for each pixel or object are compared to determine whether a change has happened.

Pixel-based post-CCD techniques are most often used with coarse to moderate spatial resolution imagery. Class labels for these relatively large pixels are compared to determine from–to change. For high spatial resolution imagery, and increasingly also for moderate resolution imagery, OBIA methods are more commonly used. In OBIA change detection (OBCD; Chen et al., 2012; Hussain et al., 2013), the first step is to create meaningful image objects through a process known as image segmentation, in which spectral, contextual, shape, texture, and ancillary information is used to group spectrally homogeneous neighboring pixels into groups called objects (Blaschke 2010). These objects can then be classified in accordance with an appropriate system of class labels. The labels are compared over multiple dates to determine change.

The main advantage of post-CCD is the provision of class-specific from–to information for each change. Disadvantages include a lack of information about the spectral magnitude of changes and dependence on the accuracy of the input classifications. The accuracy of the change map can only be as good as the input classifications. Errors in any classification will lead to errors in the change map.

The visualization, or presentation, of change results is an important component of any change detection study. The following methods are generally used to represent the change detection results: animations, difference or change maps, and change matrices. The animation technique is a qualitative tool that helps to display a set of images in sequence. Difference or change
maps allow the visualization of from–to changes for different years. For example, areas could be highlighted to represent changes from one class to another.

A change matrix provides a tabular representation of from–to change information for classes of interest. The matrix rows represent one classification date and the columns another. The cells of the matrix then show either the number of pixels or area that have changed (off-diagonal elements) or have remained the same (diagonal elements) between the two dates. For example, in a postclassification comparison analysis using a satellite image from 1990 and another image from 2000 for the same area, and using five land-cover classes, the matrix of change will contain the following information: the total area for every class in year 1990 and 2000, and a detailed distribution of how much of the original area for each class has either changed into another class or stayed the same. This matrix of change technique reveals the reduction or increase of specific land cover classes in a quantitative and straightforward way.

Validation and complications

Change detection analyses require proper data selection and postacquisition processing steps to minimize errors in the resulting change map. Data acquired by the same sensor are assumed to have similar scale and spatial resolution. Thus preprocessing steps are essential for accurate registration and appropriate temporal scales between the analysis dates. Geometric processing, atmospheric corrections, and radiometric normalization are conducted postacquisition and prior to comparing multitemporal images. These procedures are used to correct horizontal registration, adjust for atmospheric effects and cloud cover, and normalize pixel values across all time intervals in the analysis.

Geometric processing, in which the geographic coordinates of a feature on one image are matched to the same coordinates in an overlapping image, is accomplished using a reference image or ground control points, resampling method, and elevation data. This process minimizes positional errors by adjusting image pixels to the same location based on the reference image or ground control points. Elevation data are integrated to reduce displacement from the sensor passing over variable terrain and causing changes in the scale of ground features closer to or further from the sensor. Root mean square error (RMSE) provides a useful metric for comparing positional accuracy between images. This metric describes the amount of horizontal offset between several sample locations in the reference data and the geometrically corrected image. Historical data sources may also require a geographic transformation to a common projection, coordinate system, and datum prior to producing a change map. The transformation provides an updated reference for the geographic position of overlapping images and the features on them such that the same coordinates and measurement units are applied to the analysis.

The view angle, or the angle from the sensor to a geographic position within the sensor’s field of view, should be considered when selecting images for comparison. View angle is directly related to areas of occlusion from building or tree lean and shadows from varying solar azimuth and zenith angles. Optimally, images used for change detection should have the same, or very similar, view angles.

Cloud cover, atmospheric moisture, and haze should be assessed prior to the change analysis and addressed by removing or replacing clouded and shadowed pixels. Atmospheric corrections are necessary for reducing attenuation from
haze or humidity. Radiometric normalizing per scene will provide similar spectral characteristics between multiple dates of imagery, provided the acquisition dates and phenology are similar. This process adjusts individual pixel values for the images by reducing noise from atmospheric conditions or sensor errors.

Vegetation, agricultural, and urban phenology are important considerations when selecting image dates. Anniversary dates minimize the impact of vegetation phenology where different development stages modify image pixel values. Depending on the change detection method used, such variations may result in errors within the change map. Phenology must be considered when determining the temporal scale for assessing change; short temporal scales might underestimate change in general, while longer temporal scales might underrepresent change for plants that regenerate over shorter life cycles. Agricultural growth stages, the cycle of field preparation, planting, crop growth, and harvesting should correspond to the dates of analysis such that change is not falsely detected using images acquired during the growing season and compared to images acquired before the growing season or postharvest. Urban greenness changes, such as the transition from low-density to high-density development, could be underestimated over longer temporal scales where the change occurs in a dispersed pattern rather than as a continuous increase along the urban fringe. Weather events preceding acquisition must also be considered, as increased precipitation or drought conditions will impact water/wetland area, soil moisture, and vegetation greenness. Such weather-caused changes may be confused with class label change.

Spatial resolution and radiometric resolution become concerns when change detection involves data from multiple sensors. Change maps derived from sensors with different spatial resolution limit the analysis to the coarsest resolution such that change detected at a finer scale will be aggregated into a larger unit (Walsh, Butler, and Malanson 1998). Radiometric depth frequently varies between sensors and must also be adjusted so that the bit depth matches between datasets. Images acquired with the same spatial resolution but different radiometric resolution may lack sufficient comparability for identifying subtle differences between features. A forest stand surrounded by shrubs might appear discrete in images with high radiometric resolution while the same area in an image with lower radiometric resolution might appear as more transitional between the vegetation types. These concerns should be addressed using the appropriate image-processing tools prior to analysis and be considered when assessing the accuracy of the change map or the resulting classifications used for postclassification change detection.

Assessing the accuracy of remotely sensed data has proven challenging as image resolution and classification procedures have advanced in recent decades. These challenges have been well documented and discussed in the literature (Congalton and Green 2011; Olofsson et al. 2012). Accuracy assessment and quality control and quality assurance procedures specific to the intended use of the change map should be followed.

Accuracy assessments based on reference data from photo interpretation or ground-based observations provide error metrics for determining the level of uncertainty associated with a change map. However, accuracy assessments for individual classifications are insufficient for assessing the accuracy of the change map and should only be considered for the accuracy of their corresponding classification. Misclassified features within one classification may be difficult to classify in images acquired at other dates, and result in compounding error in the change map.
CHANGE DETECTION

These errors may also extend to the reference data or mislabeled features in each classification. These uncertainties are inherited in the change map; however, registration errors, mixed sensors, and different spatial resolutions should also be considered when assessing the accuracy of the change map. Small horizontal offsets between dates that produce underrepresentation or over-representation of change require assessing the accuracy of the change map independent of the individual accuracy metrics for each date. Photo interpretation or repeat field sampling should be conducted to assess the accuracy of the change map.

Classification schemes also present challenges when comparing multitemporal results. A feature classified using different values or labels at one date compared to a subsequent date can result in false changes. Further aggregation of classes or conflicting descriptions of classes such as an area classified as agriculture at one date and pasture at another date might be identified as change when the only change is in the class label scheme or definitions of the classes. Classification schemes should be reviewed and redefined to a common scheme prior to performing analyses.

Applications

Change detection techniques can be applicable to a variety of fields. The following are examples of applications of change detection.

The use of remote sensing to examine deforestation is long-standing. A study by Hansen et al. (2013) used multitemporal images for mapping global forest change. A group of researchers led by University of Maryland scientists created the first global forest change map from 2000 through 2012. They used 654,178 growing season multidate Landsat 7 satellite images to show a global loss of 888,000 square miles of forest and a gain of 309,000 square miles of forest. Also, they discovered that the deforestation rate in the Brazilian Amazon has been reduced by half since the mid-2000s, as opposed to Indonesia where the deforestation rate has doubled in the same period. In another study, conducted by Guild, Cohen, and Kauffman (2004), pre and post change detection techniques were used for identifying deforestation and land-cover conversion. They used two images (1984, 1992) from the Landsat Thematic Mapper (TM) sensor to identify deforestation and cattle pasture formation in Rondônia, Brazil, employing two pre-CCD techniques and one post-CCD technique to identify changes in the forest and other land-cover areas. The two pre-CCD techniques were used to enhance differences between the forest and cleared and regrowth areas and to identify any overall. The postclassification technique helped them to quantify specific land-cover class changes. Over eight years, they found that the forest areas decreased by 11%, having been primarily converted to pasture, and that 7% was lost because of hydroelectric dam flooding.

Another common use is tracking the extent and condition of water bodies. A dramatic example of an environmental change detection application is tracking the rapid loss of the Aral Sea. This water body was once the fourth largest freshwater lake in the world. However, between 1973 and 2000 approximately 60% of the lake disappeared due to a large water transfer project which diverted fresh water to provide irrigation for cotton and food crops. Thus, a comparison of multiple dates of remotely sensed imagery could be used to identify the changes that occurred from 1973 to 2000. For a more quantitative analysis, a post-CCD approach could be used with satellite images to identify the conversion of specific classes including water and its conversion to other land-cover classes.
Given the increasing rates of urbanization in many parts of the world, studying such increases and their implications for urban planning issues such as infrastructure development, storm water flow management, and zoning is of great importance. Yuan et al. (2005) demonstrated a method to map landscape change in a major metropolitan area over 16 years using Landsat imagery. Their results indicated that urban cover had increased from 24% to 33% of the area, with some areas exhibiting a near-total conversion of classes such as agriculture to urban. Such information is of importance to planning and policy groups at all levels of government.

Change detection is also useful for monitoring hazards. For example, pre-CCD techniques and multiple images can be used to identify changes in the landscape due to drought conditions. Washington-Allen et al. (1998) provide an example in which a 15-year time series of Landsat images from 1972 through 1987 was used to evaluate the effects of drought on vegetation covers in the Bolivian Altiplano. They identified the different changes in vegetation cover due to drought using the image-differencing pre-CCD technique. Visualization change maps were used to show how all vegetation types were impacted by drought. The results indicated that nearly 90% of the vegetation types had not changed between 1972 and 1987. Furthermore, they found that the wet meadow vegetation type was the most resistant to drought conditions, which is a key resource for the agropastoral communities in the Bolivian Altiplano. This is a practical use of change detection techniques to discover information regarding vegetation species that are more resistant to drought conditions, which may be of use to local communities.

Geomorphologists use multitemporal imagery for identifying landscape change as a result of flowing water. Water flowing from an upland area in a watershed or catchment becomes channelized as it moves downhill and forms stream channels. The meandering or winding patterns formed by streams can be measured and monitored as the surrounding landscape is modified at varying time intervals by removing or depositing sediment and vegetation. These dynamic processes result in changes to the channel width, increasing or decreasing meanders, and new landforms such as gravel bars within the stream channel. Multitemporal data can be used to detect these changes over short time intervals in dynamic streams where loose sediments and varying flows cause semi-annual and annual changes, and for longer time intervals where the channel migrates across the valley floor and impacts natural and human areas. Images provide this view for individual stream processes and the network of streams as water moves over the landscape.

Geomorphologic change detection using imagery is more broadly applied to identify changes on the landscape and the resulting impacts on natural and anthropogenic environments. Multitemporal images have been used for viewing lateral changes such as channel widening from erosion that threaten human land uses, debris jams that might create temporary dams and flood infrastructure and agricultural land, and areas where sediment deposits have straightened the channel and present flooding hazards. Erosion, flooding, and deposition of sediments that alter the stream course reduce arable lands, threaten urban infrastructure, and change property boundaries. As a result, stream channels have been straightened and armored for moving water away from an area more quickly (e.g., reducing sediment deposits and flood risks) and for minimizing loss of land from erosion or shifting channels.

Finally, satellite sensors have provided data on human rights violations and humanitarian relief efforts. Civilian satellite imagery can be acquired...
on temporal scales that facilitate monitoring human rights violations. Darfur (Western Sudan) provides an example of using satellite imagery to map military conflict and human rights abuses. Sudanese militias moved into the Darfur region in 2003 and began attacking residents and destroying their villages. Individual homes were classified in an image acquired preconflict and compared to a classification based a postconflict image (Sulik and Edwards 2010). Sri Lanka provides another example of human rights violations that were detected using high-resolution satellite imagery. Satellite imagery spanning four days (May 6–10, 2009) were acquired following reports of mortar attacks on civilians. Analysts identified the position of the mortar attacks and the location where the mortars were fired from, thereby linking the attacks to military forces. These images were also used for identifying an increase in gravesites from casualties in an area identified as safe for civilians.

Summary

Change detection is an important and widely used technique across a range of disciplines. The benefits of change detection include flexible methods that can be customized to a particular application, quantitative estimates of change in land-cover/use categories of interest, and a synoptic view of a changing landscape that may be impossible to obtain in other ways. Care must be taken to ensure that the change detection methods used are appropriate for the study goals and input data.

Chicago School

Winifred Curran  
DePaul University, USA

Based at the University of Chicago from 1914 through the 1940s, and using the city of Chicago as its laboratory, the Chicago School sought to use deep ethnography in the form of detailed neighborhood case studies to develop larger, universal theories about the city’s growth and organization. Lacking an urban tradition of its own, geography looked to the theory and methods of the Chicago School of urban sociology to build the subdiscipline of urban geography. This theory was shaped by human ecology, the assumption that the city functioned as an organism, and thus, that this landscape’s organization was shaped by competition over space in the struggle for existence. It was highly influential in the development of an urban geography, especially among those who attempted to use quantitative methods to understand the organization of urban space.

The pre-eminent figure in the Chicago School was Robert Park. Park constructed his human ecology perspective of urban sociology on accepting his job at the University of Chicago in 1914, where he served until retiring in 1933. He was heavily influenced by the philosophy of Georg Simmel and his Kantian separation of social form from content, as well as by the concept of social space: space as a mental category necessary for the study of social forms. The urban was central to this conception. For Simmel, the experience of the city was inherently unsettling, but one to which people could adapt. This concept directly fueled the Chicago School’s focus on the process of the organization, disorganization, and reorganization of urban space.

While Park was well schooled in human geography, notably under Alfred Hettner, he was at pains to distinguish it from his human ecology. He assigned to geographers the role of describing the facts of location, but saw human ecology in the much more expansive role of discovering the underlying principles used to interpret facts; geography was idiographic, ecology and sociology nomothetic (Entrikin 1980).

Chicago proved an ideal laboratory for Park and the other members of the Chicago School, notably Ernest Burgess, R.D. McKenzie, and Louis Wirth, all of whom contributed to the definitive text announcing the arrival of the Chicago School, The City (1925), as well as Harvey Zorbaugh, author of the equally influential The Gold Coast and the Slum (1929). They observed and wrote during the first period of urban life in Chicago, which had morphed from a small lakefront- and river-based prairie settlement into a major industrial city just beginning to garner national attention between 1880 and 1920. Park and Burgess came to Chicago before World War I; their personal transformations and that of the city were interconnected; as an ecologist would say, they were symbiotic. The theory went on to become foundational, the yardstick against which other American cities would be measured, such as in E. Franklin Frazier’s (1937) import of the theory and methodology of the Chicago School to his study of Harlem, in which he argued that a segregated racial or cultural group would develop the same patterns of zones in the larger city. Dear (2002) attributes
the Chicago School’s success to the model’s beguiling simplicity, the construction of a substantial body of literature, and the fact that the model was seen to work in many different cities over a long period of time.

Even within this relatively small group of researchers, there was some disagreement as to the limits of ecology as a metaphor for urban changes. Park argued that reality was constructed and that an individual’s actions stemmed from the exercise of free will within the constraints of the larger social whole, but were never determined by it. Zorbaugh, on the other hand, argued that “the city is a natural phenomenon and has a natural history”; it proves “curiously resistant to the fiat of man” (1926, 188, 187).

Regardless, there are a number of ecological processes that are central to the Chicago School’s conception of the city: centralization, concentration within natural areas within the city, competition for position, segregation over natural areas, invasion, and succession, all operating within a city that was assumed to be a unified whole.

Burgess’s (1967/1925) concentric zone model is the most visual expression of the Chicago School’s theory (see Figure 1). It presents a series of zones emanating from the central business district organized according to levels of cultural assimilation and economic and social status. Zorbaugh (1926, 190) summarized the model, which he argued applied to all American cities:

To begin with, they segregate into broad zones as they expand radially from the center — a “loop,” or central business district, a zone of transition between business and resident; an invasion by business and light manufacturing, involving physical deterioration and social disorganization; a zone of working men’s homes, cut through by rooming house districts along focal lines of transportation; a zone of apartments and “restricted” districts of single family dwellings; and, farther out, beyond city limits, a commuters’ zone of suburban areas. Ideally, this gross segregation may be represented by a series of concentric circles, and such tends to be the actual fact where there are no complicating geographical factors.

The expansion of the city involved each wave of urban immigrants in the inner zones invading the next outer zone in a process of succession, a term Burgess borrowed from plant ecology. This process accounted for both physical growth and levels of social organization within the city. Burgess describes this process as analogous to a process of metabolism in order to explain the ways in which individuals were incorporated into a city’s life. The model was predicated on continued high levels of immigration.

The resulting “differentiation into natural economic and cultural groupings gives form and character to the city. For segregation offers the group, and thereby the individuals who compose
the group, a place and a role in the total organization of city life” (Burgess 1967/1925, 56). There would be a similar process of disorganization, reorganization, and differentiation in the division of labor. Social organization broke down in areas where mobility was greatest, leading to a zone of deterioration, “areas of demoralization, of promiscuity, and of vice” (Burgess 1967/1925, 59). The disorganization fueled by the influx of lower-status immigrants created negative environmental consequences and thus generated the move outward of wealthier residents. Burgess found that variations in land values offered the best single measure of mobility, and thus of all the changes taking place in the expansion of the city. While Burgess argued that some level of disorganization was normal as it was necessary for reorganization, an oversimplified view of the model had the effect of presenting the suburbs as models of stability and implied that urban pathologies were inescapable (Warf 1990).

Each new group would cycle through this experience as part of the process of assimilation, which was considered “apparently progressive and irreversible” (Park 1950, quoted in Jackson 1984, 171), and part of the “moral order” (Park 1926, quoted in Harvey 1973, 131). As such, the Chicago School completely ignored the effects of racism and other structural constraints. This is not to say that the Chicago School was insensitive to the issue of race. Park’s own view was that race was not biological. Heavily influenced by working as an assistant to Booker T. Washington at the Tuskegee Institute (1907–1914), where the focus was on education and economic advancement, Park developed his theory of the race relations cycle, in which contact was followed by conflict, then accommodation, and finally assimilation in a pattern that was repeated seemingly everywhere. The assumption that assimilation was inevitable had the effect of naturalizing the continued segregation, most notably of African Americans, in the most marginalized neighborhoods.

Similarly, class conflicts were not adequately addressed. Harvey (1973, 132–133) comments that Engels had recognized concentric zoning in the city but had attributed it to economic class rather than culture, as the Chicago School did, arguing that it is “a pity that contemporary geography has looked to Park and Burgess rather than to Engels for their inspiration.” Instead, planners and geographers reinforced, through policies like zoning, the pattern of the model by assuming it to be true, rather than questioning how it could be changed.

While the Chicago School’s ethnographic method might come to be considered humanistic (Jackson 1984), positivist spatial scientists were attracted to the Burgess model because, Sibley (1995) argues, it was one of the few spatial theories with universal claims. Robert Park, Ernest Burgess, and the other members of the Chicago School saw their sociology as purely scientific. Burgess saw the sociologist as a “natural scientist” (Sibley 1995, 42). Sociology was to be a pure science, removed from emotion, and strictly apolitical. According to Carey (1975, quoted in Sibley 1995, 42), “an overriding concern of the time was to distinguish sociology from socialism.” As such, Sibley (1995, 46) argues, this “objective,” “scientific” (quotes mine) knowledge gained legitimacy precisely because the political climate was amenable.

The assumptions of the Chicago School heavily influenced social area analysis, factorial ecology, and other methods that attempted to make sense of the city through quantitative analysis. Spatial scientists sought to use quantitative data on housing, demographics, and socioeconomic status to understand and explain the pattern of residential differentiation. Books like Berry and Kasarda’s Contemporary Urban
CHICAGO SCHOOL

Ecology (1977) used ecological analysis of spatial distribution and processes. They go back to a Chicago School conception of community, understanding human ecology as the study of how populations adapt in environments which are constantly changing and yet restrictive. While the Chicago School model remained the foundation for further research, much of this work found disparities between the actual and expected patterns. This finding led to a more thorough questioning of urban ecological assumptions and the development of more behavioral approaches as an alternative.

The scientific detachment of the Chicago School and its followers contrasted with the other “Chicago School” doing similar work at the time, that of the University of Chicago’s School of Social Service Administration (Sibley 1995). Much of this research was carried out by women such as Edith Abbott, Sophonisba Breckinridge, and Helen Rankin Jeter, who conducted in-depth studies of the Chicago housing market, with a special emphasis on landlordism and the effects of discriminatory practices and a focus on policy implications. While Burgess recognized this research as “outstanding,” he differentiated this “practical” social work from the supposedly more serious pursuit of “theoretical” sociology. Park was more vehement, declaring that these women reformers “had done more damage to the city of Chicago than corrupt politicians or gangsters and he discouraged students from taking their courses” (Sibley 1995, 41). Modern-day urban geography has continued this gendered knowledge. Any text on urban geography and planning will include the Burgess model, but not the research of the School of Social Service Administration.

Beyond these structural critiques, there were, even early on, questions about the accuracy of the Burgess model and the Chicago School theories. Although often lumped in with the Chicago School, Homer Hoyt argued as early as 1947 that the city’s residential patterns more closely resembled sectors than concentric rings. Similarly, the multiple nuclei model of Harris and Ullman contradicted a fundamental assumption of the Burgess model. Others critiqued the model for trying to universalize the experience of the American city, for the Burgess model fails to explain the growth of many European cities, for example.

The focus on social pathology related to another fundamental understanding of the Chicago School, that of urbanism as a fundamentally distinctive way of life. Wirth (1938) argued that urban dwellers had weak primary contacts as a result of the city’s size, density, and heterogeneity, and that superficial contact was a way of immunizing themselves against the sensory assault. Wirth further argued that the only way for individuals to become effective was to organize into groups, and he sought to build an urban sociology that would make sense of the complexity of urbanism by building on this understanding. A large body of work contested this understanding of urban life, giving evidence of extensive community and nontraditional family ties, and indeed arguing against the very notion of urbanism as a separate way of life.

One positive legacy of the Chicago School is the in-depth case studies of “natural communities” that fueled the theory. In this way, communities that may not otherwise have received sustained academic attention were documented in detail, through surveys, participant observation, and interviews. So, for example, Chicago School studies serve as a resource for understanding aspects of gay life in Chicago and the geographic range of the community at the time. Burgess and Park took an interest in the urban expression of sexuality and directed graduate students to conduct field work among Chicago’s homosexual communities. Aspects of
this work were later published by Burgess under the categorization of social pathology. Glimpses of gay life can also be found in Zorbaugh’s *The Gold Coast and the Slum* (1929).

Whatever usefulness the Chicago School may have served in explaining the twentieth-century American industrial city, many argue that the process of gentrification has undone the model and renders it no longer appropriate, with upper-income professionals increasingly attracted to the central city, displacing the working class and ethnic minorities to locations farther and farther from the urban core. Even in Chicago, what had been the zone of transition has been transformed into luxury condominiums. Disused train tracks have become Millennium Park, one of the most popular attractions in the city. And yet, as Warf (1990) comments, this process exhibits precisely the characteristics of residential competition on which the theories of the Chicago School were built.

The theories of the Chicago School maintain a hold on the urban geographic imagination, with various attempts to rescue the theory from its own shortcomings. Warf (1990, 91) tries to recover some elements of usefulness from the Chicago School, arguing that it provides some of the best work on neighborhood change and ethnicity, which should be blended with an understanding of the division of labor to produce a new social ecology that underscores the “contextual nature of social action.” Even Soja (1989), in his exploration of a postmodern Los Angeles School of urbanism, recognized an underlying logic consistent with the Burgess model, with radial growth from a central core. Indeed, elements of the model are still visible in certain sections of Chicago to this day. The Loop remains the central business district, with much of the manufacturing that remains in the city concentrated in what was the industrial zone. The north and west sides of the city are bordered by suburbs (Evanston and Oak Park) that are much wealthier than the urban neighborhoods inside the city limits.

Perhaps one of the most enduring legacies of the Chicago School is the idea of a comprehensive social theory based on the work of individuals researching the same locale. This notion was revisited by Michael Dear (2002) in his call for a new school, the Los Angeles School, to replace the Chicago School, given the evolution of the city in a globalized world. Dear finds evidence of the transition from the Chicago School to the Los Angeles School in Louis Wirth’s final chapter of *The City* (Park et al. 1967). Wirth isolates two fundamental features of urban evolution: that the city lies at the center of, and provides the organizational logic for, a complex regional hinterland, and that the development of satellite cities can exert a determining influence on the direction of future growth. Dear argues that this development foreshadows the postmodern city, of which Los Angeles is the most iconic, in which it is not the center that organizes the hinterlands, but the hinterlands that determine what remains of the center. While the idea of the Los Angeles School never exerted the influence of the Chicago School, it does illustrate the longevity of the original theory.

More recent understandings of the Chicago School have tended to emphasize not the antiquated vocabulary or overly simplistic models, but rather the focus on attempts to reorganize social groupings and identities after modern urban life has disrupted the traditional institutions of family and locale. This attempt to redeem the fragmentation of urban life, to see the potential in the chaos, drives many urbanists and may explain, in part, the rediscovery of the urban work of theorists like Walter Benjamin, whose dialectical urbanism recognized the shortcomings of the capitalist city while celebrating
its potential to enhance individual potential and collective freedom.

Despite the many and varied critiques of the Chicago School, we can perhaps appreciate this focus on the city as the object of study, the depth of their methods, and agree with Park that what is best about cities is their diversity:

In the freedom of the city, every individual, no matter how eccentric, finds somewhere an environment in which [s]he can expand and bring what is peculiar in his [her] nature to some sort of expression. A smaller community sometimes tolerates eccentricity, but the city often rewards it. Certainly one of the attractions of the city is that somewhere every type of individual – the criminal and beggar, as well as the [wo]man of genius – may find congenial company and the vice or the talent which was suppressed in the more intimate circle of the family or in the narrow limits of the small community discovers here a moral climate in which it flourishes.

(Park 1952, quoted in Jackson 1984, 174)

Today nearly half of the planet’s 7 billion people are aged 25 years or younger, and a quarter are thought to be younger than 14 years. An estimated 9 out of 10 of these young people live in developing countries. Given such demographics, it is surprising that the study of children and how they inhabit, experience, adapt to, and change their environments has only relatively recently received attention from geographers. In part this is because the newly emerging studies (geographies of children) are set against a wider demographic revolution in the developed world, associated with smaller family sizes, shrinking populations, and a dramatic aging of the population. The United Nations Charter on the Rights of the Child defines children as those aged under 18 years. From postwar research into children’s understanding of maps, and map-making, to contemporary longitudinal cross-cultural and interdisciplinary research, the study of children and their environments has blossomed (Holloway 2014). This trend has been supported by the recent creation of active national research groups including the British Royal Geographical Society’s Geographies of Children, Youth and Families Research Group and dedicated journals including Children’s Geographies and Children, Youth and Environments.

Thirty years ago, developmental psychologist Bronfenbrenner (1979) defined children’s environments in social-ecological terms. Bronfenbrenner depicted children’s environments as a complex series of nested interactive systems, in which the child is both embedded in a dynamic world of everyday micro-level interactions and influenced by indirect but equally significant macro-level processes, including economic, political, cultural, economic, and physical change. These wider institutional interactions can include, for example, conditions of parental employment, media or education policy, tribal and kinship structures, and government policies about urban development, natural hazard mitigation, or climate change.

Universally, children today face four intersecting macro-environmental issues: dangerous environmental change, growing social inequality, unprecedented global youth unemployment, and weakening local democracies as communities struggle to hold global corporate power to account (Hayward 2012). Since the 1987 Brundtland Commission on sustainable development, policy advisers, urban planners, and political leaders have been urged to consider the needs of “future generations” at all levels of environmental decision-making, from macro-policy to micro-level planning. Children’s geography also encourages attention to the future generations who already live among us in this policy
process: the world’s children. By 2050, 70% of the world’s children youth will live in cities, yet children do not experience these urbanizing environments in uniform ways. For many children, urban communities afford an unparalleled quality of life, facilitating new opportunities for education, social interaction, and employment. For children in families with a high income, resource-intensive, urban consumer lifestyles may be an expression of identity; for others, however, cities may afford few choices. Some children experience little control over their environment, being “locked in” to intensive energy use in everyday living, with few opportunities to choose more sustainable alternative living environments, or displaced from place as trafficked or forced migrants.

Cities are also precarious environments for the world’s poorest young people. Half of all people under the age of 25 live in situations in which they and their families have access to just 9% of global income, and in this context child labor may be the means of survival (Ortiz and Cummins 2011, 21). UNICEF (2012) estimates that one city-dwelling child in three lives in conditions that lack security of tenure; lacks access to adequate health services, housing, education, or diet; and faces complex risks of exploitation, discrimination, and violence. Recent research is aiding greater understanding of children’s environmental experiences in the Global South and North as developed economies also struggle with recession and urban inequality, which disproportionately affects children and young migrants (Wells 2009).

Understanding children’s diverse environmental experiences

Understanding children’s diverse experiences is the subject of growing interest, culminating in the emergence of the field of children’s geographies. Early studies of children and the environment in Europe and North America often depicted children as passive, vulnerable dependents who needed to be protected from the impact of modernity and guided in their development. Rousseau and Wordsworth, for example, wrote on the importance of children’s play in the natural world as a means of countering the pressures of modernity. Elements of this Romantic perspective still resonate within contemporary debates about whether children are suffering from a “nature deficit disorder,” as a result of rapid urbanization and associated loss of access to green space and opportunities for unstructured free play (Louv 2005) and the need for biophilia (identification with the natural world) and environmental place-based education (Sobel 1996) to nurture values of environmental stewardship and a positive sense of self and a place-based identity.

Beyond efforts to bring urbanized, and often middle-class, European children into closer contact with nature, there are contrasting debates concerning the appropriateness of children’s presence – and more especially their behavior – in a range of outdoor and public spaces. At times, this debate has ignited as a moral panic, for example, over whether children are becoming more risk averse in the outdoors and turning into a generation of “cotton wool kids” over whom overly protective “helicopter parents” constantly hover to ensure their “protection” from imagined harm (Valentine 2004). Children denied the opportunity to engage in wild play, instead, are assumed to spend their leisure hours indoors, preferring screen entertainment to face-to-face interaction. In turn, this fuels worry about a new generation of isolated, lonely, and anxious children and teens who experience anomie, are losing the ability to relate to others, or are loitering in ways that threaten public order.
Public attitudes to children and their technological environments are no less fraught with contradictions and anxieties. On the one hand, the new technology of smartphones is reducing the costs and barriers to entering the virtual world, in turn enabling new opportunities and greater connection with others. Yet the digital divide continues to exist between wealthy communities and children in communities without affordable and efficient connections. Moreover, the issues of surveillance and exploitation of children through the Internet, including loopholes in popular apps such as Farmville and Facebook, mean that the Internet is an increasingly problematic environment for children as a potential platform for social interaction and social control.

In the Global North, children and young people are often seen as perpetrators of the worst excesses of consumerism in their quest for self-expression, peer affiliation, and cultural participation; yet, on the other hand, they are often held up as our “best chance” for a sustainable future; “Trojan horses” of change who care deeply about the environment and are committed to living within planetary means (Collins and Hitchings 2012). At the same time, neoliberal economies and corporations are increasingly fulfilling the role of the entities that are not only “feeding, clothing, entertaining, socialising, but also moralising and ‘caring for’ children” to build a lifetime of brand loyalty and a habit of spending” (Schor 2011, 207), thus limiting opportunities for children to practice forms of social life and interaction that are fundamental to childhood and to the development of autonomous citizens.

When children do leave the screens of their smartphones or computer games consoles to explore the physical world, their unstructured play in urban environments is often depicted as a threat to the prevailing social order (Vanderbeck and Johnson 2000). Again new surveillance technology has evolved to document children’s movements in public space from personal GPS tracking to closed circuit television, regulations, and signs or mosquito-sound alarms placed in supermarket entrances or other places where children are likely to “loiter.” Other attempts to control children include England’s wide-ranging antisocial behavior laws that can be used to restrict minor activities like ball sports to the wider prevention of youth congregating in public spaces and the searching of children if they are suspected of participation in potentially criminal acts.

Against these contradictory experiences, many researchers recognize that children can no longer be understood simply as dependents or victims but may be regarded as agents of change who have varying influence in their environment. In this context new research methods aim to give voice to the diversity of children’s experiences. Movements like “guerrilla geographers” (Geography Collective n.d.) and other critical place-based pedagogies have drawn inspiration from Paulo Freire’s liberation learning, to promote child-centered education and to help children to understand their environment, reflect critically, and act with others to implement strategies for desired change in the places they value (Gruenewald 2003).

**Child-centered, longitudinal, and interdisciplinary research**

What has the plethora of children’s contradictory experiences meant for the ways in which research is conducted? While communities experience social injustice differently, what drives much contemporary interdisciplinary study of children and their environment is an implicit or explicit recognition that children have a significant stake
in the outcome of planning decisions because they will experience the effects of these decisions over the course of their lifetime, and should therefore also have the opportunity to be heard and to influence decision-making.

Longitudinal research methods direct attention to important questions about how children engage with their environment and the way they are exposed to environmental burdens and opportunities over time. Many children in mid- to high-income communities, for example, currently have unprecedented access to world travel and quality local outdoor environments, and live in homes that are well built, heated, and digitally networked. At the same time, one in three children are disproportionately exposed to a range of risks, including domestic violence and alcohol and drug abuse, which compound macro-level socioenvironmental threats of war, civil disruption, climate change, or economic hardship (UNICEF 2012) and enormous numbers are subject to forced migration (Dona and Veale 2011). The experience of children in the globalizing South or in low-income and ethnic minority communities can be quite sharply divided. Many children in these communities are inadequately protected from, for example, toxic waste pollution; their daily lives are disproportionately impacted by clearance for private development; or they are exposed to excessive risk as child laborers. Poor children are 10 times more likely to bear the brunt of severe climate change, while women and girls are 14 times more likely to die in a disaster (Plan International 2011). Many children, especially girls of low-income ethnic minority communities, are “doubly exposed” to both physical and social-economic risks in their environment, including risks of severe storms, urban heat waves, and flood events associated with dangerous environmental change. These physical risks are compounded by the lack of quality education, information, and health security and by secure or insecure housing and exploitative work environments (Leichenko and O’Brien 2008).

Understanding of the experiences of children in their environments has been enriched by development studies and research into citizenship, globalization, mobility, development, feminism, and sexuality. Researchers in these fields have supported a growing interest in how children are socialized into power relationships and “governed” in space and time. In turn, there is also interest in youth agency, or the ability of children to imagine and effect change (Hayward 2012). In a classic lecture, Ruth Lister (2007) argued that children do not have to “become” citizens (i.e., to assume the full expectations of adult responsibility and entitlements). She argues that children already “belong” as citizens who participate in and make claims of their communities in the present. In this light, geographers have also turned their focus toward understanding the diverse ways that children’s public space is regulated and increasingly commercialized, forcing children, for example, to play in restricted ways and often in highly consumerist contexts such as shopping malls. By contrast, there are fewer spaces where children can create the conditions of play for themselves and thereby give their own meanings to those spaces.

Finding ways to better understand children’s diverse environmental experiences received an impetus with the formative work of critical children’s geographers like Valerie Walkerdine and Roger Hart. The latter argued that children’s voices are rarely given significant space or serious contemplation by adults (Hart 2008). While adult conferences might adorn their walls with children’s artwork, they rarely listen to or consider the issues that really trouble children. Hart adapted the urban planner Sherry Arnstein’s (1969) ladder of participation for children
to illustrate how children are frequently incorporated into environmental decision-making processes in ways that amount to little more than co-option or placation. He concluded that it is rare that children are regarded as partners in urban planning and even rarer that they are able to lead a decision-making process.

In response to such concerns, critical geographers and political ecologists interested in children’s issues have sought a shift in focus, widening their search for ways to bring the voices of children to the center of the research process. Research methods which do not directly involve children (such as large-scale observation) have been criticized for working on, rather than with, children. Instead, more inclusive and participatory methods have been developed, often in conjunction with longitudinal life course or cohort studies. These approaches aim to involve children as active coproducers of knowledge, raising their awareness of their own knowledge of their environments, as well as developing a deeper understanding of children’s perspectives through research methods suited to their capabilities. In particular, visual and verbal research techniques, such as drawing, photography, stories, and song can be effective ways of eliciting the experiences, opinions, and perspectives of children.

The child-centered turn in research has also begun to emphasize children’s agency in their environment in the context of enhancing children’s “resilience” (the ability to cope or recover from stress or disaster) (Tanner and Seballos 2012) and the child as a political actor in processes such as forced migration (Dona and Veale 2011). While the recognition of children’s ability to take action is welcome, there is a danger that too great an emphasis on children’s individual ability to adapt or cope to new environmental stress is undesirable. Children can accommodate significant change, but critics argue that there are limits to how much imposed socioeconomic or physical environmental change young citizens should have to adapt to before it becomes unreasonable, unsustainable, and unjust (Ungar 2012).

While much research in children and environments is driven by the Global North, new voices are highlighting the way children experience diverse local environments, as street children in mutual solidarity, as child soldiers, or as child labor. As more studies reflect the complex issues of child health and children’s exposure to natural or human-made disaster (including economic crisis), new questions arise about how children experience temporal (intergenerational) justice and spatial (intragenerational) fairness (Katz 2004; Wikenden and Kembhavi-Tam 2014). Work by authors like Wells and Katz reminds us that an emphasis on agency cannot condone or excuse unrealistic or unjust expectations, for example, that children should atone for, or carry the costs of, environmental degradation or social suffering caused by the action (or inaction) of previous generations. It may take a village to raise a child but in the twenty-first century, as the village has become the megacity, our boundaries and ethics of care for children are challenged to expand. Studies of children and their environment are highlighting the complex ways that actions in one place and community impact on the life chances of children separated by space and time (Mills and Kraftl 2014). This complexity and the enormity of the issues confronting new generations challenge social researchers to ensure that the outcomes of their work can support children in their diverse and rapidly changing environments.

**Further reading**

Children and youth are relatively new subjects and foci of study within geography. Despite their recent entry into the discipline, the growth in academic work related to this younger age group has been exponential, for two key reasons. One is that more geographers have turned their attention to working with younger people and, in this way, have contributed a great deal to understanding of the roles of space, place, and spatialities in young people’s lives. They have critically examined the concept of age, the role of structures in young people’s lives, and the complexities and contradictions around children’s and young people’s rights (Holt 2011). Second, many geographers have been determined to make children and young people more visible within the discipline as part of an intellectual and political project. Their work has demonstrated that younger people, their identities, their spatialities, their agency, and their lived experiences, illustrate different kinds of geographies from those of adults and force us to rethink our conceptual frameworks. Young people’s geographies are being examined in ways that not only “add them in” to geography as a discipline but also form a range of conceptual challenges to taken-for-granted notions and approaches within human geography. Just as young people themselves challenge adultist sociospatial constructions, geographical research with young people provides interventions in adult-centric normative geographies.

The invisibility and neglect of children and young people within the discipline of geography has been one of the key academic and political imperatives that have driven the development, expansion, and intellectual project of geographies of children and youth. With the aim of making children and young people evident within the wider discipline, the subdiscipline effectively broadened the purview of geography as a new group of social actors has been included, to challenge assumptions and presumptions about key concepts such as mobility, politics, and urban life. Just as feminist geographers challenged the masculinism of the discipline, children’s and young people’s geographers confront the power relations of adultism, recognizing that children and young people are significant members of human society and actors in the physical and social environment who should be taken seriously.

Geographers working with children and young people have had to transform existing methodological approaches and to develop new methods, tools, and techniques to capture children’s and young people’s articulations of their lives. This exercise has led to remarkable innovation and invention in order to rework adult–child power relations, and to make research fun and meaningful for participants. Children and young people’s geographers have used modern technologies such as smartphones, Global Positioning System (GPS), texting, Facebook, and other tools to develop research methods that are relevant and connect effectively with a particular age group. To challenge the power inequalities of the adult–child relation, children and young people’s geographers have adapted more equitable and engaging methodologies, such as participatory and action research as...
CHILDREN AND YOUTH

well as “go-alongs” or walking interviews. To engage younger people and make the research more appropriate, they use photo elicitation, play activities, drawing, and dynamic subject-centered cartography (Kesby 2007). Additionally, geographers (and other social scientists) have faced considerable challenges in terms of the ethical issues and tensions at play in doing research with younger people. Ethics is particularly problematic in relation to protocols that fix children as vulnerable, incompetent, or unknowing. Geographers have been influential in establishing that children and young people are competent social and spatial actors who have the right to participate in research that affects their lives, those of their families, and of their communities (Beazley et al. 2009).

Early work in the 1970s and 1980s challenged geography’s way of focusing on urban planning and experiences of place without considering children and youth. Geographers critiqued developmental psychologists’ conceptualizations of children as immature and dependent on adults by demonstrating children’s spatial and mapping competencies. In the late 1990s and 2000s geographers, influenced by debates in sociology, engaged with the new social studies of childhood where emphasis was placed on recognizing childhood (and latterly youth) as a social construction that is temporally and spatially specific. Additionally, children were conceived as agents and actors in their own right, in contradiction to the perception of their being “adults in waiting”; however, it is very clear that there are substantive differences between a child of 5, a teenager of 15, and a young adult of 25. A call for an expansion of focus away from just children was made in the late 1990s (Skelton and Valentine 1998). Drawing from youth studies and cultural studies, geographers examined the complexities of young people’s lives through spatial and scalar lenses and effectively launched young people as a legitimate and necessary focus, distinctive from and yet overlapping with the lives of children. In the context of development and geopolitics, Katz (2004) illustrated the ways in which children in Sudan and the United States experienced complex interactions with their physical environment; were active within the production of social and cultural reproduction; and were heavily affected by global economic restructuring. More recently, children’s and young people’s geographers have engaged with re-examinations of social reproduction and the role of the family. Theoretically and conceptually, children’s and young people’s geographers have drawn on and developed approaches that range from poststructural, postmodern, and nonrepresentational, to life course and transitions, through to a focus on embodiment, emotions, and affect. They have demonstrated the ways in which these theoretical orientations have relevance in young people’s lives and that attention on younger people enriches and enlivens related debates in the wider discipline.

Defining children and youth

Children and youth have much in common, yet at the same time they are quite different from each other. Geographies of children have tended to be pre-eminent and there is a wealth of published material that captures the spatial and social complexities of childhood and children’s lives in both the majority and minority worlds (otherwise identified as the Global South, or developing world, and the Global North, or developed world). Children’s geographers have rejected the notion of a singular, universal childhood tied to age-standardized durations; they work with a concept of childhood as socially and politically constructed and culturally and historically contingent. They argue that
childhood is neither biologically nor developmentally determined but, rather, is constituted through being in the world. Theoretically and politically, geographers have contributed to and expanded the new social studies approach to childhood through their exploration and identification of the diverse production and experiences of childhood in different parts of society and geographies across the world. These approaches have demonstrated that children are actors in and creators of their own childhoods, that they create their own social worlds because they are active and competent members of society. Consequently children and childhood deserve to be studied in their own right and as legitimate social entities. Once this approach became more mainstream within geography, space was created to expand from childhood and children to include young people and families.

Young people, especially teenagers, are viewed as having an in-between status, sharing characteristics of being both child and adult at the same time as not really being either. This ambiguity is seen as an unsettling position; young people do not quite fit into one age group or the other and consequently are often highly scrutinized and regulated. Nevertheless childhood and youth do converge in quite important if sometimes confusing ways. The 1989 United Nations Convention on the Rights of the Child (CRC) defines childhood as 0–18 years; hence teenagers are included in the convention. The CRC has had important implications for the protection, provision, and participation of children and youth within their families, communities, and nations. The United Nations also defines “youth” as 15–24 years; hence in this definition children are those under 15 rather than 18. The International Labour Organization has a focus on child labor, and attempts to limit and control the amount of exploitative and dangerous work to which children aged 5–17 are exposed. The legal systems within countries specify very different ages at which children and youth can legally get married, leave school, drive a car, have sex, vote, or be held criminally responsible for their actions. The chronological age definition is therefore messily split up according to international and national definitions, posing the question of how valuable categorization by age actually is. This critique allows a degree of intellectual freedom to resist categorizing younger people into discrete and universalized types, and instead focuses on age as a relational construct. This approach has further stimulated examination of the intersectionality of age with other social identities and sites of marginalization and exclusion such as class, (dis)ability, ethnicity, gender, race, and sexuality.

Much of the initial work with young people was developed in the minority world and academically engaged with cultural and youth studies. Youth studies tends, importantly, to be oriented toward policy, and legal and cultural analysis. Research with young people in the majority world is frequently related to development issues, much of it located in Africa, but we still know relatively little about young people’s lives in the Americas and Asia. This situation is quickly changing as scholars from outside and within these regions engage with geographies of young people and children in the majority world and offer critiques and new perspectives.

A predominant trope around young people is that they are either unnoticed or neglected as a group or they experience heightened attention because of their antisocial behavior, their disaffection with politics and/or society, their lawlessness, and their delinquency. The binary around children means that they are described as either angels or devils, inherently good or evil, connected with Apollonian and Dionysian discourses. For young people the same binaries exist, but they are also bound up with more
complex notions of being at risk, troublesome, out of place, or dysfunctional, and with expectations that they should be cured, contained, or coerced to become the “right” kind of citizens. For geographers working with young people there is a determined rejection of the stereotypical categorization of many young people in favor of analyses relating to place, space, and spatiality and the ways in which young people interact with, and act on, their social, cultural, political, and physical environments. Geographical work with and about young people has taken more time to develop than children’s geographies but it is growing in confidence, conceptual depth, and visibility.

The ways in which children and youth are defined and identified within geography are flexible and dynamic. The two are often linked, and linking has a conceptual and analytical validity at times, but in many instances it is important to separate out the 7-year-old from the 14-year-old. The importance of these distinctions is apparent in the varying focus on children and/or youth within major topics in geography. For instance, play might be more associated with children, and politics with young people. Increasingly, though, the broad range of empirically grounded and conceptually critical geographical work disrupts these associations; young people play in urban space through parkour, and children, like those involved in the Arab Spring uprisings in 2011, have a role in political actions.

Play

Play is often seen as quintessentially childlike and a necessary part of childhood; it is something that children expend a great deal of energy on and enjoy. All over the world children play. Play has been identified as an important factor in the enhancement of children’s intellectual abilities, socialization, and wellbeing. These are spatially and temporally contingent; not all play in all places and at all times is beneficial. Moreover, there is a plethora of adult-created forces and power relations that encroach on and delimit the possibilities of space and time for play. Such forces include reductions in safe and attractive spaces for play through modernization, urbanization, and the agroindustrialization of rural areas; increases in automobility, which moves children around but also threatens their safety as pedestrians or cyclists; a stretching of children’s everyday places where they have to spend time (the school on the other side of the city, the after-school and other organized clubs, the tuition centers, the sports training areas); and an intensification of learning and examination pressures. Time–space compression and the forceful speeding up of life that adults experience in a rapidly globalizing and developing world also affect children. They have little time or space for play, whether outside or inside, alone or with others, imaginative or organized, screen-time play, or quiet daydreaming. Despite these restrictions on children’s time and space, conceptually, play is still considered to be an extremely important part of a child’s life and essential for their social and physical development. Children are almost all experts at play and are ever inventive. Wherever they are – unless expressly forbidden (and even when they are) – children will start to play: they run around; they race against each other; they play with their voices and echoing sounds; they jump across or onto lines in the pavement; they hide from and find each other or their adult companions; they climb walls and spin around in revolving doors; they become fascinated by a small detail – a chip in a glass window, a snail in the garden, a loose brick in a wall, pamphlets in the doctor’s waiting room. Play is a form of agency children enact and create, and they can
demonstrate extraordinary competency in terms of design, construction, and contextual meanings for the spaces they play in and the things they play with. Children also enact inventive mimicry of adult worlds and through play learn to make sense of the world around them, including adult worlds and activities (Katz 2004).

The conceptualization of play by geographers recognizes that play is complex and socially and culturally constructed in sometimes problematic ways. Play is dynamic within contexts of time and space. While children and youth are decidedly agents of their own play, playing, play spaces, and appropriate play, in particular, are usually determined and designed by adults. Playgrounds are specifically designed around adult notions of what children *should* do rather than what they *want* to do. Children and youth often work to disrupt and upset these adult-defined notions of play, and conceptually play has been defined as permitting a revolutionary imagination or as lying at the intersection between being and becoming. Even in everyday spaces such as school grounds, children territorialize playgrounds through intricate practices of control, domination, and resistance that are bound up with social relations such as gender, ethnicity, (dis)ability, and age. Consequently play and the spaces/places of play create distinctive and contested sociospatial practices and material realities of childhood linked with aspects of identity and performativity. This is also true for youth if digital and screen-based play, as well as play/movement in public spaces such as skateboarding or rollerblading, is considered.

**Mobilities**

Exploration and movement throughout their environments is considered important for younger people, and is an area of research where geographers have made important contributions. Children’s investigations and engagement with spaces and places beyond their immediate home environments are seen as foundational in their social and personal development. Through such travel, children learn to exercise autonomy and independent decision-making. It also allows them to cultivate relationships beyond their immediate families and households. These elements of spatial mobility can enhance their cultural capital and lead to forms of social mobility. At the same time, such movements through spaces, especially the public space of the street, are considered dangerous and a duty of care is required to protect children and, where possible, transport them through such spaces to reduce risk. For children in poorer communities and countries, arduous, lengthy, and sometimes dangerous journeys have to be taken as they walk to school, contribute to household or economic labor, or fetch and carry necessary requirements, such as water, for their families. The actual pathways of movement themselves can be risky and dangerous. Whether it is the lack of pavements/sidewalks in new home developments in Australia, or crossing streams swollen with monsoon rains in India, the risk of injury or death for children remains. At a different scale of mobility, migrant children and youth who transition to new geographies and cultures can find the new environments difficult and distressing, especially for refugees and asylum-seekers.

A major preoccupation of children’s geographers and child mobilities in the minority world relates to the journey to and from school. In several European countries the school run can contribute up to 40% of urban traffic. Recent initiatives to get children to walk to school and to encourage traffic safety have increased the number of children walking to school, but very few of them do so unaccompanied – children’s autonomous journeys to school have decreased
CHILDREN AND YOUTH

Figure 1 In Kunming, China, children walk home from primary/elementary school: through walking, children are able to navigate their city and have independent leisure time with their peers. (Source: author’s photograph.)

as significant in young people’s lives as they have been in the past or as they are in the majority world. In the latter the street remains a space of vibrant interaction, a locale of play, but also an ambiguous site of danger, risk, and support, especially for street children (Beazley 2003).

Politics

Questions of politics and agency form another key component of geographical work with children and young people. A special issue on “Political Geographies of Children and Young People” (Philo and Smith 2003) was one of the first collections to focus on younger people and politics. Its own political project was to work against the disempowering of young people and toward a political geography that would recognize them as political actors in everyday life and beyond. Young people were shown to be very much political actors in their everyday lives.

A decade later, in “Children and Young People’s Politics in Everyday Life” (Kallio and Häkli 2013) geographers evaluated the ways in which a focus on young people’s politics had connected and critically engaged with the subdisciplines of political geography and geopolitics. The papers demonstrate the ways in which geographers take on the role of making visible young people’s actual and potential political agency, subjectivities, competencies, participation, and capabilities for decision-making. They also illustrate the diversity of ways in which children and young people are “being political” and that there is a great deal to learn about such political processes.

A focus on young people and politics provides the opportunity to critically interrogate established theories, concepts, and methodologies within political geography.

Importantly, a focus on young people and children’s politics carries a specific political
imperative of exploring social justice issues in order to expose processes of marginalization and the exclusion of young people. Borders are a key concept in political and geopolitical geographies. Children’s and young people’s geographers have provided insights into young people’s border-making, resistance, and revolutionary potential from both majority and minority world contexts. They show that young people engage with bounded events, places, and institutions and move them toward an emancipatory state of *sin frontera* (without borders) (Aitken and Plows 2010). Other work on young people’s politics is asking significant conceptual questions about what constitutes politics, and political agency in particular. It recognizes the role younger people play in politics both with a big P and a small p. The former has been examined through formal involvement in political institutions such as local youth councils in the United Kingdom or the United Nations. Small p politics is recognized as being located locally and communally and as involving children of all ages in practices of care and informal citizenship.

Since the formalization of participation as a right of children and young people by the CRC, political agency and participation have been written about as inherently positive. Some geographers, however, have begun to question what kind of agency is politically and socially acceptable and the power relations behind definitions of acceptability: What about agency used in negative ways (to promote racism or sexism, for example)? What about the participation of young people in increasing militarized activities and organizations such as uniformed groups, enforced national service, or “fun” days in military museums? When is participation in politics exploitative, brutalizing, and damaging (child soldiering, being token participants, for example) (Skelton 2013)?

**Urban identities**

“Urban studies,” a term used to encompass urban geography, sociology, economics, planning, and policy, has a mixed history in relation to young people’s geographies. Urban geography has, with some exceptions, exhibited a generic disconnection from young urban actors. In the context of development studies, urban analysis of the situation of children and young people in the world’s poorest cities has been evident for some time, and a good range of edited collections and monographs about youth and the city exists. There is currently a rejuvenation and transformation of theoretical, conceptual, and methodological approaches in urban geography, and this has created space for previously neglected urban actors, notably young people, to be part of that challenge and change. Such changes have included the revitalization of comparative methodologies, and youth geographers (alongside anthropologists) have compared key urban experiences of young people in Latin America, Africa, and Asia, focusing on spatial concepts such as home, neighborhood, and street. Young people constitute the largest demographic groups in many of the world’s cities and play significant roles in the making, changing, negotiating, and navigating of urban spaces. Increasingly, geographers are writing young people into the sophisticated approaches used to capture aspects of the intense complexities of contemporary cities (Skelton and Gough 2013).

Geographers have shown that young people remain ignored or actively excluded from decisions that affect them; most city authorities are not connected with youth in terms of politics, planning, and policy. Geographical work has revealed that young people are social and spatial agents who dwell in the city in ways that differ from those of adults and that they play significant roles in the diversity of urban life. Focusing on
the urban dimensions of young people’s lives allows different questions to be asked about the relationality of cities and the social identity of age. In a spatial context, young people are particularly interesting because of the ways in which they occupy the liminal and interstitial places of the city. These spaces are used or occupied, sometimes by choice, to avoid observation as they indulge in activities such as skateboarding, parkour, unsupervised time with their peers, or illicit and illegal activities; and at other times by force in order to avoid the authorities, find a safe space to sleep, or live out socially rejected identities.

Geographical work on young people in cities has covered a wide international geography and provided a range of analysis. For example, geographers (along with sociologists) have examined the possibility of urban, social, and cultural mobility, and the ways in which place identities serve to support young people in their environments but also hinder them from traveling to study or work in other cities. Recent work in Western, African, and Asian cities has explored the use of mobile technologies for navigating cities and building social and economic connections that can facilitate their possibilities of income generation and social connectivity across urban space. A key feature of examining the cultural and visual elements of the city links to the complex role of graffiti and creative urban expression, much of which is produced by young people. Cities are spaces of conviviality but also sites of intense inequalities. Geographers have explored the many complexities of urban processes and practices in relation to the communality and tensions between people based on gender, ethnicity, (dis)ability, race, sexuality, age, and socioeconomic status. Youth and children in urban spaces have been investigated to critique their apparent antisocial/street-living behavior and confrontations with authority in order to consider possibilities and strategies of more harmonious dwelling but also to encourage a greater respect for young people’s needs and rights as urban dwellers.

Future directions

Geographies of children and young people are continuing to expand and, in doing so, they challenge the established disciplinary approaches, theoretically and conceptually, within geography and the broader social sciences. Working with children and youth forces new theoretical questions to be asked and conceptual tools to be developed, because it is not possible to fit younger people into existing analyses. They demand more creative academic inventiveness. This is happening and will continue to be a work in progress. In order to work with children and youth, adult researchers have had to rethink methodological approaches, as described. The innovation of methodological research tools is a major contribution from the subdiscipline to human geography as a whole.

Description and purpose

The GSC aims at promoting scientific research and education in geography, encouraging the full participation of its members and geographers, popularizing geography, training professionals, and making contributions to the society. The society has over 9000 members from research institutes, colleges and universities, secondary schools, government agencies, and other organizations.

To accomplish its goal, the GSC established 29 commissions, 6 working committees, 7 regional divisions, 3 research/working groups, 31 local societies, and 13 journals. The society organizes academic conferences, scientific activities and awards, and educational programs to disseminate geographic knowledge. The society also works regularly with government and its international associates to promote the application of geography science.

scholars, young researchers, and educators (http://www.gsc.org.cn/xh/xhjj//bzjl.htm); support geographers in international geography affairs; undertake the functions commissioned by government; assist and work consistently with the International Geographical Union (IGU), International Association of Geodesy (IAG), and the Imagery Product Archive (IPA).

**Brief history**

The GSC is one of the first academic societies established in China. Its predecessor was the Chinese Geographical Society which was formed by Zhang Xiangwen in Tianjin in 1909. In 1934, Zhu Kezhen, a renowned scientist, founded the Geographical Society of China in Nanjing. After the formation of the People’s Republic of China, the two organizations were merged into the current Geographical Society of China in 1950. Since then, the GSC has grown rapidly, joined the IGU, IPA, and IAG and gradually built a strong relationship with geographical organizations in France, Japan, Korea, and the United States of America.

The GSC has been working to unite all geographers and those interested in geography to improve the development and application of geographical science and technology in China. This has involved popularizing geographic knowledge for the public and improving the geography education and training conditions, working on government projects, communicating and collaborating with 31 local geography societies in China, and cooperating with other academic disciplines. The GSC council is elected democratically and a standing council is in charge of the GSC’s routine operations. The GSC has been working for over a century to build the foundation needed for scholars, researchers, students and its members to engage in academic exchange and pursue academic freedom in geographical research.

China: Hong Kong Geographical Association (HKGA)

Founded: 1969  
Location of headquarters: Hong Kong  
Website: www.hkga.org  
Membership: 150  
Chairperson: Xu Jiang  
Contact: jiangxu@cuhk.edu.hk

Description and purpose

HKGA was founded with the aims of promoting interest in, stimulating teaching of, and cultivating research about geography. The association actively promotes geographical education and awareness through a wide range of activities including the Hong Kong Geography Day, field trips, seminars, workshops, orientations, and subject-related competitions. It serves as a platform bridging secondary and tertiary geography education, offering professional support and advice for both teachers and students. The association has been working closely with government departments on curriculum development and an assessment scheme.

HKGA also publishes papers, newsletters, and journals.

Journals or major publication series

Asian Geographer. www.hkga.org/site/resources/asian-geographer  
Hong Kong Geographer. www.hkga.org/site/resources/hong-kong-geographer

Current activities or projects

HKGA has initiated many activities to promote geography education in Hong Kong and to connect the local community with the wider geographical world. The Hong Kong Geography Day is hosted biennially in collaboration with local universities to foster academic exchange and promote geography education. The Hong Kong Geography Olympiad is an annual open competition for all secondary school students. Latest development in the discipline is constantly shared in its Annual General Meeting and Seminar. HKGA also organizes field trips to improve understanding of local and regional geographical issues. Recently, it has held a series of workshops and discussions on Hong Kong’s new geography curriculum.

Brief history

In 1969, a group of local teachers gathered and established HKGA to promote geography education. In 1981, the association initiated the first Hong Kong Geography Day for the development, popularization, and application of geography. To articulate quality education and professional studies in the subject, HKGA has published the Hong Kong Geographer and the Asian Geographer since 1982 and 1991 respectively.

HKGA has members from local universities, secondary schools, NGOs, and other organizations. It is led by an executive council which consists of the officers and honorary representatives from local education institutes. HKGA is an advisory management committee member of the Hong Kong Teachers’ Centre. In past years, it has been working on curriculum development and institutional changes, especially for the

The association has also been a dedicated player in the international arena. It is a member of the International Geographical Union, and has actively participated in events such as the International Geographical Congress and the International Geography Olympiad. The association itself has also hosted many workshops and activities in collaboration with local and overseas institutes.

Description and purpose

To serve as the leading, strategic scientific organization focused on leading and supporting the regional sustainable development of resources and environment in China, solving major natural resource and environmental problems related to long-term national development, and improving our scientific capabilities for independent innovation and sustainable development.

Journals or major publication series

Acta Geographica Sinica. www.geog.com.cn
Journal of Natural Resource. www.jnr.ac.cn

Current activities or projects

The institute focuses on physical geography and global change, human geography and regional development, natural resources and environment, geographical information system and surface simulation, terrestrial water cycle and water resources, ecosystem network observation and modeling, Chinese agricultural policy, and other related topics. It currently supports four key laboratories and three field observation stations. It supports cooperative research with corresponding academic institutions in more than fifty countries and regions. It contributes to international scientific programs through twelve branch organizations and nine joint research centers.

Brief history

For the past 70 years, our institute has been leading geographical research in China in the fields of rational use of natural resources, ecological and environmental protection, comprehensive land consolidation and management, regional sustainable development, and resources and environmental information systems. Many of these research projects have been of considerable significance, such as the integrated research on regional differentiation of China’s natural environment, the comprehensive management and development of land in medium and low yield fields in Huang-Huai-Hai Plain, the study on the uplift of the Qinghai-Tibet Plateau and its effects on natural environment and human activities, the compilation of The National Physical Atlas of China, the theoretical research and practical application of regional spatial exploitation, and setting up of a China ecosystem network. Since 1978, these outstanding scientific outputs have won 248 science and technology awards, of which 43 being at national level.

China: Royal Geographical Society – Hong Kong (RGS-HK)

Founded: 1995
Location of headquarters: Hong Kong
Website: http://www.rgshk.org.hk/public/general.php?pageId=87
Membership: 2000 (as of 2014)
Director: Rupert McCowan
Contact: director@rgshk.org.hk

Description and purpose

The Royal Geographical Society – Hong Kong is the Hong Kong branch of the Royal Geographical Society (with IBG). It provides a forum where members can regularly meet and listen to leading local and international speakers from the world of geography and related sciences, exploration, travel, research, the environment, and conservation.

The RGS-HK accomplishes its aims through holding some 65 lectures each year for its 2000 members and the public. It also runs a schools outreach program, serves as a contact point for geographical academics interested in the region, and funds geographical research.

Current activities or projects

The RGS-HK is actively engaged in advancing geography and related sciences in the region. The RGS-HK hosts some 65 lectures a year, provides annual scholarships and awards, publishes an annual review, and holds dinner events including an annual dinner and a gala dinner. It also runs a schools outreach program, through which it hosts educational events at schools throughout Hong Kong. During 2013, the Schools Outreach Programme reached over 5000 students with speakers ranging from distinguished academic geographers to explorers such as Sir Ranulph Fiennes.

Brief history

Previous speakers who have spoken at the RGS-HK include the polar explorers Sir Ranulph Fiennes and Robert Swan, mountaineers Sir Chris Bonington and Doug Scott, primate expert Dame Jane Goodall, the botanist Professor David Bellamy, leading environmentalist Sir Crispin Tickell, former space shuttle pilot Dr James van Hoften, moon walker Commander Dave Scott, Hong Kong explorer Wong How Man, round-the-world yachtsmen Sir Robin Knox-Johnston and Sir Chay Blythe, yachtswoman Tracy Edwards, and authors Simon Winchester, William Dalrymple, Paul French, Jan Morris, and Mark Tully.

Since its inception, the RGS-HK has also strived to assist geographical research in the greater China region. In addition to serving as a point of contact for geographical academia interested in the region, the RGS-HK awards multiple scholarships yearly. These include a post-graduate award and several scholarships for undergraduate and master’s degree research.

The RGS-HK’s board meets three or four times a year to review future speakers and decide policy matters. Elections to the board are held once a year at its annual general meeting. The RGS-HK’s chairman is James Riley. The branch is run by a director, Rupert McCowan, and two administrators, Wendy Poon (events and schools outreach administrator) and Frances Chim (membership administrator).

One of the most common quantitative thematic map types is the choropleth map, in which magnitudes of area-based statistics are portrayed by fill colors, shades, or patterns as they occur within the boundaries of the unit area (Figure 1). The word choropleth is taken from the Greek words chorós (place or area) and plethein (to fill). The earliest choropleth maps can be traced back to the early 1800s. Choropleth maps became progressively more common throughout the nineteenth and twentieth centuries, first with the increasing prevalence of census and other statistical data, then with the advent of computer mapping, geographic information systems (GIS), and other software that automated most of the cartographic procedures that were previously done using time-consuming manual methods. Web delivery of choropleth maps further accentuated their widespread use and appeal; this trend continues today. Some of these maps also have interactive and/or animated capabilities not available in printed static maps.

Choropleth maps are also popular because the rationale behind a sensibly designed choropleth map is typically well understood by most map-readers. They are able to see the geographical patterns in the mapped statistical values (also called attributes) and are able to compare different areas on the map. When two or more choropleth maps are involved (e.g., unemployment and education rates for a particular region or US population density in 1950 and 2000), the map-reader can compare areas between the maps. When the maps are small in size and have similar structure and context in order to facilitate comparisons between the maps, they are called small multiples (Tufte 2001). The choropleth map can also be portrayed in 3-D, where the enumeration units’ heights are scaled to the data values (Figure 2). In many interactive choropleth maps, the individual attribute values can often be seen by a simple click or mouse-over in the unit area. However, for the reader who wants to find only individual values apart from the spatial distribution, it would be more efficient to consult a table.

**Attribute data**

Effective portrayal of statistical data is of prime concern in thematic mapping. Although choropleth maps can technically be created for any area-related numeric value, cartographers emphasize that some form of derived data (e.g., rates or ratios) should be used in the mapping process. The enumeration unit areas tend to vary in most choropleth mapping situations and the use of derived data provides standardization throughout the map. Ratios can involve areas (e.g., people/mile²) or other ratios independent of area (e.g., per capita income or birth rates).

The attribute data are always tied to some form of enumeration unit, such as countries, provinces, states, counties, census tracts, regions, or other divisions. In Figure 1, the unit is the county. Since all maps are generalizations of reality, it is important to remember that a choropleth map will portray the attribute value uniformly across the enumeration unit. This
implied homogeneity is a common criticism of choropleth maps, especially when using larger enumeration units such as countries. A choropleth map can become less generalized by using smaller enumeration units, although the appropriateness of using smaller units is highly dependent on the map purpose, level of acceptable generalization, map scale, and often, most importantly, data availability. If these levels of generalization are not acceptable, one alternative is to use another thematic map type. For example, in dasymetric mapping, zones of a more uniform statistical value are created that may not necessarily follow enumeration unit boundaries.

Data classification

Attribute values are often grouped into classes in order to simplify the pattern of distribution for the map-reader (Figure 1). This type of generalization is called data classification, a process that is very common in choropleth mapping. Cartographic convention has been to use anywhere from four to seven classes as a possible starting point for choropleth maps, but the number of observations, consideration of possible data outliers, the color choices, the map medium, and the purpose of the map can all influence the number of classes. A greater number of classes reduces each class range and, thus, lessens the amount of generalization in the map, but the increased complexity may make interpreting the map more difficult. If a choropleth map does not undergo data classification, it is considered to be an unclassed choropleth map, in which there is a unique color or symbol for each observation in the attribute data (discussed below).

There are a number of different data classification methods that may be employed when classifying data for choropleth maps. Natural break methods, either by visual inspection of the

---

data or by the use of a computer algorithm such as Jenks Optimal, group data so that all values within a class are as alike as possible (maximizing class homogeneity), and class breaks occur where there are larger gaps in the data. Natural break classification methods produce visual results that a map-reader will typically expect – that enumeration units with like symbolization will have greater similarity in attribute value than enumeration units with different symbolizations. Note that this method typically produces varying class intervals and numbers of observations in each class.

Equal interval and equal frequency (also called equal step and quantiles, respectively) are two of the more traditional classification methods used in choropleth mapping. Equal interval classification groups the data so that class ranges are all the same. This method is often used for multiple choropleth maps that use the same legend, as well as animated choropleth maps, where enumeration units may change classes and their subsequent symbolization throughout the animation. Some cartographers also feel that the equivalent class ranges make the map legend easier to read. Equal frequency classification, which generates an equal number of observations in each class, is useful for statistical tests between the classes that require the same number of observations, as well as for comparing quantile classes between different choropleth maps. Note that equal interval and equal frequency methods typically fare poorly when quantitative assessment measures for class homogeneity are applied (Dent, Torguson, and Hodler 2009).

Other classification methods used in choropleth mapping include arithmetic and geometric classification, which are sometimes used for data with skewed distributions. For example, class ranges will become progressively larger to accommodate attribute data that are increasing or even increasing at an accelerating rate. When the statistical data have a normal distribution, many demographers and other social scientists employ the mean and standard deviations to determine the class breaks. In this case, class breaks fall at standard deviations above and below the mean value in the attribute data. Still other cartographers use defined breaks (user-defined) that match a special purpose. The classification breaks may fall along critical values, such as tax brackets, a poverty line, or other break point that is relevant to the map (Kimerling et al. 2012).

An unclassed choropleth map results when each observation has its own unique area symbol (Tobler 1973). Such a map eliminates the generalization caused by data classification, as each class “range” with a single observation achieves class homogeneity. Unclassed choropleth mapping began receiving academic attention in the 1970s but, until recently, relatively few unclassed maps were created compared to classed choropleth maps. Unclassed choropleth maps are typically more difficult to create than conventional classed maps; many cartographers feel that classification is a necessary part of the map generalization process and leaving the map unclassified gives it an unstructured look. Nonetheless, map-readers can detect major trends in the distribution patterns (Figure 3) and, with the influences of scientific and cartographic visualization, unclassed choropleth maps are both more numerous and, perhaps, less controversial than a few decades ago (Dent, Torguson, and Hodler 2009).

Symbolization

The symbolization used in choropleth maps involves the use of one or more visual variables to portray areas of higher and lower attribute values for each enumeration unit. In black and white (or grayscale) mapping, patterns or shades within each unit create a light-to-dark
Figure 3  Purple America is an unclassed choropleth map in which the percentage of those voting Republican or Democrat for each county or county equivalent is represented by a unique mixture of red and blue. This legend illustrates the use of a bipolar or divergent color scheme (see text for discussion). Note that visualizations such as this may or may not have an associated legend. The point is simply to get a feel for the overall data distribution without getting bogged down with numbers. Source: Robert J. Vanderbei. progression suggesting lower and higher attribute values. For pattern fills, units with the highest attribute values will have the most dense texture or pattern. With solid shade fills, the highest values (or percentage black) will have darker tones. Solid shade fills are more common today than pattern fills. Black and white choropleth mapping is still common where higher printing costs associated with color maps are an issue; it also works well for readers with color deficiencies.

Choropleth maps today are more likely than ever to be produced in color, largely because they are often produced as virtual, on-screen maps. For printed color maps, the cost disparity between color and black and white printing, while still significant, is much less than it was a few decades ago. Color also affords the cartographer many more design options, but those options make design multifaceted, as there are over 16 million colors to choose from on many platforms today. The designer has to choose wisely in order to make an effective choropleth map. In color mapping, darker hue, hue values, and/or more saturated colors indicate higher
attribute values and vice versa. The resulting sequence is often referred to as a color ramp. Sometimes the color ramp values are along one hue (e.g., light red to dark red) and sometimes multiple hues are used (e.g., light yellow to medium green to dark blue).

While most GIS and mapping software today provide quite a number of options for various color ramps that visually suggest “more” and “less” in the data, web applications such as ColorBrewer 2.0 (Brewer 2014) are commonly used to assist cartographers in making better color choices for their choropleth maps. ColorBrewer 2.0 is a guide that allows the user to select the number of classes, the type of color ramp, and the specific color scheme. A map shows what the result looks like, and will also indicate if the map will work well for individuals with color deficiencies, if it will photocopy well, and if it is appropriate for liquid crystal display (LCD) and/or print formats. Additionally, it will export the color values to a number of formats, including those appropriate for GIS, artistic drawing programs, and web programming platforms.

Sometimes statistical attribute data do not simply progress from a lowest to highest value. Occasionally, data diverge in two directions from a central value or a central class range. A bipolar map results when a divergent color ramp is applied to this type of data (Figure 3). A few examples include percentage increase/decrease, profit/loss, or above/below average (Dent, Torguson, and Hodler 2009). If the data for a bipolar map are distributed normally, the mean and standard deviation classification scheme is sometimes employed (see discussion above).

Bivariate and multivariate choropleth maps show two or more related variables on the map through symbol variations in color and/or pattern fills. For example, median age and per capita income can be compared by incorporating a 2-D color ramp to create a bivariate map (Figure 4). Although research in multivariate choropleth mapping with three or more variables has occurred (Carr, White, and MacEachren 2005), cartographers must employ quite a bit of ingenuity to create these multivariate maps, perhaps by using scripting, since they are not directly supported in most GIS and mapping software. Some cartographers will find it easier to simply juxtapose multiple choropleth maps side by side for comparison.

Bivariate and multivariate data can also be mapped by using the choropleth map as a base, and then superimposing a dot-density layer, a proportional symbol layer, or other thematic map type on top of the choropleth map. While this approach is easily done in most GIS and mapping software, some map designers caution that it is easy to visually overload such a composite map with too much data (Dent, Torguson, and Hodler 2009).

**Legends and other design issues**

The legend on most choropleth maps serves as a referent or visual anchor between the map symbols and the legend. This is a supporting role, so the legend is typically lower on a visual hierarchy (it is typically smaller than the map, for example). In Figure 1, four class ranges represent most of the counties; a fifth class has the outliers labeled. On some choropleth map legends, the class ranges are depicted in a noncontinuous fashion. That is, they represent only the minimum and maximum values for each class. Noncontinuous reporting is useful for narrowing the class ranges so the reader more accurately interprets the data in each class. The continuous style (depicted in Figure 1) has no gaps or overlaps in the class ranges and is a more traditional presentation of a choropleth map legend. The continuous style is also often applied to animated or sequential map series, in
which only one legend is used and data values can drop in and out of the different class ranges throughout the series or animation.

Legend titles are typically reflective of the attribute data in the choropleth map and will be consistent with the title or figure caption. For example, if the data is population density or poverty percentages, the legend title will be something like “People per square mile” or “Percentage” as opposed to “Legend,” “POP10_DEN,” or “%.”

Another important aspect of choropleth map design is the choice of map projection. All maps contain projection distortion, especially at smaller scales. Since the distribution of data is being compared throughout the map or between a set of maps, most cartographers tend to favor equal area (or equivalence) projections for thematic maps, including choropleth maps. For example, Figure 4 was created using an Albers equal area projection. Although other map projection properties (conformal, distance, direction) or minimum error/compromise projection (balancing distortion properties) are also used in choropleth mapping, the equivalence property is typically the most important.
As with most maps, choropleth maps have very subjective aspects to their layout and design. For example, some choropleth maps also include general reference features such as cities, roads, rivers, and the like. Some designers like to keep choropleth maps simple, arguing that the inclusion of these features causes clutter and, if taken to an extreme, may take away from the main point of the map. Others feel that selective use of reference features can provide important contextual information and enhance the value of the choropleth map. For example, a few large cities portrayed on a choropleth map may help with the interpretation of patterns such as population densities or crime rates (Figure 5).

Another example of subjectivity in choropleth map design can be found in what is included in a choropleth map layout with regard to the area surrounding the map body. Traditional

**Figure 5** The addition of some reference information can give additional context to the choropleth map. Source: Dent, Torguson, and Hodler 2009. Reproduced with permission of McGraw-Hill.
cartographers often insist that all maps must have a certain set of basic map elements, such as a scale bar, north arrow, title, legend, and so on. Designers favoring a data visualization approach to cartography often eschew most, and sometimes all, of these basic elements to allow the viewer to see the data in an as unfiltered manner as possible. Most current textbooks on thematic cartography tend to take a nuanced view in that what is required on a map may change according to the map purpose, the intended audience, the scale of the map, and the final output for the map.

The future of choropleth mapping: mashups and more technology

As noted already, web delivery of choropleth and other thematic map types is on the increase. One increasingly popular method of displaying choropleth maps is to export the map layout to a format such as KML (keyhole markup language), in order to display the map in popular web applications such as Google Earth, Google Maps, or other readily available web mapping platforms. This approach is often referred to as

Figure 6  Choropleth map mashup with Google Maps. Average gasoline prices are depicted for each county. Used by permission. Source: GasBuddy.com, http://www.gasbuddy.com/gb_gastemperaturemap.aspx.
a mashup, as the choropleth map is displayed on top of the existing map, satellite, or aerial photography provided by the web application in a single view (Figure 6). The advantage to this method is that the map-reader then has all of the benefits of using the platform’s capabilities, such as zooming, panning, and so on, as well as a familiar interface. With most choropleth map mashups, the user is also able to click on individual enumeration units to see the name, individual value, and other attributes.

At the time of writing, one possible disadvantage to this technique is that the base map on which the choropleth map is displayed uses the web Mercator projection. The conformal properties of this projection ensure that roads that intersect at 90° angles in the real world also have right angles on the map. While a necessity for traffic-routing and navigation purposes, the Mercator projection has one of the highest amounts of distortion for mid-to-high latitude small-scale maps. This distortion is most noticeable on world maps (Greenland appears as large as Africa) and, as such, is typically not recommended by most designers for choropleth or other thematic mapping activities.

Technological advances are happening at an increasing rate. While predicting technological change is difficult, support for choropleth maps in GIS software and mapping programs will, nonetheless, continue to be nearly universal, as is the case at present. Increasingly powerful computers, faster Internet speeds, cloud computing and data storage, a wider range of platforms for map display, and futuristic human–map interfaces will all likely play a role in future choropleth map developments.

Cities and development

Garth A. Myers  
Trinity College, USA

Questions about the relationships between cities and development have echoed through the last 50 years of both urban geography and development geography. Some take the relationship as a given: cities are development, cities bring development, development leads to more urbanization, and the cycle repeats. Others take nearly the opposite view: cities are parasites that suck (under-)development out of rural people, and cities destroy human development. The realities in the world fall somewhere in between, or combine some elements of each side’s claim. Cities do manifest development, but always at a cost to other places and people, and always unevenly. It is perhaps one of humanity’s greatest current and future challenges to find the ways to ensure that urbanization and both economic and social development lead to the betterment of the existence of all – or at least a great majority – of the world’s ever-increasing urban population.

It is useful to note that there are no secure agreements across the world on how to define either cities or development. Both official and scholarly definitions of what a city is vary considerably across the world, despite general agreement on the basic idea that a city is “a relatively large, dense and permanent human settlement” (Beall and Fox 2009, 7). Beyond that general understanding, though, countries use different population parameters for delineating the threshold of cityhood, to say nothing of which areas are, or are not, included in a metropolitan area. Development, too, is understood very differently around the globe beyond a generally shared basic notion of progress. Great variation exists in the relative weight given to economic versus social indicators in measurements of development (for example, a typical measure of the former is the gross domestic product (GDP) per capita of a city, while the latter might use life expectancy or adult literacy rates as proxy measures), and data vary tremendously in availability and quality across the world’s cities for making comparisons.

Another fundamental problem lies with the fact that for a long time the study of cities and the study of development existed as essentially separate realms of geography, divided by the region of the world in which scholars conducted research. Urban geography essentially belonged to cities of what is variously termed the First World, the Developed World, the More Developed Countries, or the Global North. By contrast, scholars studying cities in what is called the Third World, Developing World, Less Developed Countries, or the Global South were presumed to be studying development, since cities in the Global South were not quite developed as proper (Western) cities (Robinson 2006). To some extent, that sort of dichotomization of previous scholarship may be overdrawn, and in any case it has changed considerably in the last decade, during which a mounting critique has challenged universal understandings of urbanism that emanate from European and North American cities. This critique has energized a reconsideration of the need to construct global hierarchies of cities, the criteria for positioning on such hierarchies, and the desirability of policymaking aimed at boosting a city’s rankings on them (Myers 2014). The critique has also
coincided with a prolonged global economic crisis which has unsettled common understandings of or policy prescriptions for development (a palpable manifestation of this confounding state of things came to light, for example, when Portugal, nominally a country of the Global North, sought aid from Angola, its former colony in the Global South, amidst its severe financial crisis in 2011). While urban geography scholarship continues to be divided by world regions and by ideological economistic categorizations into Developed/Developing World, First/Third World, or Global North/South, there is now a substantial countertrend in the literature, matching the doubts which now surround the mainstream developed-world models for development in the developing world.

Many scholars of Global South urbanism now demand greater attention for the urban areas in their midst in the development of theories about cities, potentially to the point of upending the privileged place of Global North cities in these theories (Roy 2009). But there is also a growing arena of research exploring common ground and reciprocal or even reverse idea flows between Global North and Global South urban contexts, South–South comparativism, and growing networks of learning and policymaking across the Global South. There is an increasing amount of exploration of interests held in common between those working on Global North and Global South cities, leaving behind biases and assumptions of privilege in an effort to focus on emergent patterns and processes specific to different cities or city-regions.

As the divides have begun to break down, what is emerging is not necessarily a new universality – though that claim has its proponents, whether in theories of planetary urbanization or of global city-regions – but a greater appreciation for how varied the processes of urbanization are in different parts of the world, and even within one country’s cities. Instead of force-feeding cities into one lens on their development, it increasingly makes sense to speak of themes held somewhat in common but with comparative variation in urban development worldwide. The examination of seven of these themes below (urbanization itself; economic versus social development; poverty and inequality; housing; urban governance and planning; urban services and infrastructure; and urban environments) briefly highlights the commonalities and the differentiations across global urban geography. If we start from the very basic questions of what scholars study when they study both cities and development at once, then it is not difficult to center in on these themes. Since urban geography is quite vast, it is impossible to encompass the entirety of relevant work within these themes (let alone to account for other genuinely valid themes, such as crime and violence, megacities, or the future of urban design), but they definitely provide a broad map of work at the intersection of cities with development.

**Urbanization itself**

During the last decade, the proportion of people living in cities passed 50% of the world’s population. During the nineteenth and early twentieth centuries, Europe, North America, and selected countries in Latin America and Asia rapidly urbanized. Generally speaking, for much of the last half-century, though, the predominant theme has been the rapid population increase of cities in Asia, Latin America, and, increasingly, Africa. It follows that we have had several decades now of contrasting rates of growth for urban areas in the Global North and South. Many Asian and African countries, in particular, have experienced a half-century of rapid urbanization coterminous with a substantial slowing – or
even reversal – of urbanward population flows in much of Europe and North America.

What is more, the character and geographic patterns of land use for metropolitan growth have varied considerably. In some parts of the world, urban growth corridors, extended metropolitan regions, or global city-regions are highlighted, but even within these conceptualizations substantial variation exists. Where an earlier generation of urban geographers generated human-ecological models of urban land use out of development processes in cities like Chicago and applied them universally, it is more common now for scholars to seek less universalizing models given the great variability and fluctuation of the last few decades in urbanization. To wit, many of the world’s most rapidly urbanizing countries of the past half-century have been in sub-Saharan Africa, and that region’s rapid urbanization rates provide urban geographers with many questions which provoke caution for grand theorization. In some countries (e.g., Botswana or Ghana), rapid rates of urbanization appear to correspond well with high rates of economic growth, but in other countries with rapidly growing cities this urban growth has occurred during a period of economic stagnation or even amidst an economic downturn. Substantial debates have surrounded the actual data on urbanization, such that some scholars make persuasive claims for a region-wide slowing of urbanization, with even a few reverse migration trends, wherein there is no one single correspondence with overall development trends (Potts 2009).

Economic development versus social development

This debate over the relationship between urbanization and development carries over into a debate over how to characterize development. The role of cities in fostering economic development is a strong theme of longstanding centrality in urban geography research, but a parallel theme – exploring connections between cities and sociocultural development – has risen to the fore in recent decades. So on one hand, urban geographers have shown the deep connections which exist between urban growth and economic prosperity. Relatedly, as cities grow, their significance to sociocultural development in their respective societies expands. On the other hand, urban geography research has long debated the socioeconomic inequalities attendant with urbanization.

Indeed, urban geographers with deeply varied ideological commitments have focused their research concerns on the bifurcated processes and outcomes of urban development, spatially and socially. As United Nations Secretary-General Ban Ki-moon put it in his preface to the UN Habitat’s (2013, iii) *State of the World’s Cities* report, “cities can be prime driving forces of development and innovation. Yet the prosperity generated by cities has not been equally shared, and a sizeable proportion of the urban population remains without access to the benefits that cities produce.” This general understanding then leaves room for considerable discussion of urban poverty, inequality, and injustice within the realm of “cities-and-development” studies.

Poverty and inequality

Following from the concerns with the social down side to urbanization processes, research has identified the rise of inequality in many cities, in both the Global North and the Global South. The growth of the urban middle class has run parallel to persistent poverty. Gini coefficients of income inequality are fairly consistently higher
for urban areas in comparison to rural areas in most countries. Even though urban incomes are broadly twice as high as rural incomes across the world, levels of urban poverty are often shockingly high, even in the world’s wealthiest and most urban societies. Hartford, Connecticut, which a 2012 Brookings Institution study identified as the richest metropolitan area on the planet, contains at its core the city of Hartford itself, ranked as the fourth-poorest city in the United States, with a regionally high Gini coefficient of income inequality (Chen and Bacon 2013). The nearby metropolitan area of Fairfield-Bridgeport, Connecticut, is simultaneously the heart of the region’s Gold Coast bedroom communities of millionaires and billionaires, and home to the worst Gini coefficient of income inequality of any US city. Similarly, cities such as Johannesburg, South Africa, Windhoek, Namibia, and Lusaka, Zambia, contain among the world’s highest levels of income inequality, and yet each contributes a far higher proportion to its nation’s GDP than its population would warrant on a per capita basis (UN Habitat 2014). The fragmentations and polarizations attendant with urbanization in the twenty-first century demand attention from both policymakers and urban activists or advocates for social justice (Mitlin and Satterthwaite 2012). The inequality tangibly evident in urban housing and housing rights provides a visual and visceral reminder of this significant challenge for contemporary cities around the world.

Housing

As the UN Habitat (2013) report indicates, making the prosperity that cities generate available for the benefit of a larger proportion of the urban populace is now a major global urban development policy focus. The struggle to make housing and residential development more equitable has become a central feature of these policies. Housing has been a crucial research theme of urban geography scholarship across the globe for more than 50 years. Global North urban scholarship on housing development has long concentrated on the contrasting housing markets of many cities, made more intense with globalization. One major contemporary theme concerns the transformation of public housing under various forms of governance. Another focus has concerned the housing dynamics of an increasing population inversion whereby, in the United States for instance, suburbs (especially inner-ring suburbs) are becoming increasingly diverse while declining economically as city centers slowly begin to rebound economically through increasing demand for upper-income residences (Ehrenhalt 2012). These US patterns parallel patterns in some European cities, but there are also marked distinctions in the transformations of inner-city and suburban housing in London, Paris, and Rome, for instance, such as in the quite varied impact of changes in peri-urban public housing projects (discussed in the Parisian context as banlieue suburbs) or rather different dimensions of residential squatting.

The contradictory expansion of both gated communities and informal settlements (often appearing as or described as slums) is a major concern for scholars of Latin American, African, and South- and Southeast Asian cities. Migration dynamics provide for both expanded transnational housing development strategies and dramatic changes in household dynamics. The gentrification of poor and working-class areas in cities, long debated in Global North contexts, has now increasingly become a theme in Global South scholarship, with the notable twist that many researchers challenge the applicability of the debate’s Northern terms within Southern cities. Still more Global South scholarship has
highlighted the contradictions in the progress made in reducing slum housing conditions while overall slum populations continue to grow and elite housing expands apace (Huchzermeyer 2011). In some notable cases in particular such as Brazil, claims are made for approaching goals set in the Millennium Development Goals for slum eradication, and yet favela (informal settlement) populations have increased. This debate on how to measure or gauge progress in slum eradication in turn generates broader debates about urban policy in terms of governance and planning.

**Urban governance and planning**

Neoliberalism, generally speaking, entails support for free trade and free markets, and limitations on the role of governments in the economy. In urban contexts, neoliberalism is manifested in municipal governance that is heavily reliant upon private sector involvement and public–private partnerships. Urban geographers have made a broad distinction between rollback and rollout neoliberalism – where the former entails elimination of urban governmental units or agencies as part of a privatization of urban management, and the latter entails the creation of new governmental units or agencies whose purpose is to facilitate capitalism (Peck and Tickell 2007). During the 1980s and 1990s, urban policies and development policies around the world came under what came to be called the Washington Consensus, the tacit agreement among the major development donor states (the Organisation for Economic Co-operation and Development (OECD) member countries, mainly) that neoliberal strategies were essentially the only path for development. During the 2000s, and particularly following the prolonged global financial crisis that began in 2007, the Washington Consensus began to crumble, leading to substantial reconsideration of neoliberalism in the governance of many countries and cities around the world (Robinson 2011).

Debates concerning neoliberal governance have transcended geographic boundaries. The expansion of neoliberal urban governance tactics and strategies into the cities of the Global South from the 1980s onward, alongside the spread of professional urban planning practice heavily influenced by the West, has shaped much of the discussion of the roles of states in urban development. Scholars have engaged in increasing debate on what the most appropriate governance arrangements and policy approaches can be for making cities prosperous and inclusive at the same time as they forge rights to the city for all (Brenner, Marcuse, and Mayer 2012). Proponents of neoliberal urban governance are rather rare in scholarly research despite the ubiquitous turn earlier on toward various forms of neoliberal planning in urban practice and in the policy realm – and the continuing significance of neoliberal thinking in OECD development agencies and the international financial institutions (the World Bank and the International Monetary Fund).

The increasing global significance of BRICS countries (Brazil, Russia, India, China, and South Africa) as both sites of and investors in urban development has brought increasing attention to their governance and planning approaches, particularly in terms of their potential relevance, or lack thereof, in cities of the developing world. In many BRICS cities, strict adherence to neoliberal principles is rare. In Brazil, and in many Latin American cities more broadly, municipal and national governments have actually played an increasing, and often populist or progressive, role in urban management in the last decade or so. China’s unprecedented urbanization has similarly involved a substantial role for local, regional, and national state
institutions in urban governance, planning, and management.

This flows inevitably into questions surrounding the relationships between democracy and urban development. Neoliberalism’s advocacy for increasing private sector involvement in urban governance is inconsistent in regards to democracy, with highly uneven degrees of access to citizenship or to rights to the city. Cities around the world have been, to some extent, set aflame by rebellions often based around exactly this disconnect (Harvey 2012). The United Nations Sustainable Cities Program and UN Habitat as a whole brought forward an agenda for urban planning and management in the late 1990s, strongly influenced by what was then the World Bank’s Cities Alliance, advocating “Environmental Planning and Management” (EPM) in cities around the world as a means of fostering inclusiveness in planning. Yet the UN itself on numerous occasions championed fundamentally undemocratic planning practices and processes as supposed best practices of this EPM model. The reasons given for lauding these specific examples often emerged in their efficiency, particularly in service delivery, at the direct expense of popular participation and input (Pieterse 2008).

Urban services and infrastructure

The most tangible governance and planning questions in cities concern the provision of municipal services and infrastructure – for water, solid waste, electricity, transportation, and education, among other factors. The drive for the privatization of service provision, under both rollout and rollback neoliberalism, has stalled in the past decade. From Detroit and New Orleans, to Cape Town and Shanghai, and on to London or Paris, cities are in search of the most effective and efficient balance between public, private, and popular sectors for service and infrastructure provision. No one single approach has proven most effective, despite the claims of various partisans. For every case study of privatization successes in urban service provision, one can find counterexamples of failed engagements of the private sector; similarly, there is quite a range of outcomes for state-led service provision. In some cities, public–private or public–private–popular sector partnerships have improved water supply, solid waste management, or public transportation, but scholars have likewise documented shortcomings for many of these varied partnerships.

The economic rise of China in the past two decades has further transformed discussions about urban service provision in the world’s cities, particularly in terms of infrastructure construction. Across Africa, Latin America, and Asia, Chinese engineering firms have been active in developing sanitation, airport, seaport, bus, subway, highway, and light rail systems for rapidly growing cities around the Global South. Other Global South – and in some cases, Global North – development partners have expanded their urban infrastructure investments abroad as a result. This then further muddles the policy debate questions surrounding neoliberalism in urban governance. It also often draws attention to the increasingly profound environmental impacts of urbanization.

Urban environments

Urban development has profound environmental consequences. Air pollution, water pollution, and land degradation are among the most immediate of these consequences. The more rapidly that societies urbanize, the greater the potential for negative externalities in the environment. The above discussion of urban services and
infrastructure has suggested connections to the environment which can now be made more explicit: the lack of waste and sanitation services, or lack of urban management of air, water, and land, can have and has had direct negative consequences in many cities for the health and wellbeing of humans and other beings in the urban setting. From the more quotidian concerns with these externalities, recent scholarship has turned to analysis of global climate change and its implications for cities. Environmental disasters, such as the 2005 and 2011 tsunami events which devastated many eastern Indian Ocean Rim communities and then eastern Japanese cities, respectively, or the recent devastating earthquakes in Chile, New Zealand, and China, have remained a crucial focus of research in urban geography and urban development studies, but often with the added component of the climate change dynamics potentially linked with these mega-events.

Urban geographers have brought vital attention to the politics of urban environments in urban development processes. Urban political ecology has been influential in drawing a political focus on urban metabolisms into the frame in a manner which extends past concern for mere nature and environment (Heynen, Kaika, and Swyngedouw 2006). At the same time, urban political ecology has been challenged over questions of the universality of its language and applicability of its Global North-derived concepts in cities of the Global South (Loftus 2012). This critique extends to questioning the literature of sustainable urban development, which likewise often fails to account for Global South urban dynamics. The Sustainable Urban Development Reader (Wheeler and Beatley 2009), for instance, contains very few readings on Global South cities, and none on African cases. Regardless of these shortcomings, urban environments are sure to be central to research at the interface of cities and development for the foreseeable future.

Myers, Garth. 2014. “From Expected to Unexpected Comparisons: Changing the Flows of Ideas about

Citizenship

Lynn A. Staeheli
Durham University, UK

Citizenship is a complex, contested, and even confusing concept. It is most commonly defined as a legal standing that connotes membership in a national polity, the guarantee of rights, and consent to obligations associated with membership. This definition is insufficient, however, as citizenship is most often acquired passively by virtue of being born in the territory of a country (jus soli) or to a relative who is a citizen (jus sanguis); typically, only those who go through a process of naturalization or who renounce citizenship take a conscious choice to accept the status, rights, and obligations of citizens. Furthermore, the concept is freighted with normative expectations that may be hidden by defining it simply as a legal status.

Legal and substantive citizenship

Many philosophers distinguish between the legal or procedural aspects of citizenship and its substantive aspects. Discussions of the legal aspects include the mechanisms by which the formal standing of citizenship is conferred, the specific rights and protections accorded to citizens, and the obligations or responsibilities that citizens accept. In liberal political theory, the legal aspects of citizenship are generally only relevant to individuals. Individuals, rather than social groups or places, are generally the holders of rights and responsibilities, although the means by which citizenship is extended may involve an element of group struggle, such as in women’s suffrage movements in the nineteenth and twentieth centuries in the Global North. While the legal standing as citizen has always been exclusionary in some way, the narrative of the history of citizenship has been one of increasingly greater inclusivity, as citizenship has been extended from a few landed elites under a feudal system, to property-owning males, to most males (or at least in the Global North, to white males), to women, to immigrants, and so on. In this way, the legal standing of citizenship is often described as universal, or open to all, even if not everyone living in a country holds the legal citizenship of that country.

While the legal standing of citizens is important, liberal and republican theories of citizenship draw attention to different elements of it. From the perspective of liberal theory, citizenship entails a set of protections from a state (or sovereign) through law and legal standing. Such protections often include freedoms of speech and assembly, freedom from unreasonable restraints of liberty, and the rights to fair and equal treatment by the state. From the perspective of republican theory, by contrast, participation in governing is crucial, and legal supports – and requirements – for participation are highlighted. These supports might include trial by jury, systems of deliberation and voting, and other forms of participation. While these two perspectives are sometimes put in opposition, they can be seen as reinforcing one another, as protection of basic freedoms from the state may be necessary for citizens to participate in self-governance. Both perspectives, however, recognize the centrality of legal standing and legal systems to citizenship.
CITIZENSHIP

Even in focusing solely on the legal aspects of citizenship, its spatiality is evident in at least four ways. First, in many countries with a federal structure, individuals may simultaneously be citizens of multiple jurisdictions, ranging from a municipality to provinces, cantons, or states, to the national government. To some extent, then, the rights and responsibilities held by individual citizens are qualified by the geography of the countries in which they live. Second, countries that have been partitioned – often through war and subsequent “peace processes” – sometimes embed complex and contested citizenship identities associated with internal territorial division. In the case of Bosnia-Herzegovina, for instance, the country is divided into two “entities,” the Republika Srpska and the Federation of Bosnia and Herzegovina. Leaders of the entities disagree whether national or entity-level citizenship should be primary, and the persistence of these divisions reflects the continuing claims of Serbia and Croatia for territory within the country. The unsettled questions of where or of what one is a citizen are literally mapped in the geographies of citizenship in these contexts. Third, and since at least the middle of the twentieth century, with the Universal Declaration of Human Rights in 1948 and the subsequent development of supranational and international rights regimes, the ways in which citizenship is affected by legal structures at scales other than that of the nation-state have been a focus of many academic texts that posit the possibilities for, and potential of, a global citizenship regime with a legal apparatus – such as the International Court of Justice – to support it. Finally, at a time when many people live in countries other than the ones in which they have legal citizenship and when dual citizenship has greater acceptance, the spatiality of the legal aspects of citizenship becomes ever more complicated.

Citizenship, however, has always implied more than legal standing, and some scholars focus on what are described as the substantive aspects of citizenship. From this perspective, citizenship is better understood as a public standing (Shklar 1991) that is recognized by conferring a legal status labeled as “citizen”; the extension of citizenship to larger portions of the populace reflects a changing view of social groups (e.g., men without property, women, racialized minorities) as being worthy of citizenship, as being able to act as autonomous citizens, and as capable of participating in self-rule, historically at the level of the city. Scholars making this argument recognize the legal aspects of citizenship but argue that the legal standing of citizenship is predicated on social recognition of the political subjectivity and personhood of individuals.

In addition to a more inclusive view of who should be recognized as a citizen, there has also been a fluctuation in what citizenship entails. T.H. Marshall (1950) may be the most prominent exponent of this view. In his essay “Citizenship and Social Class,” Marshall argued that the rights associated with citizenship had expanded in European countries from those associated with civil rights (such as those protecting individual freedoms) to include political rights (such as voting, and the right to stand for office) to social rights (such as the right to education and social welfare support). Significantly, Marshall’s formulation emphasized the responsibilities of the state to its citizens. The recognition of citizenship as predicated on public standing and as encompassing a broader range of rights to support equality are both discussed in terms of the substantive aspects of citizenship.

Attention to the substantive aspects of citizenship considerably broadens its scope to include structural relationships and the positioning of individuals and social groups with respect to the economy, society, and politics, often in
contradictory ways. Poverty, for instance, is not simply a lack of money but also affects the ability to meet obligations such as payment of taxes. If the obligation not to be a burden on others is also seen as a responsibility of citizenship, then reliance on social welfare support – as a social right of citizenship – may also be seen as the failure to be or to act as a responsible citizen, and can be used to justify the withdrawal of social rights. Similarly, behavior and deportment that violate social norms may be used to justify exclusion from at least some benefits of citizenship, or to support claims that groups or individuals are unworthy of citizenship. Thus, debates over who should be recognized as citizens and what kinds of rights should be extended to citizens are complicated by the positioning of individuals and social groups with respect to the economy, society, and laws that extend beyond the formal definitions, the laws that condition citizenship and who will be seen as a citizen include those related to education, welfare, family structure, and more. In this way, citizenship is structured through both law and the relationships of daily life and experience (Staeheli et al. 2013).

The substantive aspects of citizenship have a complex spatiality that extends beyond that noted earlier. The complex legal structures identified earlier are, of course, important. Beyond these, however, citizenship takes on different configurations and meanings around the world, reflecting differing legal structures, economic conditions, political settings, and social relationships and histories. The rights of citizenship, for instance, differ in accordance with the development of the welfare state in different countries, as well as with determinations of who should be able to access them and the ability of the state to meet its own obligations. For instance, housing is a right of citizenship conferred through the South African constitution. The explicit mention of housing as a right is unusual in a national constitution, but it reflects the country’s vision of itself as a modern cosmopolitan country that is committed to human rights in their entirety. The inability of the country to even begin to meet that commitment, however, reflects the poverty and inequality that are enduring legacies of apartheid. It also means that the “right” to housing is rhetorical, and perhaps normative, rather than something that can be accessed in practice.

The geography – or spatiality – of citizenship is, thus, a reflection of historical legacies, social and economic cleavages and relationships, and geopolitical positionings. Sometimes these differences can be dismissed as a mismatch between rhetoric and reality, as in South Africa. Sometimes, differences between the citizenship regimes of countries reflect norms related to what it means to be capable of assuming the responsibilities of citizenship. This point is perhaps most clear with respect to children and young people; countries differ in the ways that children and young people are viewed in terms of their abilities to assume the responsibilities of citizenship and the rights that they are believed to be able to wield effectively. More controversially, differences in citizenship may reflect histories of colonialism, political “development,” “culture,” and geopolitical relationships. Put bluntly, people in some countries are discursively constructed as being incapable of acting as citizens, either because their states have “deskilled” them (e.g., this was the argument about Eastern and Central European countries during postsocialist transitions) or because of Orientalist discourses that construct citizenship as fundamentally modern/Western and therefore somehow incompatible with some cultures or regions (e.g., as is claimed about Middle Eastern countries; see Isin 2002).
CITIZENSHIP

Who can be a citizen?

As noted, legal standing as a citizen is usually conferred through birth, and is sometimes described as a birthright. Yet recognition and the ability to act as a citizen are more complicated than this assumption might imply, and the complication is not simply with respect to the substantive aspects of citizenship. One of the key issues is the perceived ability of individuals to govern themselves and to act autonomously and responsibly. One’s standing as a citizen, therefore, is evaluated in terms of personal characteristics and deportment, which are then compared with normative expectations of how citizens should behave. Failure to meet those expectations rarely results in the formal withdrawal of legal citizenship, but one’s standing as a citizen may still be called into question. In many countries, for instance, convicted criminals often lose the right to vote, in addition to the rights to movement and liberty. More controversially, “workfare” regimes sanction citizens who fail to be self-sufficient (in other words, they rely on the welfare state to meet basic needs), often through the withdrawal of welfare and some of the support that has come to be seen as constituting the social rights of citizenship, as previously noted. Thus, the characteristics and behaviors of individuals can be critical to their being recognized as citizens and to their ability to access rights in a given context.

Perhaps the most important, normative characteristic of citizens in democracies is the ability to act autonomously and rationally so that they can participate in self-governance and self-rule. In this way, citizenship is often linked to democracy, even if the nature of democracy is contested. Indeed, for some theorists, the concept of citizenship is not meaningful in the absence of democracy, and they would describe members of an undemocratic state to be subjects, rather than citizens. Citizens are required to participate in debate, to deliberate, to make decisions as to the public good, and to meet obligations. These presuppose the ability to reason, the ability to govern oneself (not just participate in the governance of others), and a degree of independence so that decisions and opinions are not coerced or subject to undue influence. Any presumed deficiency with respect to these (e.g., as with children who may be seen as irrational and not independent) becomes a reason to withhold citizenship from a social group.

The other characteristic of citizens is that they are recognized as somehow “belonging” to the entity with which citizenship is associated. In practical terms, this is often assumed to be the nation-state, and recognition is conferred through the legal status of citizen. It should be noted that the earliest philosophers did not make that assumption, however. Instead, the association between citizenship and the nation-state arose with the solidification of the Westphalian system, and has been reinforced by the legal recognition that states have the ability to determine who can be a member. Much of the research on citizenship has, therefore, focused on what Bosniak (2006) describes as the two “domains” of citizenship: boundary issues related to who belongs or who is a citizen, and issues related to the ways citizens are to be treated once they are recognized as citizens.

Aligning citizenship with the nation-state may be pragmatic and legally recognized, but the alignment is tested by the large numbers of people who live outside the state in which they hold citizenship, by the growth of dual citizenship, by the fragmentation (or at least layering) of citizenship within federal states, and by people who are not recognized by any state (Bauböck 1994). Of these, stateless people may face the greatest challenges. People become stateless and therefore lack recognition as citizens.
in many ways. Some national groups lack a state and may not be recognized by the states in which they were born or live (e.g., Palestinians in the Occupied Territories or in Lebanon); new national boundaries and laws may result in the loss of citizenship (e.g., the Izbrisani in Slovenia); children born to refugees may be unable to be registered in the countries their parents hold citizenship (e.g., babies born to Syrian refugees in Turkey or Lebanon). Without formal recognition and acceptance anywhere, such people face additional barriers in gaining the legal standing of citizenship from any state, which in turn complicates their ability to access rights and to combat prejudicial treatment against them.

Making citizenship and citizens

When citizenship is understood as a status or standing that can change, attention is directed to the political, economic, and social structures that create or enable those changes, to broad processes of citizenship formation (Marston and Mitchell 2004), as well as to efforts to encourage behaviors and qualities in individual citizens who can act rationally and autonomously in order to support democracy and the public good. Each of these terms — “rational,” “autonomous,” “democracy,” “public good” — is contested and malleable, so there is a politics and agonism surrounding the development of citizenship and citizens (Mouffe 2005).

The structural context of citizenship formation has been described by Sandel (1996) in terms of the political economy of citizenship. This includes the kinds of economic opportunities in a society, the distribution of wealth and well-being, as well as political and social structures that enable the development of a public sphere in which individuals can participate, unencumbered by gender, race, religion, age, or other social differences. In different times and places, these structures are configured in ways that make it possible — and sometimes impossible — for people individually and for members of different social groups to act as citizens. Feminist philosophers, among others, have argued that, while formal standing as a citizen has been gradually extended, inequalities are endemic, and they limit the ability of groups to participate as citizens. Feminists note the formation of “subaltern counter publics” in which the qualities of citizens (or, in their terms, members of the public) are developed in specific ways (Fraser 1990).

Autonomy and rationality might be seen as ideal characteristics of citizens, but at a practical level the kind of rationality required under particular circumstances rarely occurs without concerted effort to foster it; indeed, political and cultural economies militate against the development of citizens who can participate as equals. Furthermore, as economies, social relations, and governing strategies change, new qualities of citizens may be desired. As such, considerable effort is expended in fostering citizens who are capable of acting in ways that seem rational and appropriate given a particular context. As noted, however, there is a politics to the ways that citizens and citizenly characteristics are imagined, encouraged, and trained.

One of the primary sites in which citizens are trained is in public education systems supported by nation-states. Such training has typically focused on imparting the skills necessary to support the state and to build loyalty to and identification with the nation; as noted, the desired qualities of citizens reflect the broader political and cultural economies in which citizens are embedded, so specific elements of the training may differ. Consider two examples. As the United States was consolidated as a state and nation in the late 1700s, public education was intended to create a new kind of citizen who embodied a particular political subjectivity.
CITIZENSHIP

These subjects were to be American (rather than European), hardworking, capable of supporting the economy of the new country, law-abiding, able to make rational judgments in many arenas, and adaptable to new circumstances without guidance from the state. Thus, the public education system emphasized reading, mathematics, animal husbandry, and farming more than it emphasized history, science, or moral philosophy. By contrast, the postapartheid education system in South Africa was designed to train citizens with a slightly different set of skills and characteristics that would allow the country to assume a new place in the world. As in the early American system, history was downplayed but, in this case, it was because attention to past injustice and redress was believed to limit the ability of the country to move forward in a unified fashion. Instead, self-sufficiency, commitments to human rights and justice, and healthy behaviors were emphasized; for a country in the midst of an HIV/AIDS epidemic, the latter was important if citizens were to avoid being a burden on the state or other citizens. In this way, South Africa was little different from other countries emerging from conflict, where agreement on a common narrative for the country and identity can be difficult. The result was a curriculum that seemed to overlook or to forget apartheid and instead emphasized the ways citizens would be treated going forward. Looking at these two cases, it is apparent that the ways in which citizenship is taught and the desired characteristics of citizens may differ, but the belief in the role of education in creating citizens and solidifying the state is held in common.

Yet, learning about citizenship does not occur solely in classrooms. Critical education scholars use the term “pedagogy” to refer to a broad set of practices and ideologies that are used to reproduce social orders, such as that implied in a citizenship regime; a regime in this sense is a routinized set of practices that reinforce dominant power relationships. Contemporary pedagogical practices often discursively locate citizenship in civil society and local communities, rather than in the state. The practices and qualities of “good citizens” include civility, volunteerism, and active engagements to meet the needs of oneself, one’s family, and fellow citizens in the community. These are generally discussed and promoted as “active citizenship.”

This form of citizenship has been prioritized in the current context of neoliberalism. A component of neoliberal governing strategies, contemporary pedagogies of citizenship promote the ideology that citizens are disempowered by state incursion into arenas and activities that are more appropriately the realm of citizens. Engagement in civil society is proposed as the means of empowering citizens so that they can make their needs known and, crucially, take responsibility for meeting the needs of themselves and their communities; Jessop (2002) describes these moves as combining neoliberalism with neocommuunitarianism. While the governing strategy and political economic context may be neoliberal, the form of citizenship that is promoted is better described as a blend of liberal and republican citizenship, with the state imagined as protecting basic freedoms and individuals assuming responsibility for what had, in Marshall’s theory, been seen as the social rights of citizenship. Whether the resultant form of citizenship is described as liberal, neoliberal, neocommunitarian, or republican, there is a shared view of a basic quality of citizens as self-governing, autonomous, participating in their communities in order to reduce demands on the state, and reliant on the state only for the protection of basic freedoms rather than for social rights.

While much of the academic discussion of contemporary citizenship regimes has focused on the Global North and on countries that have
long been recognized as democracies, there is considerable effort devoted to developing citizenship in the Global South and countries where democracy is only now being established or consolidated. Such efforts are often funded and supported by international or supranational organizations, such as UNESCO or the European Commission, or by government agencies from the North, such as the United States Agency for International Development (USAID) or the Swedish International Development Agency (SIDA). While sharing some elements of the pedagogy of citizenship that circulates in the North, such as the commitment to self-sufficiency, self-governance, and active participation in civil society, the pedagogy in the South and in newly emerging democracies and citizenship regimes also typically includes attention to rule of law, nonviolence, cross-cultural communication, human rights, and entrepreneurship. Many concepts, however, need to be translated to suit both the political structure of countries and the goals of international organizations. In such circumstances, manifestations of the complex spatiality of citizenship are evident: international organizations may promote a form of citizenship that is legally recognized by the state, takes its inspiration from cosmopolitanism and human rights, and is enacted or performed within civil society and communities.

In trying to make good citizens, educators and practitioners do not rely directly on more theoretical or philosophical treatises, so the kind of citizenship they promote does not map neatly onto divisions between legal and substantive aspects or between liberal and republican theories. Instead, and drawing on the pedagogy of citizenship articulated by Osler and Starkey (2005), they often work with a model that conceptualizes citizenship as involving three elements: status, feeling, and practice. Status involves the legal standing of citizenship, as well as the rights and responsibilities that citizenship entails. Feeling reflects individuals’ affective sense of belonging to a political community. The practice of citizenship refers to collective activities in which individuals engage. These elements of citizenship are seen as mutually reinforcing, which means that one might be highlighted or emphasized in promoting citizenship when another element is seen as lacking. For instance, a feeling of belonging might be used to encourage participation in civic affairs, creating a more active citizenry. When that feeling of belonging is either muted or suppressed, people can be reminded that their legal status means that they belong to, or have a stake in, the community and, in turn, that they have responsibilities to be engaged in collective activities to improve the community. Finally, when noncitizens participate in those collective activities, they are likely to be recognized as worthy members of the political community and this recognition may be used to leverage changes in their legal status. Importantly, practice is often associated with localities and involvement in local communities, thus offering individuals affective recognition as citizens, even if legal status may be denied or be impossible. Thus, partial and hybrid citizenships may be formed, even in the absence of legal status.

Critique and alternative formulations of citizenship

There is not a singular, unified account of citizenship. Like all political categories and concepts, the very essence of the term is contested and fragmented. While some of the main lines of debate have been outlined here, there are emerging fault lines in citizenship debates and alternative formulations of the concept.

One of the most significant debates is whether – or perhaps how – citizenship can ever
CITIZENSHIP

be a unifying concept or identity that lends itself to the formation of an inclusive political community or political entity. When citizenship is associated with the nation-state, its very production relies on processes of inclusion and exclusion: people are included as citizens of a particular state with certain expectations of how they should be treated or they are excluded from that nation’s citizenry. These are the boundary issues mentioned previously. But inclusion is not simply based on legal status; questions of deportment, rationality, autonomy, and so forth serve to include and exclude members of social groups as citizens. The characteristics of citizens and the efforts to promote those characteristics, it is thus argued, play an important role in disciplining individuals so that they can be recognized as belonging to the political community.

Many scholars argue that the boundaries of citizenship rely on assumptions about who can perform as rational, autonomous political subjects as they engage in debate and complete their duties and obligations. Because there is a presumption of equality among or between citizens, such political agents are described as disembodied and unencumbered when they operate in the public sphere. Feminists, queer theorists, and cultural critics, to name a few, highlight the ways in which the private sphere and the embodied realities of life condition people’s abilities, their views, and the ways they are perceived – or recognized – in public, and how such recognition in turn affects their standing as citizens. Important strands of argumentation from these perspectives include analyses of the ways in which certain subjects are constructed as incapable of acting as citizens, but also of the ways in which citizenship represents a moral claim and political resource in their struggles for inclusion and justice. Thus, ideals about citizens are used to exclude subjects from citizenship, but those same ideals can be used to demonstrate the injustice that comes from the exclusion of particular groups. For example, women’s suffrage movements in the Global North used the figure of Liberty, who is always depicted as a woman, in their campaigns to argue that women had the requisite characteristics of citizens. Yet the moral argument about the injustice of excluding women did not extend to racialized minorities, thus demonstrating the partial or, at best, incremental potential that citizenship offers to drives for inclusion and justice.

Other critiques imagine alternative sites or locations for citizenship, often by attempting to de-link citizenship from the nation-state; doing so, however, necessitates a conceptualization in which legal status is less important than citizenship’s substantive aspects. Some of these critiques draw from long-standing ideas about the importance of civil society as a site in which citizenship is enacted and from which the state can be held to account. As noted, enacting citizenship in civil society lends itself to action at the local level and to civic or republican forms of citizenship. Radical theories of citizenship, however, also emphasize local action and practices. Such theories argue that citizenship should not be granted by the state but, instead, be based on inhabitance. Inhabitance draws on the lived experience that comes from living and participating in the city and that generates an affective attachment and feeling of belonging. Radical citizenship theorists argue that inhabitance generates a better understanding of the needs of others, and, without being constrained or defined by the state, gives rise to politics in which concerns for social justice will be dominant. In this view, the state is not irrelevant but, rather, blocks or channels the democratic impulses that citizens would otherwise enact. Such views may be particularly compelling in postcolonial contexts in which the state and its system of governance have often been imposed externally, rather than
emerging through democratic iterations within a country.

Yet another strand of critique argues that the nation-state is becoming irrelevant to citizenship owing to forces of economic globalization, to transnational migration, and to the development of human rights regimes at the international level. These critiques often lead to arguments for global citizenship and highlight its potential for creating more just citizenship regimes, even as inequality between and within nations seems to be increasing. Many scholars also argue that attention to human rights and global citizenship can provide a counterweight to nationalist tendencies and policies enacted by states as they attempt to fortify their boundaries, often excluding people from citizenship outright or marginalizing them through the withdrawal of social rights.

Implicit in many of these critiques are questions about agency and whether citizenship – the standing or status – affects the actions of individuals as citizens. Historically, agency did not figure prominently in descriptions of citizenship, other than through questions of autonomy, rationality, and performance of duties and obligations. More recently, and often attributed to neoliberal citizenship, emphasis has been placed on the development of active citizens who will be engaged in their communities through volunteerism and other similar activities. Some analysts are concerned, however, that volunteerism and engagement are channeled into activities that allow state withdrawal from supporting the social rights of citizenship; these scholars also argue that active citizenship may mute claims on and against the state as communal responsibility becomes internalized. In its place, such scholars call for activist citizenship, in which the state is directly challenged by citizens in what Isin (2008) has called “acts of citizenship.” Such acts break with the everyday practices of citizens and of the state, and potentially call forth or enable new relationships and new political practices, including acts of insurgency. Such insurgent citizenship (Holston 2009) represents a destabilization of existing citizenship regimes, often through urban-based struggles for housing or equality. Insurgent citizens struggle for more radical forms of democracy, reconfiguring the rights and protections of citizenship in ways that pose fundamental challenges to existing state structures and to the political economy of citizenship more broadly. Insurgency is never complete, however, but is an ongoing struggle. In this way, it reflects the continually contested nature of citizenship itself.

Further reading

“City logistics” is a recent term in the scientific literature as well as a new practice. It has been mostly developed in Europe since the 1990s and is now applied worldwide. City logistics represents more than the mere transportation of goods within urban areas. It can be defined as any service provision contributing to efficiently managing the movements of goods in cities and providing innovative responses to customer demands. The objective of city logistics is to make deliveries to urban residents and businesses possible at the highest economic, social and environmental standards.

City logistics includes physical operations such as order preparation and packaging, transportation and deliveries (including home deliveries), short-term storage of goods, management of drop-off/pick-up boxes for parcels, return of goods, waste management including the management of recycled goods, and the management of empty pallets and packages. City logistics makes use of sophisticated information and communication technologies to increase coordination, efficiency, and adequate enforcement of urban delivery operations.

Defined as such, city logistics does not apply well to the way goods are currently delivered and picked up in cities worldwide. A significant portion of these activities remains inefficient, with numerous and poorly coordinated freight trips and many unclean delivery vehicles (Dablanc 2007). To decrease cost, increase efficiency, and promote environmental sustainability, there has been a recent surge in innovative practices in urban freight and city logistics. These operations involve various stakeholders, such as trucking companies, logistics providers, real estate developers, and major retailers, as well as start-up companies. New logistics services have emerged in cities around the world, especially in areas with high levels of activity, such as city centers.

Although not yet significant in terms of volume and environmental benefits, these practices provide new directions for more sustainable city logistics activities. Organizations and projects in city logistics have been described in books (Melo and Macharis 2011; Gonzalez, Semet, and Routhier 2013). Giuliano et al. (2013) compare city logistics issues for the United States and Europe. Wolpert and Reuter (2012) provide a review of city logistics in the scientific literature. An International Conference Series on City Logistics (Taniguchi and Thompson 2016) provides an opportunity to share academic results in this field every other year. The US Transportation Research Board and the European Commission organized a joint symposium to discuss city logistics research issues (TRB 2013).
chains, from the supply of office products to commercial activities to the delivery of food to restaurants. These urban supply chains are the result of logistics decisions that are, in turn, based on the demands of the production and distribution sectors, themselves dependent on the behavior of economic agents such as households and firms. Each activity (commercial, service, industrial, administrative) taking place in an urban environment can be associated with a specific freight profile. Freight vehicles are very diverse: trucks and vans of all sizes and weights, motorbikes and bicycles, pedestrian push-carts, and, more rarely, rail and waterborne transport. Urban delivery systems unique to one city can also develop, such as the famous “dabbawallas” in Mumbai, India: 200 000 lunch boxes made at home are delivered each day to businessmen at their workplace through a collection/sorting/delivery system using bicycles, trains, and pedestrian modes of transportation. Cities can have individual logistics specificities. For example, Chicago has been preoccupied with maintaining its prominence as a rail freight hub for North America, and is thus concerned about rail freight movements between the numerous rail terminals located within the city. Los Angeles is primarily concerned with air pollution and targets drayage associated with the ports of Long Beach and Los Angeles. Shanghai has become the largest cargo port in the world and its logistics added value is estimated at 13% of its GDP. Activities from the three ports of the bay of Tokyo add much truck traffic to Tokyo’s streets. In Mexico City, 42% of the working population works in microcompanies, of which half are home-based or street-based, generating very specific patterns of deliveries. The wholesale market in Mexico City (Central de Abastos) generates 52 000 truck trips every day.

A sustained effort in urban freight data collection and modeling has yet to be accomplished in many cities around the world. Although a lot of progress has been made in the last decade, survey methods remain heterogeneous, making it difficult to compare results from one city to another. In France, the FRETURB model (Laboratoire Aménagement, Economie, Transports, Lyon) has adopted a methodology well suited for urban economics. It identifies detailed freight patterns of urban establishments from extensive — but expensive — “urban goods movements surveys.” The last surveys were made in Paris and Bordeaux in 2011–2015. These surveys revealed a key ratio for French cities: there are about as many urban deliveries a week as there are jobs in a metropolitan area (Ambrosini, Patier, and Routhier 2010).

Urban freight is more polluting than long-distance freight transportation because of its modal profile; the average age of the vehicles and the high number of short trips and stops. Impact surveys carried out in European cities (BESTUFS 2006), show that urban freight generates between 20 and 60% (according to the pollutants considered) of local transportation-based pollution. Nitrogen oxides (NOx) and particulate matter (PM) are pollutants for which urban freight has a particularly important responsibility. Both pollutants are very harmful to the health of urban residents, and in European cities their concentration tends to stagnate or even increase, contrary to many other urban air pollutants. In Mexico City, the average age of trucks and vans is twelve years. The renewal of urban freight vehicles is generally slow (slower than for nonurban road freight traffic), because most trucking companies operating in urban areas are very small, competition among operators is acute, and profit margins are low: many operators save money by buying used trucks or vans and using them as long as possible.

Greenhouse gas emissions and noise pollution are also among the most severe environmental impacts of freight in cities. Freight represents
about one-quarter of transportation-related CO₂ emissions in European cities.

A survey of 1650 Mexico City truck drivers (Lozano Cuevas 2006) identified the challenges met by urban freight operations that are actually common to operators in large cities in many countries: congestion, lack of loading and unloading space, complex legislation, risk of theft, and lack of safety are among the drivers’ greatest concerns. Another important urban freight issue is road safety related to truck traffic. Trucks have a low share of accidents in cities but the accidents involving them are more serious. The reconciliation of truck traffic with rapidly increasing bicycle use has been a recent cause of concern in Paris and London following much-publicized fatal collisions. Recent marketing trends such as same hour delivery for residents in selected cities (such as New York) put delivery personnel at risk. Drivers, often on bicycles or motorbikes, use whatever driving and parking tactics they find that can make them meet the promised delivery times.

Emerging city logistics services

City logistics services respond to new demands from urban businesses and consumers. Consumer behavior has changed rapidly in recent years. In many countries, online shopping has become a mainstream consumer activity, especially in large cities. This generates a demand for new logistics and freight services, among them home deliveries or deliveries at the office or in drop-off/pick-up depots. Demand for instant deliveries is growing. Companies also have a growing demand for new logistics services. Surveys have shown that many inner-city retailers are interested in, and willing to pay for, new services such as the rental of storage space, the provision of dedicated areas for receiving deliveries out of the stores’ premises, and specialized services for the pick-up of pallets and empty boxes and packages. City administrations have also expressed growing demands for a more efficient urban freight and city logistics global organization.

In response to these demands, entrepreneurial initiatives in city logistics have emerged, first in Asia and Europe, then in the United States and other regions. Companies such as Shurgard provide urban storage space for storekeepers. Star’s Service, a transportation company with 1500 truck drivers, has been highly successful by specializing in home deliveries of food products to Paris households. In Germany, DHL/Deutsche Post has installed thousands of “PackStations,” or automated lockers, in cities’ public spaces so that e-commerce consignments can be delivered to customers at any time. In Japanese cities, takkyubins (or takuhaibins; such as Yamato and Sagawa) have responded quickly to the evolution of consumer behavior and deliver everything from general parcels to frozen goods to large products, such as luggage or golf equipment. The size of their networks, the diversity of their services, their high level of logistics efficiency, and the extensive use of home deliveries by Japanese families make takkyubins stand out as a model, not yet applied anywhere else in the world. In Paris and London, cargo-cycle companies provide last-mile parcel delivery services to businesses and residents in urban locations. The use of cargo cycles brings environmental benefits. It has been estimated that the Paris-based freight company La Petite Reine, using 40 electrically assisted freight bikes, saves 200 tons of CO₂ per year compared to the previous organization based on diesel vehicles. However, the use of cargo cycles necessitates the use of small terminals located in inner city locations to prepare delivery tours. Since 2003, the municipality of Paris has carried out a program to implement “urban logistics spaces,” small trans-shipment facilities located
CITY LOGISTICS

in the densest areas of Paris, most of them in underground municipally owned car parking facilities. These logistics spaces are allocated at a low rent to the logistics operator offering the greenest mode of delivery. Cities in the United States have recently experienced a surge in sophisticated city logistics services. Amazon provides goods pick-up lockers to urban residents in 7-Eleven convenience stores. It is testing grocery deliveries by appointment to residents of Seattle, San Francisco, and Los Angeles, and the company has generated much attention with its futuristic drone parcel delivery idea. In major US cities, instant deliveries are provided by services such as Uber Rush, Postmates, or Instacart. FedEx and UPS routinely use electric delivery vehicles to operate in urban areas or university campuses across the country.

Public policies for city logistics

Involvement in urban freight and city logistics for the public sector can be manifold and at various levels. Cities are in charge of the urban road network, which is heavily impacted by commercial vehicle traffic. Cities are also interested in local economic development and, therefore, have to make sure that the provision of goods and logistics services is adequate. Cities control the use of land, including the land necessary for logistics activities (warehouses and terminals), and are in charge of local traffic and parking regulations, including all regulations that relate to delivery vehicles. Finally, cities are concerned with environmental and social issues, which are associated with urban freight activities.

Despite these many mandates and potential objectives, actual local public policies regarding freight and logistics are quite modest. Most cities still view truck traffic as something that should be banned or at least strictly regulated, and few of them consider freight activities as a service they should help organize. Local policies are generally very parochial and can be conflicting. In the Lyon metropolitan area (France) there are as many as 30 different municipal rules on truck access regulations based on weight and size, forcing truck drivers to decide which rules they will comply with, and which ones they will disregard. Major events such as the organization of the Olympic Games provide opportunities to organize a change in urban freight operations citywide. Barcelona and London, today, are cities that have a clear logistics strategy. In many other cities, major urban development projects, such as the implementation of a tramway or a subway system, can also play that role.

The tool that cities, when confronted with freight activities, often use first is truck access restriction. These restrictions are based on various criteria such as time windows, weight, and size (length, surface). The most famous truck ban in Europe is the London lorry ban, in place since 1975. Heavy goods vehicles over 18 tons cannot circulate at night and weekends. All trucks in Seoul have been banned since 1979 from the central areas during working hours. Truck access rules based on weight or size policies have several drawbacks. They tend to promote small-capacity vehicles (vans, light trucks), which increases total congestion and reduces the efficiency of urban freight. Regulating truck access requires enforcement and control, meaning a sufficient and well-trained staff. The most recent trends in access restrictions are environmental standards and road pricing. Both can be combined, as is the case in the London congestion charge. Urban tolls are not specific to commercial vehicles, while many environmental zones or “low emission zones” are. In London since 2008, a low emission zone prohibits access to trucks older than the Euro IV emission standard (trucks manufactured since 2001). Large vans have also
been targeted. The area where the rule applies is surrounded by the M25 motorway and covers about 600 square miles. New enforcement technologies have increased the efficiency of truck access policies. Automatic control systems, such as automatic number plate recognition cameras, mobile enforcement, vehicle positioning and on-board equipment, have been introduced in many cities in Asia and Europe. This technology comes at a cost and generates controversy over privacy issues. The reduction of noise caused by deliveries and the promotion of night (or early morning/late evening) deliveries are also an emerging urban freight policy target. According to a survey carried out in New York City, businesses most likely to change to off-peak deliveries are shippers doing their own deliveries (own account transportation), and receivers open during extended hours, such as restaurants (Holguin-Veras 2008). In the Netherlands, in 25 pilot cities, the national government provides financial help for operators investing in silent delivery equipment, which includes vehicles and handling equipment generating noise emissions below 65 dB, for night deliveries at supermarkets. Tests have shown that companies delivering at night save 30% in delivery costs and 25% in diesel consumption.

Freight operators need good access to dedicated loading and unloading areas, be they public or private, on-street or off-street. The lack of sufficient delivery spaces transfers delivery operations onto traffic lanes or sidewalks, and leads to congestion and traffic accidents. In busy urban areas and city centers, adequate on-street loading and unloading bays must be identified and their use must be better controlled. Time sharing is a good way to improve street parking capacity for trucks and vans. In Barcelona, the municipality has created an innovative organization on some of its main boulevards by devoting the two lateral lanes to traffic during peak hours, deliveries during off-peak hours, and residential parking during the night. The city is also renowned for its dedicated mobility motor squad, consisting of 300 agents circulating with a motorbike and controlling all on-street parking activities, including loading/unloading zones. This has prevented illegal long-term parking and made these zones always available to delivery truck drivers.

Consultation processes in urban freight provide collaborative opportunities between private companies and local administrations that otherwise are not willing to work together. In September 2013, the city of Paris and the most important carriers’ and shippers’ associations signed a charter for sustainable city logistics. In the United Kingdom, freight quality partnerships have been developed in many cities. Consultation processes can lead to initiatives, such as certification processes, that identify the best urban freight operators. Certification confers privileges on an operator, such as extended delivery hours or the use of designated loading/unloading facilities. It may also provide operators with a competitive advantage when bidding for contracts. An example of such an initiative is the FORS (freight operator recognition scheme) in London. The FORS certifies operators that comply with a list of efficiency, safety, and environmental impact criteria at bronze, silver, and gold levels. It gives companies access to data, benchmark information, and training programs for their drivers.

Local policies for city logistics also include the control of logistics land use through planning provisions. A pattern of “logistics sprawl” (Dablanc and Ross 2012) has been identified in several North American and European metropolitan areas in which warehouses are being sited in increasingly ex-urban locations. Decentralized logistics facilities tend to generate more truck miles, as delivery trucks need to cover much longer distances to reach urban
CITY LOGISTICS

destinations. This adds to regional congestion. A regional overview of logistics land uses is therefore needed. Another potential strategy is the development of logistics parks (sometimes called freight villages), partly through public investment. Some notable examples include Güterverkehrszentrum (GVZ) at the outskirts of large German cities, or the Raritan Center in New Jersey. These logistics parks commonly include services for all companies located on the site, such as surveillance, catering, fueling and cleaning stations for trucks, overnight truck parking, and night accommodation for drivers. Former industrial areas (brownfields) can be used when developing freight villages. However, necessary remediation efforts (e.g., for the removal of polluted soil) should not be too expensive, as programs for logistics spaces cannot tolerate high land costs.

Many cities impose the building of off-street delivery areas in new commercial or industrial developments. The Tokyo off-street parking ordinance of 2002 compels all department stores, offices, and warehouses to provide for loading/unloading facilities when they have a floor area of more than 2000 m². Cities should also be careful in avoiding inadequate regulations in their building and planning codes. Access to underground parking, for example, whether in public parks or in private buildings, can be very difficult for commercial vehicles, even small ones, because of height and size limits. The Chicago Downtown Freight Study (January 2008) mentions this as an important problem for truck drivers, and the municipality has worked on a freight plan including recommendations for building provisions.

Some municipalities accept or even promote the development of multi-activity buildings, with logistics on street levels and other activities on the upper levels. Some also welcome multistory warehouses. The logistics developer Prologis has built seven-story logistics terminals in downtown Tokyo. The acceptance of such projects is increasingly conditioned to environmental criteria and to a careful attention to the integration of buildings into the existing urban landscape. The development of “urban consolidation centers” has often been identified as an interesting strategy to reduce urban freight impacts. These facilities provide a service of bundled and coordinated deliveries, often requiring public subsidies. Up to 200 such terminals existed in European cities in the 1990s and early 2000s. However, due to operating costs, most of them closed down when municipalities could no longer subsidize them. Today, a few urban consolidation centers still operate, mostly in medium-size cities: Bristol in the United Kingdom, Modena, Padua, and other Italian cities, La Rochelle in France, and Yokohama in Japan. These consolidation centers are expensive and the allocation of operating costs is difficult.

Conclusion

Despite traffic difficulties and costs associated with activities in urban areas, freight operators manage to serve the vast majority of their urban customers. In this way, today’s urban logistics are highly efficient. However, this often comes at an environmental cost. Goods movements represent 10–15% of all transportation in an urban area (in vehicle miles), but one-third or even more of the local pollutants related to urban transportation. Patterns such as “logistics sprawl” add more vehicle miles and congestion to the metropolitan and regional road network. To these many challenges, city logistics has recently emerged as an innovative response. It intends to meet urban businesses, and customers’ demands for new services while responding to cities’ concerns over the environmental impacts of current urban
deliveries. However, the pace of actual introduction of city logistics in urban areas is slow and varies greatly from one city to another. To characterize this diversity, Dablanc and Rodrigue (in press) have proposed four illustrative categories of city logistics cities: (i) land-efficient urban logistics cities (such as Tokyo) that integrate freight facilities in very dense urban settings; (ii) cities as mega distribution centers (large US and European gateways) acting both as distribution facilities for local markets as well as regional hubs for the grouping and redistribution of goods to regional and national markets; (iii) dual urban logistics system cities (megalopolises of developing countries) in which a modern freight and logistics sector coexists with an informal system of pick-ups and deliveries for home-based artisans or street vendors; and (iv) smart logistics cities (the historical centers of some European cities, some Asian cities) with an emphasis on cleaner, more silent operations, consolidated deliveries, a high level of home delivery services, and high-tech enforcement systems. This last category still represents a marginal share of total freight activities in metropolitan areas, but receives a lot of media and decision-makers’ attention.

Civil society

Andrew D. Davies
University of Liverpool, UK

The Enlightenment conception of civil society

The concept of civil society is generally used to describe an understanding of politics that has its roots in European Enlightenment thought, where it is the sociopolitical domain that exists between the household or family and the state. In particular, Hegel’s work on the links between civil society and the state has become central to many understandings of civil society. As he set it out most clearly in *Philosophy of Right* (1967/1821), Hegel, saw civil society as a liberal political formation, grounded in modernity and operating through *Gesellschaft*, or societal and social practices – an arena of relatively formal political behavior. This distinct zone was separate and untainted by the more affective and potentially emotional sociality of *Gemeinschaft*, or community practices, which have the potential to be more populist and are driven by issues concerning familial or communal identities (see also Tönnies 1955). This liberal conception creates a clear zone where there is a distinction between the community, civil society, and the state, and, as a result, civil society is central to processes like democratic deliberation. While civil society is a zone where individuals can come together to mobilize and make claims on the state, it is also far from being a zone of equality – power relations between individuals and groups determine their ability to change their circumstances. Thus, from the outset, the functioning of civil society is contingent on the ability of individuals and organizations to mobilize and act with or against each other in order to convince the state of the merits of their case. The state therefore becomes the top of a relatively linear hierarchy, in which individuals sit at the bottom. This hierarchical understanding crucially reifies the state as the core arbiter of political activity. Organizing in civil society, therefore, occurs in a buffer zone, wherein the state arbitrates from “above,” and people mobilize from “below.” Given this framing of the state, this conception of civil society lacks the potential for radical political change: the core dynamic of politics is the interaction between civil society and the state, and thus any radical reform that sees the state as something to be defeated or removed (e.g., an anarchist politics) does not fit into this political framework.

While Hegel himself was critical of this liberal version of civil society as a bourgeois construct grounded in an overly rational modernity, the understanding of civil society as a buffer zone between the state and the family or individual remains the dominant framing of the term. The liberal Enlightenment conception of civil society was contested by a Marxist reading, particularly that developed by Gramsci (1971/1929–1935). While keeping the hierarchical architecture of the Hegelian reading of civil society, Gramsci argued that the links between the formal political society of the state and civil society were actually closely interwoven, with bourgeois and capitalist interests often shaping the two domains for their own benefit. Gramsci argued that, instead of a liberal zone of potential freedom and...
democratic deliberation, civil society was where hegemonic relations were made in order to maintain class differences. These two readings of civil society – as a space of liberal negotiation and deliberation or as a domain where hegemonic power plays out – remain the two pre-eminent interpretations of the term.

Today civil society is still broadly conceived as the space where negotiation, resistance, domination, and other political practices take place and are worked through, although it also incorporates a diverse range of nonstate actors such as social movements and nongovernmental organizations (NGOs) and is increasingly influenced by social media and the Internet. Despite being theorized as outside the state, civil society is closely linked to, and indeed exists only because of, the state. Unsurprisingly, given the Hegelian origins of the term, the state and civil society are often linked in a dialectical relationship. As a result, through its claim to represent those political actions that sit beyond formal, state-based politics while at the same time being closely implicated in formal decision-making, civil society has become a key term for geographers, especially development and political geographers, although the term still assumes a relatively linear system – with the state at the top; individuals, families, and communities at the bottom; and civil society operating in the middle ground. Crucially, this framing also conceives of civil society as a relatively orderly and structured part of the political system. Both of these principles – civil society fitting into a hierarchical scalar order and as an orderly space of politics – have been critiqued (as we shall see). In addition, there remains considerable conceptual vagueness about civil society, and, as a result, the utility of the term can often be called into question; put simply, is “civil society” such a broad umbrella term that it generalizes and obscures the range and depth of political activity in the world? Going further, given Gramsci’s treatment of civil society as a zone of hegemony, does civil society actually have the potential for change that it is supposed to offer? Can we actually rely on civil society as a buffer zone to change society for the better, or can we at best hope to change the odd marginal decision while powerful stakeholders maintain their hegemony? These questions lie at the heart of many contemporary debates about civil society.

Contemporary forms of civil society

With the rise of NGOs (and later international NGOs) as institutions in the 1970s, civil society became a crucial topic of contemporary political concern. This rise shifted the concept from a topic of debate for political philosophers to a key object of study across the social sciences. This is often seen as a part of an emerging neoliberal economic consensus, with state powers being rolled back and diminished as market-led approaches became dominant. As a result, civil society organizations, particularly those in the “third sector,” came to be seen as providers of services that the state was now unable or unwilling to provide. Over the next two decades, and with the decline of state socialism globally (including a perception that civil society was important in precipitating this decline in Eastern Europe), there was increased conjecture about the role of civil society. As a result, from the early 1990s onward there was a huge range of writing about civil society, particularly the potential benefits and problems associated with it. In particular, once globalization became a key academic and policy buzzword, the potential for a new “global” form of civil society sat quite comfortably among discourses that stressed the increasing economic and cultural integration of the world. At their most optimistic, ideas about global civil society stressed the potential
for new forms of peaceful integration at a global scale. These works also attempted to expand the concept of civil society as it was used by Enlightenment scholars and to map out the new spaces for engagement that were emerging as the world globalized. For example, Kaldor’s (2003) global form of civil society encapsulates three overlapping contemporary areas: an activist sphere, based on self-organization and a rejection or contestation of state or market power; a neoliberal sphere, based on third sector charities and NGOs taking on increased responsibility as the state was rolled back by market forces; and a postmodern sphere, an anti-universalist space, where the difference between individuals and groups is recognized and accepted. This reading of a new global civil society was an attempt to categorize and understand the increasingly complex political, economic, and social structures that were (and are) emerging as a consequence of globalization.

Although it moved beyond the liberal-democratic framework of early conceptions, the broad notion of a global civil society still regards civil society as a key arena for redressing imbalances in global power structures, and holds that the increasingly globalized economy will respond to and can be regulated by the activities of civil society as well as those of the state. Campaigns against and boycotts of transnational corporations over, for example, perceived unfair labor practices became one of the most visible signifiers of this turn. More problematically, such conceptions of globalism often create the ideal of civil society as a normative project, where certain universal standards are seen to be applicable to many groups across the world. This marks a shift from using civil society as an explanatory tool for understanding how societies negotiate their political differences into a more prescriptive term where what and which social practices take place are of equal importance. In turn, this normative reading has meant that civil society can arguably be seen as a new vehicle for the enforcement of neocolonial and neo-imperial practices where those who are judged to be more valid civil society actors (most often those based in the Global North) are able to tell others what they regard as acceptable standards of behavior and to set goals or standards for those others to aspire to.

The idea of a liberal global civil society is further complicated by examining how the political practices of civil society play out in reality. The play of power between interest groups in civil society is often far less certain than the optimistic readings of advocates of globalist thinking. Authors have increasingly argued, following Gramsci’s conception, that civil society in practice often fails to create the leverage necessary to create more just alternatives to existing political structures and practices (see Bénit-Gbaffou 2012 for a geographical perspective), and in many cases has served simply to reinforce existing hegemonic frameworks that prioritize the powerful at the expense of the powerless. Indeed, to some, civil society is a meaningless concept in a world where state power has been amalgamated into the more complex framings of the neoliberal global order. James Ferguson (2006, 91), for example, argues from an anthropological perspective that treating civil society uncritically simply serves to obscure, and at worst legitimate, a “profoundly antidemocratic transnational politics” that works, through civil society, on the globally poor and disenfranchised in both the Global North and South. This argument harks back to Gramsci’s earlier critiques of civil society as a tool for maintaining capitalist hegemony; in particular, Ferguson critiques the inherent hierarchy present within liberal civil society and argues for a topological reading of the power relations that structure global development.

This topological reading, rather than seeing power as rooted in nation-states, places power in the hands of those who create and perpetuate the
CIVIL SOCIETY

unequal relations of power at work within civil society. This means complicating the conceptual framework so that, instead of creating a linear hierarchy between the individual or family, civil society, and the state, we should include market structures within our understanding of the global order, but also recognize that power operates through and across these various spheres in contingent and dynamic ways. This vision develops globalist perspectives and creates a reading of power that goes beyond seeing civil society as a mere buffer zone, and instead as complicit in the various political projects that seek to maintain or alter existing social structures. This is particularly attractive to geographers, who have long argued for relational understandings of spatial processes, particularly John Allen’s (2011) work on topological space which sees power relations as more nuanced than being blunt practices of domination and resistance. These geographical understandings of power emphasize the limitations of seeing civil society as a rational space of deliberation which the state, market, and individual somehow sit outside. Indeed, as Craig Jeffrey (2011, 148) has recently pointed out in relation to work on young people and politics, continuing to read civil society as clearly divided between Gesellschaft and Gemeinschaft occludes relations where identities and political formations can shift over time and space as they come into contact with other actors and organizations. Thus, the idea of civil society as a separate zone of rational activity is inherently problematic because it is not clear where civil society begins and ends, but also because it fails to account for how groups move across or straddle these boundaries; for example, according to UK law, a registered charity cannot take part in political activity, yet many often have implicit political purposes (e.g., many registered charities were involved in the 2005 Make Poverty History campaign against the G8, which had clear political aims). This is a problem of how UK law defines politics, but also an example of how civil society’s limits are often unclear and permeable. This lack of clear conceptual boundaries, together with the continuing desire to see civil society as a distinct political sphere, lies at the heart of postcolonial critiques of the concept, as we shall see.

These conceptual difficulties can be seen by examining one area where civil society has undoubtedly expanded over the past few decades, as global forms of interaction facilitated by the Internet have hugely increased, particularly driven by Web 2.0 practices such as blogging, social networking, and wiki creation. This growth has also necessarily raised questions about the potential for change allowed by civil society activity. On the one hand, movements like the Zapatistas in Mexico offer relatively hopeful tales of transnational organization facilitated by the Internet. There is obviously the potential within these movements to rework and transform social relations as they occur across space, and to share knowledge, organizational practices, and strategies across a transnational civil society (see Jazeel (2010) for key geographical issues here). However, the tensions raised by the Internet also raise questions about what it means to be truly active within civil society. Olivier Marchart (2011) has argued that “minimal” politics represents the lowest threshold of what can be considered an actual form of political activity. The Internet’s ability to spread knowledge means that a new range of interaction takes place, such as the organizing of international meetings, writing blogs, and more mundane activities such as signing an e-petition or posting news of a topical issue on websites like Twitter. Internet civil society has become an important topic in academic studies, but it is a further development away from the rigid, state-led structures provided by the original liberal Enlightenment
conception. This creates a whole new range of activities that can be identified as broadly belonging to civil society, which in turn also expand the boundaries of what count as attempts to mobilize in civil society. For example, is it now possible to be political without leaving one’s desk or home, and what new forms of politics are created as a result? In addition, thinking about what counts as minimal raises questions about how effective and useful these new forms of civil society action are. This is not to say that the mundane cannot be politically effective in the transnational spaces created by the Internet. Far from it: these actions could potentially act as a useful rejoinder to accounts that see only certain forms of engagement (demonstrating, voting, lobbying, etc.) as truly political. But we do need to question how (and whether) these new forms have the potential to reshape what we regard as political behavior, removing an emphasis on supposedly grander forms of mobilizing and allowing for more action from what would traditionally be seen as “below.” There is also a need for caution here, as the Internet’s potential for change is often overstated, and not everyone has access to this new online civil society, and this means recognizing that these online domains are fraught with power relations and access issues just like any other part of civil society (see, e.g., the debate about blogging and public geography in Kitchin et al. 2013). Indeed, it is from critiques of civil society as an elite space that one of the major conceptual challenges to the term has emerged since the beginning of the twenty-first century.

Moving from “civil” to “political” society?

Despite the changes in civil society driven by globalization and the Internet, postcolonial critics have continued to question the elitist and universalizing tendencies inherent in the term. One of the most visible of these critiques comes from the work of Partha Chatterjee (2004, 2011). Given the large numbers of people around the world who occupy various informal or illegal statuses, Chatterjee has argued that large swaths of the global population do not have formal citizenship and are therefore excluded from civil society. If civil society is regarded as a domain that belongs to the relatively privileged, Chatterjee argues, popular politics in much of the Global South occupies a differential zone, what he calls “political society.” Political society stems from the particular forms of governance that many states now employ. Instead of being treated as individual, rights-bearing citizens, in the Foucauldian language of governmentality, people are grouped according to their characteristics (e.g., as informal settlers or as belonging to a certain communal group), thus allowing the state to target these populations according to their criteria, and therefore to fulfill the state’s perceived obligation to “improve” these populations’ conditions. However, not all groups can be targeted because of the limitations of the “rolled back” neoliberal state. As a result, it is those groups that can make themselves visible but also argue that they are the most worthy of aid that are able to claim resources from the state. Thus, groups that are able to mobilize effectively and present their case in a way that the state can understand, and that the state sees as worthwhile (e.g., fitting with the latest policy target) are more likely to receive the benefits of limited state funds. Here, then, is not a formal, rational, Hegelian civil society. Instead, political society occupies a “normatively nebulous zone” (Chatterjee 2004, 50), where practices like clientalism, brokerage, and other more or less formal/legal activities take place as those excluded from formal civil society try
to get what they can from the state. Again, here the boundaries between *Gesellschaft* and *Gemeinschaft* become indistinct as groups move strategically between the categories according to their need. As a result, the concept of political society explicitly argues for a more diverse set of political practices than is usually allowed under the term “civil society,” which Chatterjee, following Marx and Gramsci to an extent, frames as a bourgeois zone. Political society then, is a space where a series of mundane, possibly minimal, political activities – such as visiting the office of a government official on a daily basis – rather than the clearly “political” gestures of formal civil society, are practiced. It is also avowedly not a radical space of transformation, but a space where communities and individuals try to get by as best they can by explicitly engaging with and utilizing the state’s facilities.

Chatterjee, with his background as a scholar in the Subaltern Studies Collective in the 1980s and 1990s, sees the intellectual trajectory of political society as fundamentally a rejection of the idea that there can be a global and universal civil society. Civil society as defined by “the West” is fundamentally normative, where certain democratic and moral choices are viewed as the ideal for everyone. Instead, Chatterjee argues that it is the incomplete and problematic application of European thinking across the Global South, as a result of colonialism, that lies at the heart of the problem, as a result of which civil society does not adequately cover the range and scope of political activities available to the majority of the world’s population. The challenge is to think through how European modernity has created a normative set of rules that in turn have created the sense that civil society (and any other category that emerged from European thought) is a form of hegemonic domination. Thus, the task is to interrogate how these universal norms are taken up, interpreted, and appropriated according to specific historical, social, cultural, economic, and political circumstances. Political society then can be read as a project that partially continues the subaltern studies ideal, which in turn demands that the legacies and unequal power relations caused by colonial rule in any discussion of civil society and that we still see at work today are taken seriously in any discussion of civil society. The key geographical question then is interrogating how these power relations play out in reality, and how the difference between political society and civil society functions for those who are involved in contesting and negotiating with the powerful on a daily basis. Chatterjee leaves this relatively unexplored in his own writing, but it has been taken up by numerous authors since (Gudavarthy 2012), and indeed it takes us back toward the ideas about contingency and specificity raised by the earlier discussion of topology.

Political society has brought renewed vigor to discussions of the limits of civil society, and the concept has become one of the most widely debated interventions on civil society in recent years (Gudavarthy 2012). However, political society has been discussed overwhelmingly in an Indian context, and as a result the question remains as to how far political society functions in other areas of the world. In *The Politics of the Governed* (2004), Chatterjee argues that similar processes must be occurring in other areas where people are governed and treated as populations. This opens up interesting questions about the limits to civil society and how these are spatially uneven, with different states/spaces/places experiencing differing forms of governmental activity. As Harrison (2012) has pointed out, however, the danger of political society is that it replaces one conceptual black box (civil society) with two (civil and political society). In arguing that political society exists as a realm distinct from civil society, and leaving civil society as a
relative ideal occupied by the elite, Chatterjee has little to say about either his conception of civil society or the relationship between civil and political society. Political society shares many characteristics with civil society and, in its direct contact with state functions through processes like corruption, vote rigging, and clientalism, it is seemingly less democratic and more entangled with the state than civil society. However, this again highlights the dynamic nature of the interaction between the state, its citizens, and wider market forces. Chatterjee’s political society is not an alternative to civil society; it is, instead, a recognition that civil society is a fundamentally limited concept that fails to grasp the messy, and often morally dubious, nature of politics as it is practiced by those who sit outside the traditional liberal political framework which underpins it.

Conclusions

Civil society remains a central concept to geographical understandings of politics, democracy, and social organization. However, it is also a concept that should be approached with a degree of care. Despite the seeming logic of compartmentalizing extra-state, extra-communal, and extra-market political practices into a distinct zone, there are continuing issues as to how this framework, rooted as it is in Enlightenment values, creates normative hierarchies and in many cases fails to deliver on its supposed promise for democratic deliberation. With transnational and global interconnections making ever more visible the complexity of social relations across the globe, the conception of civil society as a distinct arena remains problematic. Optimistic readings would still view civil society as performing a useful service in helping us to understand non-state political activity. For left-leaning liberals, civil society can be seen as still possessing the potential for change and resistance to the increasing corporate and capitalist hegemony of the world. Chatterjee’s more pessimistic reading has led to the more troubled zone of political society, where the majority who cannot gain access to civil society are left to compete for the scraps that neoliberal governmentality offers them. What is clear is that geographical understandings of politics and political organization are still informed and shaped by these competing conceptions of civil society as a space of political potential, and debates about their utility are likely to continue.

Class

Marianna Pavlovskaya
Hunter College and CUNY Graduate Center, USA

Class is one of the most important, widely used, and complicated concepts in human geography and the social sciences. Its meaning varies according to particular social theories and human geographical traditions, and to related conceptualizations of the economy. Different geographers, therefore, use and understand class in a number of ways. It is important to understand these distinctions because they affect our understanding of how class works and have different implications for policy, politics, and geographic research. Class as a concept is foundational to economic geography; it permeates research on local and global issues, the gendering of work and socioeconomic space, geographies of race and racialized economies, postcolonial struggles, and labor migrations.

Class as a group (neoclassical economics)

The concept of class entered Anglo-American economic and social geography after World War II. The Great Depression and the war made such a profound impact on the economic activities of the time that they required special analytical and theoretical understanding. The works of the prominent German sociologist Max Weber on social stratification and social class, published in the first decades of the twentieth century and translated into English in the 1940s, became influential in modern American sociology and neoclassical economics. Influenced by Karl Marx, Weber observed social groups marked by dramatic differences in wealth and social standing. Rich industrialists and impoverished immigrant laborers, middle classes and state bureaucrats, large masses of destitute homeless—all were emerging in a society being remade by the seemingly unruly forces of capitalism. According to Weber’s theory of social stratification, these groups possess drastically different fortunes which are shaped by differential access to economic opportunities provided by the market (called economic class), social status, and access to political power. Weber saw economic class as a major factor in the stratification of social classes. This factor, in contrast to more vague notions of status and power, can be relatively easily measured in terms of income.

At the same time, the economy was increasingly explained in terms of neoclassical economic theory and as an entity governed by its own objective internal laws. These laws, which economists aimed to discover, guided the invisible hand of the market in sorting people into groups based on their economic performance. This concept of class as a group of people with particular characteristics of income has dominated social sciences for decades and is still widely used today in reference to the upper class, middle class, and lower class, for example. In geography, this concept led to prolific research on social and residential differentiation that sought to identify homogeneous neighborhoods using social area analysis techniques and, with the advent of computation, so-called factorial ecologies. Measures of income were often combined with those of educational attainment,
household size, and race/ethnicity. Using census data and surveys, geographies of class were calculated and mapped for research into housing markets, access to schools and other services, and even, to a degree, the creation of foundational urban models (concentric, sectoral, and multinuclear). These models explained spatial and socioeconomic differentiation as a result of a tradeoff between land values and commuting costs contingent on advances in transportation. Mobility between classes (and therefore urban neighborhoods) depended on a household’s ability to raise higher income through participation in the labor market (usually as a function of education or entrepreneurial acumen). Class mobility had a spatial component, most prominently expressed in the relocation of upper and then middle classes to the suburbs (where money can buy more land and a better house and absorb commuting costs) and, in recent decades, back to the rapidly gentrifying inner city. Such census-based empirical analyses have received another boost in the current era of mapping, which allows a combination of advances in geographic information science, geocomputation, and big data analysis. Explanation, however, now draws on theories of class rooted not only in neoclassical economics but in Marxism, feminism, poststructuralism, and their many combinations.

Class as structural relation (Marxism)

Although Marx developed his theory of class much earlier than Weber, his legacy took hold in Anglo-American geographical theory considerably later. Marxian theory was introduced into geography most prominently by David Harvey, Doreen Massey, Dick Peet, Bill Bunge, and others in the 1970s and 1980s, as part of the critique of the post-World War II quantitative revolution and neoclassical economics. Class is a central concern of Marxism but its meaning differs from that of neoclassical economics. Marx viewed class as a structural relation that informs the whole of human history but is hidden from direct empirical observation. Classes are distinguished by their position in relation to ownership of the means of production instead of as groups of individuals with similar socioeconomic characteristics. The source of wealth lies in exploitation, which results from the appropriation of surplus from those who produce it but who do not own the means of production. Under capitalism, the means of production includes factories and other modern ways of manufacturing material and nonmaterial commodities, and the two main classes are capitalists, who own the means of production, and workers, whom they employ for wages and whose surplus they appropriate and use for capital accumulation. Tied into an exploitative relationship, classes are in tension and their struggle defines the workings of the capitalist economy and development more generally. Accordingly, Marxist scholars reject market-based causes as valid explanations for the making of economic geographies. Instead they advance explanations tied to the logics of capital accumulation and the dynamics of class exploitation. Class mobility, therefore, depends on the ability to gain control over the means of production and can be achieved by joining the capitalist class or by working toward social change which would transfer this control to workers themselves.

Marxist geographers have theorized space as integral to the process of capital accumulation and class relations. Thus, David Harvey (2001) advanced a theory of spatial fix as a means of temporarily resolving— or of always delaying—the crisis of accumulation. He argued that capitalism must search for new geographic markets, into which to invest surplus capital
in order to avoid losing it. In this way, new territories and resources enter the circuits of capitalist accumulation, a process that has become increasingly globalized. Similarly, surplus capital can be invested into (re)building infrastructure within capitalist space once an obsolete urban fabric becomes a new investment frontier (through, for example, suburbanization, urban redevelopment, and gentrification). Both geographical expansion and the remaking of the built environment offer only a temporary spatial fix; capital never rests securely and continues to produce new capitalist space and, by extension, class relations. Neil Smith (2008) refuted the tendency toward equilibrium espoused in neoclassical economics and argued that uneven spatial development is a necessary condition for creating new frontiers for capital. The production of the built environment, and its destruction, channel investment into real estate, including suburbanization and, most recently, gentrification, during the recurring crises of capital accumulation. Thus, Marxist geographers mainly focus on the production side of capital accumulation and examine geographies of the working class primarily as part of this process. Gordon’s (1978) explanation of urban form, for example, is that it is an attempt by capital to retain its control by spatially dispersing the working class. In Marxist analyses of class politics in the Fordist era, the working class was largely assumed to consist of unionized male and white industrial workers, an assumption challenged by feminist developments in understandings of class.

**Class as social reproduction (feminism)**

Since the 1960s, Marxian theory has been taken up, critiqued, and radically transformed by feminist scholars. While they allied with the idea of class exploitation as the cause of economic and social inequality, feminists have challenged the omission in Marxist analyses of (working-class) women in waged work. They have also challenged the conceptualization of social reproduction – the space of women’s unpaid work in patriarchal societies – as secondary to the sphere of production in which the exploitation of the (male) working class takes place. Feminist scholars have argued that unpaid women’s work in social reproduction is as important for capital accumulation as waged manual work and that this unpaid work has been the source of the specific exploitation of women by capital and by their household members. Early theoretical debates focused on the relationship between two structures of exploitation: capitalism as the exploitation of workers and patriarchy as the exploitation of women. In the course of theorizing this relationship, feminist scholars have developed a gendered critique of capitalism that links class exploitation to other dimensions of experience such as gender and extends it beyond the workplace: capitalists exploited working women as well as working men, while capitalists and working-class men also exploited women in the household. Feminist scholars, therefore, placed or positioned social reproduction alongside production, profoundly changing the meaning of class.

Feminist geographers have specifically focused on the relationship between class, gender, and space. They have shown that the gender gap in wages, for example, is also related to differences in commuting time between men and women and that commuting time also differs for women with different class and racial backgrounds (McLafferty and Preston 1991); that the gendered nature of the workforce plays a major role in shaping regional economies (McDowell and Massey 1984); that access to work outside the home is mediated by unequal
domestic responsibilities (Hanson and Pratt 1995); that, within the workplace, women have systematically been undervalued and underpaid (McDowell and Massey 1984; Wright 2006); and that women are generally more likely than men to engage in the informal economy. More recently, feminist scholars have also problematized the conflation of women’s unpaid domestic work with emotional support and care (Atkinson, Lawson, and Wiles 2011) and argued for the recognition of women’s agency as a means of empowerment.

Another important contribution of the feminist rethinking of class is that it has enabled scholars to see class experiences as embodied and class subjects as empowered actors (Mitchell, Katz, and Marston 2004). The embodied class subject stands in stark contrast to neoclassical economics, which regards labor as an input and class as an income category. It also contrasts with Marxist theory which highlights the power of capital over workers and rarely recognizes the agency of workers in the production of capitalist landscapes. By creating an embodied and empowered class subject, feminism has also opened class analysis to further theorization through the lens of black, postcolonial, and poststructuralist theory.

**Racial economy and class**

Antiracist, black, and postcolonial scholars have drawn on Marxism to understand the political economy of racial exploitation while also complicating the Marxian concept of class. They argue that colonialism and slavery have been instrumental in enabling large-scale capital accumulation in Europe and the United States. Structural racism, in other words, has been a necessary condition for the rise of capitalism. The exploitation of colonies supplied the capital needed for expanded capital accumulation during industrialization, and secured a food supply for impoverished and overexploited European industrial workers and peasants. Not only did slavery make plantation economies prosper in the southern parts of the United States, Latin America, and the Caribbean, but slave labor in the American North supported most middle-class households, urban economies, and city governments in crucial ways. Moreover, modern capitalism continues to thrive because of continuing racial exploitation. Examples include concentrated poverty in urban ghettos in the United States, where people of color have no prospects of work but experience the ever-present threat of incarceration; continuing institutional racism at the workplace and in the housing market; and the exploitation of numerous immigrant workers, many of whom are undocumented, and who have fled economic devastation, war, or gang violence in their home countries (Wright 2006; Gilmore 2007; McKittrick 2011). In short, capitalism moves surplus from black and brown bodies to capitalist owners and to larger segments of white waged workers, who often fail to recognize their white privilege and exclude people of color from their solidarity struggles for wages and benefits. Capitalism, of which a racial economy is an integral part, can be thought of as a thoroughly racialized class relation at scales from local to global.

**Intersectionality and class as a process**

The constitution of class by the social relations of gender and race can be illuminated using the concept of intersectionality. Articulated in the 1980s by black feminist scholar Kimberlé Crenshaw to explain black women experience
as defined by both race and gender, it has gained in popularity in the social sciences. Intersectionality draws on poststructural concerns with decentered identity, that is, when the identity of an individual or a group is simultaneously shaped by class, gender, race, sexuality, nationality, and other relevant power relations. As these intersecting registers of social experience can be understood only in their interaction, intersectionality provides an entry point into the analysis (Valentine 2007).

This thinking is clearly related to earlier feminist theorizing of class and gender, as well as race and gender, as inseparable or mutually constituting relations. But an explicit reworking of class and gender through the lens of poststructuralism occurred in feminist geography in the works of Julie Graham and Katherine Gison who wrote together under the pen name of J.K. Gibson-Graham (1996; 2006). Drawing on a Marxist anti-essentialist concept of class, J.K. Gibson-Graham do not see class as a group or structural relation but as a process that leads to the production and appropriation of surplus. Class processes occur when any kind of work takes place – as a waged relation within a factory or as unpaid domestic work within the household – because class exploitation takes place when those who produce the surplus do not control its distribution, and in a patriarchal household men typically appropriate the surplus produced by women through cleaning, cooking, and caring. Patriarchy, therefore, generates a class process, albeit one that is different from waged employment in a factory.

Another crucial consideration of class as a process is that people can participate in more than one class process, and can be exploited as well as exploit others (e.g., a waged factory worker who appropriates his family’s surplus at home). Capitalism and patriarchy can interact with other exploitative but different class processes such as modern slavery (i.e., forced labor, human trafficking for sex work, and the enslavement of ethnic and religious groups). The bottom line is that, while capitalism is dominant discursively and in terms of traditional measures of wealth, modern societies are complex and embrace many types of class processes including those with the potential for progressive class politics.

In sum, poststructural class analysis seeks to identify a range of class processes within capitalism and to explain how they are mutually constituted with social relations of gender, race, sexuality, nationalism, and so on. In this respect, J.K. Gibson-Graham’s approach and intersectionality go hand in hand but Gibson-Graham explicitly use Marxist concepts of class and exploitation as a point of entry while intersectionality may or may not be concerned with class. Gibson-Graham’s “diverse economies” approach also aims to advance transformative class politics and eliminate class exploitation.

Class in the neoliberal era and changing labor geographies

The era of post-Fordism or late capitalism has been associated with the rise of neoliberalism, which promotes privatization, globalization, and the deregulation of markets at all scales. These developments have profoundly changed the nature of economies and posed new challenges to class theories and analyses. Unions representing working-class, white-collar, and professional workers have long, and with some success, advocated for secure employment that provides financial stability for working families and communities. Yet one of the most striking developments is the shift away from permanent full-time employment, with a living wage and benefits as a golden standard of the modern economy, and its replacement by
temporary, part-time, low-paying jobs with no benefits (Standing 2011). In many cases, even the remaining full-time jobs no longer pay a living wage. Those who work multiple jobs but still remain in poverty join the growing ranks of the “working poor” while the relatively secure middle class continues to shrink.

Highly paid professional occupations in banking, law, information technology, and higher education are also moving rapidly toward temporary contracts that no longer provide job security. Temporary labor agencies now supply highly skilled professionals in addition to low-skilled service workers. Information technology specialists, graphic design artists, and lawyers get hired for a project and are fired when the project is terminated. In many North American universities, adjunct professors now teach the majority of courses at a fraction of the salary of a full-time professor. While professional workers usually have more resources than low-paid service workers to weather periods without work, the point is that job security and wage levels across sectors and occupations have declined. The trend amplifies as corporations push for the further deregulation of employment and justify reductions in wages and benefits by global competition. The decentralized global production networks that rely on multilayered subcontracting have fragmented employment to a high degree.

As well as the nature of work, both the composition and the geography of workforces have also changed. Today’s working class is no longer white, male, and unionized but largely female, nonwhite, and fragmented. It includes Sun Belt workers in the United States, immigrant and minority workers in the Global North, and outsourced industrial and service workers in the Global South (Wright 2006). And, while notions of the working class have expanded to embrace the greater numbers and diverse kinds of working people, the power of class politics in the last several decades has declined because it has been centered on a male industrial working class.

Is class still relevant?

This question raises the possibility that class may not be relevant in the neoliberal world, where both work and workers are fragmented along lines of gender, race, nationality, occupation, and other dimensions. Neoliberalism, to some, has made it impossible for working people to connect and articulate collective demands on corporations and capitalism. With traditional class politics linked to unionism in decline, no other leverage is in sight. Some see the subjection of working people to corporate power as almost complete. The only resolution to unfettered domination and exploitation may be the inevitable, large-scale class war that may replicate forms of militancy in armed struggles against colonial regimes (see Harvey 2014).

Yet others think that, although traditional working-class politics is declining, neoliberal restructuring has created not only new sites of exploitation but new class subjects as well. As disenfranchised workplaces extend to household economies, agricultural fields, urban neighborhoods, biotechnology labs, university campuses, and global production networks, new class subjects come into being. Domestic workers, unemployed college graduates, service and construction workers, immigrants, teachers and university professors, lawyers, and information technology specialists, peasants and farmers, and subcontracted garment workers across the globe can now all fill the ranks of the working class. These diverse class subjects have different levels of education; work in manual, service, and professional occupations; and can be of any racial group or gender identity. But they all...
share the condition of the increasingly precarious employment and income that, therefore, makes vital new class alliances and transformations that can potentially bring these new workers security and control over the economy. Social theory struggles to understand the nature of impending class transformations, with one frequently invoked scenario being the rise of the “precariat” – economically and culturally precarious and politically ambiguous proletarian masses of all walks of life (Standing 2011; Munck 2013; also see Harvey 2014). At the same time, the diversification of class subjects may provide an opportunity to broaden progressive class politics to build alliances across places, scales, and cultures and to cultivate imaginations of the shared future. The major challenge is how to build these alliances and make them work. In short, class analysis and politics have not lost its relevance; class remains a central concern.

Economic crisis, the problematic of class, and new class struggles

Class relations have indeed gained new attention during the protracted and continuing global economic crisis triggered by the financial collapse of 2008 in the wake of the pervasive foreclosure crisis in the United States. The Occupy Wall Street movement has somewhat waned since then, but it achieved astonishing success in bringing the problematic of class into the center of public debate, albeit a problematic framed more in liberal than in Marxian terms. Liberal discourse usually tolerates economic inequality under capitalism as a price for economic efficiency and growing overall prosperity, but the extreme concentration of wealth becomes counterproductive to capitalism as it interferes with growth. This reframing of class inequality as an impediment to economic development has rung bells across the political spectrum, and produced a feeling of disillusionment with capitalism as the principal model of development. At the same time, it has created room for debate about new economic policies and economies that are different from capitalism and that could lead to more sustainable social, economic, and ecological futures. It is vital, therefore, to turn to theories that begin to point to the ways in which progressive class transformations can occur.

Primarily concerned with the analytics of class, J.K. Gibson-Graham grounded their vision of transformative class politics in feminist and poststructuralist theory. Feminist theory helped to expand the scope of class processes into households and communities and to advance the possibility of decentralized but widely spread class transformations. These transformations are theoretically possible when the economy is read in poststructuralist terms as constituted by multiple economic processes, of which capitalism is only one. Some already existing noncapitalist practices, such as cooperative enterprises or egalitarian households, may act as the seeds of progressive class transformations, leading to the development of community economies. The latter are economic practices at all geographic scales, from household to international, that are guided by ethics of cooperation, care, and mutual support, and in which the participants collectively create and appropriate a surplus. On the one hand, seeing the economy as diverse instead of homogeneous and capitalist fragments of capitalist space and diminishes the power of capitalism over societal practices more generally. On the other hand, it creates and multiplies opportunities for progressive class transformations. Once in the realm of public imagination, the already existing alternatives to capitalism, such as economies of cooperation and solidarity, may stimulate creative engagement and the creation of new progressive class processes.
While J.K. Gibson-Graham have most prominently advocated for the possibility of transformation here and now (1996; 2006; Gibson-Graham, Cameron, and Healy 2013), other conceptions of class also work to advance the politics of possibility. Thus, Andrew Herod’s (1997) insistence that workers, in addition to corporations, actively shape economic landscapes can be pushed further to argue that workers can exercise their agency to produce noncapitalist landscapes by, for example, reorganizing social production based on cooperative ownership of enterprises, land, and housing.

Intersectionality also helps in understanding the nature of class subjectivities as embodied, gendered, and racialized. This proliferation, instead of being seen as a barrier to solidarity, can be regarded as multiplying opportunities for both resistance and progressive class transformations. Thus, households can work to eliminate domestic exploitation; transnational immigrant households can make economic demands of national governments based on the impact of their remittances; fishermen can set up community-supported fisheries instead of working for corporate boats; indigenous people may work to rebuild their communal economies even in neoliberal contexts; and domestic workers can exercise their solidarity by using the Internet to overcome dispersed workplaces. Working people can join collectively owned enterprises at greater scales, which would help to increase worker security, pool resources around collective housing, and use the financial services of credit unions instead of private banks. New community economies can also form around the commons that ensure collective control over land, oceans, housing, and urban space (Gibson-Graham 1996; Pavlovskaya 2013; Gibson-Graham, Cameron, and Healy 2013; Roelvink, St Martin, and Gibson-Graham 2015).

While the politics of resistance retains its importance in the face of the continued consolidation of neoliberal control over the economy and politics, there is also a need to cultivate the capacity of diverse working classes to enact progressive class transformations. This capacity is already evident in the growing international movement of solidarity and social economies, economic democracy, and other creative innovations coming together at the World Social Forum (Miller 2005). These movements seek to build alliances between economic actors who pursue ethical goals (e.g., social justice, workplace democracy, cooperative ownership, and environmental sustainability) instead of profit maximization and competition. By forming noncapitalist production networks with each other, they have the economic power to grow and to nurture new solutions and imaginations.

Despite the fragmentation of class politics by neoliberal policies around the globe, the relevance of class as a dimension of social experience and category of analysis has not diminished. The concept of class has been evolving to account for the fragmented nature of work and the embodied nature of class processes. The experiences of diverse – in terms of gender, race, ethnicity, gender, occupation, economic sector, nationality, and so on – labor forces are in need of new theoretical insights that can articulate opportunities for progressive class politics here and now, in multiple economic contexts, and across geographic scales.

Their differences notwithstanding, notions of class in different human geographic traditions are not mutually exclusive; they may all usefully address specific aspects of class problematics. Census-based socioeconomic variables are helpful for constructing the changing geographies of class differentiation, while Marxist concepts of class as social relations help to focus critique on growing capitalist class exploitation and
consolidation of economic power as causes of this differentiation. Made ever more powerful by analytics of gender and race, class analysis is now able to account for complex social experiences and to be more in tune with the rich fabric of daily life while poststructuralist interventions open class to progressive transformations here and now.

Climate adaptation/mitigation

Gordon A. McBean
Western University, Canada

As human activities have evolved and expanded, they have had, and continue to have, impacts on the climate system through emissions of greenhouse gases (GHGs) and aerosols and changes to Earth surface characteristics which affect the climate; conversely, there also continue to be impacts on humans. The economic disaster losses from weather- and climate-related disasters have generally increased over the past decades, ranging from a few US$ billion in the 1980s to above $200 billion in the period since the turn of the century (IPCC 2012). Economic, including insured, disaster losses are higher in developed countries while fatality rates and economic losses expressed as a proportion of gross domestic product (GDP) are higher in developing countries.

The objective of the United Nations Framework Convention on Climate Change (henceforth Climate Convention) is (Article 2): “…stabilization of GHG concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system. Such a level should be achieved within a time frame sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened, and to enable economic development to proceed in a sustainable manner.” The Intergovernmental Panel on Climate Change (IPCC 2014) has concluded that for crop yields there have already been more negative than positive impacts of a changing climate.

The Climate Convention addresses the two fundamental policy responses to the risks associated with climate change: mitigation and adaptation. Mitigation, which means actions to reduce GHG concentrations in the atmosphere, generally through reductions in emissions to the atmosphere or the enhancement of uptake of GHGs from the atmosphere, has been the central focus of most national and international policies concerning climate change. Climate change adaptation is defined as adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities. It should be noted that in the disaster risk management field the word mitigation means structural and nonstructural measures undertaken to limit the adverse impact of natural hazards, environmental degradation, and technological hazards, which makes it closer to adaptation in terms of actions.

Projected climate changes

To guide actions there is need for enhanced information on future climate change impacts at a scale necessary for decision-making (NRC 2010). Over the next few decades, the range of Intergovernmental Panel on Climate Change (IPCC 2013) scenarios does not produce discernibly different climate change outcomes, with projected warming of about 0.2°C per decade. After 2040, the projected temperatures diverge so that by 2100, for the range of scenarios and including the uncertainties, the warming is between 0.3 and 5.5°C. For most of the scenarios, warming continues for centuries to follow. Note that these are global mean
changes, and temperature changes over land at higher northern latitudes will be at least twice as great. Sea level rise is a critical parameter for the billions of people who live on or near the coasts. For the same scenarios, the IPCC (2013) projects sea level rise in the range of between 0.4 and 0.76 m by 2100. With the uncertainties, the sea level rise could be close to a meter by 2100.

One important issue is very much the possibility of abrupt changes in the climate system. As noted in the National Research Council (NRC) report *Abrupt Impacts of Climate Change: Anticipating Surprises* (NRC 2013), there is need to pay increasing attention to the possibility that at least “some changes will be abrupt, perhaps crossing a threshold or ‘tipping point’ to change so quickly that there will be little time to react.” It is noted that the rapid decline of Arctic sea ice over the past decade due to warmer polar temperatures was not really projected and there is evidence of very rapid changes (over a few decades or less) in the past with major impacts on ecosystems. Since the rates of warming over the past few decades and projected for most of the rest of this century are “probably as fast as any warming event in the past 65 million years,” there are increased risks of species extinctions. The destabilization of the West Antarctic Ice Sheet, which would result in raising sea level by tens of meters and more, with huge impacts, is still an abrupt change of unknown probability.

**Response strategies**

This entry is about mitigation and adaptation as responses to a changing climate, recognizing that adaptation is also necessary for a naturally varying climate and, as such, has been underway to some extent since the beginnings of life on this planet. Actions for climate adaptation, with adequate support, usually result in benefits for the short and medium term and locally to globally. Because of the global nature of the climate system, the mixing of GHGs, and the delayed response of the climate system, mitigation benefits are delayed and are hence long term; further successful mitigation requires global agreement or, at least, agreement of all significant emitters.

**Mitigation – emissions reductions**

Although overall GHG concentrations are rising, now at a greater rate than in the 1990s and reaching 400 ppm in 2013, there are in place effective policies and economy-wide packages of policy instruments for reducing GHG emissions in different sectors and many countries. Substantial technical and economic potential exists for the mitigation of global GHG emissions over the coming decades. An illustrative way of looking at changes of emissions in the future is (IPCC 1996):

\[
\Delta CO_2 \text{ emissions} = \Delta (\text{pop}) \times (\Delta (\text{GDP/pop}) \\
\times (\Delta (\text{energy/GDP}) \times \Delta (\text{CO}_2/\text{energy}))
\]

Here, pop is population and GDP is gross domestic product (wealth by many definitions). Hence, changes in future emissions will depend on growth in population, per capita wealth, energy intensity (how much energy is needed to produce the wealth), and carbon intensity (what fraction of the energy is derived from fossil or carbon-based energy sources). The main focus needs to be on how to reduce energy intensity and the carbon intensity of the energy being generated. There are important human choices through changes in lifestyle and behavior and management practices.

Under the Climate Convention, countries, depending on their capacities, are required to mitigate climate change through limiting GHG emissions and protecting and enhancing
sinks and reservoirs, and are required to update national inventories of GHG emissions and removals. Mitigation can be applied to different sectors, such as energy supply and demand, transport, buildings, industry, agriculture, forestry and waste management, or across the economy. Some techniques for carbon dioxide removal include: land-use management to protect or enhance land carbon sinks; use of biomass for carbon sequestration as well as a carbon neutral energy source; enhancement of natural weathering processes to remove CO₂ from the atmosphere; and the direct capture of CO₂ from ambient air.

The Kyoto Protocol of the Climate Convention had an overall target for developed countries of 5% emissions reductions compared to 1990 levels over the five-year period 2008–2012. Under the Climate Convention and its Kyoto Protocol there are mechanisms for countries to work together in reducing emissions in effective ways. These include: joint implementation of projects that assist one industrialized country to meet its targets by participating in projects with another country; international emissions trading (IET) enabling the buying and selling of GHG emission allowances between industrialized countries; and the clean development mechanism (CDM), which allows public or private entities to invest in GHG-mitigating activities in developing countries and earn abatement credits. Mitigation can also be addressed through protecting and enhancing sinks and reservoirs. Examples of the latter are: reducing emissions from deforestation and forest degradation (REDD) and land use, land-use change, and forestry (LULUCF), whereby the rate of buildup of CO₂ in the atmosphere can be reduced by taking advantage of the fact that carbon can accumulate in vegetation and soils in terrestrial ecosystems.

Under the Climate Convention, Annex I parties (43 parties) are required to submit a GHG inventory according to a common reporting format. Over the period 1990–2014, total aggregate GHG emissions including LULUCF for all Annex I parties decreased by 22.6% (UNFCCC 2014). The United States never ratified the Kyoto Protocol, and Canada, which did ratify it in 2004, withdrew in 2011. Although many countries achieved Kyoto Protocol targets, others did not and non-Annex I countries did not have targets. Conditional pledges have also been made through the Copenhagen Accord. The future of these processes is not clear at this time.

Changing climatic events

The IPCC (2014) has concluded that changes in climate have in recent decades caused impacts on natural and human systems across the continents and oceans. Further, the impacts of climate-related extremes events have shown the significant vulnerability and exposure of some ecosystems and many human systems. People living in poverty have especially negative outcomes. The IPCC (2012) concluded that economic losses from weather- and climate-related disasters have increased, noting there is large spatial and interannual variability. The economic losses associated with weather, climate, and geophysical events are higher in developed countries but the fatality rates and economic losses expressed as a proportion of GDP are higher in developing countries. Their assessment is that the increasing exposure of people and economic assets has been the major cause of long-term increases in economic losses from weather- and climate-related disasters. As the climate changes, these pressures will increase (Burton 2008). It is important to note that strategic approaches to mitigation can have adaptation benefits and vice versa. There is at least some inherent capacity to cope with variable weather and climate in every nation and community but the changing climate threatens to exceed this “coping range.” As the climate...
changes, there will be changes in the frequency, intensity, spatial extent, duration, and timing of extreme weather and climate events; these may come together in unprecedented ways (IPCC 2012).

Based on climate model projections (IPCC 2012, 2013) for the rest of the twenty-first century the frequency and magnitude of warm daily temperature extremes will increase while cold extremes will decrease. A 1-in-20-year hottest day is likely to become a 1-in-2-year event by the end of the twenty-first century in most regions. Although there are other factors, the increases in hot days will add to impacts on human health (IPCC 2014). Health impacts will also occur due to storms, air pollution resulting from more hot days, and other factors.

Although changes in total precipitation will vary, extreme precipitation events over most of the mid-latitude land masses and over wet tropical regions will very likely become more intense and more frequent by the end of this century. The monsoon regions are likely to expand in space and time, with monsoon winds likely to weaken but the monsoon precipitation likely to intensify due to the increase in atmospheric moisture. Heavy rainfalls associated with tropical cyclones are likely to increase with continued warming. Increases in heavy precipitation will result in a 1-in-20-year annual maximum daily precipitation amount likely becoming a 1-in-5 to 1-in-15-year event by the end of the twenty-first century. These changes in extremes are already having their impacts and additional actions are needed (ICLR 2012). Another issue identified by IPCC (2012) is the combination of heat waves, glacial retreat, and/or permafrost degradation leading to high mountain phenomena such as slope instabilities, movements of mass, and glacial lake outburst floods.

With regard to the global frequency of tropical cyclones, the numbers will either decrease or remain essentially unchanged, but there will be a likely increase in both global mean tropical cyclone maximum wind speed and rainfall rates. The frequency of the most intense storms will increase substantially in some basins. These projected precipitation and temperature changes imply possible changes in floods. With mean sea level rise, these higher winds will lead to even greater risks of coastal storm surges, which are a major cause of fatalities and damage in coastal communities, such as with Hurricane Sandy in 2013, and particularly in tropical small island states.

The possibility of abrupt climate changes and abrupt climate impacts also needs to be considered in adaptation policies (NRC 2013). The National Research Council recommends that action be taken to improve society’s ability to anticipate abrupt climate changes and impacts through the development of an Abrupt Change Event Warning System (ACEWS). This could allow for the prediction and possible mitigation of such changes before their societal impacts become severe.

Adaptation strategies

The impacts of climate hazards on a community or ecosystem depend not only on the climate threat but very much on their exposure and vulnerability, which are the key determinants of disaster risk and of impacts when risk is realized (IPCC 2012). The occurrence of certain weather or climate events may affect community vulnerability to future extreme events by modifying resilience, reducing coping capacity, and increasing sensitivity to the stresses they impose, thus reducing the capacity to adapt to these stresses. Climate adaptation policy is a course of action chosen by public authorities to mandate or facilitate adjustments to practices,
processes, or structures, aimed at gaining benefits and reducing current and future impacts of a changing climate while also linking it closely to disaster risk management. The central goal of adaptation policy must be to reduce exposure and vulnerability. Adaptive capacity refers to the ability to adjust practices, processes, or structures to moderate or offset potential negative impacts associated with climate change (Burton 2008). A community with a greater capacity to adapt is less vulnerable to negative impacts associated with climate change. The core of countries’ capacity to meet the challenges of observed and projected trends in exposure, vulnerability, and weather and climate extremes will depend on national systems (IPCC 2012). The IPCC (2014) lays out adaptation principals for managing future risks and building resilience. These adaptations will be place and context specific and can be enhanced through individuals’ and governments’ complementary actions. Noting that climate-resistant pathways need to be consistent with sustainable-development trajectories, additional research may be needed on the socioeconomic costs of extreme events and the savings and benefits of adaptation strategies to influence decision-makers.

With the broad implications of climate change, the involvement of many government organizations, including industry, economic development, and trade, is important so that the resulting development of the climate change adaptation strategy can be “mainstreamed” into all public- (local, subnational, national, and international development) and private-sector policies and practices (IPCC 2012). Climate change adaptation actions will need to address the human impacts and disaster losses in sectors with the closer links to climate, such as water, agriculture and food security, forestry, health, and tourism. In these sectors there are also potential benefits from a changing climate, such as longer and warmer growing seasons enabling the growing of some crops. With the increased risk of heavy precipitation events and possible high wind conditions, there are risks to infrastructure that can be addressed through building codes and municipal planning. Early warning systems are important for reducing impacts on humans.

The scientific basis for concern about a changing climate is strong, and humans will have to adapt to a changing climate (McBean 2015). Adaptation challenges which are already very large will be much greater if stronger actions on mitigation are not taken (IPCC 2014). Some ecosystems will not be able to adapt and there is also the risks of abrupt changes. Research questions include how to develop and implement optimum adaptation and mitigation strategies, including the factors that will influence public and private decision-makers to undertake them. There is a need for all societies to more aggressively address these issues.

Climate and societal impacts

Colin Polsky
*Florida Atlantic University, USA*

Climate shapes the behavior of all living organisms. Variations or changes in climate should therefore affect human and ecological processes. Such effects are broadly known as “climate impacts.” This concept is intuitive and widely shared among biophysical and social scientists, and the general public. However, from a research perspective, definitively classifying a given change in social or environmental systems as a climate impact is not as straightforward as it might seem. For example, paleoclimate reconstructions suggest a significant warming, and then cooling, in Greenland ≈ 1000–800 years BP. These climate variations appear to correspond with the timing of the colonization, and then abandonment, of the region by the Norse (D’Andrea et al. 2011). It is therefore tempting to infer that the climate produced specific impacts on humans by making habitation tolerable, or not tolerable. Similar claims of climate controls on humans and ecosystems have been made for many other cases. In the Norse case, the warming (and subsequent cooling) presumably affected the population by significantly enhancing (and then degrading) the local habitats for livestock and agriculture.

Yet an observed correlation between a change in climate and a change in human or environmental systems does not necessarily imply causation. For example, variations at a given point in time in the abundance of wildlife or fish, or in political-economic conditions, might be unlinked to climate, and yet contribute to the observed changes thought to be the product of climate. Climate should therefore be analyzed in the context of other contemporaneous processes. In general, any statement about climate impacts needs to be evaluated by testing alternative, non-climate explanations for the human–environment changes hypothesized to be linked to climate (see Wisner et al. 2004). Despite the challenges in classifying whether or not specific outcomes in human and environmental systems are the product of climate variations, there is a compelling and growing need to do so. The promise of anthropogenic climate changes in the coming decades due to atmospheric loading of greenhouse gases means that understanding the specific conditions under which a given climate change will negatively (or positively) impact people and ecosystems is a pressing research and policy need. This encyclopedia entry begins by providing a brief overview of recent climate impacts scholarship and ends with a review of some observed climate impacts trends and future research needs.

The roots of climate impacts scholarship

Climate impacts research is not new. This field has examined both how people affect climate and how climate affects people and ecosystems. The human role in modifying climate is not limited to the case of modern atmospheric accumulations of greenhouse gases. Other human–environment
CLIMATE AND SOCIETAL IMPACTS

interactions (such as when deforestation modifies local radiation and water budgets) have long been known to shape local climates (see Marsh 1965/1864). The direct impacts of heat waves, drought, storms, and so forth, on human and environmental systems have also been a focus of study for generations.

By contrast, the more systematic study of changes in meteorological parameters over space and time is a relatively new, and growing, science. The development of climatology as a discipline – and by extension, the allied field of climate impacts research – had to wait until enough meteorological variables had been measured for a sufficiently long time, and in a sufficiently large number of locations, that comparisons of trends and anomalies had sufficient statistical power to make reliable predictions and inferences about the trends and underlying physical processes. Thus despite the long history of interest in climate impacts, systematic studies linking environmental and social outcomes to climate – as opposed to links with non-climate contemporaneous trends or events such as wars or earthquakes – begin to appear only in the twentieth century when meteorological instrumentation networks had generated sufficient data for synoptic study.

Unfortunately, some of the early scholarly climate impacts studies (e.g., Semple 1911) were used to support discriminatory policies or practices by, for example, claiming that human characteristics or achievements were strongly or even necessarily linked with climate. Typically the inference was that higher temperatures retarded human, social, and cultural progress. This logic suggested that tropical societies were limited by climate in their potential to develop. These arguments supported racial discrimination. Such explicit “environmental determinism,” which was generally grounded in opportunistic case studies, is now absent from mainstream research, even if some contemporary scholarship continues to attribute a definitive and independent role to climate impacts on economic development (e.g., Nordhaus 2006).

Much recent climate impacts scholarship draws on a comprehensive conceptual-analytical framework that emerged in the second half of the twentieth century. The “environmental risks and hazards” approach examines how social and biogeophysical processes interact to produce specific adverse environmental and social outcomes. This field has largely examined environmental phenomena not framed in climate change terms, such as earthquakes, floods, landslides, and even nuclear waste or other technologically related hazards. To the extent that climate or meteorological phenomena were examined (e.g., tropical storms, droughts), the motivation was grounded in the phenomena on their own merits, that is, without respect to climate change.

Yet following the growing concern in recent decades of scientists and policymakers about global warming, this risks-hazards framework has been adopted for the systematic study of climate dynamics and the associated potential implications for terrestrial, freshwater, marine, and human outcomes in an anthropogenically warmed world. In this framework, three dominant human–environment processes are highlighted for explaining why groups of people exhibit varying impacts from environmental, including climate, processes: land use, emergency response, and adjustment control.

Land use refers to activities that individuals and groups of people undertake to support the provision of their basic needs and luxury wants. At a high level of abstraction, agriculture and urban settlement are examples of land use. In the “climate impacts” context, the land-use system is important to understand because these activities can introduce social dependencies on climate. Farming by definition introduces social needs
for specific levels and timings of precipitation and solar insolation for production to reach economic levels. Understanding land use is also important in the climate impacts context because land use can increase (or decrease) social and ecological exposures to climate variations. For instance, urbanized landscapes tend to enhance nighttime temperatures and convective storm development by modifying local energy budgets due to the replacement of vegetation with impervious surfaces.

Second, the emergency response process is the means by which people or goods are rescued from immediate harm following exposure to an environmental hazard, and then provided short-term relief to mitigate the most pressing negative impacts. The plight of many elderly New Orleans residents exposed to the flooding associated with Hurricane Katrina illustrates how this process can succeed, or fail. Finally, the process of long-term adjustment control describes the human decisions, often but not always regarding land-use planning, that are, or could be, implemented with the explicit aim of reducing the incidence of future adverse climate impacts. Relevant to this domain of climate impacts research is the (at times paradoxical) role of government policies (e.g., Burby 2006) and the expected recovery time for a city following exposure to a major climate/weather event (e.g., Kates et al. 2006).

Recent climate impacts scholarship and some notable climate impacts

The field of climate impacts research was arguably codified for a global audience in the 1980s. In 1985, the landmark SCOPE (Scientific Committee on Problems of the Environment) report Climate Impact Assessment: Studies of the Interaction of Climate and Society was published. Then in 1988, the World Meteorological Organization joined with the United Nations to create the Intergovernmental Panel on Climate Change (IPCC; see www.ipcc.ch). The IPCC is charged with reviewing the most recent scientific literature on how climate affects human–environment systems. The IPCC makes no policy prescriptions but instead cleaves to evaluating the scientific research on global climate processes and associated drivers, impacts, and feedbacks. The first IPCC report presented a tentative conclusion about the presence and causes of contemporary and future climate conditions across the globe, with more speculations than definitive statements about climate impacts. By contrast, the most recent fifth IPCC report, finalized in late 2014, argues unambiguously that climate change is underway, that it is produced by human loading of atmospheric greenhouse gases, and that, consequently, a suite of impacts spanning terrestrial, freshwater, marine, and human domains can now be observed and should be expected to continue for the coming decades – and for longer duration if significant emissions reductions are not achieved soon.

Given this evolution of increasingly confident (and high-profile) statements about global climate change from IPCC, the volume of information about specific trends in climate impacts on human and environmental systems, and associated policy and other response options, has grown significantly in recent decades. Periodic accounts are found in multiple scholarly journals, such as the Bulletin of the American Meteorological Society, and Annals of the Association of American Geographers. The US federal government has also produced a series of accounts of trends in climate, climate impacts, and associated response options, in the form of the recurring National Climate Assessment, published by the US Global Change Research Program.
Climate and Societal Impacts

Select findings from this rapidly growing collection of conclusions include the observations that climate has already contributed to an 80% decrease in Caribbean coral cover in recent decades and to increasing wildfire extent across the western United States. Significant changes in biological and ecological properties, such as individual fitness, population dynamics, distribution and abundance of species, and ecosystem structure and function, have also been observed in recent decades across the United States. Recent warm and dry conditions in the Colorado Rocky Mountains have resulted in increased insect outbreaks. Glaciers and ice sheets continue to shrink in many locations worldwide, with direct effects on runoff and downstream water resources. A host of social and economic impacts on human health and infrastructure is also being observed, and acted upon, by governments (local, state, federal), the private sector, and community groups.

Future research needs

This growing catalog of observed and projected impacts of climate change on human and ecological systems suggests that the research template has been set for the coming decades. Specifically, future climate impacts research needs to center on adding to this database of climate impacts across space and time. Yet there is at least one additional research frontier in the climate impacts domain: adaptive capacity. Beginning with the third IPCC report, scholars have increasingly turned to arguing that even though scientific understanding of climate dynamics (i.e., the processes that generate exposures to climate variations or changes) and of short-term socio-ecological responses to the exposures (i.e., the sensitivities to the exposures) is rapidly improving, much less well understood, by contrast, are the longer-term capacities of these systems to adapt such that the exposures and/or sensitivities are eventually diminished.

The term “vulnerability” has been adopted to refer to this three-dimensional concept: not only the exposures and associated short-term sensitivities, but also the longer-term adaptive capacities that dictate how well the system can learn from specific events by reducing future negative impacts from repeated climate exposures (Turner et al. 2003; Figure 1). Accordingly, the climate impacts literature has experienced a renewed interest in the adaptive capacity process (what the earlier literature termed “long-term adjustment control”), resulting in a considerable number of publications in recent years.

However, the insights from the recent scholarship on climate-related adaptive capacities (as well as on climate exposures and sensitivities), as valuable as they are considered individually, may be difficult to generalize. The wide variety of processes involved in socioecological adaptation means that finding a common set of metrics meaningful to all systems has proven elusive to date. Systematizing the study of climate impacts, adaptive capacity, and, by extension, vulnerability, will require translating a growing library of results of varying natures into comparable qualitative statements that permit decision-makers of all kinds to plan for the future based on our understanding of the past. The analytical means for advancing on this front exist (Polsky, Neff, and Yarnal 2007), but has yet to be applied systematically to the climate change impacts domain. A generalization of the factors that lead to greater, or lesser, climate impacts is as needed now as ever in the United States. The recent tragedy of Hurricane Sandy is just one of what appears to be an increasing incidence of weather events the impacts of which are measured in the tens of billions of dollars. Hence the growing call among urban planners, politicians, private

Climate change adaptation and social transformation

Karen O’Brien
University of Oslo, Norway

Climate change is among the most complex and challenging problems facing humanity. The impacts are being observed around the globe through increases in temperature; changes in the amount, timing, and intensity of precipitation; warming of the oceans; reduced sea ice in the Arctic; shrinking of glaciers almost worldwide; sea level rise; and changes in extreme weather and climate variability. These changes have widespread yet differentiated consequences for human society, with implications for health, livelihoods, settlements, and security. They also influence the number, geographical range, migration patterns, and seasonal activities of individual species, and the composition and distribution of ecosystems. Continued emissions of greenhouse gases will cause further warming and long-lasting changes in the climate system, increasing the likelihood of severe, widespread, and irreversible impacts for people and ecosystems (IPCC 2014).

Reducing the risks of climate change requires human responses at all levels of society. Both mitigation and adaptation have been the focus of climate change policies in international negotiations and through regional, national, and local strategies and actions. Mitigation refers to the reduction of concentrations of greenhouse gases in the atmosphere in order to limit future climate change, while adaptation refers to the process of adjusting to actual or expected climate and its effects. These are seen as complementary responses, as there is no doubt that adaptation to observed and near-term climate changes is necessary regardless of mitigation, but it is also clear that substantial mitigation is a prerequisite for successful long-term adaptation. Yet mitigation and adaptation alone are not considered sufficient for realizing an equitable and sustainable world. There is increasing recognition of the links between climate change and other environmental and social issues, including poverty and inequality, hence the growing attention to the need for broader and deeper social transformations in response to climate change.

Climate change impacts and vulnerability

Humans have always influenced the climate, for example through land-cover changes that alter the surface reflectivity, or albedo. However, the rate, magnitude, and scale of human influence on the climate have been increasing since the onset of industrialization, through the extensive use of fossil fuel energy sources (coal, oil, and gas), land-use and land-cover changes such as deforestation, and increases in livestock production. The consequences of these activities are global and systemic. The latest assessment report of the IPCC (2014) documents numerous changes in the climate system. For example, the globally averaged temperature is estimated to have increased by 0.85°C in the period from 1889 to 2012. Each of the three decades following 1980 has been successively warmer than any preceding decade since 1850, and in the Northern Hemisphere the most recent 30-year period from 1983 to 2012 was likely the warmest in the last
1400 years. The IPCC (2014) concludes with 95% certainty that human influence has been the dominant cause of an observed warming since the 1950s.

Although human influence on the climate system is clear (see IPCC 2014), relatively little has been done globally to reduce emissions of carbon dioxide (CO$_2$), methane (CH$_4$), nitrous oxide (N$_2$O), and other greenhouse gases. In fact, CO$_2$ emissions have increased significantly over past decades and are likely to continue increasing under most business-as-usual scenarios. Unless greenhouse gas emissions are drastically reduced, the IPCC expects global average surface temperature increases to exceed 1.5°C by the end of the twenty-first century, relative to the period from 1850 to 1900. Some scenarios show a globally averaged warming of more than 3°C by the end of the century. Sea levels are expected to increase under all scenarios by 0.25 cm to 0.88 cm in the coming century, with further increases for centuries to come. Projections of future global and regional climate change are highly dependent on global emission trajectories, which are usually linked to scenarios of economic development, technological change, and population growth.

The consequences of climate change have been observed in all parts of the world, with the strongest impacts visible in natural systems. Climate change affects the global water cycle, leading to increasing contrasts between wet and dry regions and seasons (although with regional exceptions). Agriculture and food production are affected by increased variability and changes in temperature, precipitation, soil moisture, pests, and diseases. The warming of oceans influences ocean and atmospheric circulation patterns, as well as fisheries and coral reefs. Sea level rise contributes to greater storm surges, coastal flooding, and salinization of soils. As a result of the cumulative effects of past, current, and future emissions, and the thermal inertia of the warming oceans, most of these changes will persist for many centuries, even after emissions of CO$_2$ are dramatically reduced. Increases in carbon dioxide are contributing not only to climate change, but also to ocean acidification, which has implications for marine and coastal ecosystems and the human livelihoods associated with them.

The impacts of climate change on human systems are particularly visible through changes in climate variability and extreme events, which tend to reveal the social dimensions of risk, including the differential impacts within and across societies (Blaikie et al. 2003). Droughts, floods, wildfires, or cyclones can influence ecosystems and food production, damage infrastructure, affect human health, and contribute to injuries and deaths, loss of livelihoods, and population displacement.

Both increased variability and long-term climate change have significant implications for human security; in addition to decreasing food and water security, they can indirectly increase the risk of violent conflicts, serve as a “push” factor for migration, and challenge the territorial integrity of many low-lying and small island states (IPCC 2014). With more than half of the world’s population living in cities, the impacts of climate change on urban populations are of particular concern. Many of the world’s largest cities are located in coastal areas and are thus vulnerable to sea level rise, cyclones, and storm surges. The effects of heat stress are likely to be felt by urban populations, particularly the elderly and poor. Although populations or households that lack access to infrastructure and services, or live in marginal areas, are often the first to experience the impacts of climate change, the impacts on urban infrastructure (transport, waste management, water, electricity, buildings) can make large populations vulnerable to climate change and extreme events.
Adaptation to climate change

There has been a surge of attention in recent years to adaptation research, policy, and practices as a means of reducing the risks of climate change (or, in some cases, as a means of taking advantage of new opportunities). This growing interest in adaptation is tied to the recognition that climate change is already happening and affecting species, ecosystems, economic sectors, livelihoods, and human security in most parts of the world. Although strategies and actions to reduce greenhouse gas emissions can significantly influence the rate and magnitude of future climate change, society will still have to adapt to impacts over the next decades. This is because some heat-trapping gases, such as CO₂, can remain in the atmosphere for many decades, as it takes time for accumulated emissions to be reabsorbed. In addition, about 90% of the accumulated heat has been taken up by the oceans, and this heat will be released slowly because of the thermal inertia accumulated. Although there have been intensive international efforts to promote mitigation of climate change through agreements such as the 1992 UN Framework Convention on Climate Change (UNFCCC), the 1997 Kyoto Protocol, the 2014 Lima Accord, and the 2015 Paris Agreement, these political commitments alone are not considered sufficient to limit global temperatures increases to below 2°C, and many experts are suggesting that average temperatures may rise by 2.7°C or more by the end of the twenty-first century if business-as-usual scenarios persist. Adaptation is now considered an increasingly necessary part of planning and development processes, as warmer temperatures, sea level rise, ocean acidification, and other impacts have implications for sustainable development, poverty reduction, and other societal goals.

Adaptation research has expanded significantly since the mid-1990s, and includes theoretical papers that discuss definitions, typologies, and approaches, as well as case studies from diverse communities, sectors, and world regions (Smit and Wandel 2006; Schipper and Burton 2008). It has also become an important part of climate change policy debates, adding to discussions about the reduction of greenhouse gas emissions through mitigation strategies. Questions are raised in these discussions regarding the transfer of technology, the means of increasing adaptive capacity, mechanisms for financing adaptation, and the governance of adaptation processes. More recently, issues of responsibility, including compensation for loss and damages, have become an important part of adaptation debates.

Adaptation requires coordinated and complementary responses across all levels, spanning a wide group of stakeholders, including citizens, policymakers, nongovernmental organizations, and the private sector. The governance of adaptation across different interests and groups is not always clear, particularly in relation to questions of funding and finance for low-income households, communities, or nations. There have been discussions about mainstreaming adaptation into all sectors of society (Ford and Berrang-Ford 2011), including into overseas development aid (ODA) (Tanner and Horn-Phathanothai 2014). Approaches to adaptation are closely linked to understandings of the causes of vulnerability. A focus on the biophysical drivers of vulnerability usually draws attention to adaptations that minimize the impacts associated with different scenarios of climate change. Such adaptations are often sectoral, focusing, for example, on water, agriculture, energy, health, or buildings. There is a tendency for such adaptations to emphasize technical measures, which may include changes to standards and regulations, better technologies, new types of seeds and cropping techniques, infrastructure and engineering projects, as well
CLIMATE CHANGE ADAPTATION AND SOCIAL TRANSFORMATION

as early warning systems and other “climate services.” They may also include changes in behaviors and management practices, such as drinking more water during heat waves or planting crops earlier.

While adaptation projects and programs that address a specific climate risk are important (not least because they can be more easily implemented, monitored, and evaluated according to various success criteria), there is a risk that these technical adaptations will result in piecemeal solutions that address specific impacts without considering systemic factors and the underlying causes of vulnerability, or the wider consequences of adaptation, that is, the implications for other sectors, systems, or groups. There is also a risk that they will ignore or be insensitive to cultural aspects, such as traditional practices, cultural values and preferences, identities, and sense of place. Cases where adaptation in one sector or by one group exacerbates or contributes to new vulnerabilities for others, both in the present and future, are often referred to as “maladaptation.”

Social approaches to adaptation tend to focus on the underlying drivers of vulnerability, whether by improving social services and safety nets, increasing education and awareness, developing new economic instruments, providing insurance, or by identifying other policies and measures that specifically target the most vulnerable groups. Such approaches recognize that vulnerability and risk are not merely the result of the hazard but, rather, are also an outcome of historical conditions and social structures that expose people to risks or limit their capacity to respond. These conditions often include social relations linked to gender, class, or ethnicity, which are related to historical, cultural, and political contexts. From this perspective, adaptation is about changing social relations and addressing historical injustices and contextual factors that surface as “climate change vulnerability.”

However, adaptation policies and measures that focus on a broader social context can be difficult to distinguish from general development projects and processes, and may not be uniquely recognized by some as climate change policies. Alternative approaches to adaptation that address systemic causes of vulnerability are less common, and few have challenged dominant development paradigms that are associated with increasing risk and vulnerability (Bassett and Fogelman 2013).

Resilience approaches to adaptation focus on complexity, feedbacks, linkages, flexibility, and adaptive capacity of social–ecological systems. As Nelson, Adger, and Brown (2007, 412) argue, “Whereas much of the adaptation literature is focused on reducing vulnerabilities of specific groups to identified risks, a resilience approach is concerned with developing sources of resilience in order to create robustness to uncertainty and to maintain the flexibility necessary.” They show how a resilience perspective on adaptation can contribute to better understandings of both incremental and transformative systems change. Indeed, as the observed and projected impacts of climate change become more visible and better understood, it is increasingly recognized that small adjustments are, in some cases, unlikely to be sufficient responses to climate change. More recently, the concept of transformational adaptation has attracted attention within the research community. Transformational adaptation goes beyond incremental adjustments or approaches, and may include changes in form or structure through novel, large-scale actions. Examples include relocating coastal populations in response to sea level rise or shifting to new types of agriculture. Transformational adaptation may be pursued in anticipation of or in response to observed or expected impacts; it may involve coordinated or uncoordinated actions; and it may be deliberate or inadvertent. Kates, Travis, and Wilbanks (2012) describe three types of
transformational adaptations: those adopted at a larger scale or intensity; those that are novel to a region or system; and those that transform places or involve a shift in location. Transformational adaptation may be more needed for some places and systems than for others.

Although there are diverse approaches to adaptation, there has been relatively little discussion of what constitutes “successful adaptation” to climate change, especially in cases where climate change is only one among many changes that are being experienced (Moser and Boykoff 2013). Successful adaptation is a relative and subjective concept, and has spatial, social, and temporal limitations. One location or group’s adaptation may increase the vulnerability of others, in relation, for example, to flood or fire management, irrigation schemes, migration, or coastal protection. Current adaptation measures may also increase the vulnerability of future generations, particularly if they do not take into account climate change mitigation, distributional effects, and other aspects of sustainability. What appears to be successful adaptation at one point in time may be considered inadequate in the future, as climate change is characterized by nonlinear and systemic changes that include tipping points and other ecological surprises. It is recognized that there are limits to adaptation or cases where something of value will be permanently lost (Adger et al. 2009). This raises important ethical issues regarding who decides about the policies that influence not only the rate and amount of climate change, but also the types of adaptation responses that are acceptable.

Adaptation to climate change is not a neutral, apolitical process. From a critical geographic perspective, it can be considered problematic, particularly when it involves adapting to changes that are associated with existing political, social, and economic relations, perpetuated by some interests, and normalized by media, habits, and social practices. Across the emerging field of climate change adaptation, discussions and debates rarely address the full complexity of the challenge, including whose interests and ways of doing things are strengthened by promoting adaptation to climate change impacts, particularly through technical measures. When it is delinked from climate change mitigation politics and policies or from discussions about past, current, and future development pathways, adaptation can be considered an alibi for business as usual. Indeed, adaptation could be interpreted as the active promotion of passive responses to climate change, diverting attention from other possibilities, including responses that minimize risk and vulnerability by challenging existing systems, structures, and power relations. Rather than simply a technical problem that can be addressed with more expertise, know-how, and innovation, climate change can be considered as an adaptive challenge that is fundamentally linked to mindsets, particularly individual and collective beliefs and assumptions (O’Brien and Selboe 2015). Viewed from this perspective, adaptation to climate change is about integrating the personal and political dimensions of change to promote larger social transformations toward sustainability.

From adaptation to transformation

As described, adaptation is an important strategy for reducing vulnerability to climate impacts, yet rarely does it involve questioning the systems, structures, and interests that perpetuate climate change risks and vulnerability. There are, however, more progressive interpretations of adaptation that do not involve merely complying with or adjusting to changes that are already occurring or are expected to occur. For example, Pelling (2011) distinguishes between adaptation as resilience, adaptation as transition, and adaptation
as transformation. While the first two types are seen as preserving or reforming existing systems, adaptation as transformation offers the potential to fundamentally change the underlying causes of risk and vulnerability. Distinct from the transformational adaptations made in response to the impacts of climate change, adaptation can thus be thought of as a potential mechanism for progressive and transformational change that shifts the balance of political or cultural power in society, overturning established systems and imposing new regimes (Pelling 2011).

Policies and decisions associated with transformation extend beyond the status quo, and often challenge traditional ways of thinking about things, doing things, and planning for the future. As with adaptation, transformation is not a neutral, unbiased response to climate change; it reflects the beliefs, values, worldviews, and interests of different actors and institutions, and there is no doubt that power and politics influence discourses on transformation. Transformation is a concept with wide appeal, and it can be interpreted and used to promote diverse interests and agendas, ranging from transformations to a green economy to transformations through geoengineering. Thus, although transformation is widely talked about, there are many partial, fragmented, and even contradictory understandings of what needs to change and how such changes come about.

Transformation encompasses many different approaches, interests, focal points, goals, and objectives, and these can sometimes threaten traditions, interests, power structures, and social hierarchies. This in turn can trigger resistance, opposition, oppression, and fear. Because transformations often upset the status quo, it can be difficult to see or agree on their benefits, and it is not surprising that conservative responses tend to dominate. As Pelling (2011) points out, history is replete with examples of transformation processes being captured by vested interests or new elites. Importantly, “both the poor and powerful are aware of the costs of change and prefer the known even if it is a generator of risk” (Pelling 2011, 97). Thus, even as climate change and other environmental and social changes radically transform the world, there is a tendency to avoid deliberate transformations to sustainability for fear of change.

Transformation is nonetheless considered by many to be a necessary means of responding to environmental challenges. However, it is important to recognize that there are many theories of social change based on different understandings of the role of human agency and its relation to social and political structures, and different conceptualizations of human–environment relationships. A materialist understanding of social change considers physical matter as the fundamental and only reality, and thus tends to view change as causal manifestations or results of physical properties and processes. Consciousness, or subjective experience, is seen as a product of brain interactions, and free will and intentionality thus have no real role in social change. Interpretivist and constructivist understandings of social change, in contrast, recognize the significance of ideas, meaning, and perceptions, including how power and interests forge or perpetuate relationships that hinder or facilitate change. Alternative nondual understandings of nature–society interactions have fostered new approaches to engaging with social change (see, e.g., Castree 2005). It is important, however, to recognize that dominant discourses and paradigms still tend to define both problems and solutions, “naturalizing” the types of transformation that are considered possible and desirable.

For example, often the transformation of human behavior is promoted as the most important climate change response. Pointing to the individual, numerous efforts have been
made to understand, influence, manipulate and “nudge” behaviors toward sustainable practices. A focus on “attitude, behavior and choice” has been criticized by Shove (2010) for ignoring the underlying systems of provision and the extent to which behavioral options and possibilities are structured by institutions and governments and social practices. A body of research on transformations to sustainability focuses on social-technical transitions, drawing attention to the need for changes in energy, transport, agriculture, and other systems. This research emphasizes the importance of learning processes, adaptive management, innovation, and experimentation, yet also points to the limits to rapid transformative change because of deep structures and the lock-in of technologies. Such approaches tend to be consistent with ecological modernization, which seldom challenges dominant political structures and economic paradigms centered on competition and growth.

Many “transformative” responses to climate change ignore the role of politics and power in perpetuating business as usual. Swyngedouw (2010) is critical of the nonpolitical and non-partisan nature of climate change responses, particularly its implicit acceptance of capitalism and a market economy as the only possible organizational structure for the social and economic order. This, he argues, comes at the expense of a “politics of the possible” and a naming of alternative socioenvironmental futures that introduce difference, conflict, and struggle. The repoliticization of climate change is thus seen as an important means of envisioning, enacting, and realizing alternative futures. Yet repoliticization is difficult when dominant paradigms downplay the role of human and political agency in change processes. The structural changes or changes in activity considered necessary to reduce greenhouse gas emissions, for example, include improvements in reductions in greenhouse gas emissions intensity, more efficient use of energy, behavior and lifestyle changes, and improved carbon sinks (afforestation, bioenergy and carbon capture and storage) (IPCC 2014). While these may be important, the scenarios pay little attention to individual and collective agency, social movements, and the potential for radical social change. One challenge for successful climate change responses involves integrating recent research from the natural sciences, social sciences, and humanities to develop new narratives of both adaptation and transformation. Integrated approaches are more likely to view successful adaptation to climate change as a transformation to sustainability rather than as a response to the inevitable impacts of a changing climate.

Alternative futures that are equitable and sustainable represent key challenges for this century. Such futures are unlikely to come about without the questioning of many of the assumptions that are explicit and implicit in current development pathways and practices; without challenging many of the beliefs, interests, and loyalties that maintain power relations that support the status quo; and without changes to science itself. There are tensions between adapting to climate change and transforming the very systems and structures that contribute to risk and vulnerability. While both can be considered necessary, a critical understanding of the relationship between adaptation and transformation is needed to respond to the complex challenges of climate change. All transformations associated with climate change responses are likely to involve a combination of technological innovations, institutional reforms, behavioral shifts, and cultural changes. However, successful responses to climate change are likely to be those that question the paradigms and patterns of thought that normalize climate change and its impacts, and instead recognize the role of humans in collectively shaping the future.
through conscious social transformations. These are likely to involve changes in both science and society, and to depend on individuals and groups who are willing to critically engage with adaptation through social transformation.

Further reading

The Intergovernmental Panel on Climate Change report that the “warming of the climate system is unequivocal” (IPCC 2013, 4). Extreme weather events such as heat waves and heavy precipitation are likely to have become more frequent in many regions, while it is very likely that we are seeing fewer “cold wave” events at the global scale (IPCC 2013). While there is considerable uncertainty in climate change models, which has implications for policy, analyses suggest that these trends will continue for a considerable time into the future.

Health geographers have researched diverse issues concerning the links between climate change and human health, as reviewed, for example, by Curtis and Oven (2012). The theoretical frameworks informing this research draw on diverse approaches to health geography and are also situated in a wider interdisciplinary literature on risk and resilience. Key themes include: the physical and psychological health impacts of environmental conditions associated with climate change; the processes of mitigation, adaptation, and resilience to climate change and extreme weather events; and the socially and geographically unequal pattern of these impacts that give rise to research on environmental justice.

Changes in prevailing average temperatures and in the frequency of extreme weather events are expected to impact physical and mental health. Our understanding of these impacts is situated in the literature which views environmental risks to health as dependent both on exposure to hazard and on characteristics that influence vulnerability to the hazard.

Changes in the pattern of death and illness associated with extreme weather-related events such as heat waves and floods are expected to become more common as the climate changes. Heat waves (and associated deterioration of air quality) are associated with excess mortality and morbidity due to physical health conditions such as cardiovascular disease, stroke, and respiratory illness, especially among older people and others who may be at particular risk due to existing health problems. Changes in the prevailing climate also have the potential to impact the prevalence of mortality and morbidity due to increases in vector-borne infections and food poisoning, as well as food shortages. Although excess mortality associated with cold weather is expected to decline in future as colder periods become less frequent, it is likely that they will continue to be significant, partly because the population may in future be less well adapted to cold weather (Oven et al. 2012; Curtis and Oven 2012).
CLIMATE CHANGE AND HEALTH

Mental health may also be impaired by post-traumatic stress and losses arising from extreme weather events. This reflects the ways in which attachment to place is disrupted and undermined by the loss of places, people, and livelihoods that are important to wellbeing in psychological as well as physical terms.

Mitigation, adaptation, and resilience

Individual and collective responses to the threats to human health and wellbeing presented by climate change can be considered in terms of mitigation, adaptation, and resilience. Fundamentally, mitigation would involve action to reduce the rate and severity of climate change, notably through reduction of carbon emissions due to human activities in agriculture and industry. From a health geography perspective, it is particularly interesting to consider that the medical and pharmaceutical sector is in itself a significant source of carbon emissions. The sector is looking to become more sustainable, and there is a growing debate about how this can be achieved by changes to health-care processes and to built infrastructure such as hospitals and clinics.

Strategies to improve adaptation and resilience accept that mitigation measures, even if they are effective in slowing the rate of climate change, are unlikely to prevent or reverse it in the foreseeable future. Therefore, to protect health in the face of continuing climate change, we must also change health-related behaviors and strategies to become more resilient. Health geography concerned with climate change therefore connects with the wider geographical agenda on the social and ecological dimensions of resilience. It is important to understand the social processes influencing human knowledge, perceptions, and behaviors, at the individual and collective levels, which may contribute to vulnerability or resilience (Wolf et al. 2010). There is also a growing literature in fields including geography that demonstrates how individual and local community knowledge and action may contribute to adaptation and resilience to climate change in ways that protect health and wellbeing (e.g., Pelling 2011).

Geographical dimensions of environmental health and social justice

Much of the literature on health impacts of climate change demonstrates socially and geographically unequal effects. It also shows that the individuals, communities, and places that are most severely impacted are often those that have relatively limited resources, or are societies, mainly in the developing world, that are dependent on resources that are sensitive to climate change. Furthermore, the societies being impacted most significantly may not be contributing most heavily to the human activity thought to be responsible for accelerating climate change. This work highlights the links between this field of health geography and other geographical research concerned with sustainability and environmental justice.

Geographical discussion of climate change and health also reflects the broader interest among health geographers and other public health specialists in debates concerning global health, and conceptual frameworks offered by political ecology concerning the complex and emergent relationships between political, social, and environmental processes at different scales that influence inequalities in human experiences of climate change affecting human health (King 2010).

In order to address the challenges to human health presented by climate change, action will need to be taken at the international and national scales, as well as the local level. The future agenda
for health geographers will need to be framed by these theories informing understanding of the global health agenda, as well as through fundamental geographical inquiry into how local variations in populations and places relate to health risks associated with climate change.

Climate change and land ice

Andrés Rivera
Centro de Estudios Científicos, Chile
Universidad de Chile

Claudio Bravo
Giulia Buob
Centro de Estudios Científicos, Chile

Glaciers provide excellent records of climate change. Samples of particulates and gases can be extracted from ice cores, from which the past composition of the atmosphere can be reconstructed. Ice cores also record temperature and moisture, and all of this information is stored in dateable, consecutive layers. The position of end moraines, past and present, can be used to discern past glacier positions, and these deposits can be dated with radiogenic isotopes to reveal the timing of past shifts in climate. The response of a glacier to climate change may be fairly immediate for alpine cirque glaciers, but a response time is usually involved, ranging from decades for valley glaciers to thousands of years for ice sheets. Long-narrow glaciers will have a longer response time than will compact ice caps of the same area. A negative mass balance may cause an immediate response in the position of the glacier snout, but a positive regime may not be detected at the snout for many years. Weekly, monthly, and seasonal variations in glaciers are especially sensitive to ablation rates and meltwater lubrication. Glacier response over years and decades is tied to mass balance, which reflects a range of climate conditions, especially as influenced by ocean temperatures and position of the jet stream. Glacier response also depends on the distribution of glacier area with elevation. As climate warms, the elevation of the snow line will progressively experience upstream migration, shifting precipitation from solid to liquid on low-altitude glaciers. In this context, a small mountain glacier with most of its area at lower elevations will experience retreat and thinning due to rain. However, a valley glacier with an important accumulation area at higher elevations will experience stability or even thickening if the maximum snowfall is also migrating upstream. Thus, glaciers with bigger and higher elevation accumulation areas may advance during periods of climate warming, whilst small glaciers without high-altitude areas will more likely tend to disappear if ongoing climate trends persist over time.

Scientists have incomplete geographic coverage for monitoring long-term glacier changes, especially for cold-ice glaciers in the high latitudes. The Fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) provided enough evidence of human-induced climate change, especially in connection to the generation of greenhouse gases such as CO₂, which has increased 40% since 1750 (IPCC 2013). According to the same IPCC report, worldwide glaciers continued to shrink in the past decade, as revealed by time series of changes in glacier length, area, volume, and mass. In a global context of glacier area reduction, an outline of glacier changes taking place in the extra-tropical Andes of Chile and Argentina since 1985 is presented.

The selected glaciers are located from the northern arid zone down to the humid and cold
southern tip of South America (Figure 1), and their areal changes have been mapped between 1985/1986 and the most recent cloud-free available satellite image (Table 1).

Methods

Variations in glacial areas have been obtained through a comparison of several satellite images, acquired for all the selected glaciers. The glacier outlines have been obtained by analyzing false color composite scenes produced from Landsat Multispectral Scanner (MSS), Thematic Mapper (TM), Enhanced Thematic Mapper (ETM), and Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) bands. The outlines were manually digitalized using ArcGIS commercial software.

The error of the glacial area calculation was estimated by multiplying the pixel size, or image resolution, by the perimeter of the digitized polygon. The average relative error for each zone varies between ±0.2% and ±12%.

Finally, the temperature reanalysis data from NCEP-NCAR (National Centers for Environmental Prediction-National Center for Atmospheric Research) is compared with the observed glacier area changes. NCEP-NCAR reanalysis data corresponds to monthly mean values at the pressure level close to the altitude of each glacier area (Table 1). The annual mean and anomalies estimations have been calculated with respect to the 1977–2006 mean.

General overview of Chilean glaciers, climate, and climate changes

The water cadastre (Dirección General de Aguas) of the public works ministry (DGA 2013) of Chile is the governmental institution in charge of updating the Chilean glacier inventory. Recent figures they have for the total number of Chilean glaciers is 24 114 with a total area of 23 460 km² (2013). This inventory includes any ice body bigger than 0.01 km², including rock glaciers, glaciarets, debris-covered ice, and clean ice. These glaciers are distributed from 18°S down to 55°S and experience a contrast of climatic conditions, from areas with only a few millimeters of precipitation per year along the Atacama Desert in northern Chile, to more than 3000 mm along the islands facing the Pacific in the southern part of the country (Quintana and Aceituno 2012). Glaciers located in northern Chile, at high altitude, are characterized by cold ice, little summer melting, high sublimation, and very low ice velocities. Located in a dry environment, these glaciers are more sensitive to precipitation changes, with sublimation being the main process defining ablation; therefore, these glaciers are particularly sensitive to changes in atmospheric humidity which affect the ratio between sublimation and melting at the ice surface. Conversely, glaciers located in southern Chile, under wet and cold conditions, are more sensitive to temperature changes because ablation is mostly dominated by melting. These characteristics of the ablation process define somewhat the different sensitivity of glaciers located at the same latitudes in the Andes in response to orographic effects.

Changes in temperature have a double influence on glacier mass balance: first, they affect the amount of energy available for the melting process; and second, the air temperature determines whether precipitation falls as snow or rain, defining the amount of accumulation during the hydrological year. However, the effect of changes in air temperature depends on the 0°C isotherm position, since an increase in air temperature will not affect the mass balance of a glacier until the freezing line reaches the elevation of that glacier.
Figure 1  Location map of selected glaciers.
For instance, in northern Chile, where glaciers are far above the 0°C isotherm, an increase or decrease in temperature probably would have a scarce effect on the mass balance; by comparison, a change in precipitation is likely to strongly affect the net mass balance of such glaciers.

**Recent climate change in Chile**

Several studies indicate that air temperatures in Chile have warmed in recent decades. However, the spatial pattern of these temperature changes exhibits a considerable variability. In situ radiosonde and satellite information from 1979 onwards indicates a marked cooling (−0.20°C/decade) along the coast of north-central Chile between 17°S and 37°S, and a marked warming (0.25°C/decade) inland and over the Andean slope (Falvey and Garreaud 2009). In southern Chile (38°S to 48°S), temperature trends over land are weak and do not show a clear identifiable spatial pattern (Falvey and Garreaud 2009). By comparison, in the Chilean Lake District (38°–42°S) the surface temperature trend exhibits a cooling in the second half of the twentieth century; nevertheless, in the middle to upper troposphere, radiosonde data from Puerto Montt show a warming trend between 0.019°C a⁻¹ and 0.031°C a⁻¹ (Bown and Rivera 2007). This warming is demonstrated by the increase of the 0°C isotherm elevation in central Chile, both in summer (200 ± 6 m) and in winter (122 ± 8 m) (Carrasco, Casassa, and Quintana 2005). All these observed data suggest that mid-troposphere warming is the main cause of glacier retreat along the Chilean Andes.

In Chile, precipitation trend changes are clearer south of 30°S. For instance, Quintana and Aceituno (2012) detected a negative trend in annual precipitation between 30°S and 43°S from the beginning of the twentieth century. Between 30°S and 35°S annual rainfall showed a persistent negative trend from the beginning of the twentieth century until the mid-1970s, followed by a significant increase in the 1980s; since then, the rainfall regime has exhibited a marked decadal variability in the absence of a well-defined trend (Quintana and Aceituno 2012). Between 37°S and 43°S a downward trend in annual precipitation is detected from 1950. This trend is, however, interrupted by a positive trend in the mid-1970s, registered by all the stations taken into account, except between 40°S and 43°S. In general, annual precipitation rates between 37°S and 47°S have reduced since 1950. This negative trend intensified in the last part of the twentieth century (Quintana and Aceituno 2012). According to Garreaud et al. (2013) a tendency for weaker westerlies has been detected at mid-latitudes (approx. 45°S); meanwhile, around 60°S, an increase in westerlies prevails. This tendency in the westerlies accounts for a decrease of 300–800 mm/decade over north-central Patagonia and an increase of approximately 200 mm/decade further south (50°S and beyond).

Independently from the changes in precipitation, the warming detected over the Patagonian ice field has caused a decrease in the amount of solid precipitation.

Recent decadal glaciers changes

Semiarid northern Chile

The Maranceles (28°25′S/69°40′W) and Tronquitos (28°32′S/69°43′W) glaciers are located in the dry Andes of northern Chile, at very high altitude from 4800 to almost 5800 m asl. These mountain glaciers have suffered important areal reductions, with a total loss of 41% since 1985.

Mediterranean central Chile

The Marmolejo (33°44′S/69°55′W) and San José (33°49′S/69°54′W) glaciers are contributing meltwater to the Maipo basin located in the central zone of Chile near Santiago, Chile’s capital. These glaciers are located on the western and southern flanks of active volcanoes that have not experienced any eruptive events since the beginning of the nineteenth century. The Marmolejo and San José glaciers have an extended altitudinal range (between 3500 and almost 6000 m asl), and have suffered some of the smallest changes within the studied glaciers, with areal losses of 5% since 1986.

Chilean Lake District

The glaciers in Sierra Velluda (37°28′S/71°25′W) and at Tolhuaca volcano (38°19′S/71°39′W) in the Lake District, have smaller altitudinal ranges than those in central Chile, ranging between 2000 and 3250 m asl. This is due to a generally lower altitude Cordillera, interrupted by few volcanoes rising above 3000 m asl. Sierra Velluda is partially covered by several mountain glaciers, all of them experiencing strong area shrinkage, with a total area loss of 40% since 1985 (Figure 2). The active Tolhuaca volcano is also partially covered by mountain glaciers, showing the strongest areal reduction of this study, with areal losses of 50% since 1985.

Northern Patagonia

Active ice-capped Volcán Michinmahuida (42°48′S/72°27′W) has experienced a total areal loss of 9% since 1985. This area shrinkage
Figure 2  Sierra Velluda glacier changes (Chile).
is similar to the changes observed by Rivera and Bown (2013) in other ice-capped active volcanoes of the region.

Central Patagonia, Los Moscos

In central Patagonia, the Los Moscos mountain complex (48°25’S/72°25’W) is situated at the border between Chile and Argentina. This mountain complex is covered by several valley glaciers that have experienced retreat since the first aerial photographs from 1944/1945. A total area loss of 12% has been observed since 1985. On the Chilean side, the Mosco 1 and 2 glaciers (Figure 3) were merged in 1985; however, at present, due to frontal retreat they are completely separated. On the Argentinean side, the Narváez Norte glacier was calving into a lake in 1985, but at present the glacier front is noncalving (Figure 3).

Southern Patagonia, Campo de Hielo Sur

Campo de Hielo Sur (Southern Patagonian Ice Field) is a large glacier complex spanning from 48.3°S to 51.6°S, considered the biggest temperate ice field in the Southern Hemisphere, with almost 12 500 km² of ice (DGA 2013). In the southern end of this ice field (50–51°S), at the Torres del Paine National Park of Chile and at the Los Glaciares National Park of Argentina, five glaciers located in the eastern side have been selected for this study: Grey, Olvidado, Dickson, Cubo, and Frías (Figures 4 and 5). Their historical (since the Little Ice Age) elevation, frontal, and areal changes were studied in detail by Rivera and Casassa (2004), and here all these glacier areal changes have been updated up to 2014.

The selected glaciers in this region have experienced a total area loss of 11% (42.7 km²) since 1986, a higher percentage compared to the changes obtained by Rivera and Casassa (2004) between 1945 and 2000 (8%). All of these glaciers are at present calving into freshwater lakes; however, at the beginning of the series, in 1986, the Dickson glacier had two arms, a freshwater calving front to the south and a noncalving arm to the north, which were merged together at that time with the Frías and Cubo glaciers. In 1986 only small proglacial lagoons were visible at the common debris-covered front between Frías, Cubo, and Dickson’s northern arm. Now, all are clearly separated with both arms of the Dickson glacier calving into an expanded Dickson lake, where the Cubo glacier is also calving (Figure 4). The Frías glacier is completely separated from the two other glaciers, having a debris-covered lower tongue that is partially calving into several lagoons that are progressively increasing their size. This glacier experienced shrinkage at a rate of 0.3 km²/year between 2000 and 2014, almost three times the rate recorded between 1945 and 2000, of 0.11 km²/year (Rivera and Casassa 2004).

Dickson glacier’s southern arm has been calving into the homonymous lake since the Little Ice Age (Figure 4). In total, the Dickson glacier reduced its area at a rate of 0.35 km²/year between 2000 and 2014, an accelerated rate when compared to the 0.15 km²/year observed between 1945 and 1975, 0.3 km²/year between 1975 and 1986, and 0.17 km²/year between 1986 and 2000 (Rivera and Casassa 2004).

Located a few kilometers further south, the Grey glacier is calving into its homonymous lake (Figure 5). The lower tongue of Grey has two calving fronts separated by an island where trim lines are clearly visible, showing the retreat and thinning since the Little Ice Age. Of all the selected glaciers in this study, the Grey glacier has experienced the largest area shrinkage during the observation period (a total loss of 19.2 km², or 7% of its 1986 area). Areal reduction rates reached 0.71 km²/year between 2000
and 2014, again accelerated when compared to the 0.15 km²/year observed between 1945 and 1975, 0.27 km²/year between 1975 and 1986, and 0.46 km²/year between 1986 and 2000 (Rivera and Casassa 2004).

A couple of kilometers north from Grey is the Olvidado glacier (Figure 5), which in 1986 was a valley glacier without any adjoining water body. At present, as a result of retreat, a small lake has formed next to the frontal position into which the glacier now calves. This glacier has lost almost 16% (3.6 km²) of its 1986 area, and has retreated at a rate of 62 m/year between 2000 and 2014, more than twice the rates observed between 1945 and 1975 (25 m/year) and 1975 and 2000 (29 m/year) (Rivera and Casassa 2004).

Tierra del Fuego, Cordillera Darwin

The Cordillera Darwin ice field is located in the main range of Isla de Tierra del Fuego in southern Chile (55°S). Six tidewater calving glaciers have been selected for this study (Figure 6), all of them located at the end of the Parry fjord. Most of these glaciers have been relatively stable since 1986; however, the biggest glacier (Darwin, 54°42'W/69°29'W, 41.5 km² in 2014) suffered a strong frontal retreat (almost...
Figure 4 Dickson (Torres del Paine National Park, Chile), Cubo, and Frías (Los Glaciares National Park, Argentina) glaciers. Pre-1985 data from Rivera and Casassa 2004. Reproduced from Regents of the University of Colorado.
Figure 5  Grey and Olvidado glaciers (Torres del Paine National Park, Chile). Pre-1985 data from Rivera and Casassa 2004. Reproduced from Regents of the University of Colorado.
3 km, 1985–2014). This particular frontal retreat is more likely related to the bathymetry of the fjord and is not necessarily fully connected with climatic changes. In total, the six glaciers studied here have lost 10% of their area since 1986.

Related climate change and glacier areal losses

When comparing all the glaciers studied in each zone (Figure 7), it became clear that there is a general trend of areal loss, and that the rate of loss has accelerated in recent years, especially in northern Chile. However, the largest individual percentage glacier area loss was observed in the Lake District, where the reduction trend does not show a significant variation since 1989. Overall, glacier area change rates (Table 1) show that in some zones, glaciers may disappear by the end of the twenty-first century if ongoing deglaciation continues without alteration. Conversely, glaciers in Patagonia will likely last for many more centuries, even in the worst scenario of climate change that will be discussed in the following section.

In the Chilean Andes, high-altitude climatic stations that are in close proximity to glaciers are sparse. One of the few stations with such characteristics is El Yeso (33°41’S/70°06’W, 2475 m asl) (Figure 1). Data from this station shows a clear warming trend since the 1960s (Figure 8), a trend that is also observed in Santiago (Quinta Normal at 527 m asl). However, this warming trend is highly dependent on the climate shift of the 1970s associated with the El Niño Southern
Oscillation phenomenon (Falvey and Garreaud 2009). This long-term warming trend, at high altitude in the Andes where the glaciers are located, is forcing an upward migration of the regional snowline, effectively increasing ablation and reducing snow accumulation on glaciers (Carrasco, Casassa, and Quintana 2005).

Figure 9 shows a comparison between glacier areal losses for each glacier considered in this study and the temperature anomalies obtained from NCEP-NCAR reanalysis at the approximate altitude of the glaciers (Table 1). All these time series of temperature anomalies show that the climate shift of the mid-1970s, described above and below, exhibits contrasting behaviors.

The northern zone shows a clear trend of higher temperatures in the past 15 years, which could be triggering the strong upward migration of the snowline, reducing snow on the glaciers, which would explain the area shrinkage of the Maranceles and Tronquitos glaciers. The central zone shows very small temperature increases after 1970, as observed in El Yeso (Figure 8); consequently, a small glacier retreat is understandable for glaciers on the Marmolejo and San José volcanoes, illustrating the variety of glacier behaviors in this region. Further south, where the Tolhuaca volcano and Sierra Velluda glaciers are experiencing very high areal losses, there is no temperature trend in NCEP-NCAR reanalysis data (Figure 9). Since little volcanic activity has been observed in this zone, the glacier shrinkage must be related to precipitation reductions, as detected by Quintana and Aceituno (2012). Near Michillinahuida volcano, air temperatures have shown a moderate increase since the mid-1970s, and the areal reductions must be explained by precipitation changes and volcanic activity (Rivera and Bown 2013). In the rest of Patagonia, near the Northern and Southern Patagonian Ice Fields, the air temperature trends are clearly positive, especially in the past 10 years, this trend being the more likely triggering factor in the generalized negative areal changes.

**Climate projections**

For the twenty-first century, the IPCC (2013) indicates an increase in warming and a decrease in precipitation throughout Chile. The north of Chile (from 18°S to 30°S) appears to be the most affected zone in CMIP5 (Coupled Model Intercomparison Project Phase 5) models’ mean composite for each scenario, with temperature anomalies in 2100 (with respect to 1986–2005 mean climate) from 1.2°C (rcp26) to 5.3°C (rcp85) (Figure 10). The projected temperature change for the central zone is estimated to range between 0.8°C and 3.4°C. Precipitation appears more consistent in all future scenarios, with reductions ranging from 5 to 10%, between 30°S and 43°S, without significant changes further south.

In all these future scenarios of climate changes, glacier retreats will continue, with glaciers especially affected in northern Chile, where
small and low-altitude glaciers will very likely disappear by the end of this century. In central Chile, the glaciers will be increasingly affected, as long as end-of-summer snow lines (equilibrium line altitudes) keep rising (Carrasco, Quintana, and Casassa 2005). In the Lake District, the ongoing deglaciation will accelerate if the ongoing reduction in precipitation is not reversed. In Patagonia, temperature trends will certainly increase ablation, inducing high thinning and negative mass balances, as observed in the past decade.

Conclusions

The 41 selected glaciers included in this study, located along the Andes, including a wide variety of glacier types, are showing area reductions and negative frontal changes. This trend is not uniform among the selected glaciers, with the strongest changes taking place in northern Chile and in the Lake District. In central Chile, glaciers are also retreating but at lower rates than in northern Chile. In Patagonia, the changes are important in terms of total areas, but due to the huge amount of ice in this southern zone, areal loss percentages are much smaller. In this zone, there are also some anomalies, especially among calving glaciers, some of them exhibiting an enhanced retreat compared to noncalving glaciers, and in two cases there are advances. The changes detected in this work are representative of the area reductions taking place in other glaciers along the Chilean Andes, with some of them showing much stronger area shrinkages (some in connection with volcanic activity) and some exhibiting smaller area reductions (for example on the partially debris-covered glaciers). The main driving factor explaining these generally negative changes is certainly the observed atmospheric temperature changes, especially at high altitude in the Andes. However,
precipitation variability also plays an important role. All the scenarios of climate change for the rest of this century are indicating an increment in temperatures for almost the entire country, and a reduction of precipitation along the Andes between 30°S and 43°S. In these scenarios, glaciers will experience further reductions, with the smaller and lower-altitude glaciers probably disappearing by the end of the century. In central Chile and Patagonia, the ongoing changes will be enhanced, but the great number of large glaciers, the altitudinal ranges of these glaciers, and the amount of accumulation will certainly preclude their disappearance in the long term.

NASA Goddard Space Flight Center, USA

One of the most contentious issues that are confronting society in recent years has been the influence of humans on the Earth’s climate system. The warming impact of the increase of greenhouse gases in the atmosphere was studied in the late nineteenth century by Svante Arrhenius and his results indicated that a doubling of CO$_2$ would cause an increase of about 4°C in global surface temperature. It was estimated at that time that it would take more than 3000 years for this doubling to occur. Since 1880 when accurate surface temperature measurements around the globe became available increases in surface temperature have indeed been observed. It became apparent, however, that the rate of increase in CO$_2$ in the atmosphere as observed from the 1950s at Manoa Loa, Hawaii, by Charles Keeling has been a lot faster than was initially anticipated. Current measurements indicate that the fraction of CO$_2$ in the atmosphere has increased by more than 30% since the 1880s and is already much higher (400 ppm) than the peak (290 ppm) of observed natural fluctuations of CO$_2$ (and also methane) over the last 850,000 years as inferred from ice cores. The impacts of such high rates of increase and the ability of humans to control it have been the subjects of many studies (IPCC 2014).

Globally, climate change is already manifested in many observational studies and confirmed by modeling studies to be caused primarily by increases in anthropogenic greenhouse gases. The confidence has steadily increased as more in-depth studies were made leading to the conclusion by the Intergovermental Panel on Climate Change (IPCC) 2014 that climate change as influenced by humans is unequivocal. The increased confidence compared to previous assessments has been made possible by significant advances in our knowledge of the climate system that have been strongly aided by satellite technology and the advent of high performing computer systems. Satellite sensors enabled the collection of much needed global datasets while high performance computers greatly enhanced the capability and accuracy of numerical models.

The impact of global warming to human society can be profound if not devastating. For example, warming is expected to cause an intensification of the global hydrological cycle since a warmer atmosphere holds more water. Such intensification may be occurring already since in recent years we have observed a higher frequency of extreme events exemplified by the occurrences of super hurricanes like Katrina that almost wiped out the city of New Orleans in 2005, Sandy that devastated the US east coast in 2011 and Haiyan that almost destroyed the city of Tacloban, Leyte in the Philippines in 2013. Persistent rain has caused intense flooding and landslides in England, the Philippines, China, and other regions from 2009 to 2014 while largescale droughts have been occurring in Australia and California since 2012. Moreover, higher sea surface temperature and glacial melt have caused an acceleration in the rise of sea level that in turn caused the disappearance or abandonment of some inhabited islands. Also, higher temperatures have led to persistent heat waves that have caused the death of thousands of people and have
CLIMATE CHANGE AND SEA ICE

had serious direct and indirect effects on human health, biodiversity, and the environment. There are currently still gaps in our knowledge about the linkages of the various variables and more scientific research is needed to establish the strength of the correlations. But in the meantime it is apparent that serious mitigation measures are needed to prevent even more serious impacts and possibly irreversible consequences of climate change.

Observed changes in our climate system

Surface temperature measurements from meteorological stations, buoys, and other sources made using modern instruments since the 1880s have been very useful in quantifying recent changes in the climate system. Such global surface temperature data have been compiled and quality checked to take into account errors or biases such as those associated with expanding urban areas. The result of linear regression analysis of yearly averages of global temperatures from 1880 to 2013, using data described by Hansen et al. (2010), reveals a trend in surface temperature of about 0.0650 ± 0.003 °C per decade. Such trend in temperature is considered unprecedented over the last 1000 years (Mann 2012) and the impact could be more serious than expected because the warming is not uniformly distributed spatially and could be much stronger in some areas than in others. Such spatial variability in the trends is not unexpected and could vary depending on the time period evaluated as depicted in Figure 1. Three periods were selected: (a) 1880 to 2013 for optimal record length using modern data; (b) 1964 to 2013 for an intermediate record with a more robust dataset; and (c) 1981 to 2013 to be able to make use of satellite records (Comiso 2003) that provides greater spatial coverage than the pre-satellite data. The long-term trend map presented in Figure 1a shows the most uniform distribution with a consistent warming evident almost everywhere except for small areas in the Antarctic and south of Greenland. The trend map for the intermediate period, as depicted in Figure 1b, shows stronger positive trends (than those in Figure 1a) in the Northern Hemisphere and especially in the Arctic region but more cooling in parts of the Southern Ocean and the Pacific Ocean. This period is also when the global data are enhanced with more meteorological stations and other data sources and therefore provide improved spatial coverage. The trend map during the satellite era as presented in Figure 1c represents a further improvement in global coverage including high latitude regions and shows an even more intense warming in most parts of the globe especially in the Arctic. During the same period, there also appears to be more significant cooling in many areas like the eastern Pacific Ocean region and parts of the Antarctic region. Such cooling is relatively mild compared to the warming in most other regions. The unexpectedly large areas of negative trend appear counter-intuitive but are consistent with those derived from other datasets (e.g., Reynolds et al. 2002). Analysis of the data from 1981 to 2013 yielded a global trend of 0.17 ± 0.02 °C per decade which is 2.6 times that of the 1880 to 2013 period indicating an apparent acceleration in the warming (Comiso and Hall 2014).

It is also apparent that warming is amplified in the Arctic region with the trend for the region >64°N over the period 1880 to 2013 being 0.153 ± 0.011 °C per decade while that for the period from 1981 to 2013 period is 0.60 ± 0.07 °C per decade using the Hansen et al. (2010) data. Using AVHRR satellite data, the trend for the same region from 1981 to 2013 is 0.67 ± 0.06 °C per decade which is a bit higher because of improved coverage especially in the mid-Arctic region where the trends are
Figure 1  Global surface temperature trend maps for the periods (a) January 1880 to December 2013; (b) January 1964 to December 2013; and (c) August 1981 to December 2013 using data as described by Hansen et al. (2010). The trend map in Figure 1(c) makes use of AVHRR data as described in Comiso (2010) for polar regions generally higher than 55° North or South.
CLIMATE CHANGE AND SEA ICE

higher than average. The warming is much more modest in the Antarctic region as indicated in Figure 1 likely in part because of large differences in the geographical distribution of land and ocean areas and different atmospheric circulation patterns in the two hemispheres. The warming trend in the Antarctic (>64°S) is estimated to be $0.037 \pm 0.014$ °C per decade using the 1881 to 2013 data while the trend for the period from 1981 to 2013 as derived from satellite AVHRR data is about $0.072 \pm 0.038$ °C per decade. The aforementioned warming is expected to continue in the foreseeable future unless the emission of greenhouse gases into the atmosphere is controlled. Since CO$_2$ has a residence time in the atmosphere of a few centuries, it will actually take a long time (after a reduced emission of greenhouse gases) for the surface temperature to stabilize and reverse its course.

The generally warming trends are clearly manifested in multiple and independent observations in the atmosphere, ocean, land areas, and the cryosphere. The number of warm days and nights has increased on a global scale while the frequency of heat waves has increased in large parts of Europe, Asia, and Australia. Ocean salinity measurements have also indicated that the contrast between wet regions and dry regions over the ocean has increased in the last 60 years suggesting changes in precipitation patterns. Increases in the frequency, intensity, and amount of heavy precipitation have also been observed in land areas while the number of extremely intense tropical cyclone activities has been going up. The characteristics of the ocean which covers more than 70% of the Earth’s surface and where about 60% of the net increase in energy is stored are also changing significantly. The heat content of the ocean up to 700 m in depth have been observed to be increasing with the upper 75 m layer warming by about 0.11 °C per decade (IPCC 2014).

Overall, warming signals are most apparent in the polar regions and in particular in the various components of the cryosphere. This is mainly on account of the amplification of climate signals in the polar regions associated with ice-albedo feedback (Holland and Bitz 2003). A large fraction of solar radiation is usually reflected back to outer space because of the high reflectivity of snow and ice that covers the region. But as the snow and ice cover retreats, more heat from the sun gets absorbed by the exposed surface that in turn cause the surface to be warmer causing further retreat of the snow and ice cover. An acceleration in the loss of ice mass in land has been observed with the rate of loss in the Greenland ice sheet increasing from 34 Gt per year from 1992 to 2001 to about 215 Gt per year over the period 2002 to 2011 while the rate of loss in Antarctic ice sheet changed from 30 Gt per year over the period 1992 to 2001 to 147 Gt per year for the period 2002 to 2011. Meanwhile, the rate of loss of ice mass in the glaciers increased from 226 Gt per year over the period 1971 to 2009 to 275 Gt per year for the period 1993 to 2009 (IPCC 2014). The snow cover in the Northern Hemisphere has also been declining in spring from 1967 to the present at the rate of 2.17% per decade (Comiso and Hall 2014) and at a much faster rate of about 12% per decade during the month of June. The permafrost temperature has been increasing by about 2 °C to 3 °C in parts of Alaska and Russia while the discontinuous permafrost has been advancing to the north. The most dramatic change, however, especially as observed during the satellite era, is the large decline in the perennial ice cover or the ice that survives the summer melt in the Arctic as discussed in the following section. Sea ice is a key component of the climate system and drastic changes in the ice cover could profoundly change the state of the climate.
The polar regions have been referred to as the heat sink and changes in the sea ice cover could have a profound effect on the global heat balance and hence the weather and the climate (Fletcher and Kelley 1978). In winter, sea ice keeps ocean heat from being released to the atmosphere while in summer it limits the amount of heat from the sun that is absorbed by the ocean. Sea ice also redistributes salt in the ocean in that it releases low salinity water where it melts in the spring and summer while it enhances salinity through brine rejection where it forms in autumn and winter. The melt of sea ice in spring and summer has also been associated with the occurrences of ice edge blooms and high productivity near the ice edge regions because the layer of low density meltwater becomes an ideal platform for photosynthesis since the layer stays at the surface where sunlight is abundant. Also, the growth of ice in coastal polynyas and other regions causes the production of high salinity and high density cold water that sinks to the bottom and becomes part of the global ocean thermohaline circulation. Furthermore, the marginal sea ice region is regarded as the site of strong ocean–atmosphere interactions and is usually visited by intense storm activities, known as polar lows, and cold-air outbreaks.

Satellite passive microwave sensors have provided much of what we now know as the seasonal and interannual variability in the global sea ice cover. These sensors are able to provide day or night almost all weather coverage for the sea ice cover in both hemispheres on a daily basis. The resolution of the sensors is relatively coarse (around 12 to 25 km) but algorithms have been developed to estimate the concentration of ice within the field-of-view of the sensor. Other parameters can also be quantified through the use of the multichannel data. The sea ice concentration data have been used to assess the spatial distribution of the sea ice cover and to locate areas of divergence, polynya formations, and other features of the ice pack (e.g., occurrence of an Odden, or ice tongue, in the Greenland Sea). The geophysical parameters that have been used to quantify changes in the sea ice cover are the sea ice extent and sea ice area. Sea ice extent has been defined as the summation of the area of all data elements with concentration of at least 15% ice concentration while sea ice area is the summation of the product of the ice concentration and corresponding area of each data element. The ice extent provides the means to assess how the ice covered ocean has been changing, while ice area has been used to estimate the volume and hence the ice mass, knowing the average thickness.

The sea ice cover is very seasonal with the Arctic ice extent changing typically from $6 \times 10^6$ km$^2$ in summer to $16 \times 10^6$ km$^2$ in winter while in the Antarctic the corresponding change in sea ice cover is from 3 to $19 \times 10^6$ km$^2$. With more than 34 years of satellite data it is now possible to assess not just the interannual changes but also the trends in the sea ice cover. Because of the large seasonality, it is useful to use monthly anomalies as shown in Figure 2 for trend studies. The monthly anomalies were derived by subtracting the climatological average (average of data from 1978 to 2013 for each month) from each monthly ice extent data. Figure 2a and 2b show the monthly anomalies in the Northern and Southern Hemisphere, respectively, and it is apparent that the trends are not only different but also have opposite signs. The trend lines indicate that the sea ice extent in the Arctic has been declining at the rate of $-480 000 \pm 21 000$ km$^2$ (or $-3.79 \pm 0.16\%$) per decade, while the Antarctic ice extent is expanding at the rate of $174 720$ km$^2$/decade (or $1.77 \pm 0.18\%$/decade).
Figure 2  Ice extent monthly anomalies (in black) and yearly anomalies of ice minimum (in red) for the period 1979 to 2013 in the (a) Northern Hemisphere; (b) Southern Hemisphere; and (c) combined Northern and Southern Hemispheres. Trend lines from regression analysis of the data are also shown.
For comparison, the trend in ice area (not shown) is $-527,000 \pm 20,000 \text{ km}^2$ (or $-4.5 \pm 0.2\%$) per decade for the Northern Hemisphere while that for the Southern Hemisphere (not shown) is $207,841 \text{ km}^2/\text{decade}$ (or $2.2 \pm 0.1\%$ per decade). The errors indicated are statistical error (one standard deviation) of the slopes of the trend line and do not include systematic errors that may be associated with other factors like differences in instrument calibration, resolution and incident angle between the different satellite passive microwave sensors used in this study. The impact of the latter on the trend, however, is expected to be minor because the techniques used to derive sea ice concentration accounts for such error sources (Comiso 2010).

The asymmetry in the trends for the two hemispheres is intuitively surprising but not totally unexpected because of the large regional variations in the warming as indicated earlier (see Figure 1). The big difference in the geographical distribution of land and the ice cover in the two hemispheres may also contribute to the difference in the interannual changes in sea ice distribution. The significance of the magnitude and sign of the trends in the two regions is also different. In the Arctic, the sea ice cover is primarily in the Arctic Ocean basin where the surface temperature is extremely cold and is surrounded by land that restricts expansion of the ice cover beyond the land boundary. On the other hand, the coldest region in the Southern Hemisphere is a snow covered continental area called Antarctica. The sea ice cover that surrounds Antarctica is in relatively warmer water and the extent is basically controlled by sea surface temperature. The summer ice cover in the region is also dispersed and relatively small compared to that of the Arctic and the location changes from one year to another. The impact of ice-albedo feedback in the two regions is therefore different. In particular, the observed retreat of summer ice in the Arctic causes a significant warming of the mixed layer of the Arctic Ocean while a retreat in the summer ice cover in the Antarctic is likely not as impacting because of large interannual variability in the location of summer ice and because of the more dynamic ocean environment that minimizes the change in mixed layer temperature associated with less summer ice.

It is apparent that in the Arctic, there is large monthly but small interannual variability from 1978 to 1996, followed by a relatively modest variability but consistent decline up to 2007 which was then followed by a much larger monthly and interannual variability. The large interannual variability in the recent period is associated with the large decline in the perennial ice cover which is the ice that survives the summer. The perennial ice extent has been derived from summer minimum extent (Comiso 2010) and is shown in a red dashed line in Figure 2. In the 1980s, the Arctic basin region was almost all covered by ice even at the end of summer melt because of the abundance of multiyear ice (or ice that survives at least two summers) which is the thick component and mainstay of the Arctic ice cover. In recent years, however, the perennial ice cover, represented by the ice cover during ice extent minimum in summer, has been reduced to less than half of what it was in the 1980s with a yearly trend of $-11.4\%$ per decade. The percentage decline in the multiyear ice extent is even larger which is about $13.5\%$ per decade (Comiso 2012; Parkinson and Comiso 2013) and in addition, this ice type has been observed to be thinning (Kwok and Untersteiner 2011). The loss of this thick component of the sea ice cover would make the Arctic ice at the end of the summer vulnerable and the high rate of decline suggests that the Arctic basin might become totally ice free in a few decades unless a sustained cooling in the region occurs and the sea ice cover recovers its previous thickness. The latter will not
happen if the warming in the region as indicated earlier continues. The occurrence of an ice free summer will be unprecedented since, historically, a significant summer ice cover has been observed in the Arctic for at least the last 1450 years. A disappearance would have profound effects on the climate, ecology, and environment not just of the region but also globally.

It should also be noted that the magnitude of the trend of the ice cover in the Arctic is more than two times that in the Antarctic. Global sea ice cover can be studied by simply combining the extents and areas of sea ice in the Northern and Southern Hemispheres for each month. To estimate the trend, monthly anomalies of the combined Arctic and Antarctic monthly sea ice extents are presented in Figure 2c. The results show a relatively uniform extent for total sea ice cover with a net reduction over the 34-year period and a trend of only $-0.13 \pm 0.125\%$ per decade. It is interesting that the trend of the global sea ice cover when compared with the trend of the Arctic ice cover is analogous to the trend in global temperatures when compared to that of the Arctic.

The trend of the sea ice cover in the Antarctic is relatively modest with the magnitude less than half the trend in the Arctic. Some studies indicate that the trend is related to more ice production owing to the decrease of ocean salinity in the region as a result of the melting of ice shelves. Others point out that a warming in the ocean would result in more evaporation that causes more solid precipitation over the region leading to colder surface temperature that enables higher rate in the growth of sea ice. A key observation is the increase in the dynamics of sea ice in the region and enhanced formation of coastal polynyas that serves as ice factories. Through modeling studies, it has been postulated that the increased dynamics might have been caused primarily by the occurrence of the ozone hole in recent years. The ozone hole apparently causes a deepening of the lows in the west Antarctic region which in turn leads to stronger southerly winds and higher ice production along the coastal region of the Ross ice shelf leading to the increase in the extent of the sea ice cover in the Ross Sea. Actually, the ice cover in the Bellingshausen and Amundsen Seas has been declining at a high rate but such decline is overwhelmed by the increase in the ice cover in the Ross Sea. There are also studies that indicate that the average extent of sea ice cover in the 1950s, as observed from whaling and other data during the period, was actually higher than the average extent during the more recent years as observed from satellite data. This is further supported by observations that the surface temperature in the region has increased significantly since the 1950s.

Ice–atmosphere–ocean interactions and modeling studies

Changes in the global climate and those in the polar regions are strongly influenced by processes that are occurring in the atmosphere and the ocean. In the Arctic, atmospheric circulation is believed to be basically controlled by the arctic oscillation (AO) sometimes referred to as the Northern Hemisphere Annular Mode (NAM). A similar phenomenon called the Southern Hemisphere Annular Mode (SAM) occurs in the Antarctic region. The characteristics of the AO have been studied using AO indices that represent the difference of the average sea level pressure of two Arctic regions. Previous studies indicated that the indices are highly correlated to the extents of the sea ice cover in the 1980s and 1990s. However, the correlation fell apart and became weak in the 2000s (Overland and Wang 2005), which was a time period when drastic changes in the sea ice cover were occurring.
This led some to hypothesize that the phase of the AO and the circulation patterns in the Arctic atmosphere has changed.

A very prominent sea ice feature in the Greenland Sea, called Odden, was reported in the early 1900s and was observed almost every year using satellite data in the 1980s and 1990s but the feature was basically missing in the 2000s (Comiso 2010). The bay surrounded by the Odden called Nordbukta has been regarded as one of only four regions of the world where deep ocean convection is observed. Moreover, the temperature of the mixed layer of the Arctic Ocean has also been observed to be warming in part because of a rapidly declining summer sea ice cover. The demise of the Odden and the warming of the Arctic Ocean are likely influenced by the increases in surface temperature in the Greenland Sea. In the Antarctic, a large open water region, called polynya, in the middle of the ice pack was observed using satellite data in 1974, 1975, and 1976, and caused significant cooling up to 3000 m depth in the region. Since then the polynya has not reappeared likely because of changes in climate of the region as may be associated with SAM. Although the Antarctic sea ice extent has generally been increasing, there are some regions, like the Bellingshausen/Amundsen Seas near the Antarctic peninsula where sea ice is declining at a relatively rapid rate comparable to those in the Arctic. The peninsula has also been regarded as an anomalous region since it has been experiencing warming at a rate higher than most regions of the world. Ice shelf melting has also been occurring at a relatively fast rate in the region and also adjacent regions in recent years causing significant calving. These phenomena illustrate apparent inconsistencies that may not be unexpected because of the existence of offsetting fluctuations, seesaw patterns, and teleconnections in the climate system.

Studies of the drivers of the changes in climate reveal that the largest contributor of the radiative forcing since the industrial revolution is the increase in atmospheric CO₂ followed by the increase in CH₄. Modeling studies indicate that the most dominant cause of the observed warming since the twentieth century is anthropogenic greenhouse gases (IPC 2014). In particular, the changes in the sea ice cover, in the ice sheet, glaciers, snow, and permafrost as well as the heat content of the ocean is caused primarily by human influence. This means that the future climate would depend primarily on future greenhouse gas emissions. A control of these emissions is apparently imperative to avoid dangerous if not irreversible impacts of climate change. A modeling study by Washington et al. (2009) reveals that emission reduction of about 70% is needed by 2100 to prevent half of the expected changes in temperature and precipitation from occurring.

Discussion and conclusions

Multiple indicators of climate change are observed in the atmosphere, land, ocean, and ice from instrumental and paleoclimatic sources. Global circulation models have been able to simulate many of these observed changes and to distinguish human–induced from natural changes making it possible for the IPCC to conclude that anthropogenic climate change is unequivocal. Ocean salinity measurements indicate that the contrast between wet regions and dry regions over the oceans has increased over the past 60 years while the heat content of the ocean up to 700 m depth has increased significantly. Among the strongest signals of warming are those from the polar regions where climate change is expected to be amplified and even slight increases in temperature have caused significant changes in the timing of the melt season, retreats in the snow cover, loss of
mass in ice sheet and glaciers, and thawing of the permafrost. But among the most dramatic change that has been observed on a global scale has been that of the sea ice cover in the Arctic.

The annual mean extent of the Arctic ice cover has declined at the rate of 4% per decade while the perennial and multiyear ice extents have declined at 11.5 and 13.4% per decade, respectively, during the 1979 to 2013 period. In addition, a significant thinning of multiyear ice in the Arctic basin has been observed while the length of the melt season has increased. The multiyear ice cover is the mainstay of the Arctic ice and the trends suggest that the Arctic basin could become ice free in the summer in the foreseeable future. The impact of an ice free summer in the Arctic can be profound and would include a change in the climate, ecology, and environment of the region and changes in ocean circulation. Strong mitigation measures through reduced greenhouse gas emissions are needed to stabilize surface temperature and reduce warming thereby minimizing potentially devastating if not irreversible impacts of climate change.

Climate change and biogeography: observations

Biogeography is the study of the distributions of species and ecosystems through time and space examined at global, regional, or local scales. Modern research in this discipline combines theories and data from biology, geology, ecology, and physical geography. Climate change, including rising temperatures, modified precipitation regimes, and altered chemical concentrations in the atmosphere and oceans are being investigated as a driver of biogeographical changes on our planet.

The Earth has witnessed a long period of variable climate over the past 2.5 million years which included multiple glacial–interglacial cycles. During the glacial periods, temperatures at the regional level may have changed as slowly as 1°C per millennium, or as rapidly as several degrees over a few decades, and included changes in precipitation and CO₂ concentrations. Numerous types of paleoecological records can give precise and detailed records about past plant species distributions and their responses to postglacial warming events.

Through research done by palynologists, fossil pollen patterns have shown that many taxa found in tundra, boreal forests, and temperate forests migrated to lower latitudes during glacial periods – spending the long glacial periods in refugia (region in which a species spends an unfavorable period). However, populations from a subset of species may have persisted in low densities in more poleward locations in cryptic refugia. As temperatures increased when global conditions transitioned from glacial to the warmer interglacial periods, vegetation undertook a poleward migration. Pollen evidence from both North America and Eurasia over the last 18 000 years, when the last glacial period began to ameliorate, shows tree species generally spreading poleward from the margins of their glacial refugia.

Given the high density of fossil pollen sites in eastern North America palynologists have created detailed species range maps covering the past 18 000 years for dozens of common tree genera (and species in some cases). From these maps it is possible to determine the speed of migration, the timing of postglacial migration events, and migration routes followed. In North America most boreal tree taxa (e.g., *Picea, Pinus*) spent the glacial period in proximity to the southern limit of the Laurentide ice sheets. The tree taxa currently associated with the present-day temperate deciduous forests (e.g., *Acer, Fagus*) were found south of the boreal taxa; and those species currently found in today’s warm mixed forests (e.g., *Liquidambar, Carya*) of the southern United States were found in the extreme southern United States (Florida). It is clear from pollen studies that tree taxa responded individually to postglacial warming, thus vegetation community assemblages formed over the
past 18 000 years as taxa moved north were often different from contemporary ecosystems, in some cases comprised of combinations of species not currently found in North America. These novel combinations of species have been termed “no-analog” communities. Similar patterns have been recorded in Europe, with vegetation shifted to lower elevations and southern refugia in the Iberian, Italian, and Balkan peninsulas.

Based on pollen range maps, rates of post-glacial poleward tree migration ranged from 100 to 400 m/year, in large part depending upon seed dispersal vector. However, based on recent chloroplast DNA surveys it is possible that some taxa maintained cryptic refugia near the ice sheets (and therefore near modern range limits). In those cases the estimated migration rate might be significantly lower than those rates inferred from pollen evidence. In examples from both North America and Eurasia, routes of postglacial migration differed by taxa, with some largely migrating up coastal plains, others migrating along river valleys, and some moving along mountain chains.

With these documented biological responses to the postglacial increase in global temperatures over the past 18 000 years, ecologists have speculated that recent and future anthropogenic warming will lead to similar ecosystem responses mirroring patterns deduced from pollen evidence — although future temperature changes are modeled to be substantially more rapid than those from the past.

Since global surface temperatures from 1906–2005 warmed by 0.74 °C, and the Northern Hemisphere has seen an earlier spring as the length of the frost-free season has increased (IPCC 2007), field studies over the past several decades have been undertaken to examine biological responses to recent climatic changes. A meta-analysis by Parmesan (2006) found that every continent, ocean, and taxonomic group has documented evidence of direct recent climate change impacts. Although general observations can be made at the species level, most research is conducted at the local scale and fewer at the regional level. There has been a geographical bias in this research with the majority of studies conducted in North America, Europe, and Russia. While there has been limited research in Africa and Asia, more information is available from South America, South Africa, and Japan. The global impact of climate change is generally acquired from independent yet similar surveys including plants, animals, insects, and aquatic life, which are compared using statistical meta-analysis to identify recurring patterns. For example, in a study of 1598 species, 59% displayed alterations to their distributions, phenologies (timing of biological events), or both in the past 20–140 years, and these changes followed the expected patterns caused by regional climate change (Root et al. 2003).

**Phenology**

Recent changes in the timing of biological events (phenology) have been well documented in light of warming climates over the past century. A meta-analysis of over 500 plant species found 78% of all springtime phenological records advancing, while only 3% were delayed. The changes include advances in the leaf out dates of deciduous species, earlier flowering, egg laying, migration, and breeding dates. Meta-analyses of phenological changes across the Northern Hemisphere find that biological spring events are occurring 1.0–5.1 days earlier per decade. Timing of fall events (e.g., leaf fall) has changed much less, with events occurring 1.3 days later per decade. Several studies have found little or no change in phenology. In some cases these studies were undertaken in areas experiencing stable temperatures over the past century, but
a few studies found no change in phenology despite warming temperatures. While documented phenological changes are most common in spring, advances in the timing of early spring events are more pronounced than late spring events. Advances in spring timing may be occurring faster in coastal areas compared to inland regions. Organisms living at higher elevations are advancing in the spring more rapidly compared to lower elevations; however, little difference has been detected in magnitude of phenological change across latitudinal gradients. Temporally, rates of phenological changes over the past few decades (since the 1970s and 1980s) are greater than in previous decades.

Migration

A meta-analysis (Chen et al. 2011) of elevational range changes found species shifting upslope at a median rate of 11.0 m per decade in Europe, North America, and Southeast Asia. In the Ural Mountains, during the last century, treeline advanced approximately 20–60 m upslope, corresponding with a doubling of winter precipitation and summer warming of 0.9 °C during the twentieth century. A study from the European Alps documented the expansion of vascular alpine plants toward the summit of 0–4 m per decade. There was an increase in species richness at 70% of the summits in the Alps that may be the result of global warming trends since the nineteenth century.
