Wetland soils – also known as hydric soils – are found wherever the combination of physiography, hydrology, and climate allow for prolonged saturation. Anaerobic (oxygen-depleted) conditions alter biogeochemical processes, favoring chemically reducing conditions and giving rise to a diagnostic suite of redoximorphic features in soils. Wetland soils include those that have developed in both mineral and organic materials. Some wetland soils are well understood, including peatlands, coastal soils, and paddy soils; others have often fallen into the gap between soil science and wetland science due to their ephemeral nature, such as vernal pools and prairie potholes. For this reason, these types of wetland soils are more poorly understood. Saturation in wetland soils may be permanent, temporary or seasonal, but any soil where saturation is persistent enough for anaerobic conditions to develop in the rooting zone can be described as hydric (Richardson and Vepraskas 2001). Sometimes wetland soils are defined in terms of their ability to support hydrophilic vegetation, but given the ubiquity of land-use change, wetlands that have retained their native vegetation are increasingly rare and therefore the hydric soil concept was developed to recognize the longer-term imprint of hydrology on soil properties.

Classification

In mineral soils, hydric soil characteristics are recognized at different levels in different systems of soil classification: as a moisture regime in United States Department of Agriculture (USDA) soil taxonomy (Aquic suborders), at the order or subgroup level in the Canadian System of Soil Classification (Gleysol order or Gleyed subgroups), and as major groups in the World Reference Base system (Stagnosols, Planosols, Fluvisols, Gleysols). Soils dominated by decomposed plant residues or peaty material (>12–18% organic carbon) can classify as Histosols (USDA order, World Reference Base group) or Organic soils (Canadian System order). However, not all of these soils develop under saturated conditions, and thus, organic soils alone do not universally indicate a hydric soil system.

Hydrology

Typically, hydric soils develop in environments of imperfect to poor drainage, leading to saturation. The source and duration of saturation varies; in some areas, hydric soils develop due to a humid climate or proximity to persistent water bodies (lakes, rivers, or oceans). In others, an occluding or slowly permeable subsurface layer (bedrock or heavy clay) prevents adequate drainage following spring snowmelt or precipitation events. This situation is especially common on level landscapes with minimal run-on or runoff. On sloping landscapes, saturation is often associated
with specific slope positions, with hydric soils occupying the lowest positions on the landscape. For example, even in semiarid regions, like the prairie pothole region of North America, hydric soils may develop in the bottoms of depressions. This region is also an example of how groundwater can play a major role in hydric soil formation. Groundwater discharge from unconfined aquifers, which are common in the glacial deposits throughout the region, can be an important water source in some wetlands (Bedard-Haughn 2011). The upward gradient of groundwater movement contributes to saturated conditions near the surface and prevents drainage of surface waters.

The source and duration of saturation, along with the biophysical environment, affect the properties of the soil. For example, where the dominant direction of water movement is downward through the profile (recharge wetland; Figure 1) the profile will have more typical horizon development and may include evidence of downward transfer of clays, organic matter, or other compounds (eluviation-illuviation). In contrast, profiles dominated by upward movement of groundwater (discharge zones; Figure 1) may have weakly developed horizons and evidence of secondary salt deposition, if these compounds are present in the groundwater. Where plant residue inputs are sufficiently high and saturation is persistent, organic soils are likely to develop regardless of the dominant groundwater flow.

Redox processes and redoximorphic features

Hydric soils are characterized by properties and processes that reflect their prolonged saturation. These features develop via oxidation-reduction (redox) reactions that occur when oxygen is depleted from the soil. The soil microbial community (i.e., bacteria and fungi) decomposes (oxidizes) organic residues from flora and fauna. Heterotrophic micro-organisms use organic tissues as a carbon source for respiration; these tissues release electrons that are then available for reducing reactions. Under aerobic conditions, oxygen \( \text{O}_2 \) is the preferred electron acceptor (O is reduced), but under the anaerobic conditions in wetland soils, an alternative electron acceptor (Table 1) must be reduced for microbial respiration to continue (Richardson and Vepraskas 2001). Some reducing reactions give rise to observable redoximorphic features; others are less visible, but are nonetheless important wetland processes. The most obvious expressions of redox reactions in wetland soils are (i) accumulation of soil organic matter, (ii) iron and manganese masses and/or depletions, and, in some cases, (iii) smell of hydrogen sulfide \( \text{H}_2\text{S} \) from sulfate reduction (Richardson and Vepraskas 2001).

Organic matter accumulation in wetland environments is due to slowed decomposition under saturated conditions; some of these sites are also colder, which further slows organic matter decomposition. Oxygen dissolved in the pore water is rapidly reduced; after it is depleted, microbial decomposition slows dramatically. The resulting accumulation of organic carbon occurs as layers of peaty or mucky material, or as accumulations of dark-colored organic material (humus) within a mineral horizon. Organic matter accumulation is not diagnostic of reducing conditions because it can also accumulate in highly productive, well-drained soils; nonetheless, it is a common feature of wetland soils. Consequently, wetlands are a major global carbon sink. For example, peatlands, which cover only 3% of the terrestrial surface, store up to 33% of global soil carbon. Freshwater mineral soil wetlands are estimated at about 10% of the peatland storage (global estimate: 462 Pg
in peatlands versus 46 Pg in freshwater mineral soil wetlands), but are still a substantial pool and vulnerable to loss under changing land use and climate (Bridgham et al. 2006).

The most common redoximorphic features that are used to delineate and differentiate hydric soils include masses and/or depletions of iron and manganese. Under moderately reducing conditions, these elements serve as electron acceptors for facultative anaerobes, and thus, manganese and iron oxides are reduced (from Fe$^{3+}$ to Fe$^{2+}$ and Mn$^{4+}$ to Mn$^{2+}$). Their reduced forms are more mobile in soil water and tend to impart a greyish or low chroma (≤2 in the Munsell color system) to the soil matrix. Low chromas develop when Fe$^{2+}$ and Mn$^{2+}$ are present in the soil (reduced matrix) or when manganese and iron have been removed from the soil, such as along root channels (redox depletions). This dull, often blue-grey, color can be described as “gleyed.” Typically, the reduced iron will move within the profile and be reoxidized when the soil dries out, forming mottles, which are rust-colored oxidized masses, pore linings, or nodules (Bedard-Haughn...
SOILS OF WET AND HYDRIC LANDSCAPES

Where manganese is present, the mottles may be black. Expression of redoximorphic features will vary with mineralogy, organic matter content, and texture, but in most cases they provide key morphologic information about the wetness status of a soil. For that reason, the location, size, and color of redox features in soils is central to their classification as to drainage class or wetness status.

Under more strongly reducing conditions, sulfate (SO$_4^{2-}$) can be reduced to S$^-$ or H$_2$S, giving rise to the “rotten egg” smell of hydrogen sulfide. In North America, sulfate reduction is commonly associated with sulfate-rich (oceanic) coastal systems, but is also widespread in areas of the Great Plains where the subsurface glacial till is rich in pyrite, which contributes sulfates to the groundwater as it oxidizes.

Two other key wetland redox processes include reduction of nitrate (denitrification) and carbon dioxide (methanogenesis). Both have been much studied in recent years because their products include potent greenhouse gases: nitrous oxide (N$_2$O) and methane (CH$_4$). Denitrification is a stepwise process, whereby nitrate (NO$_3^-$) is reduced first to nitrite (NO$_2^-$), then to gaseous N$_2$O, and finally to N$_2$. Under saturated conditions, the reaction proceeds all the way to N$_2$. Where some oxygen is present within the soil (60–80% water-filled pore space), there is greater potential for N$_2$O to be released to the atmosphere. In contrast, methanogenesis occurs under the most strongly reducing conditions, where no other electron acceptors are available. Methane production may also be limited by the availability of labile organic substrates for decomposition and by the activity of methanotrophic (methane-consuming) bacteria.

Theoretically, redox reactions would proceed in sequence, reflecting their respective redox potentials (Eh), with O$_2$ being reduced first and CO$_2$ reduced last (Table 1). Consequently, the presence of soil nitrate may inhibit iron reduction because nitrate reducers are able to outcompete iron reducers for electrons. Similarly, high levels of sulfate have been shown to inhibit methanogenesis in both coastal soils and those prairie potholes affected by sulfate-rich groundwater. However, microscale variability in water and oxygen contents, along with other biogeochemical properties (concentrations of alternate electron acceptors, location of organic matter and soil microbes), implies that different redox reactions can occur simultaneously over short distances.

### Land use

When drained, wetland soils, characterized by high levels of organic matter and nutrients (returned to the soil by plant residues and accumulated from upslope soils by erosion), are excellent for agriculture. Both peatland and mineral wetland soils are commonly drained for production (for example, Dutch peatlands and widespread drainage of tropical peatlands for palm oil production). However, this practice is known to result in rapid carbon loss (i.e., greenhouse gas emissions) and subsidence via soil compaction (Verhoeven and Setter 2010). Up to 70–90% of freshwater mineral soil wetlands throughout North America have already been drained, contributing substantially to greenhouse gas emissions, downstream nutrient loading, and lake eutrophication. However, not all agriculture results in wetland loss. Globally, paddy soils for rice production cover nearly 155 million hectares (Kogel-Knabner et al. 2010). These soils may not have been hydric prior to rice production, but now function as hydric soils due to the saturation maintained throughout most of the growing season. Wetlands are also created for regulatory requirements (i.e., to compensate for wetland loss via development or resource extraction).
and pollution attenuation, including mitigating excess nitrogen (via denitrification), phosphorus, pesticides, pathogens, and trace metals (O’Geen et al. 2010). Created wetlands of this kind differ in origin, of course, but when carefully developed and maintained can perform many of the same ecosystem functions as their natural counterparts.

**Current and future research**

Current research emphasizes measuring and modeling (i) the effects of climate and land-use change on wetland soils, and (ii) the effects of wetland soil management on climate change and water quality. There is also an emphasis on determining economic value for the ecosystem services provided by wetlands and wetland soils, such as habitat, flood mitigation, and improved water quality. Food and water security are intertwined in hydric soils. Wetlands provide some of the most productive agricultural soils. However, the destruction of wetlands for agriculture alters local and regional hydrology, potentially increasing the risk of downstream flooding and/or contamination with agricultural pollutants. One of the challenges faced in the study of wetland soils is the lack of a detailed inventory of wetlands or hydric soils, particularly in developing nations and sparsely populated regions. Where inventories do exist, many fail to take into account smaller (<1 km²) or temporary wetlands, because these are not as readily captured with common remote sensing technologies, nor are they included at the scale of many soil maps. Going forward, efforts to (i) model the effects of land-use and climate change on wetland soils and (ii) make sound long-term land management decisions will require a high-resolution baseline inventory and a detailed assessment of ecosystem services provided by wetland soils.

Soils on slopes: catenas

Peter C. Almond
James L. Moir
Lincoln University, New Zealand

Hillslopes are a pervasive feature of Earth’s surface. The proportions of land with slopes greater than 5°, 15°, 20°, and 30° are 25%, 9.4%, 5.9%, and 1.8%, respectively (Larsen, Montgomery, and Greenberg, 2014). Soils on hillslopes thus represent a significant resource for producing food and fiber for a growing global population and provide other important ecosystem services.

Most hillslopes on Earth result from the interaction of (i) rock uplift resulting from crustal deformation, combined with (ii) the downcutting response of agents of denudation, for example, rivers and glaciers. Once formed, hillslopes act as both the sources and conveyors of sediment, focusing that sediment and water into valley floors. Soils on hillslopes serve an important hydrological function by allowing precipitation, which would otherwise travel rapidly overland on the inclined surface, to infiltrate and to be transmitted to streams via subsurface flow paths. This phenomenon slows the flux of water to streams, thereby reducing flood peaks, enhancing water quality, maintaining baseflow, and, overall, fostering stream habitat quality.

Globally, and over geological timescales, soils on hillslopes have probably contributed disproportionately to the development of Earth’s climate. Primordial Earth’s atmosphere had very high concentrations of CO₂, which, being a greenhouse gas, sustained hothouse climates unsuitable for most life. Weathering of silicate minerals by carbonation (in soils) has sequestered much of the atmosphere’s original CO₂ as biogenic carbonate minerals (limestones, dolomites) within the oceans. Hillslope soils are especially important because rejuvenation of soil by erosion supplies fresh soil minerals to maintain these C-consuming weathering reactions. In contrast, flat landscapes with no erosion and minimal deposition become cloaked in thick soils and chemically altered rock (regolith) that is more completely exhausted of weatherable minerals. The rejuvenating effect of erosion on hillslope soils also extends to depositional landforms on valley floors and piedmonts. Relatively unweathered sediment from hillslopes is distributed onto fans and floodplains and may be remobilized to form drapes of windblown sediment (loess) over surrounding landscapes. The unweathered minerals in soils rejuvenated by erosion and deposition also contain large pools of biogeochemically important elements.

The persistence of soils on hillslopes

Whether or not hillslopes are soil-mantled depends on the balance between denudation (chemical and physical erosion) and the rate of conversion of the underlying substrate (by physical disintegration) into mobile (colluvial) materials (regolith and soil). The rate of conversion of bedrock to regolith, in the geomorphological literature, is referred to as soil production (Figure 1). In general, where soil can be produced faster than the denudation rate, slopes are described as being transport limited and will be soil-mantled. At first inspection, this condition would appear to create a progressively (and
unlimited) thickening soil mantle. However, an internal soil feedback occurs whereby increasing soil thickness is associated with declining soil production rates. The soil thickens until it forms at a rate that matches denudation, at which point a steady state prevails. Two forms of the relationship between soil production rate and soil thickness (the soil production function) have been proposed. The bulk of empirical evidence from measurement of cosmogenically produced beryllium-10 at the bedrock/soil interface supports an exponentially declining soil production rate with increasing soil thickness (Heimsath et al. 1997). Maximum soil production rates (at soil depth = 0) vary two orders of magnitude from 0.03 to 2.5 mm year$^{-1}$ depending on a range of factors including rock type, climate, and the intensity of biological disturbance from vegetation and burrowing animals. On gentle slopes where soil is thick, the rate at which the chemical weathering front advances downward may exceed the soil production rate. Then, the colluvial soil is underlain by essentially in-place but chemically weathered rock (saprolite).

Where denudation occurs faster than the maximum soil production rate, slopes are described as weathering (or detachment) limited and the soil mantle tends to be patchy and thin. However, even where the denudation rate exceeds the maximum potential soil production rate, it is still possible for large parts of hilly or mountainous landscapes to be soil-mantled. In the Southern Alps of New Zealand, for example.
Zealand, for example, rock uplift and denudation rates reach 10 mm year$^{-1}$ and are as much as four times faster than the maximum soil production rate of 2.5 mm year$^{-1}$ (the fastest measured), yet slopes largely remain soil-mantled. In this landscape, mass movements (landslides) are the dominant denudation process but their recurrence at any one location has a return period long enough for soils to form at this high rate.

**Hillslope-soil models and the soil catena**

The emphasis on research of soils on hillslopes varies among the different branches of the earth sciences. Geomorphologists have been interested in soil-mantled hillslopes from the perspectives of landscape evolution, delivery of sediment and dissolved load to rivers, and interactions of hillslope soil weathering with climate. Hydrologists are interested in the properties and spatial variability of soils on hillslopes with respect to flow paths and dissolved load of water transmitted to surface and groundwater. Soil scientists’ interests include understanding soil variability on slopes, for applications in soil survey, soil erosion, and soil fertility studies. There is considerable overlap among the disciplines; however, the need for models to explain and predict soil variability on hillslopes is common to all.

Although geomorphologists have incorporated soil production as a mechanism of denudation in mathematical hillslope and landscape evolution models, the depiction of soil has generally been limited to the single descriptive variable of soil thickness. Models, often qualitative in nature but incorporating more complete descriptions of soil (vertical and lateral differentiation of properties and horizons), have been developed and used primarily within the realm of soil science. All models take as their fundamental premise the downslope movement of sediment, water, and solutes in response to gravitational force.

Geoffrey Milne, working in East Africa in the 1930s, proposed the “soil catena” concept to embody the interrelationship between soils and hillslope form and process. Brown (2005), quoting Milne, wrote that, “The name itself ‘was intended to serve as a mnemonic, the succession of different soils corresponding to the links in a hanging chain’ in a progression from one hilltop to the next.” The catena concept was advanced as a practical response to a soil survey problem: meeting the demands of agricultural advisors who needed fine-scale resolution of the soil pattern on the one hand, and of cartographers, who needed regional scale soil information for incorporation in a world soil map, on the other (Milne and East African Agricultural Research Station 1936). Although in its conception the catena was an expedient for soil survey and was directed to illustrating and predicting the occurrence of different soil taxa, it explicitly included the role of processes: “Soil differences are brought about by differences of drainage patterns, combined with some differential reassortment of eroded material and the accumulation at lower levels of soil constituents chemically leached from higher up the slope” (Milne 1935). Milne also recognized that the effects of parent material would be apparent where a slope cut across different underlying lithologies.

A complementary notion by Polynov (1935) evolved at about the same time in the Russian literature. Polynov posited that element redistribution on hillslopes occurs according to their inherent mobility and that soils on hillslopes were linked by the lateral migration of chemical species for a single geochemical landscape, according to the sequence of mobility: $\text{Cl} > \text{SO}_4 > \text{Ca} > \text{Na} > \text{Mg} > \text{K} > \text{Si} > \text{Fe} > \text{Al}$.

The two concepts have since merged as reflected by Yaalon, Brenner, and Koyumdjisky’s
SOILS ON SLOPES: CATENAS

(1974) metaphor of the sequence of soils along a catena behaving as a chromatographic column for elements released by weathering and translocated by lateral water movement. The catena has thus become the conceptual framework in which both (i) relationships between soil taxa and elements of hillslopes and (ii) the continuous variation of soil properties in relation to slope position and form are expressed.

Hillslope hydrology

Net precipitation on hillslopes, resulting from the balance of total precipitation minus interception and evapotranspiration, moves within hillslopes either as overland flow, throughflow, or percolates into the substrate to recharge groundwater (Figure 2). Throughflow is shallow subsurface downslope flow; it occurs in saturated subsoil zones, which, because they parallel the sloping ground surface, create a pressure head gradient that drives the flow. Saturation of the soil is commonly caused by contrasts in hydraulic conductivity among horizons. Water moving as throughflow carries with it mobile (dissolved and dispersed) soil constituents and has the potential to differentiate soils in a downslope direction, just as vertical percolation of water promotes translocation, producing eluvial and illuvial zones in soils. This tendency is particularly well expressed in some dryland areas where salts released by chemical weathering of rocks in upslope positions are translocated downslope and precipitate there as salty encrustations resulting in salic soils in lowlands.

Overland flow (runoff) results when the rate of net precipitation exceeds the soils’ infiltration capacity, whereupon it is referred to as infiltration-excess or Hortonian overland flow. Overland flow may also occur because the soil is saturated (saturation overland flow) (Figure 3).

Hillslope processes and form

Hillslopes come in myriad forms, but they result from a finite set of processes, some of which have distinctive geomorphic signatures. Hillslopes most commonly connect the ridges and valleys and form drainage basins. In soil-mantled landscapes of the humid temperate regions, the ridge tops are convex upward. The convexity arises because soil creep is the dominant soil transport process on ridgetops. Soil creep is a slow shuffling of soil material downslope at a rate dependent only on local gradient. It results from soil disturbance processes such as rainsplash, bioturbation, or cryoturbation. The convex form of ridge tops is a response to the need for an increasing creep rate in a downslope direction to accommodate the increasing flux of soil generated by soil production from the slope above. On the gentle slopes of ridge tops where creep rate is directly proportional to gradient, convexity is directly proportional to erosion rate. The crest and shoulder slope elements (Figure 2 and Figure 4) that make up the convex ridgetop are usually dry parts of the landscape, because there is limited contributing area and an increasing downslope angle favors acceleration of throughflow.

A backslope element may be found between the shoulder and the footslope below (Figure 2). The backslope is the steepest part of the slope and is usually straight in form. On long slopes, this form arises because the rate of soil creep increases rapidly and non-linearly once slopes increase to about 20°. Hence, the downslope-increasing soil flux can be accommodated with imperceptible increases in hillslope angle and the slope appears linear. On the backslope, erosion rate and curvature are decoupled. Linear backslopes may also be found where slopes are steep enough (>26°) that soils and even bedrock reach a threshold of stability and undergo episodic mass
movement by processes such as landslides or earthflows (*Threshold slopes*). Alternatively, backslopes may simply be short transitions between convex shoulders and concave footslopes.

A non-linearly increasing flux rate with slope angle does not apply to throughflow, however, and at the point at which flow accumulation overwhelms the transmissivity of the soil, soil saturation and saturation overland flow can occur.

At this point, soil transport involves sheetwash, and the rate of transport is no longer dependent on the local slope angle alone. The transport capacity of overland flow grows non-linearly with increasing upslope contributing area and hence further down the slope lower gradients are sufficient to accommodate the soil flux, and slopes take on a concave upward form. This slope element is called the footslope (Figure 2),
SOILS ON SLOPES: CATENAS

Figure 3  Saturation overland flow in shallow soils over schist bedrock, central South Island, New Zealand (photo: P. Almond).

and being at the base of the slope it is often a zone of net sediment deposition. Being a zone of slowing throughflow flux and because of interactions with groundwater, footslopes are commonly wet. Soils are characterized by high and seasonally variable water tables, low redox potentials, and redoximorphic features (gleying) (Figure 4). Below the footslope, toeslopes mark

Figure 4  Typical catenary variation along a convex–concave slope transect in a superhumid temperate climate, western South Island, New Zealand. Note the transition to the concave footslope coincides with soil thickening and the increase of gray soil colors, which indicate prolonged soil wetness (photo: P. Almond).
the interaction of hillslopes with floodplains and soils here may be very wet and complex in their layering. Toeslopes and even footslopes may be absent if fluvial erosion is efficient.

A proper consideration of water and sediment movement on slopes must also consider their three-dimensional (3-D) configuration. Concave or convex curvature of hillslopes in plan form cause convergence or divergence of flowlines, respectively, for sediment, water, and the dissolved and dispersed materials. Slopes of different 3-D form are consistently arranged across the hollows and noses that define zero-order drainage basins (erosional drainage basins with no, or only an ephemeral, channel) (Figure 5). Convergence or divergence of flow lines intensifies or dampens, respectively, the effects of water and material transport in the downslope direction. For example, the strong convergence in the concave planform hollow intensifies wetness and can form a zone of intense saturation known as a saturation wedge at the basin outlet. Alternatively, divergent noses tend to be the driest parts of the landscape. Convergent hollows also accumulate the greatest thickness of soil.

Figure 5  Zero-order drainage basins, northern South Island, New Zealand. Terracettes formed by animal tracking following contours and highlight areas of convex plan curvature and divergent flow lines (noses), and areas of convex plan curvature where flow lines are convergent (hollows). The area in red identifies the inferred saturated wedge. Image from Google Earth.
The soil catena concept encapsulates the systematic variation of soil properties along hillslopes. This variation occurs as a result of the interactions among hillslope, hydrological, and pedogenic processes as outlined above. However, the particular kinds of soils and the different properties formed along a soil catena also depend on the local state factors of parent material, organisms, climate, and time. For example, as precipitation increases progressively more mobile elements become differentiated spatially along the soil catena. In higher rainfall environments saturation of soils and gleying enhance the mobility of elements such as Fe and Mn. Mobility of metal ions, including Al$^{3+}$, can be further enhanced where acidifying vegetation supplies organic compounds that can form organic-metal complexes with higher solubility (Figure 4).

The notion of soil age on hillslopes has some nuances. Whereas it is meaningful to ascribe an age to a soil on a non-eroding geomorphic surface, colluvial soils on hillslopes are made of an ensemble of mineral particles each with its own history of detachment from the immobile substrate. The relevant concept is the soil residence time ($T_R$), which for a steady-state soil thickness is given by

$$T_R = \frac{\rho_s h}{\rho_r P_h}$$

where $\rho_s$ and $\rho_r$ are the bulk densities of the soil and substrate, respectively, and $P_h$ is the soil production rate corresponding to soil thickness $h$. For example, in the Oregon Coast range in northwestern United States, soils are commonly about 40 cm thick, the production rate at this soil thickness is about 0.01 cm year$^{-1}$, and the ratio of the soil and bedrock bulk densities is about 0.5. The residence time, which is equivalent to the time for the whole soil volume to be replaced by soil production, is about 2000 years. Correspondingly, soils are relatively weakly developed Inceptisols (Figure 6). In general, more rapidly eroding parts of hillslopes will have soils with shorter residence times and more slowly eroding parts will have longer residence times. These residence times are reflected in the age distribution of mineral particles in the soils and the extent of pedological (including chemical) differentiation. On rapidly eroding slopes with short soil residence times catenary differentiation may be poorly expressed (Yoo et al. 2011).

The effects of soil residence time on soil taxa and properties are overprinted and often dominated by the redistribution of dissolved and dispersed soil materials and changing weathering environments brought about by hillslope hydrology. One of the most detailed accounts of these effects is reported by Park and Burt (2002) in a study of a zero-order drainage basin in Somerset in the United Kingdom. Figure 7 shows the pattern of soils within the drainage basin, which is formed in Devonian sandstone and under acidifying shrub vegetation and a humid climate. They measured 32 soil properties from 69 pits across multiple soil depths over an area of about 2.5 ha.

The soil pattern is quasi-symmetrical with respect to the axis of the hollow. Stagnoluvic gley soils occur on the gently sloping interfluve where lateral drainage is negligible and vertical drainage is limited by slowly permeable horizons – these soils are strongly gleyed. They give way to stagnogleyic podzolic brown soils on the convex shoulder slope, where enhanced throughflow due to the convex curvature improves drainage and leaching. Stagnogley podzols form in the hollow as a result of convergent throughflow, intensifying leaching, and saturation above the low permeability, subsurface horizons. Lower in the hollow these soils give
way to lateral podzolic soils where an open network, gravelly, colluvial deposit, inferred to have formed as a result of past periglacial processes, permits deeper and more rapid percolation. The concave footslope in the lower hollow is characterized by springs and hence is dominated by strongly gleyed soils. Along the noses, where throughflow is divergent, a catenary sequence of soils lacking gley features occurs as podzols grade to podzolic brown soils to orthic brown soils. Gleyic phases of the orthic brown soils occur in the saturation wedge that forms at the base of the noses adjacent to the seepage soils.

It is clear that the distribution of soil taxa across the slopes of the drainage basin can be reconciled in a qualitative way with the inferred patterns of topographically determined throughflow. Quantitative analysis of the spatial variation of soil chemical properties also demonstrated catenary patterns. Soil properties relating to relatively mobile soil constituents such as exchangeable bases showed the strongest spatial patterns. Between 31% and 69% of spatial variability of total exchangeable bases (TEB) could be explained using multiple regression against morphometric terrain variables calculated from a digital elevation model of the
SOILS ON SLOPES: CATENAS

**Figure 7** Distribution of soils within a zero-order drainage basin, Quantock Hills, UK (after Park and Burt 2002).

Aboveground influences on catenary patterns

Although gravitational organization may be the most consistent effect in catenary redistribution of soil materials, it may not be the dominant one in some circumstances. In grazed pastoral hill country, nutrient elements move independently of gravity, powered by energy from photosynthesis. Grazing animals harvest nutrients throughout the landscape and deposit them in concentrated form as dung and urine in preferred congregation sites (Haynes and Williams 1993). As a result, some areas of the
landscape become enriched with nutrients while others become depleted.

Preferential stock congregation often occurs on the gentle slopes of ridge tops, particularly in steep, hill country. Typically, the animals will congregate in such areas (referred to as “campsites”) through the night and graze the slopes in daylight hours. Campsites often cover 15% or less of the total grazable land area (Haynes and Williams 1993).

Soil chemistry, both organic and inorganic, is profoundly influenced by animal grazing behavior. In general, animals tend to harvest nutrients from backslopes and footslopes as they graze the pasture and deposit them on stock camps and on the tracks on which they walk. The tracks mostly run horizontally around hills (Figure 5) making it easier for the animals to move around the landscape particularly on steep slopes. Using nutrient balance approaches researchers have demonstrated that large accumulations of nutrients occur on campsites and stock tracks and a corresponding depletion of fertility develops on the majority of the hillslopes. The nutrients moved in relatively large quantities in this way include nitrogen, potassium, and sulfur in urine and phosphorus and sulfur in dung. At these rates of movement, large quantities of nutrients are translocated from hillslopes to campsites and tracks (Gillingham, Syers, and Gregg 1980). Nutrient redistribution creates feedbacks involving pasture sward composition, N-fixation, nutrient cycling, and C-fixation rates, which tend to reinforce the heterogeneity of soil fertility.

The future for hillslope-soil studies

Recent mathematical process models of catenary sequences advanced by geomorphologists have made major contributions to our understanding of soil-mantled hillslopes. These studies have incorporated soil production and transport, mineral dissolution and soil mass balance, and carbon dynamics to provide new insights into chemical denudation, redistribution of biogeochemically important elements, and C sequestration on slopes as well as within soils on slopes. Developing similar models, which incorporate a more comprehensive suite of soil and aboveground ecosystem processes, is the next major challenge.

Soils: salinization

Graciela Metternicht
University of New South Wales, Australia

Soil degradation is the decline in soil quality caused by its improper use, usually for agricultural, industrial, or urban purposes. Processes leading to soil degradation include chemical, physical, and biological actions and interactions that affect soil functions and productivity (Lal, Hall, and Miller 1989). Factors involved in soil degradation include natural and human-induced agents and dynamics that set in motion the processes leading to changes in soil properties and life-supporting attributes (Figure 1).

Physical processes of soil degradation lead to changes in the physical, mechanical, hydrological, and rheological properties of soils. Change in soil structure is, for example, an effect of physical degradation. Factors responsible for physical degradation include deforestation, intensive row cropping, and overgrazing. Reduction in soil organic matter is an example of a biological process of degradation that can be caused, for example, by intensive cropping, or surface erosion. Chemical degradation processes include (i) changes in soil’s chemical properties that regulate nutrient activity and capacity, which maintain a favorable balance among main nutrient elements, and (ii) the accumulation of chemical substances, possibly to toxic concentrations. Soil chemical degradation often results in depletion of major plant nutrients and/or accumulation of salts and heavy metals in concentrations detrimental or even toxic to plant growth. Main processes leading to soil chemical degradation include leaching, acidification, and salinization (Figure 1).

Salinization is a natural process resulting from migration and dissemination of water-soluble salts from a source area to an area originally free of salt. It can occur in any sediment, whether it be soil or rock-like material, as long as it is porous. Hereafter in this entry, salinization will be considered mainly as a human-induced process, sometimes called secondary salinization.

Salinization results from excessive accumulation of water-soluble salts such as chlorides, sulfates, and carbonates of sodium, magnesium, or calcium on the soil surface, in the subsoil, or in groundwater. Human-induced salinization increases salt concentrations in soils already affected by natural salinity, or leads to contamination of salt-free soils because of inadequate water and land management (e.g., using brackish water for irrigation, or overgrazing).

Salinization is a concern because salts – when found above a certain threshold level – hinder the growth of crops by limiting their ability to take up water. Excess salts have the same effect on plants as does drought. For this reason, although salt is “the savor of foods” it is said to be the scourge of agriculture (Figure 2).

Salinization can take any of several forms, and a rich nomenclature has developed to describe these forms and processes (Figure 3). Soils with a high concentration of salt in the root zone are called saline soils if the electrical conductivity (EC) of the saturation extracts is above 4 dS m$^{-1}$ at 25°C, and the sodium absorption ratio (SAR) is less than 13. Soils are called alkaline or sodic if they contain sodium salts capable of alkaline hydrolysis, the SAR exceeds 13, and the soil EC
SOILS: SALINIZATION

Figure 1  Various factors and processes of soil degradation. Created with information from Lal, Hall, and Miller (1989).

is below 4 dS m$^{-1}$. Soils are called saline-alkaline or saline-sodic if the EC and the SAR are above 4 dS m$^{-1}$ and 13, respectively.

Geography and global extent of salt-affected soils

Saline soils tend to dominate in arid and semiarid regions, where low rainfall and high evapotranspiration concentrate sodium (Na), magnesium (Mg), and calcium (Ca) salts in soils, mainly in the form of chlorides and sulfates. Sodic soils are found in semiarid and subhumid regions, where Na carbonate and bicarbonate dominate, and Na ions get adsorbed on the soil exchange complex. Salinization and alkalinization processes also manifest in some coastal regions where rainfall mixes with sea spray, affecting areas located relatively far away from the coastline, as is the case with inland salt deposits present in the Western Australian “wheat belt” (Hingston and Gailitis 1976). The intrusion of saltwater into freshwater aquifers in low-lying coastal areas is another process leading to soil salinity in some delta and estuary areas of countries such as Bangladesh and India. Figure 4 presents the dominant ions causing salinity and/or alkalinity, their dominant environment of formation, and the main effects they have on soils.

Statistics on the worldwide extent of salt-affected areas vary according to data sources, and the most recent inventories are out of date (dating back to 2000). Nonetheless, according to the Food and Agricultural Organization of the United Nations (FAO), the global surface area affected by salinity was 831 million ha in 2000, including 397 million ha of saline soils and 434 million ha of sodic soils. Other estimates (IIASA and FAO 2012) raise the area affected by excess salt
Figure 2 Examples of impacts of salinity on soils in a semiarid area of Bolivia (the Cochabamba valleys): (a) puffy crust containing soil aggregates, spots of thin salt crust, and salt-tolerant Chenopodiaceae; (b) sodium sulfate-rich crust broken by cattle or sheep trampling, leaving the underlying dispersed soil material exposed to wind erosion (c); (d) topsoil degradation from combined salinization and wind erosion; (e) salt crust maximized in an irrigated parcel, at the end of the dry season; (f) irrigated agricultural field with local salt concentration affecting alfalfa growth; (g) stunted barley in a salt-affected paddock in the southwest of Western Australia.

Accumulation to 1.39 billion ha; this is about 7% of the Earth’s surface, and equates to the size of a country like the United States or Canada, or 20 times the size of Spain. Besides naturally saline areas, the global assessment of human-induced soil degradation (GLASOD), carried out in the 1980s (Oldeman, Hakkeling, and Sombroek 1991), determined that about 76.6 million ha have been salinized in “modern times” as a consequence of human activities. This figure represents 3.9% of the 1.96 billion ha affected by human-induced soil degradation worldwide (Figure 5). About 58% of all salinized soils are located in arid or semiarid, irrigated areas. On average, 20% of the world’s irrigated lands are affected by salts (45 million ha of the 230 million ha irrigated worldwide). Furthermore, of 1.5 billion ha of dryland agriculture, 32 million ha (2.1%) are salt-affected, with varying degrees of human-induced degradation (FAO 2000).

Salinized soils have expanded in area since the inventories of the 1970s and 1980s, as newly affected areas most probably exceed the areas remediated by reclamation and rehabilitation efforts. At the national level, data on salinization are generally more reliable and sometimes more current. For instance, in 2001, Australia, a country with large areas of naturally occurring saline soils, reported 2.5 million ha of land salinized since the introduction of European farming practices. These data compare to the 0.9 million ha identified by the GLASOD project in the
SOILS: SALINIZATION

Chemical indicators:
EC < 4dS m^{-1} / SAR > 13 / pH < 8.5

Dominant anions:

Dominant cations:
Na: not more than half of the soluble cations.
Ca and Mg: considerable amounts.
K: not common.

Gypsum and lime present sometimes.

Other properties:
Organic matter dispersion and dissolution.
Clay deflocculation.
Columnar or prismatic structure.

Main effects on soil profile:
Changes in structure and decreases in permeability and porosity.
Changes in soil biological activity
pH increases beyond 9 or 10.

Saline soils

Chemical indicators:
EC > 4dS m^{-1} / SAR < 13 / pH < 8.5

Dominant anions:
Chlorides, sulfates, and bicarbonates. Carbonates: small amount.

Dominant cations:
Na: dominant.
K: sometimes (exch. and soluble).
Ca and Mg: small amounts. At high pH and in the presence of carbonates, Ca and Mg will precipitate.

Other properties:
Generally flocculated; permeability equal or higher than that of similar nonsaline soils.
White crusts on soil surface.

Main effects on soil profile:
Higher osmotic pressure.

Saline-alkaline (sodic) soils

Chemical indicators:
EC > 4dS m^{-1} / SAR > 13 / pH variable

Dominant anions/cations:
If excess of salts: appearance and properties similar to saline soils (i.e. pH < 8.5, particles remain flocculated).
If soluble salts are leached downwards: appearance and properties similar to sodic soils (i.e., pH > 8.5 and soil particles are dispersed).

Main effects on soil profile:
Soils become unsuitable for the entry and movement of water and for tillage.

Figure 3  Types of salt-affected soils and associated chemical and physical parameters. Created with information from Richards (1954).

late 1980s (Oldeman, Hakkeling, and Sombroek 1991). Projections for Australia conclude that salinization may affect a total of 17 million ha of valuable farmland by 2050 (National Land and Water Resources Audit 2000). For Australia, salinization has become one of the most costly forms of land degradation.

Salinity intertwines with other major soil degradation processes such as particle size dispersion, flocculation, and compaction, and as a result often leads to increased soil erosion. Degradation assessment and hazard prediction require that the causes of salinization be clearly identified; this topic is discussed later.

Salinization: causes and process

The primary minerals of igneous and metamorphic rocks, mainly silicates and alumino-silicates, are the original source of all salts found in nature. Upon weathering, primary minerals release cations and anions that combine to form a variety of salts such as chlorides, sulfates, carbonates, and bicarbonates of sodium, calcium, magnesium, and potassium, among others. The most soluble salts are removed as water traverses the terrain surface or percolates through the soil profile. Thus, salts commonly are translocated...

Figure 5  Global assessment of the status of human-induced soil degradation (GLASOD) as of 1990. Chemical deterioration includes: salinization/alkalinization; acidification; pollution; and loss of nutrients/organic matter. Created with information from Oldeman, Hakkeling, and Sombroek (1991).
from their original areas to (i) deeper locations within the soil, and (ii) lower landscape positions. In both cases, they naturally contaminate soils or soil horizons that might have originally been salt-free. The onset of salinity causes salts to be redistributed in the soil profile according to their solubility under prevailing climatic, topographic, and hydrologic conditions, and increasingly under the influence of land use and management practices (Figures 6 and 7). More soluble salts are translocated to greater depths, and to lower-lying landscape positions. These factors affect the soil water balance and, therefore, the movement and accumulation of salts within the soil profile (Zinck and Metternicht 2009).

**Identification and classification of salt-affected soils**

Throughout the world, different approaches are followed to identify and classify salt-affected soils. In the 1960s, Russian soil scientists developed a system based on *salt types*, that is, the chloride, sulfate, and carbonate *anion ratios* present in the soil saturation extract (Plyusnin 1964). Using this classification, types of saline soils include sulfate (SO₄) soils, chloride-sulfate soils, sulfate-chloride soils, and chloride (Cl) soils, all according to their Cl/SO₄ ratio. The *World Reference Base for Soil Resources* (Sparr 1994) also follows an approach based on anion groupings, distinguishing six facies of salt-affected soils (Table 1).
Good practices

- A healthy tree cover uses groundwater reserves and evapotranspiration which keeps the water table at a safe depth.

- A vegetative cover together with minimal runoff ensures surface stability.

- The lower slopes of a well-timbered catchment permit a range of productive agricultural land uses.

- A low water table does not bring salts to the surface.

- Land degraded by saline seepage and affected by a high water table severely limits productive agricultural activity.

- Surface stream becomes saline through runoff from saline seepage and interception from the water table.

Poor practices

- A cleared catchment increases infiltration which in turn raises the water table. A minimal amount of moisture is transpired while an increase is experienced in surface runoff.

- A rising water table brings natural salts towards the surface, killing existing vegetative cover.

- A low water table does not bring salts to the surface. A rising water table brings natural salts toward the surface, killing existing vegetative cover.

- Land degraded by saline seepage and affected by a high water table severely limits productive agricultural activity.

- Surface stream becomes saline through runoff from saline seepage and interception from the water table.

Alternatively, the classification system developed by the US Department of Agriculture Soil Salinity Laboratory (Richards 1954) makes no distinction between salt types and considers only the total salt level in the soil as the guide to its classification – in this case, estimated from the EC of the saturation extract, expressed in dS m⁻¹ at 25°C, and the exchangeable sodium percentage (ESP) or SAR. Using these data, soils are classified as saline, saline-alkaline, or alkaline, as presented in Table 1. In addition to the chemical and physical soil properties, Soil Taxonomy (IUSS Working Group WRB 2014) uses diagnostic horizons to further discriminate among salt-affected and similar soils, including the salic horizon with soluble salts and the
SOILS: SALINIZATION

natric horizon with high levels of exchangeable sodium, as well as gypsic and petrogypsic horizons, sulfuric horizons, and calcic and petrocalcic horizons.

Effects of salts on soil properties

The accumulation of soluble salts in soils produces changes in both physical and chemical properties, mainly affecting soil structure, permeability, and chemical balance. The specific effects of water-soluble salts on soil properties depend on environmental conditions as well as on the types of ion causing the salinity and/or alkalinity.

In agricultural areas, high levels of water-soluble salts are harmful to crops. However, determination of a salt percentage limit for agriculturally limiting saline and nonsaline soils is very difficult, because some crops are more tolerant than others to the effects of high salt content. Furthermore, not all salts are equally harmful: sodium salts, for instance, are more harmful to most crops than are calcium and magnesium salts (Table 2). The detrimental effect of adsorbed sodium on the physical properties of soils results in low water infiltration rates, low permeability rates for water and gases, and most importantly, poor soil structure or even loss of structure entirely. The degree to which the physical condition of the soil deteriorates in the presence of exchangeable sodium is a function of content and mineralogy of clay particles versus the electrolyte concentration of the soil solution.

Mapping and monitoring soil salinity distribution

The management of salt-affected areas requires information on salinity-alkalinity classes and their severity. Conventional ways of determining, and then tracking, changes in soil salinity are based on field observation and laboratory analysis, both of soils and of crops. Usual indicators of developing or increasing salinity include the invasion of salt-tolerant weeds, irregular, patchy patterns of crop growth, lack of plant vigor, and other indicators of crop stress that result from the direct effect of high osmotic pressures on plant growth. Other, nonbiological indicators of salinity problems that can be observed in the field include the presence of white crusts and efflorescences in saline soils and dark spots in alkaline soils, and the presence of white spots and streaks in both saline and alkaline soils. Where salt efflorescence is not visible, laboratory determinations of soil parameters such as pH, ESP, and SAR can detect early onsets of soil salinity. All of these salinity indicators and estimations are used in commercial dry farming, the management of irrigation schemes, and the reclamation and rehabilitation of salt-affected areas for agricultural production. They are best applicable at farm level and, in the case of laboratory determinations, might be too expensive for frequent replications, if the intent is to enable accurate monitoring of salinity changes. Remote sensing tools, therefore, offer complementary data, and often constitute a less costly, more versatile and timely option to conventional monitoring, especially at regional or smaller scales (Metternicht and Zinck 2003).

Summary and conclusions

Soil degradation is the decline in soil quality caused by improper land use and management practices, usually for agricultural, pastoral, industrial, or urban purposes. It encompasses a wide range of physical, biological, and chemical deterioration. Currently, about 33% of the world’s land masses have been reported as highly or moderately degraded (FAO 2011).

Soil salinization is a specific form of chemical soil degradation, frequent in arid and semi-arid regions and low-lying coastal areas, in which it affects soil functioning and productivity. In agricultural areas, salinity is of concern when the accumulation of salt in the root zone is at a concentration that causes a reduction in yield, often accompanied by other changes in physical soil properties. Yield reductions occur when the crop is unable to extract sufficient water from the salty soil water solution. Salinization also affects other soil degradation processes such as particle size dispersion, flocculation, and compaction. It changes soil structure and the soil biological activity. Therefore, it is considered a major global environmental problem, and in countries such as Australia, salinization is the most costly form of land degradation.

Sonar

ZhaoBao Fang

Guangdong Society of Remote Sensing and Geographic Information Systems, China

Overview

Sonar is the acoustic equivalent of radar. Pulses of sound are used to probe the sea, and the echoes produced are then processed to extract information about the sea, its boundaries, and submerged objects. An alternative to sonar, known as passive sonar, focuses on similar goals by listening to the sounds radiated by underwater objects.

Sonar was originally the acronym derived from SOund Navigation And Ranging. Today, however, its meaning has far exceeded this original definition. Sonar is the use of sound waves propagated in water for underwater target detection, positioning and communication. It is one of the most important and widely used underwater acoustic techniques.

Sonar technology has been used for approximately 100 years. In 1906, Lewis Nixon invented the first sonar receiver to detect icebergs. During World War I, submarine detection became essential and, as a result, interest in sonar increased. The first sonar equipment made was passive receiving equipment, in which no signal was generated. In 1918, Britain and the United States established a sound transmission system. The system used sound waves that were transmitted and received using sonar equipment. The invention of the sound sensor and effective sound emission made it possible to create more advanced forms of sonar.

Sonar is currently the main technique used by naval forces for underwater surveillance, target detection, classification, positioning, and tracking. It is used for underwater communications and navigation, and by security vessels, anti-submarine aircraft, and anti-submarine helicopters in weapon systems and for tactical maneuvers. Sonar technology is also widely used for torpedo guidance, mine fuse and fish detection, offshore oil exploration, marine navigation, underwater operations, hydrological measurements, and seabed geology reconnaissance.

Structure and working principles of sonar

Sound waves are used to detect, observe, and measure objects in water, as they possess advantages over other detection methods that can detect only at very short distances in waters. The penetration of light in water is limited, even in clear water; objects can only be observed at a distance of tens of meters. Electromagnetic wave attenuation in water is too rapid; the shorter the wavelength, the greater is the loss, even with high-power, low-frequency electromagnetic waves, which only span dozens of meters. However, the attenuation of acoustic waves propagated in deep water means that it is possible to receive signals from the detonation of a few kilograms of explosive material at a depth of 2000 m. Additionally, low-frequency sound waves can penetrate the sea bottom through thousands of meters of stratum to obtain formation information. Measurements and observations made with electromagnetic waves
in water have yet to be proven more effective than those made with sound waves.

Generally speaking, sonar array devices, electronic cabinets (for analyzing the echo signal, processing and recognizing the electronic signals), and auxiliary equipment exist as three separate parts. In a geometric pattern array an acoustic transducer is usually spherical, cylindrical, flat, or an in-line column, with a receiving array, a transmitter array, or a single, combined receiver/transmitter array. Electronic cabinets generally have a bisected launch, receive, display, and control system. The auxiliary equipment comprises a power supply, a connecting cable, an underwater junction box, a repeater, and sonar array transmission control matched with the lifting and rotating, pitch, receiving, towing, dipping, release device, sonar dome, and so on.

The transducer — a device that converts energy from one form to another — is an important device in sonar, converting not only sound energy but also other forms of energy, such as mechanical, electric, and magnetic energy. For example, the piezoelectric sensor is a type of energy conversion sensor that can convert mechanical energy into electricity and electrical energy into mechanical energy. An electrical signal transmitter and a transducer (piezoelectric crystal) are commonly used to transform an electrical signal into a sound signal, which is then launched into water. If any submarine, mine or fish targets are present in water, sound is reflected back to the receivers as electrical signals, which are then processed to enlarge them and displayed on a screen or presented as an audio signal through headphones (Figures 1 and 2).

According to round-trip signal time, the distance to a target can be determined and the high and low tones used to evaluate the character of the target. For example, submarines possess a steel shell and, therefore, the echo is clear and has a long playback time. Echoes from deep fish are chaotic. If a target is in motion, the echo of a tone changes as a result of the relative motion of the observer and target.

**Animal sonar**

Many animals possess sonar. Bats emit a sound from their larynx 10–20 times per second. Bat ears receive ultrasonic pulses back as echoes. With the aid of this type of “sonar,” small insects and obstacles as small as a 0.1 mm thick wire can be detected. With the aid of sonar that has a range 40 meters greater than that of a bat’s ultrasound, insects such as moths can clearly hear to avoid attacks. Therefore, animals and humans can experience “sonar war.”

---

**Figure 1** Working principle of sonar.
The sonar sensitivity of dolphins is very high and can detect small objects, such as thin wire or nylon rope. Fish can detect a target from several hundred meters away, can cover the eyes and can move quickly through bamboo poles without running in to the poles. Dolphin sonar target recognition ability is very good; not only can dolphins identify different fish and distinguish yellow copper, aluminum, Bakelite, plastic and other materials, but also they can separate their voice echoes from the voice echoes of people and record and replay them as sound waves. Dolphin sonar anti-interference ability is also very impressive. If noise interference exists, dolphins can improve the sound intensity over the noise to make their own judgments. Dolphin sonar also has emotional expression ability; dolphins “talk” through their sonar system.

Many whales use sound to detect and communicate. It is at a much lower frequency than that of dolphins; their sound travels over a far greater distance. Other marine mammals, such as seals and sea lions, emit sound signals for detection as well.

Animals in the extreme dark depths of the ocean have been forced to adopt various means, including sonar, to search for prey and avoid being attacked. Animal sonar performance is far more advanced than modern human technology. Thus, solving the animal sonar mystery remains a research topic of modern sonar technology.

Russian researchers, using the principle of dolphin sonar, developed a new radar positioning method. They reported that compared with the traditional radar positioning method, their new strategy’s main difference is that it can simultaneously measure the distance of an object and its moving velocity or acceleration. With multiple radar transmitters, this method can be applied to better control the movement of a ship, making its docking capability more accurate at a large dock.

**Application and development of sonar technology**

Early submarines relied on periscopes for observation. However, a periscope can only observe the surface of a target, and observing an underwater target is pointless; therefore, there was a high accident rate in early submarines, which often hit reefs, mines, and other underwater submarines. During World War II, German submarines sank more than 100 ships.

Modern submarines are equipped with a variety of sonar technology. For example, a United States submarine that is equipped with sonar technologies for different uses can possess more than 15 types of sonar. Vessels with a sonar detection instrument can intercept and listen to an enemy’s sonar signal. If sonar is employed, a special password is used to assay the signal. Communication sonar can be used for communication by the vessels, while other sonar is responsible for navigation, ranging, vigilance, detection, measuring landforms, and so on.
SONAR

In many countries, in the areas near to naval ports and important straits, large sonar transducer arrays are often installed in the main channel and other places, and thousands of transducers on seafloor are controlled by computer control onshore. Accordingly, a submarine force can be found in a timely manner. Latent prevention early warning systems of this type were built as early as 1952 and are now in their fifth generation of development, in which alerts can be generated up to several hundreds of kilometers away.

In addition to fixed warning sonar systems, submarines can use airborne sonar for detection. A helicopter can lower a 100-meter-long cable to act as a cable hanging sonar. Sonar depth changes in seawater according to the fall or rise of a fuselage. A plane flying above the sea can undertake detection over a large area (dragging sonar).

A new airborne dipping sonar has been developed that is “wireless,” so does not need to connect with a cable and a plane. It is only 10 kg in weight and is dropped by anti-submarine aircraft into a predetermined area, where it floats on the surface of the sea. Anti-submarine aircraft can deploy many of these floating sonar, which have an antenna out of the water and a hydrophone submerged in the water. The hydrophone converts underwater acoustic signals into received electrical signals that are then sent out through the antenna. According to the signals received, the anti-submarine aircraft can determine the position of a submarine.

In the past 20 years, underwater sonar technologies with respect to positioning, target detection and recognition, communication, navigation, remote control, remote ocean floor sensing (bottom, formations, landforms, etc.), mineral, oil, and gas exploration and military developments have seen extremely widespread application.

Detecting sonar systems in the marine environment

Three research and application aspects exist for sonar in marine environments. The first application uses sonar for marine pollution detection. Using an acoustic backscattering instrument that records acoustic scattering intensity, the concentration of waste in the ocean can be measured. The second application concerns the design of ocean engineering structures, for which marine environment parameters, especially wave and current statistics, employ sonar systems for measurements. The principle here is to fix a sonar system at the bottom of the sea to record sound waves, launch sound waves in the direction of the bottom of the sea, and receive reflections from waves; thus, the propagation time of rolling waves of the relevant parameters can be detected. The third application is to use a low-frequency sound wave that can spread far in the ocean to measure water temperature change; this is similar to medical chromatography.

Marine surveying, mapping, and exploration

With the aid of the global positioning system (GPS), sonar systems, such as sounding sonar, side-scan sonar, sonar imaging, and so on, can generate an electronic chart, on-site, in real-time integrated with the ship’s navigation system, establishing an important technical foundation. Regarding acoustics, the Chinese Academy of Sciences, Institute of the East China Sea Station, National Ocean Technology Research Institute, and other units have been successful in profiling sea bottom sediment, the bottom of the sea, and geological structures of shallow and deep seas, as well as in engaging in seabed oil and gas resource exploration, underwater archaeology, port construction, oil pipeline and sea platform installation, and engineering. Engineering has
been widely used to equip underwater robots with many types of sonar.

**Integrated ship sonar system research**

As demonstrated during the Gulf War, ships and, especially, submarines play important roles in modern naval battles. When ships reach a certain depth, for underwater activities sonar is only effective as an external information tool. Additionally, from the perspective of anti-submarine warfare, submarine sonar represents the main counter. Because the future naval combat system is comprehensively integrated and distributed, an integrated ship sonar system configuration with new requirements has been proposed. The integrated ship sonar system uses information provided by sonar, including comprehensive processing, display, and control, to complete detection, location, tracking, and recognition processes.

Currently, the study of integrated ship sonar systems at home and abroad follow a number of development trends. The first is the continued development and research on towed linear sonar sensor arrays, multiple sensors, and perfecting the function of the complementary base sonar (Figure 3). Multisensor configuration implies that a high density of observable data can improve the credibility and accuracy of target data. The second development trend is the integration of a sonar system with data fusion technology. An integrated sonar system is configured with multiple sensors. The amount of information gathered from the various sensors is vast and must be filtered through target information fusion technology for dimension reduction to provide integrated sonar systems with optimal and unique target information sets. The third development trend is the study of underwater acoustic countermeasure systems for ships. Using computer simulation technology,
research vessel sonar, and acoustic confrontation, the demonstration and design phase before sonar development must be completed to assess whether its performance can meet the practical requirements, providing a theoretical basis for determining the acoustic equipment performance indicators. The underwater ship acoustic countermeasure simulation system is mainly composed of attackers, defenders, and public control, among which are the offensive submarine platforms and weapons (e.g., wire-guided torpedoes, remote control mines, etc.); defenders are composed of ship’s surface and defense weapons.

Underwater acoustic signal processing
and underwater target recognition research

Modern sonar and acoustic technology primarily focuses on research into underwater acoustic signal processing and target recognition because of their importance and complexity. Due to the complexity of the marine environment, underwater target identification has become increasingly complex. Because microelectronics, signal detection, processing, and computer technology are inseparable, modern sonar technology has become very advanced.

The main research directions are: (i) matching underwater acoustic signal processing problems and (ii) digital sonar design. Digital sonar has undergone six generations of development; digital signal processing technology, computer system structure, and microelectronics technology have been combined in digital sonar design. This technology is being extended to generate (iii) a new method of increasing the accuracy of underwater target recognition. Wavelet analysis and fractal theory are used for the extraction of target parameters, using a fuzzy inference neural network classifier design, which is a combination of neural network and expert system identification research.

Weapons and mine applications in water

Weapons used in water primarily comprise torpedoes and mines. Torpedoes are active offensive weapons, whereas traditional mines represent passive defensive weapons. Modern mines are
intelligently designed, having the ability to be disguised and hidden, as well as to attack. A torpedo can be launched after passive sonar has been used to search for and track targets; mines and especially modern mines (remote control mines) use a sonar system that relies on their own sonar detection and target identification.

Mine warfare is also closely related to sonar technology. It generally requires high-performance, high-precision equipment when searching for underwater bombs. Currently, side-scan sonar and depth-variable sonar are commonly used. The armed forces began with synthetic aperture sonar.

Special dolphin forces

Dolphins are an object investigation due to their striking ability of using “natural” sonar in water. Dolphins have the ability to distinguish obstacles and the nature of artificial objects from natural objects in the water. Dolphins can find the location of mines and signal divers to conduct demining work. Due to a dolphin’s search capabilities, special dolphin forces have been formed (Figure 4).

Further reading

Geographic information systems (GIS) process both spatial and attribute data (also known as feature data). Their performance is greatly dependent on the representation of the data and the extent to which they can integrate the data. Ideally, this integration is done through the use of database management systems that are designed to deal with attribute data and, hence, must be modified to also handle spatial data. One of the main issues for spatial data is the volume of the data, which affects how they are stored and accessed, and what operations will be applied to them.

There are two types of operations. The first type of operation processes the data in their entirety, as is the case with operations such as map overlay and connected component labeling in the case of raster images. At times, the operations are applied to several datasets, in which case they should be applied in such a way that the same locations in the two datasets can be accessed at the same time. This means that the order in which the data are processed is of importance; this is usually achieved by sorting the data.

The second type of operation processes only a small subset of the data, as is the case when the data are accessed at random or the portion of the data that is processed satisfies some predicate, which can involve both its spatial and/or attribute components. An example is when browsing through the data looking for cities with a population greater than one million within 10 miles of rivers (Brabec and Samet 2007; Esperança and Samet 2002; Samet et al. 2003). The latter type of processing is important as its efficient execution (other than using brute force to examine every data item) brings into play the need to incorporate notions of sorting, as its use is a prerequisite for its efficient retrieval.

In this entry, the use of sorting to enable the efficient execution of operations on spatial data is discussed. The discussion focuses on the type of the spatial data, which in this case fall into raster and vector. The application of sorting to raster data, where the main motivation is the fact that the data are extremely voluminous and, thus, all of them cannot be fit into memory at once, is reviewed in the next section. Therefore, external storage must be used. In this case the motivation for the sorting is to enable efficient execution of operations. Later, the application of sorting to vector data is reviewed, although, as will be pointed out, the methods that are described are also applicable to raster data. Concluding remarks are drawn in the final section.

**Raster data**

The natural representation for raster data (i.e., 2-D images) is as an array of pixels, where the array serves as an access structure to the raster image. The problem is that even for moderately sized images the storage requirements are high, and thus the array does not always fit into memory. Hence, it is stored on disk in some order with the aid of a mapping from the multidimensional space (two in this case) to a 1-D space (i.e., $Z \times Z$ to $Z$), which reflects
the order in which the array elements (i.e., the pixels here) are stored. There are many ways of ordering the pixels that make up a raster image. The objective of the ordering is to provide a systematic way of processing all of the pixels with the property that every pixel in the image will be processed (i.e., none are missed). Any ordering that is devised must satisfy this property, as otherwise it is not useful. Such orderings are termed space-filling curves (Sagan 1994).

Some of the most important orderings for a 2-D space are illustrated in Figure 1 for an 8 × 8 portion of the space and are described briefly here. Of course, orderings can also be devised
for data of three dimensions and higher, but examples involving them are beyond the scope of this discussion. Choosing among the different orderings is not easy because each one has its advantages and disadvantages. A few of their desirable properties are reviewed here and which of the orderings satisfy them, and which do not, are indicated.

The mapping from the higher-dimensional space to the integers should be relatively simple, and likewise for the inverse mapping. This is the case for all but the Peano–Hilbert order (Figure 1d). For the Morton order (Figure 1c), the mapping is obtained by interleaving the binary representations of the coordinate values of the pixel in the grid. The result of the mapping (i.e., the number associated with each pixel) is known as its Morton number. The Gray order (Figure 1g) is obtained by applying a Gray code to the result of bit interleaving, and the double Gray order (Figure 1h) is obtained by applying a Gray code to the result of bit interleaving the Gray code of the binary representation of the coordinate values. The U order (Figure 1i) is obtained in a similar manner to the Morton order, except for an intermediate application of \( d - 1 \) “exclusive or” (\( \oplus \)) operations on the binary representation of selected combinations of the coordinate values prior to the application of bit interleaving. Thus, the difference in cost between the Morton order and the U order in \( d \) dimensions is just the performance of additional \( d - 1 \) “exclusive or” operations. This is in contrast to the Peano–Hilbert order, where the mapping and inverse mapping processes are considerably more complex.

The ordering should be stable. This means that the relative ordering of the individual locations is preserved when the resolution is doubled (e.g., when the size of the two-dimensional space in which the pixels are embedded grows from 8×8 to 16×16) or halved, assuming that the origin stays the same. The Morton, U, Gray, and double Gray orders are stable, while the row (Figure 1a), row-prime (Figure 1b), Cantor-diagonal (Figure 1e), and spiral (Figure 1f) orders are not stable. The Peano–Hilbert order is also not stable, as can be seen by its definition. In particular, in 2-D, the Peano–Hilbert order of resolution \( i + 1 \) (i.e., a \( 2^{i+1} \times 2^{i+1} \) image) is constructed by taking the Peano–Hilbert curve of resolution \( i \) and rotating the NW, NE, SE, and

![Figure 2](image)

SORTING SPATIAL DATA

SW quadrants by 90° clockwise, 0°, 180°, and 90° counterclockwise, respectively. For example, Figure 2(a–c), gives the Peano–Hilbert curves of resolutions 1, 2, and 3, respectively.

Two pixels that are adjacent in the sense of sharing an edge or a side (also known as 4-adjacent) in space are neighbors along the curve defined by the ordering and vice versa. This property is impossible to satisfy for all pixels at all space sizes. However, for the row-prime, Peano–Hilbert, and spiral orders, every element is a 4-adjacent neighbor of the previous element in the sequence, while this is not the case for the other orders. This means that the row-prime, Peano–Hilbert, and spiral orders have a slightly higher degree of locality than the other orders.

The process of retrieving the neighbors of a pixel should be simple. Finally, the ordering should be admissible (Dillencourt, Samet, and Tamminen 1992) – at each pixel position in the ordering, at least one 4-adjacent neighbor in each of the lateral directions (i.e., horizontal and vertical) must have already been encountered. This is useful in several algorithms (e.g., connected component labeling). The row and Morton orders are admissible, while the Peano–Hilbert, U, Gray, and double Gray orders are not admissible. The row-prime, Cantor-diagonal, and spiral orders are admissible only if the direction of the 4-adjacent neighbors is permitted to vary from position to position along the curve. For example, for the row-prime order, at positions on odd rows, the previously encountered 4-adjacent neighbors are the western and northern neighbors, while at positions on even rows, they are the eastern and northern neighbors.

The row order (Figure 1a) is of special interest because its mapping function is the one most frequently used by the multidimensional array, which is the most common access structure for a raster image. Assuming that the first entry in the linear structure that is accessed by the mapping has an index value of 0, location \((a, b)\) in an \(8 \times 8\) collection of pixels is mapped to index value \(8b + a\). An alternative ordering that is also used in the multidimensional array is known as column order, where the difference from row order lies in the order in which the various dimensions are scanned. In the column order, the \(y\) coordinate value (row number) varies most rapidly; in the row order, the \(x\) coordinate value (column number) varies most rapidly. The one to choose is arbitrary, although the row order is preferred as it yields a lexicographic ordering when array references are of the form \(T[i, j]\), corresponding to an element in row \(i\) and column \(j\) of array \(T\) (i.e., at pixel address \((x, y) = (j, i)\)).

The Morton order has a long history, having been first mentioned in 1890 by Peano, and is often used. It is also known as a \(Z\) order and as an N order. The Peano–Hilbert order was first mentioned soon afterwards by Hilbert and a number of researchers.

The \(U\) order is a variant of the Morton order but also resembles the Peano–Hilbert order. The primitive shape is a “U,” which is the same as that of the Peano–Hilbert order. However, unlike the Peano–Hilbert order, and like the Morton order, the ordering is applied recursively with no rotation, thereby enabling it to be stable. The \(U\) order has a slight advantage over the Morton order in that more of the pixels that are adjacent (i.e., in the sense of a \((d - 1)\)-dimensional adjacency) along the curve are also neighbors in space. This is directly reflected in a lower average distance between two successive positions in the order, which can also be shown to be lower than that of the Gray and double Gray orders. However, the price of this is that, like the Peano–Hilbert order, the \(U\) order is also not admissible. Nevertheless, like the Morton order, the process of retrieving the neighbors of a location in space is simple when the space is ordered according to the \(U\) order.
At times, the number of pixels may be so large that application of statistical data compression techniques from coding theory may be worthwhile. However, the interest is in methods that exhibit progressiveness. Therefore, as results of processing the data are obtained, the partial results of the operation can be seen rather than having to wait until the operation is complete. The result is that we limit ourselves to the situation where many of the pixels have the same data values in which case we try to reduce the required storage by grouping them into blocks of identically valued constituent pixels. This is especially the case for binary images or other images where adjacent pixels often have the same value. For example, consider a crop map where each crop type is assigned a different numeric code or color.

There are two ways to group identically valued pixels into blocks. The first aggregates consecutive identically valued pixels into 1-D blocks and is termed a runlength encoding (Samet 2006). This is particularly useful in the case of the row order (Figure 1a), where the elements of the ordering are pairs of the form \((a, b)\) where \(a\) is the value representing color/type and \(b\) is the length of the block.

The second approach applies a 2-D aggregation into blocks where the sizes of the blocks are constrained to be powers of two and are located at specific positions. In particular, assuming an origin at the upper-left corner of the image, the coordinate values of the upper-left corner of each block (e.g., \((i, j)\) in two dimensions) of size \(2^i \times 2^j\) satisfy the property that \(i \mod 2^i = 0\) and \(j \mod 2^j = 0\). The resulting block decomposition is known as a region quadtree (Klinger 1971), which also serves as the basic data structure in the QUILT (Shaffer, Samet, and Nelson 1990) GIS and spatial library. Such a block decomposition is particularly useful in the case of the Morton, Peano–Hilbert, Gray, double Gray, and U orders (Figure 1). In this case, again, the elements of the ordering are pairs of the form \((a, b)\) where \(a\) is the color/type and \(b\) is the side length of the square block.

The result of the ordering is an effective linearization of the data. The orderings are adequate when the operations require that all elements in the dataset (i.e., image) be accessed from start to end. However, some operations require access to particular elements of the array (known as random access) and, therefore, performing a sequential scan from the start is very inefficient. In this case an access structure is useful and can be the 1-D array corresponding to the result of the mapping from 2-D to 1-D. However, this is more complex once a start is made grouping identically valued blocks and keeping them in the ordering, as the image elements corresponding to the elements in the ordering are no longer the same size. Thus, a tree-like access structure is re-sorted to, where associated with each element of the ordering is a number corresponding to its position in the ordering, and this is the number used to access the tree. The tree can be a binary search tree, B-tree, and so on. For example, in the case of the Morton ordering this number is formed concatenating the result of interleaving the binary representation of the \(x\) and \(y\) coordinate values of the pixel in the upper-left corner of the block (assuming an origin in the upper-left corner of the image) and the binary representation of the base two logarithm of the block’s side length. Traversing the tree in the order NW, NE, SW, and SE yields an ordering of the blocks in increasing order.

**Vector data**

The application of sorting to vector data has its roots in visualization applications in computer graphics. The earliest examples are the hidden-line and hidden-surface elimination
algorithms due to Warnock that recursively decompose the picture area into rectangles that are successively smaller while searching it for areas that are sufficiently simple to be displayed. The determination of what part of the picture area is hidden or not is equivalent to sorting the picture area with respect to the position of the viewer. The concept of “sorting” is used in two ways in the above hidden viewing algorithms. The first is the conventional one of ordering the visible part of the picture area with respect to the viewer. However, a different interpretation of “sorting” is given when the picture area is recursively decomposed into rectangles stopping when their complexity is reduced. In this case, the dictionary definition of “sorting” is being used, which is one of “putting in a certain place or rank according to kind, class, or nature”. Notice the absence of “ordering” in the definition.

Notwithstanding the above definition, sorting usually implies the existence of an ordering. Orderings are fine for 1-D data. However, they do not exist in two dimensions and higher. For example, suppose all of the cities in the United States are sorted by their distance from Dallas. This is fine for finding the closest city to Dallas, say with population greater than 200,000. However, the same ordering cannot be used to find the closest city to Miami, say with population greater than 200,000, without re-sorting the cities. In contrast, once the sort is made with respect to a reference point in one dimension (e.g., people by their height), the nearest value for any other reference point can be found; there is no need to re-sort the data.

The problem is that for two dimensions and higher, the notion of an ordering does not exist unless a dominance relation holds – that is, a point \( a = \{a_i | 1 \leq i \leq d\} \) is said to dominate a point \( b = \{b_i | 1 \leq i \leq d\} \) if \( a_i \leq b_i, \ 1 \leq i \leq d \). Thus, the only way to ensure the existence of an ordering is to linearize the data, as can be done, for example, using a space-filling curve as described in the previous section. The problem with such an approach is that the ordering is explicit. Instead, what is needed is an implicit ordering so that it is not necessary to re-sort the data when, for example in the sample query, the reference point for the query changes (e.g., from Dallas to Miami). Such an ordering is a natural byproduct when objects are sorted by spatial occupancy, and is the subject of the rest of this section.

The indexing methods that are based on sorting the spatial objects by spatial occupancy essentially decompose the underlying space from which the data are drawn into regions called buckets in the spirit of classical hashing methods with the difference that the spatial indexing methods preserve order. In other words, objects in close proximity should be placed in the same bucket or at least in buckets that are close to each other in the sense of the order in which they would be accessed (i.e., retrieved from secondary storage in case of a false hit, etc.).

There are two principal ways of implicitly sorting spatial data. The first distinguishes occupied from unoccupied space, while the second sorts the regions so that the number of spatial objects that they contain is within the same range.

The first method makes use of an object hierarchy that initially aggregates objects into groups based on their spatial proximity and then uses proximity to further aggregate the groups, thereby forming a hierarchy. Note that the resulting object hierarchy is not unique as it depends on how the objects were aggregated to form the hierarchy. Queries are facilitated by also associating a minimum bounding box of an appropriate shape (e.g., hyper-rectangle, sphere) with each object and group of objects, as this enables a quick way to test if a point can possibly lie within the area spanned by the object or group of objects. Negative answers mean that no further
processing is required for the object or group, while a positive answer means that further tests must be performed. Thus, the minimum bounding box serves to sort the space according to the occupation status. Data structures such as the R-tree (Guttman 1984) and the R*-tree (Beckmann et al. 1990) illustrate the use of this method. As an example of an R-tree, consider the collection of straight line segment objects given in Figure 3a shown embedded in a $4 \times 4$ grid. Figure 3b is an example of the object hierarchy induced by an R-tree for this collection. Figure 3c shows the spatial extent of the bounding rectangles of the nodes in Figure 3a, with heavy lines denoting the bounding rectangles corresponding to the leaf nodes, and broken lines denoting the bounding rectangles corresponding to the subtrees rooted at the nonleaf nodes.

The drawback of the object hierarchy approach is that the resulting hierarchy of bounding boxes leads to a nondisjoint decomposition of the underlying space. This means that if an object is not found in one search path starting at the root, then it does not mean that the object will not be found in another search path starting at the root. This is the case in Figure 3c when searching for the line segment object that contains Q. In particular, first nodes $R_1$ and $R_4$ are visited unsuccessfully, and thus there is the need to visit nodes $R_2$ and $R_5$ in order to find the correct line segment object $i$.

The second method is based on a recursive decomposition of the underlying space into disjoint blocks, so that a subset of the objects associated with each block satisfies some predetermined criterion. There are several ways to proceed. The first is to simply redefine the decomposition and aggregation associated with the object hierarchy method, so that the minimum bounding rectangles are decomposed into disjoint rectangles. This implicitly partitions the underlying objects that they bound. In this case, the partition of the underlying space is heavily dependent on the data and is said to be at arbitrary positions. The K-D-B-tree (Robinson 1981) and the R$^+$-tree (Sellis, Roussopoulos, and Faloutsos 1997) are examples of such an approach.

The second way is to partition the underlying space at fixed positions so that all resulting cells are of uniform size, which is the case when using the uniform grid, also the standard indexing method for maps. Figure 3a is an example of a $4 \times 4$ uniform grid in which a collection of straight line segments has been embedded. The drawback of the uniform grid is the possibility of a large number of empty or sparsely filled cells when the objects are not uniformly distributed. This is overcome by using a variable resolution representation such as one of the quadtree variants (Samet 2006), where the subset of the objects that are associated with the blocks are defined by placing an upper bound on the number of objects that can be associated with each block (termed a stopping condition for the recursive decomposition process).

The PM$_1$ quadtree (Samet and Webber 1985 (also the related PMR quadtree (Nelson and Samet 1987)) is an example of a variable resolution representation for a collection of straight line segment objects, such as the polygonal subdivision given in Figure 3a. In this case, the stopping condition of its decomposition rule stipulates that partitioning occurs as long as a block contains more than one line segment unless the line segments are all incident at the same vertex which is also in the same block (Figure 4). A similar representation has been devised for 3-D images (Ayala et al. 1985) where no block contains more than one face, edge, or vertex unless the faces all meet at the same vertex or are adjacent to the same edge all in the same block. In this example, the PM$_1$ quadtree represents the polygonal subdivision.
by its constituent objects, which are the line segments of arbitrary orientation. When the line segments are constrained to be orthogonal to the coordinate axes, the line quadtree (Samet and Webber 1984) uses a decomposition rule in terms of both the boundary and interior of the subdivision so that decomposition into blocks takes place until no boundary element passes through the interiors of the blocks.

In the case of regions, the quadtree decomposition rule halts the decomposition once the data in the block are uniform. It has been used primarily in two and three dimensions where they are known as octrees (Meagher 1982), as well as for surface data (Sivan and Samet 1992). In the case of point data, quadtrees enable the execution of many queries without having to perform explicit sorts of the data. They are

Figure 3  (a) Example collection of straight line segments embedded in a 4 × 4 grid; (b) object hierarchy for the R–tree corresponding to the objects in (a); (c) spatial extent of the minimum bounding rectangles corresponding to the object hierarchy in (b). Notice that the leaf nodes in (c) also store bounding rectangles, although this is only shown for the nonleaf nodes. Copyright H. Samet.
especially useful for determining the nearest object to a particular location (i.e., a “pick” operation in computer graphics). In this case, the underlying space is recursively decomposed into four congruent square blocks until each block contains no more than a predetermined number of points (a variant of a bucket PR quadtree) (Samet 2006). The advantage of the implicit sorting of the underlying space into the blocks is that the position of the subdivision lines vis-à-vis the position of the query object can be used to prune certain blocks from further consideration when executing the operation. Note that the same pruning properties also hold when the blocks are not congruent, as in the case of the point quadtree (Finkel and Bentley 1974; Samet 1980). Quadtree and their variants are to be distinguished from pyramids (Aref and Samet 1990; Tanimoto and Pavlidis 1975), which are multiresolution data structures.

The principal drawback of the disjoint method is that when the objects have extent (e.g., line segments, rectangles, and any other nonpoint objects), then an object may be associated with more than one block. This means that queries such as those that seek the length of all objects in a particular spatial region will have to remove duplicate objects before reporting the total length. Nevertheless, methods have been developed to avoid these duplicates by making use of the geometry of the type of the data that are being represented (Aref and Samet 1992) to avoid multiple reporting of the same object. Another approach known as the MX–CIF quadtree (Kedem 1982) represents each object just once by associating it with its minimum enclosing quadtree block. The loose quadtree (Ullrich 2000) and the cover fieldtree (Frank and Barrera 1989) take this approach further by expanding the size of the minimum enclosing quadtree blocks, so that the size of the expanded minimum enclosing quadtree block is not completely independent of the size of the object (Samet, Sankaranarayanan, and Auerbach 2013).

Note that the result of constraining the positions of the partitions means that there is a limit on the possible sizes of the resulting cells (e.g., a power of two in the case of a quadtree variant). However, this means that the underlying representation is good for operations between two different datasets (e.g., a spatial join) (Hoel and Samet 1995) often implemented as top–down tree traversals (Samet 1985), as their representations are in registration (i.e., it is easy to correlate occupied and unoccupied space in the two datasets, which is not easy when the positions of the partitions are not constrained, as is the case with methods rooted in representations based on an object hierarchy, even though the resulting decomposition of the underlying space is disjoint).
Concluding remarks

An overview of the utility of sorting spatial data for use in geographic information systems has been provided. A distinction has been made between the application to raster data and vector data. This is important, as in the case of raster data the sorting is based on ordering the actual data, while in the case of vector data the sorting is more in terms of the underlying space in which the data are embedded. Hence, the sorting is characterized as being explicit in the former and implicit in the latter. It has been pointed out that sorting is useful in finding nearest objects. In this case, the distance was measured in terms of “as the crow flies.” However, these methods are also useful in finding neighbors in road networks where the distance is defined along the network (Sankaranarayanan and Samet 2010). The sorting has also been used in a distributed peer-to-peer setting (Tanin et al. 2005).

“Soundscape” is both a popular term and an academic concept. As the former, it is used widely by the general public, and particularly by individuals working in sound-related sectors (such as the music and film industries) and related media. As the latter, it is increasingly used by researchers across the sciences and social sciences, either in passing as a useful descriptor or as a dedicated subject of study.

Soundscape is rarely narrowly or strictly defined, and thus is open to a wide variety of interpretations and understandings. In basic terms, it is a metaphor – a play on the word “landscape” – that denotes the way in which sound fills, and makes, environments in various ways and at various scales. The connection between landscape and soundscape is also more than just metaphorical. Because soundscapes unfold in environments – that is, across time and space – a landscape of some description necessarily has to exist for a soundscape to exist (even if it is very modest in scale, such as a small room, for example). Soundscape is often, but not exclusively, talked about in the context of musical sound. Soundscapes can, however, be composed of a range of nonmusical natural and human-made sounds – such as those found in natural environments (Matless 2005), outside in towns and cities (Raimbault and Dubois 2005), and within buildings. These sounds – including those from electronic devices, motor vehicles, human speech, construction work, wind, and rain – are of course the most common components of soundscapes, constituting a constant auditory backdrop to, and an essential part of, everyday life (albeit not always the most obvious, explicit, or entertaining).

A wide range of academic disciplines discuss soundscapes, including acoustic ecology (from where it “officially” originates), the sociology of music, musicology, ethnomusicology, cultural studies, urban planning, and, largely because of its spatial dimensions and character, human geography; specifically the subfields of music geography (Connell and Gibson 2003) and sonic geography (Matless 2005). It was, however, a seminar paper, itself named “Soundscape,” published in 1994 by Susan Smith, that made the first compelling case for the development and investigation of the concept in the parent discipline. Indeed, Smith (1994) argued that the (then) new cultural geography’s engagement with and reading of landscape had been rooted almost exclusively in the visual, neglecting how sound structures space and characterizes place. She claimed that scholars had looked at the world and had written about it without listening carefully to or hearing it. Smith posited that sound was inseparable from natural, built, and social landscapes and that, consequently, scholarship that does not consider sound is incomplete in a sensory sense. Moreover, rounding off her case, she argued that sound signifies place, enhances place’s spectacle, and reflects aspects of society in particular places. Since then, much research has been informed and influenced by Smith’s observations. In music geography the term “soundscape” emerged soon after, hand in hand with a change in emphasis whereby scholars began to look beyond the
SOUNDSCAPES

basic locational and distributional aspects of music (often involving quantitative research methods to map broad musical trends across the Earth’s surface) to consider the relationships and dynamics between music and places. This endeavor involved the use of qualitative research methods to unpack places as complex social and cultural phenomena, to understand how music is wrapped up with place experiences, meanings, attachments, representations, and identities, and to do justice to music itself; its complexity, richness, diversity, aesthetic qualities, and cultural and political language (Leyshon, Matless, and Revill 1998).

Underpinning the aforementioned tradition since the mid-1990s has been a social constructivist theoretical approach. This approach digs down to uncover meaning in, and attempts to represent and theorize, the nature of soundscape. Here a loose reading of soundscape has emerged, which does not always take it to be an immediate and momentary experience. On the one hand, research has considered the more fixed and territorial aspects of soundscapes, for example, the form and implications of musical “sound scenes” as they form in situ (Connell and Gibson 2003). This might be where particular types and genres of music become associated and entwined with places (such as particular towns or cities), or where particular forms of music become associated with particular types of urban spaces (such as subways or cafes). On the other hand, research has considered the fluidity and mobility of musical sound, including, for example, changes in musical styles across time and space (often at the international scale) and issues related to the authenticity and hybridity of the emerging forms (Connell and Gibson 2003). Research has also considered the economic, political, and cultural drivers, mechanisms, and mediators for such movements, often locating them within forms of nationalism, regionalism, and wider globalization processes (Connell and Gibson 2003). In these ways – through both fixing and fluidity – a soundscape can be a multiscaled phenomenon, by which sound takes a prominent yet not exclusive role in defining and making place.

Most recently in the new millennium, the idea of soundscape has been influenced by the emergence of nonrepresentational theory in human geography, which has taken the discipline far closer to the literal and popular understanding of soundscape as an immediate – often all-enveloping – experience and environment. In contrast to social constructivism, nonrepresentational theory places far greater emphasis on sound’s performative aspects, on what actually happens in time and space and on the momentum in how it takes place. Moreover, nonrepresentational theory brings into view the subtle and often unspoken dimensions involved in soundscapes, including how they relate intimately to the human body and embodiment (people’s senses, immediate responses, and expressions). In this research, the Deleuzian concept of affect has been drawn on to help articulate the role soundscapes play in how the world is experienced and acted on precognitively (its somatically registered “feeling states,” “vibes,” and “atmospheres”). Scholars have discussed how, through affect, music might assist people’s transitions from one experiential state of their body to another, potentially impacting on their capacities and wellbeing (in either positive or negative ways). They have also considered how, within soundscapes, affective feelings might slide into more conscious realms – such as attitudes, opinions, and emotions – which are even more clearly relational to the social world.

Although the consideration of musical soundscapes remains predominant in human geography, an ever-wider range of subjects is now being tackled by scholars taking both
social constructivist and nonrepresentational perspectives. Well-established subdisciplines have become involved in the debates. In rural geography, for example, the emphasis has turned to how contests over identity, aesthetics, and land use are played out with, and over, specific sounds as much as other factors, presenting moral geographies of appropriate conduct in these areas (Matless 2005). In urban geography it has been proposed that research move beyond thinking about urban noise as pollution and a problem and seek a more neutral starting point that accounts for other forms of sound (particularly subtle forms), subjectivity/differences in attitudes and experiences, and temporal change over different time frames (Raimbault and Dubois 2005). More specifically, there are emerging interests in particular facets of soundscapes, signifying a more sophisticated engagement with and development of the concept – such as voice and conversation, silence and stillness, art and movement, and therapeutics. Methodologically, as Smith (1994) highlighted, problems will always persist when studying soundscapes, in no small part because many sounds – unlike words and images – if not recorded, disappear. Moreover, writing tends to deaden soundscapes, the change of medium killing the essential energy, and soul of the real-time experience. Hence, researchers are gradually coming to grips with a range of methodological, representational, and theoretical challenges that will help them better understand and convey soundscapes.

Description and purpose

The Society of South African Geographers’ main objective is to advance the research and educational activities of all South African geographers by collectively representing the interests of South African geographers regionally, nationally, and internationally; encouraging and supporting high quality research and teaching in geography; providing a national geographic information resource for geographers and interested groups; and stimulating awareness of geographic and environmental matters through academic collaboration with other intellectual communities and accountable interaction with the public at large.

Journals or major publication series

South African Geographical Journal. www.tandfonline.com/loi/rsag20

Current activities or projects

The SSAG focuses on publishing and disseminating scholarly research results in the South African Geographical Journal and other occasional publications; and by organizing a biennial conference and an annual student conference hosted by geography departments in South African universities. We also aim to support projects that build geography beyond universities and to represent geographers on various official regional and national Department of Education and National Science Foundation groups, as well as internationally through links with the International Geographical Union. The society recognizes the achievements of its members through several types of awards, among them the Jubilee Bursary (for an Honors student), the Bronze Medal (for an outstanding Master’s thesis), the Gold Medal (for outstanding service to the geographical community in South Africa), and the Fellowship award (for outstanding and sustained scholarly contributions).

Brief history

The Society of South African Geographers is an organization that focuses on building geography and supporting the work of departments across South Africa, most of which are small in size. The society was founded in 1994, during a period of tremendous change in South Africa with the advent of democracy and the restructuring of the state, universities, and the education system after apartheid. In this contemporary period, our efforts have focused on building an inclusive and supportive context for scholarly work and teaching as well as for the building of geography in schools and the public more broadly. This work builds on close to a hundred years of disciplinary history in South Africa, with the first organization founded in 1917 (the South African Geographical Society – SAGS) dominated by English-speaking universities and academics and with the Society of Geographers
(SG) founded in parallel in 1957 and representative of Afrikaans-speaking geographers, teachers, and lecturers. Continuing through and reflective of the divisions and politics of the apartheid period, these societies merged in 1994 forming the present organization inclusive of all South African geographers across the country’s racial, ethnic, and linguistic divide, and a significant focus of the SSAG in its contemporary form.

Description and purpose

The Korean Geographical Society was founded in September 1945 to promote the “advance-ment of geographic research” and has since been at the forefront of geographical research in South Korea. The society also serves as the Korean Committee of the International Geographical Union. The society has around 1400 individual members and more than a hundred member organizations.

Journals or major publication series

Current activities or projects

The society advances geography in academia, industry, research, and education through its journal, newsletter, research projects, annual meetings, and educational programs. The society publishes the *Jirihak*, a quarterly newsletter, and is committed to publishing scholarly empirical and theoretical research articles. The society conducts various research projects which are either under contract with government agencies or jointly with private sector organizations. Through the contract with the Ministry of Land, Infrastructure, and Transport, the society has published the *Korean Geography* and *National Atlas* series. The annual meetings are the largest events of the society and approximately 150 papers and presentations on geographic topics are delivered by 600 attendees. A wide array of research symposia, informative workshops, special events, field trips, exhibits, and paper and poster competitions for students are also prepared. The society runs the Geography Olympiad, which is designed to challenge Korea’s most talented students and reward them for their success. Each year, more than 4000 high school students representing their schools participate in the Olympiad on university campuses across the country.

Sovereignty

Ishan Ashutosh  
*Indiana University, USA*

Sovereignty has been traditionally defined as a political authority practicing ultimate power over a given territory and population. The sovereign has the monopoly of violence and the determination of right through the making of laws within its jurisdiction. Moreover, the sovereign produces spaces subject to its power, as associated with territory as well as a population who are united as the people in their subjection to the supremacy of the sovereign. There is an internal and external dimension to sovereignty, since in principle a sovereign is not subordinate to other political authorities and acts autonomously within its jurisdiction, yet sovereignty is predicated on its recognition as such by other sovereign powers. Today sovereignty is most commonly associated with the state and indeed, the concept acts as the primary basis of state legitimacy. Transformations of political authority over time and space, however, reveal that sovereignty is a problematic concept and one that is best seen as complex, contingent, and Janus-faced.

The distinct and often contradictory understandings and utilizations of sovereignty over the past five centuries reflect broader struggles over order, legibility, and the operation of power that shape geographic processes of politics and law. Embedded within the very concept of sovereignty are histories of conflict, domination, and resistance, although sovereignty is often granted an a priori status that takes the concept for granted. As the expression of absolute political authority, sovereignty remains critical in the range of activities and processes that comprise social and political life, including membership and belonging to a political community, the rights and obligations of subjects and citizens to political authority, the conducting of war, and the regulation of human migration. Over the past quarter century, international treaties and the appearance of supranational entities, alongside the rise of transnational capital and international human migration have seemingly signaled the withering away of state sovereignty. Such evaluations, however, have been shown to be premature and scholarship in geography has departed from the “end of sovereignty” accounts. Instead, geographers have provided grounded and theoretically rich insights into the spatial transformations of sovereignty and its intersection with other forms of political entities and organizations to reveal that the concept is characterized by a range of multiple and contradictory practices that characterize the diffusion of political authority.

**The longue durée of sovereignty: from the sixteenth century to the present day**

As a concept in Western philosophy and political organization, the emergence of sovereignty was as discontinuous as it was fractious and contested. Saskia Sassen (2006) has shown that in Europe during the mid-Medieval period power was shared between three forms of political organization: the church, feudalism, and empire. By the thirteenth century, sovereignty became an increasingly important principle for monarchical authority, and by the Tudor period had found representation in the split of the king’s two
bodies – the body natural and the body political (Kantorowicz 1957). On the one hand, the body natural was the physical body of the king, and thereby corruptible and mortal. On the other, the immortality of the body political attempted to portray the indissolubility of the sovereign as a godlike form of political power that resides above and in control of the finitude of human life.

In conventional accounts of sovereignty, its rise is owed to the gradual erosion of the Church’s political authority in favor of political power being located in the state. By the sixteenth century, the juridical conception of sovereignty based on rights, the duties of subjects, and the monarch became central to political conflict in Europe and were concomitantly elaborated on in debates on the nature of politics and the state. For the French political theorist Jean Bodin, the supremacy of the sovereign rested on a moral and legal basis and reveals the shift in thinking about the legitimacy of political power when contrasted with Niccolò Machiavelli’s earlier realist argument that political authority is simply predicated on the ability to rule and not on a moral or even a legal basis. In spite of such differences the political philosophies from the late sixteenth to the mid-seventeenth centuries highlight the shift in thinking about how political power is achieved, maintained, and legitimated.

The treaties that comprised the Peace of Westphalia (1648), designed to bring an end to the long-standing feuds and wars of major European political powers that still consisted of overlapping forms of political authority are frequently seen as the primary manifestation of sovereignty in territorially based states. Basic aspects of Dutch jurist Hugo Grotius’s political and legal philosophies, which stressed the importance of sovereignty as the ability to act without external interference, became a cornerstone in the treaties of Westphalia. In calling for singular political authorities over demarcated space in which a political power would have exclusive authority, the treaties enshrined a system of state sovereignty predicated on mutual recognition. Moreover, the interstate system ushered in by Westphalian sovereignty produced political authorities whose legitimacy was increasingly independent of papal command in contrast to the shared, overlapping, and conflicting political organizations that existed during the medieval period.

For the social contract theorists of the Enlightenment, juridical sovereignty would produce a political order that would progress society beyond the state of nature or a society without the protection of the sovereign that would provide order and security. Like the philosophies that underwrote the treaties of Westphalia, conceptions of sovereignty were cast in light of political conflict and colonial conquest that raised fundamental concerns over the legitimacy and status of sovereignty. The English Civil War, which pitted Charles I against Parliament, with the former arguing that political power was ordained from God and encompassed a duty to provide security to the people in exchange for their subjection, served as the immediate political context for Thomas Hobbes’s *Leviathan* (1968/1651). Hobbes depicted the pre-sovereign state of nature as one of constant war and fear that can only cease with a social contract between the people and the sovereign. In exchange for security, the people subsume their freedom in the state of nature to the sovereign, who is tasked with maintaining peace and order. The figure of the leviathan, a behemoth that stands above both territory and its subjects illustrates the commanding vision and authority of the sovereign.

While John Locke’s state of nature departed from the Hobbesian view, sovereignty was nevertheless needed in order to protect property. Much like Hobbes, Locke also argued that sovereignty rested on a contract with the people, rather than between God and the king. The shift
from divine right as the basis of monarchical power to the people as the basis of sovereignty. Made its largest pronouncement during this time in the decidedly anti-monarchical works of Jean Jacques Rousseau. For Rousseau, the sovereign is nothing other than a representation of the general will of the people and as such, Rousseau elaborated and expanded on the notion of popular sovereignty. The sovereign’s identity is equivalent to the people in their entirety and is therefore an undivided expression of the will of the people, a philosophical understanding of sovereignty that has been used for gaining legitimacy by democrats and totalitarians alike. Post-Westphalian philosophies of sovereignty revolved around a number of key issues that remain fundamental to understandings of contemporary sovereignty, most notably the transfer of sovereignty to the people and the ties between subject/citizens and sovereign protection.

To locate the concept of sovereignty as merely a narrative of European statehood, however, elevates that Westphalian moment to a mythic status and produces a history that itself mirrors sovereignty’s desire for legitimacy. Sovereignty was in fact founded on violence and not simply through the convening of a peace conference attended by representatives of the European powers. The consolidation of the political entity of Europe based on political equivalencies among sovereign powers and enshrined in the principle of reciprocity as the basis of Westphalian sovereignty, furthermore, elides how the philosophies and political treaties that characterize sovereignty were largely conjured beyond Europe. Given this context, sovereignty is best seen as a political ideal of supreme authority that also emerged through the violence and oppression of slavery and colonialism.

Though traditional accounts of the philosophies of sovereignty view the term as the political corollary of the broader Enlightenment project, the concept should not be severed from its development and application in colonial conquest and subjugation. Sovereignty is, in the first instance, constituted through projects of violence and colonialism. By the sixteenth century, European attempts to dominate much of the world proved to be the grounds under which the uneven application of sovereignty was utilized to dispossess non-European political entities. The universality of political organization was dismissed under the arrogation of European sovereignty over other lands that were in turn violently stripped of their sovereignty through claims of despotism, civilization, order, and peace. The Berlin Conference of 1884–1885, to provide one notable example, extended European sovereignty by stripping African political powers of their autonomy and organization in the name of European colonialism. In the colonial context, the violence of sovereignty becomes clear and is not merely an aberration of sovereignty. The ability of the sovereign to determine arbitrarily what constitutes right as a measure of its authority is achieved at the expense of its colonized subjects.

The logic of sovereignty was also expressed in anticolonial movements, which argued that their political and cultural sovereignty were oppressed and demanded recognition. Following formal decolonization, in many instances postcolonial nation-states are beset by fragmented sovereignty, in which more than one political organization attempts to act as the final authority, leading to displacement, pogroms, riots, and daily performances of violence in an attempt to mimic the supreme authority of sovereignty that was founded through the dispossessing acts of colonialism. Of course, the postcolonial context reveals a central problematic of sovereignty that extends well beyond the condition of oppressed states, by highlighting the fact that sovereignty is fundamentally predicated on violence and exclusion. Moreover, the violence of colonialism
SOVEREIGNTY

and sovereignty illuminates the variance of sovereignty in which some states practice greater sovereignty within their borders than others. The uneven application of sovereignty can be extended to the international arena in which contemporary colonialism and imperialism continue in the name of sovereignty as it shapes the politics of war and marginalization in the present day. The invasions of Afghanistan, Iraq, and drone strikes in Pakistan, for instance, are all acts carried out in the name of American sovereignty, but such displays of sovereign power violate the sovereignty of other states.

Geography and sovereignty: from authority over territory to authority over life and death

While sovereignty has long been a key concept in the discipline of geography, the focus has tended to be on the objects of sovereignty, such as population and territory, or on its institutional organization, as with the state. In the late nineteenth and early twentieth centuries, the emphasis of geopolitics on territory and natural resources during the age of high imperialism championed the control of space as central to national sovereignty as well as global political power. For instance, Halford Mackinder’s “Heartland Thesis” postulated that control of a particular geographic zone located in the central Eurasian landmass would lead to world domination, and thus a global sovereign. Similarly, Fredrich Ratzel’s call for expanded sovereignty for the purposes of lebensraum (living space) ensured that the discipline of geography would become a crucial site in knowledge production in the aid of empire building. Dominant geopolitical discourse based on a defense of national sovereignty would come to play the premier role in the exacerbation of inter-imperialist rivalries and in the first and second world wars.

Recent scholarship in political geography, especially in critical geopolitics, has called into question the realist model of sovereignty championed by classical political geography and has cast new light on the discipline’s role in promoting colonialism and imperialism by positioning sovereignty as a necessary spatial strategy in maintaining political control and order. Poststructural and postcolonial perspectives in particular have been used to reconceptualize sovereignty within the discipline as well as in the related fields of political science and international relations. Sovereignty is today understood as having been unmoored from the territorial nation-state and is the product of a range of political actors beyond the state. The territorial nation-state is no longer necessarily the locus of sovereignty, as de facto forms of sovereignty that include diasporic political organizations characterized by long-distance nationalism, global financial institutions that act with greater sovereignty than many states, and networks of public–private partnerships now also dominate the political landscape.

The disarticulation of sovereignty from its traditional referents has led to new research paradigms examining contemporary political power, including the movement of rights and obligations associated with citizenship beyond national territory and new forms of political authority predicated on a mixture of state and nonstate actors. Given the diversification of contemporary political authority, it is therefore necessary to distinguish between different types of sovereignty. Agnew (2009) identifies four distinct “sovereignty regimes” that are formed in relation to state authority and territoriality. These regimes consist of “classical” sovereignty based on the territorial state of the Westphalian model, the imperialist type in which economic control supplants territorial sovereignty, integrative
sovereignty composed of levels of political power beyond the state, and the globalist sovereignty regime in which ultimate political authority rests on the hegemony of the global sovereign over and often with the consent of the sovereigns of dominated states. In each of these ideal types, the fundamental aspects of sovereignty, such as authority, territory, and legitimacy are reconfigured and respatialized through the new international division of labor and transnational capital.

Current research on sovereignty centers on territoriality, or the use of territory by political actors for domination and subordination. The use of territory includes border enforcement (Coleman 2007), extra-territorial detention (Mountz 2011), and new practices of citizenship and belonging that are made possible through a dispersed network of sovereignty. The dispersal of sovereignty beyond national territory engages with not only the spatial distribution of sovereign power, but also on new forms of subject-making predicated on forms of inclusion and exclusion from the political community. In many cases, insights into the functioning of contemporary sovereignty stem from the work of German political theorist Carl Schmitt, who as a constitutional adviser to both the Weimar Republic and then to the National Socialists, viewed sovereignty in Hobbesian terms in which its legitimacy in a constant state of conflict rested on securing order. Schmitt’s (1985/1922, 5) formulation that the “sovereign is he who decides on the state of exception” has engendered a conception of sovereignty that focuses on the exclusions that political authority rests and relies on. For political philosopher Giorgio Agamben (1998), who also contends that sovereign power is manifest in the production of the exception, in the figure of homo sacer, or sacred man, who represents the politicization of bare life, it is the sovereign’s control over the physical wellbeing and very life of its citizens/subjects that grants the sovereign supremacy over all other forms of political authority. Agamben cites the concentration camp as the exemplary space of exception that grants sovereign power its authority. The camp also points to the fundamental paradox of sovereignty, namely, that the sovereign exists both inside and outside of the law. Agamben’s exclusive emphasis on state sovereignty and bare life has generated important geographical analyses of the spaces of exception that include the Guantanamo Bay detention camp, refugee camps, and prisons.

Another theoretical strand of contemporary research on sovereignty is indebted to Michel Foucault’s concepts of biopolitics and biopower (2003). Like those of Agamben, these terms are meant to focus on the ways in which natural life becomes central to political power, although the emphasis here is on the regulation of bodies and the production of the subject through disciplinary power. Most significantly, Foucault has urged us to look beyond juridical conceptions of sovereignty, which, it is argued, have constrained understandings of how modern political power functions. The anachronistic Hobbesian figure of the sovereign towering over territory and representing a centralized form of power above and apart from its subjects obscures the ways that subjects are produced through a dispersed disciplinary power. Biopolitics and biopower have refined analyses of the intersection of sovereignty alongside other forms of political authority that produce new geographies of political control and contestation.

Research in geography has interrogated sovereignty from multiple perspectives, as a spatial practice of political authority, as a discourse that enables and legitimizes political control, and as a means for domination over others. What unites these diverse strands is the challenge to think through the concept of sovereignty rather than dismissing it as having eroded under conditions of globalization. While sovereignty
SOVEREIGNTY

does not operate in its ideal form as theorized in
traditional accounts as the centralization of polit-
ic power in the supreme authority of the state,
the concept remains crucial to understanding the
geographies of political power and the produc-
tion of territory, the nation-state, and citizenship.

The concept of space of exception has become particularly relevant in geography and the social sciences in the context of the “war on terror” launched by the Bush administration after the 9/11 terrorist attacks in New York and Washington, DC. The term is often used to describe an extraterritorial enclavic space in which the juridical order is intentionally suspended for a number of purposes, including the imprisonment of individuals via procedures dismissive of “the rule of law.” The academic literature adopting this concept has accordingly focused mainly on the most recent proliferation of camps, often described indeed as spaces of exception, and in particular on the paradigmatic case of the infamous Guantanamo Bay detention complex, located in an extraterritorial enclave in Cuba controlled by the US military, where suspected terrorists have been detained for years with essentially no legal protection and no formal arraignment. The US-led program of “extraordinary renditions” of suspected terrorists launched in the same period has also been sometimes defined as a globally connected archipelago of enclavic spaces of exception, based on detention centers located in a large number of countries around the world, not only kept largely secret in terms of their location and function, but also exempt from the effects of the ordinary legislation operative in those countries.

More broadly, the concept of space of exception is often recalled to qualify many diverse situations in which the “normal” juridical order is suspended (sometimes temporarily, sometimes permanently) in order to pursue specific military and police objectives (like indefinite detention, torture, and other unconventional treatment of detainees) beyond the rule of law, especially in reference to international legislation concerning prisoners and the respect of individual human rights.

While the arbitrary enforcement of exceptional rules to specific places and moments in time is certainly not new historically, the concept of space of exception discussed here may be understood as somehow the by-product of relatively recent academic debates focused on the parallel concept of state of exception. A key influence in these latter debates is that of Italian philosopher Giorgio Agamben, whose widely cited analysis of the principles of modern sovereignty is largely based on a critique of Carl Schmitt’s theory of sovereign exception. In his influential Political Theology, German conservative legal thinker Carl Schmitt (1998/1922) famously described the sovereign as “he who decides on the exception,” and who therefore has the capacity to determine, in case of emergency, the state of exception. While denouncing Schmitt’s affiliation with the Nazis, Agamben in both Homo Sacer (1998) and State of Exception (2005) draws on this definition to explain the workings of contemporary sovereign power via the regime of exception, in particular by making reference to Nazi biopolitics (and the Bush administration’s arbitrary approach to the rule of law after 9/11), but also, more generally, to the functioning of contemporary democratic societies.
modern totalitarianism can be defined as the establishment, by means of the state of exception, of a legal civil war that allows for the physical elimination not only of political adversaries but of entire categories of citizens who for some reason cannot be integrated into the political system. (Agamben 2005, 2)

Agamben’s work is particularly important for geography, since it shows how, to be implemented, the state of exception must happen somewhere and must be linked to specific spaces. These spaces, where the rule of law is suspended and where arbitrary power may be exercised on subjected individuals, are indeed described by many geographers as spaces of exception. Spaces of exception are often linked to the existence of broader geographies of exception, consisting of the networks and the overall relations of power that make these spaces of exception effective, and part of a specific set of political interventions normally justified by situations of emergency.

The concentration camp is often presented as a paradigmatic space of exception. Furthermore, a space of exception emerges every time sovereign power is enacted through legitimate exceptions to the “normal” rule, every time specific subjects are “banned” from ordinary legislation and the violence operated on them is exempt from sanction. In other words, a space of exception is created when, despite the existence of juridical order, a situation of perceived emergency strips an individual or a group of legal protection and, in some cases, even enables the killing of them without committing a crime. Agamben, again, has described this situation as one that reduces individuals to bare life (zoe), to biological bodies deprived of a political identity, and therefore entirely controlled by the sovereign power. The significant corpus of literature that has in different ways incorporated the notion of space of exception, including, among many others, the works of Butler (2006) and Mbembe (2003), suggests that the existence of spaces of exception is indeed fundamental to all biopolitical regimes, like the proliferation of camps and the realization of a greater geography of exception on the part of both the Nazis and Stalin’s Soviet Union have demonstrated.

In geography, the concept of space of exception has been initially popularized by Derek Gregory, especially in his works on Guantanamo and on the production of bare life in the global geographies of the war on terror, including the US interventions in Afghanistan and Iraq, but also the political situation in Palestine (Gregory 2004, 2006). Here Gregory explains that, while Agamben often refers to the state of exception as the space of exception, this spatiality must be understood as a performance, a doing, in order to show how the passages between “inside” and “outside,” law and violence, are effected. After these initial interventions, the concept of space of exception has then been used in geography not only for work on camps, prisons, and detention centers of all kinds, but also to describe special economic zones, borders, airports, refugee hospitality centers, and, more generally, all the sites where the suspension of the rule of law is enacted.

While Agamben goes as far as claiming that the camp has become the “paradigm” of our time, work in geography engaging with his theory of sovereign exception (sometimes even in critical terms) has attempted to link the contemporary geographies of exception to broader questions of geopolitics as well, showing how the creation of lawless spatialities has often become a strategic tool in waging war, or in managing the mobility of refugees or of individuals deprived of any juridical status (i.e., protection). Spaces of exception in fact sometimes also characterize the compounds offering temporary hospitality to illegal migrants landed on the northern Mediterranean coasts, or the detention
(centers) of individuals caught while transgressing the topographies of surveillance enforced along the United States–Mexico or Schengen borders.

Empirical work has illustrated how these spatialities of exception may operate on a permanent basis in cases like that of the Palestinian refugees hosted for decades in Lebanese camps, but may also emerge in sudden temporary spatiotemporal windows created by the ad hoc operations of CIA agents in countries such as Italy, where a local imam suspected of terrorist connections was kidnapped in Milan in 2003. Spaces of exception may be generated by the sudden intervention of the regular police as well, when conditions perceived as an emergency threat allow them to legally suspend the ordinary rule of law and, if deemed necessary, even to kill – as in the controversial episode that led to the death of a Brazilian electrician in the London Underground in July 2005, three weeks after London had suffered a series of lethal terrorist attacks directed at its transportation system.

Finally, much work has been preoccupied with the normalization of spaces of exception – like the Guantanamo detention complex – where the juridical order may be permanently suspended. The consolidation of countless spaces of exception around the world, together with the establishment of a broader US-led global geopolitics of exception in the post-9/11 age – the “drone war” patrolling and hitting “exceptional” targets being one case of the exceptional spatiality of war deserving particular attention – has therefore drawn lots of academic attention to this concept. This was also the response to much-needed new theorizations of power in order to understand the changing geo-biopolitical global conditions and the increasingly pervasive implementation of biometrical forms of control and policing intervention that affect our everyday lives, and in relation to which anyone can potentially be suddenly projected into a (spatial) regime of exception.

Space

Nigel Thrift
*Schwarzman Scholars, USA*

We live in a world that is fundamentally diverse, a world of endless complexity, with billions of human inhabitants, animals, plants, and objects. Such a world cannot be reduced to one or even a few things, and that is why geography exists. Geography doesn’t just document the diversity and richness of the world. It doesn’t just celebrate it. It is *about* difference and what that means. It is about the connections in each moment that lead to change. Because things exist in space and as space, they do not – indeed, they cannot – stay the same. They move. They spread. They stumble. They stutter. They fracture and they corrugate. They widen their contacts. They multiply discrepancies. They do all kinds of things that would be impossible if all that we looked at was time, a dimension which is often wrongly depicted as though it were somehow of greater significance than space.

And that world’s diversity and richness are stunning in both scale and extent. Take the total mass weight of living things on the planet – the weight of life itself. It is reckoned to be 1.7 trillion tonnes, excluding bacteria. The overwhelming majority of this quantity is plant life – probably about 99%. The total human mass is about 350 million tonnes. Cows add in another 520 million tonnes. There are about 4200 million tonnes of fish and 2700 million tonnes of ants. Then bacteria weigh in at nearly the same as all other living things put together, at about 1.3 trillion tonnes (D’Efillipo and Ball 2013).

Now, take in the fact that there are estimated to be somewhere between 5 and 100 million different species of plants and animals that currently exist (with most experts fixing on around 8–30 million), many of which still remain to be described and archived (Maro et al. 2011).

Now, put all of this biomass and all of these species together in a vast network of different locations where they are mixed together as different ecologies that require different kinds of interdependence, ecologies which are themselves vital actors since through them new pressures to adapt and new combinations of life can come into existence, not least because all of the evidence suggests that these ecologies evolve towards more and more complexity.

Now stir human beings into the mix. They have had an enormous impact on the Earth’s surface, as geographers have known for a long time. We live in what is now called the Anthropocene: a permanent alteration of the geological record resulting from the actions of human beings. Climate change is perhaps the most obvious example of that impact. Climate change has been written about in many ways but still perhaps the most extraordinary figure that can be mustered up is that our global civilization is powered by around 13 terawatts of human-made energy. To give some points of comparison: the flux of energy from the center of the Earth is about 40 terawatts; the primary production of the biosphere via photosynthesis is 130 terawatts; and the Earth receives 170 000 terawatts from the sun (Morton 2009). The point is that human beings already act as an energy source that begins to compare with the energy generated by plate tectonics. But human impact on the Earth has
been expressed in many other ways too. This entry will mention just two of them.

Most particularly, human beings make objects: buildings, tools, machines, and all manner of general bric-a-brac. By one estimate, an average human being will come across something like 20,000 different objects in their lifetime. These objects now inhabit the world with us – as part of us. Then, human beings move things around – and around. These include objects, of course, but also plants and animals. Plants and animals can mix quite well without our help. Indeed, recent scientific studies suggest that epic journeys by plants and animals – so-called long-distance dispersal – may well have been a norm of life and a key driver in evolution: plant seeds were carried in the plumage of ocean-going birds, frogs and mammals as large as monkeys were cast this way and that by driftwood and icebergs, tiny spiders drifted hither and thither on storm winds, and so on. These journeys may have been flukes but their consequences were not (de Queiroz 2014).

All that said, it is clear that human beings have redistributed a large part of the Earth’s flora and fauna, sometimes gradually, sometimes through ecological blitzkriegs. They have reassembled large parts of the biosphere in ways which challenge the whole idea of “native” species (Thompson 2014). Thus, the photosynthetic machines we call plants have regularly swapped countries and continents. For example, Britain only had 35 native tree species a few thousand years ago but many hundreds of others have now been added to the roster. Animals have been even more spatially promiscuous. Take the humble rat. The rat has traveled with human beings wherever they have journeyed on the Earth’s surface. Indeed, so numerous and well adapted to almost any conditions are these fellow travelers that they might well claim to be the main beneficiares of human evolution (Zalasiewicz 2009).

The Pacific rat (Rattus exulans) has traveled all around the Pacific but its travels have been as nothing compared with the Norway rat (Rattus norvegicus), actually from China originally, which has become common almost everywhere, and especially in large cities such as New York. Or take the starling, introduced to North America by a Bronx pharmacist intent on bringing to New York every bird mentioned in the works of Shakespeare and now the continent’s most numerous avian population. Or take that living fossil and geographical adventurer, the ubiquitous cockroach. The average New Yorker is most likely to encounter the German cockroach, which probably originated in Southeast Asia, while the “American” cockroach is actually a native of Africa, and so it goes on.

But it doesn’t end there. We still don’t know a lot of what is in the world. Though the first age of exploration of the Earth may have ceased, we are now engaged in a second round. But this one depends on exploring our own social and technical creations as well, creations that we have made but which are not entirely within our control, some of which, indeed, could produce Doomsday in one way or another. These creations only underline that things never just add up in this world: they combine and multiply. There isn’t anything (including us) that is just one thing. There are no essences, just passages, as Bashō says. A new age of contingent mapping beckons, a mapping of “us” where what we are is no longer either certain or restricted to what we used to regard as the human: the individual human body and “mind.” In a sense, we are all geographers now trying to make sense of fragmented and therefore partial spaces in which everything is a part of something else – while also trying to cope with all of the problems the planet needs to resolve. To paraphrase the philosopher Wittgenstein, we must build the
boat that is supposed to carry us while we are already swimming in the water.

And finally, there is no reason to think that we are it, that human beings are the end point. We might keep our grip forever and go on to conquer the universe, or we might be the equally temporary equivalent of the formerly ubiquitous but now extinguished North American passenger pigeon to which we bear quite a few similarities, not least the fact that we too have descended on the Earth like a plague of locusts. We might end up like a phantom limb, remembered still but lost from the body of history – and geography – like the elephants we are so busily and criminally slaughtering. After all, let’s just remember our place in the scheme of things: “take away humans and the present world will … function quite happily as it did two hundred thousand years ago. Take away worms and insects, and things would start seriously to fall apart. Take away bacteria … and the viruses and the world would die” (Zalasiewicz 2009, 192).

**Knowing where we are in space**

Maps are important to geographers because geographers tend to think about the world as terrain to be crossed. Space is hard work. It has to be traveled. It has to be journeyed. It has to be molded. It has to be experienced. It has to be gripped in some way, even if that is with the lightest of touches. History is littered with examples of expeditions getting lost in space and grand navigational blunders leading to nautical and aeronautical disasters. But we don’t need to opt for such grandiose instances of spatial delinquency. People still get lost, even now in a world where technology seems to offer a permanent locational crutch, while many people simply fail to return home from their journey. Even today, journeying remains a stressful proposition, one which is, in many parts of the world, time-consuming and, in many countries, a major cause of death. For example, about 1.2 million people die on the roads each year globally – they do not arrive at their destination – but certain countries are far more dangerous to travel in than others: whereas countries such as Great Britain have an annual death rate of 2.75 per 100,000 inhabitants, others, such as Venezuela, are up in the thirties.

One of the first things human beings needed to know is where they were and where they were going, and as people began to make longer and longer journeys, the problems of fixing location and wayfinding became correspondingly greater. There are a lot of ways of knowing where is where and many of these do not require all the paraphernalia we have come to regard as imperative for finding that out. In the past, sophisticated means of wayfinding existed without any recourse to the battery of devices we now regard as a normal part of everyday life. Take the example of the sea. People sailed long distances without charts or any but the most basic of instruments by means of simple but effective techniques such as sun and star sightings, as well as by learning the habits of wind and water. These skills could be found equally amongst Inuit or Polynesian or Norse or Medieval navigators, although their exact use varied. Such skills could be extraordinarily sophisticated and lead to the ability to travel long distances with relative accuracy. For example, many Pacific Islanders used the rising and setting stars and a mental system which allowed them to think of their boat as static and the world as moving relative to the boat, as well as other maritime information such as ocean swells caused by islands. But as navigation improved and became susceptible to measurement and calculation, so it became possible to take both the old and the newly discovered navigational knowledge and insert it into devices
and machines. A whole history of these almost forgotten devices and machines exists, remarkable in its diversity, devices and machines which peppered the historical record as navigators attempted to work out basic problems such as the position of the sun and stars, elapsed time and, of course, longitude: rudimentary compasses, logs, sandglasses, cross-staffs and back-staffs, quadrants and sextants, watches and chronometers, all now replaced in a bonfire of space by satellite navigation (Glennie and Thrift 2009).

Often, early nautical travelers possessed only the most rudimentary of maps, pictures of coastal features and, if they were lucky, a simple chart. But, of course, maps – a part of the world represented on a paper or other surface – have become the pre-eminent way of finding where we are. Determining when the first identifiable map was created depends in part on what is counted as a map. If we take wayfinding maps as the gold standard (in that, unlike many other early maps they are less easy to contest as recognizably maps) then the earliest surviving map showing roads and other pathways on either land or water seems to be a papyrus map from ancient Egypt dating from 1160 BCE (Akerman and Karrow 2007), although there are earlier examples of ancient nonwayfinding Babylonian maps on clay tablets dating from 7000 BCE which show parcels of land as well as evidence of surveying techniques. But maps proliferated as the demand for them increased (as a result of the needs of the state (and especially colonization), trade, and a host of more mundane everyday concerns), as mapping technology became more and more sophisticated, and as it became possible to mass produce maps. Now, of course, we are surrounded by maps. Indeed, it is possible to argue that we have reached an era of mapping which is as consequential in its way as the great age of mapping that followed the initial European exploration of the globe. Maps are becoming sewn into the very fabric of everyday life through their rejuvenation as geographical information systems which are becoming the locational underpinning to just about everything and, in turn, have become one of the chief means of cultural experimentation.

Sometimes the history of maps and mapping is downplayed. But that history is, of course, one of the great human conceptual achievements born out of successive mathematical and geometrical innovations which gradually locked the world into the semblance of a grid on which, at least in theory, everything could be located from outside its location. They provided a new “grammar of the gaze” (Jacob 2006, 6).

There is a standard history of the idea of “space,” which is often assumed to run alongside this cartographic history, in which a “Newtonian” world view develops, based on a grid of coordinates which “without relation to anything external, remains similar and immovable” (Newton, cited in Jammer 1954, 33). It is a notion subsequently championed, although only in part, by philosophers such as Kant, for whom absolute space was an a priori form that organizes our cognition – an “intuition” – and was not in itself cognitive or conceptual at all. But it is also a notion which made its way into science in the shape of classical mechanics and even religion as evidence of the divine.

One of the problems with this view of the world is that it can be made to suggest that the Earth is held in a rigid, contained frame. But, beginning in the eighteenth century, another way of thinking about space began to take hold which privileged relative space in which space is no more than the relative location of things, a network of places, so that when motion is ascribed to a body rather than to its reference point that is simply an arbitrary convenience. This was the view of the philosopher and mathematician Leibniz. It prefigured Einstein’s
invention of relativity theory, which, in turn, was borne out of urgent practical necessity: the practical spatial challenges of the late nineteenth century provided the essential background to his theoretical breakthrough (Galison 2003). One of the challenges that engaged the younger Einstein was the spatial and temporal complexity of Europe’s burgeoning rail network. Only a century previously, the continent had had hundreds of time zones, and no universal system for synchronizing them. Given that local time could therefore vary from town to town, scheduling rail services was hard but also vital – not least to stop trains from colliding. Synchronized clocks, set by telegraph, were vital to determine longitude and therefore provide precise coordinates.

In other words, the history of ideas about space and practical spatial concerns can rarely be divorced. Again, as this example of spatial measurement and timetabling shows only too well, geographers as varied in their approach as Torsten Hägerstrand and Doreen Massey have come to understand that space and time cannot be easily separated out. Space always has temporal extension and vice versa: neither dimension is privileged over the other since both depend on each other for their expression. In turn, four consequences have unfolded.

To begin with, we have come to realize that there is not really such a thing as “empty” space. Quite the reverse: space is chock full of stuff. We can think of this fullness in several ways. One is as all the things that are there but of which we have as yet no conception, just momentary glimpses, what Bruno Latour calls “dark matter.” Another is as a gathering of matter like the glial cells in the brain. These were first thought of as being a little like wallpaper – as a necessary but generally unimportant background to neurons – but now we know that glial cells are themselves important elements of how the brain functions. Then, we can think of this fullness as all manner of geographies we can sense but cannot yet fully grasp: for example, according to quantum theory, in the same moment, the same atomic particle can be in two places far apart. Finally, we can think of that fullness as being like the light that arises from distant galaxies, echoes of events long past which ghost everything that we do.

Then, we understand to a much greater degree than formerly large expanses of time and space which in previous eras would have been much more difficult to conceive of. Think, for example, of our ability to peer back into the early history of the universe via telescopes like the Hubble or the Square Kilometer Array. But it is not just large expanses of time and space that have become visible. We have also become able to see and operate in small moments in time, with the result that new spaces have opened up in this realm too. Many examples of this adage can be found. For example, international finance often operates in the realm of seconds and even microseconds. But, equally, we can track the way in which information and trends make their way around the world in seconds, as in the periodic global Twitter storms that can surround the doings of celebrities – storms that they have often whipped up – or events such as the outcome of soccer matches. In other words, human spatiality has both stepped up and stepped down a level.

Then again, the link between time and space has become more visible through movement. As transport and communications technology improve so new perceptions of movement become possible. In the latest iteration of this process of boosted journeying, it becomes possible to see each step in the chain of movement of people and things and to adjust that movement whilst in movement: this logistical thinking has now become commonplace. But smartphones and tablets, global positioning,
SPACE

instant geographical search, and the panoply of other technological advances we now regard as indispensable, have only existed for a very short time within the historical record. Only 30 years ago, people still set out in cities like London with an A to Z gazetteer or map, a street finder first produced in the 1930s which became indispensable for a series of generations, just like the Thomas Street Guides that were so familiar in Los Angeles and other cities of the United States. Even armed with a street finder, drivers and walkers still navigated with considerable degrees of uncertainty, often roaming up and down streets searching for the right turn-off and then the right house number – and they couldn’t call anyone to find out if they were on track until the widespread adoption of handheld mobile phones (invented in 1973) in the 1990s. Equally, drivers couldn’t use anything like satellite navigation in their cars until the widespread adoption of these devices in the late 1990s and early 2000s, and walkers couldn’t use simple smartphone apps like Google Maps until the mid-2000s.

There are still relics of the old way of proceeding, even in the most technologically enabled cities. For example, in London, the black cab or taxi (from taximeter, the machine invented in 1891 that measured the distance and time to make a journey) drivers have to take “the Knowledge,” a test, first introduced in 1851, of their ability to find their way around the city without anything like a global positioning system (GPS). Not surprisingly, it usually takes two to four years to pass muster. To become an all-London taxi driver – a Green Badge holder – you need to master no fewer than 320 basic routes, all of the 25,000 streets that are scattered within the basic routes, and approximately 20,000 landmarks and places of public interest that are located within a 6-mile radius of Charing Cross. This is where the famous Blue Book is required, a handbook for budding taxi drivers which contains all of these routes and landmarks. Now there is pressure from GPS systems and apps like Uber and Hailo to automate this process of learning geography. In other words, London taxi drivers could go the way of other craft workers. Or maybe not: London’s traffic geography changes so often that ideal routes can switch in the blink of an eye and automated systems still find that recalibration hard to achieve.

Finally, the question of where we are in space and time has also expanded as aerial views have become a norm. Being able to see over a space is not a natural right: it had to be constructed. For a long time, that meant high vistas, towers, and the like. Even when the idea of a bird’s-eye view became engrained, it was not always easy to portray particular features such as the Grand Canyon. Then, along came balloons. A number of geographers have considered the early history of ballooning, precisely because it was the first time that aerial views became commonplace: as early as the French revolutionary era, for example, a group of “aérostiers” was established whose task it was to sketch the contours of a battlefield and communicate them to officers on the ground (Adey, Whitehead, and Williams 2013; McCormack 2014). Subsequently, the spread of aviation and the aerial photograph cemented the view from above – the view from falling up instead of down – as a normal way of seeing space. Now people all around the world think of the view from an aircraft window as somehow natural and rarely remember the assorted cloudscapes that they traverse. One of the most privileged moments the author can remember was flying into London on November 5 at a time when, by ancient custom, bonfires are lit and fireworks are set off. Another was flying past London when the cloud base was very low and seeing the taller buildings in London sticking up out of the cloud like jagged teeth.
But, at the same time as revealing this other often joyous way of seeing, it is likely that the view from above also prompted a greater emphasis on abstract spatial form, on diagrams of the world to which the world should conform, which has been responsible for some of the worst excesses of “top-down” state planning (Haffner 2013).

But, in the 1960s, another view from above became possible as photographs of the globe taken from space began to circulate, and specifically the Apollo 11 photographs of 1968 of a “spaceship” Earth hanging in the sky as taken from the moon (Cosgrove 2003). This view undoubtedly helped to stimulate a rise in ecological thinking about the fragility (and beauty) of our habitat. But now yet another view of the planet from above has become the norm: urban networks depicted at night as a weave of artificial light. Significantly, this latter-day view is constructed more as an assertion of a kind of erstwhile human supremacy: these networks of light are our new pyramids supposedly marking our supremacy across all of the Earth.

Knowing space

However precise and sophisticated our tools for mapping may be and however lofty the vantage point we are able to build, surveying where we are isn’t the same as knowing all there is to know about space, although you might think so from a lot of what you read. When we live in and encounter space, we are doing more than tracking its contours. It is what we are. It is the fiber of our being. It is both the folly and the grandeur of our nature. We are internal to it. All animals, including human beings, have particular dispositions towards space that are a part of what their bodies are. A nineteenth-century ecologist, Jakob von Uexküll, described the way in which animals live in different but intersecting life-worlds, a series of “Umwelten.” So a bee might only fix on just a few cues which go to make up its visual field – bright flowers, the sun, and so on – which are registered in relatively fixed corridors. A snowy owl has a quite different spatial footprint and correspondingly different spatial cues – wintering snowy owls spend 98% of their time sitting still during the day and probably do most of their hunting after dark using their extraordinarily acute sight and hearing; and they tend to roam extensively when they hunt (Strycker 2014). A human being might fix on many more but often markedly different spatial cues, not all of which are as discriminating as those of the bee or the owl. In other words, living beings see very different things or they see the same things very differently.

Human beings aren’t so different from animals, then, in that their spaces of existence reveal things selectively. At one level, our spatial disposition follows from the immense debt we owe to sensation in how we move and thereby think: we rely on all manner of physical forms of intelligence to make judgments, most of which exist at the interface between our bodies and the animated spaces within which we live. We touch things that manifest different temperatures and textures; we smell different odors; we see all kinds of colors; we lift or push against objects and so sense their weight and force, and so on. In turn, these simple sensations produce all kinds of unconscious effects up to and including moral judgments (Lobel 2014). At another level of spatial disposition, philosophers such as Heidegger concentrated their attention on how the world shows up — makes itself present — to us. Heidegger argued that we ordinarily encounter entities like tools as being for certain kinds of practices (hammering, cooking, writing, and so on). He asserted that we achieve our relationship with the world around us not through looking at
an entity such as the hammer, or through some
detached theoretical study of it, but rather by
becoming involved with and skillfully manipu-
latin it. In turn, this engaged, “ready-to-hand”
way that the world shows up to us means that we
do not have a straightforward spatial relation to
it of the kind that might be found using a GPS
device. We “dwell” in it in the same sense that
to dwell in a house is not merely to be located
inside it but to exist, or to belong, in a familiar
place. At one other level, spatial disposition
follows from the “atmosphere” with which
we surround ourselves, a bubble of attentive
involvement – of “inhabited orbs” (Sloterdijk
2013, 11) – in which life, thinking, and the
formation of these “spheres” amount to the
same thing. Living means building spheres, and
these spheres, made up of a scaffolding of bodies,
things, and signs, form an innate geometry of
knowing where and therefore what you are
which is both internal and external. In other
words, “we are in an outside that carries inner
worlds” (Sloterdijk 2013, 27): the scratches and
 scrapes of experience which make up what we
regard as our inner life are made by the way we
construct that outside.

The experience of space is a quality that we
all think we know well but it is one that remains
very difficult to describe. It is no surprise that
geographers have spent so much time trying to
do precisely that, usually by linking it to the
body and the web of practices within which
the body exists. This kind of space can never
be reduced to an aesthetic quality or simple
utility, though it might have such dimensions.
It is not so much observed as felt in the interac-
tion of body and landscape. Practices of living,
inhabiting, and thinking all have to take place
 somewhere, whether that somewhere is close
and snug or abstract and exposed, in a relation of
connectedness, and the notion of place provides
an orientation to thinking precisely what that
connectedness might be. Philosophers such as
Heidegger and Sloterdijk have often argued that
the problem of modern life is precisely that place
 is being reduced to an aesthetic or a utilitarian
dimension, so blocking out a certain kind of
freedom to be in place and of place. Whether
this sense of loss, apparently caused by the can-
nula of “modernity” draining color out of the
world, is a valid one or not, the fact remains
that this feeling has been a staple of Western
cultures, echoing down from the time when
the opposition between “culture” and “nature”
became established and nature somehow seemed
to move offshore. The sensuous character of life
was displaced.

What is clear is that the bodily experience
of space – the different sensations it engenders,
the different complexities it lends to life, the
different ways that it folds into how life and
its practices show up, its different character, if
you like – has varied through time. (Although I
suspect that some experiences are held in com-
mon, such as the aching void left in space when
someone close to us dies.) Let’s take just one
obvious example: different bodily experiences
of space in Ancient Greece and Rome. It is
a particularly appropriate example given that
Homer is often regarded as the founding father
of geography, while Greek geographical knowl-
dge is often thought to underlay the Roman
Empire, as evidenced by Strabo’s Geography. Just
as the Ancient Greeks and Romans had different
words for different colors than us, so they had
different means of apprehending space. So there
is no word in Ancient Greek that simply and
unproblematically maps onto what we now
think of as space, and there is a considerable
debate about how accurate Greek maps were.
Meanwhile, the Roman “spatium” meant stretch
or extent and again it is not equivalent to what
we think of as space. Equally, Greek and Roman
cities and sacred sites were run on different spatial principles, which provoked different bodily experiences of the world. Until recently, such insights have been difficult to articulate because of the tendency for archaeological excavation reports to be split by function, thus making it problematic to trace the linkages that produce that holistic sense of space. But now we have begun to see the range of spatial experience that was apparent in those times (Scott 2013); for example, towns and cities in the Roman Empire tended to use the template of Rome while Greek towns and cities were much more varied in style. The Greek agora was genuinely meant to be an open space (at least for certain classes of persons), whereas Roman public spaces were much more ordered in terms of which and what activities were allowed. Greek understanding of geography tended to be based on world maps, whereas the Roman understanding of geography was modeled on itineraries, and so on.

In other words, we need to be careful. As this brief excursion into the historical record shows, there is no reason to think that the world turns up the same for all people. The bodily experience of space varies on all kinds of dimensions, which are both physical and cultural, as numerous studies of gender and ethnicity have shown only too well. But such experiences can vary even more fundamentally. Take the case of those cultures that are often described as having an “animist” outlook – that is, cultures that ascribe nonhumans like animals and plants an interiority identical to their own. “We are a long way from the reassuring world of Being and existing beings, of primary and secondary qualities, of perennial archetypes and of knowledge as revelation. For all those weary of an overuniform world, that realization is surely a cause for a measure of rejoicing” (Descola 2013, 143). In animist cultures, animals and plants are “humans in disguise.” They are persons sometimes thought of as having their own cultures. Humans and nonhumans differ by virtue of the form of their bodies but the substance of their souls is counted as similar. So, for example, animals might be thought of as essentially human but they have been transformed into animal forms by means of the outward clothing of their skin. Or all beings are thought to be made from the same substances. The result is that human beings are joined by all manner of other humans – but humans who do not present a human appearance. The myths of animist people nearly always remember a time when humans and nonhumans were not differentiated, and shared “Umwelten.”

Then there is “totemism.” In this scheme of things, each person belongs to a group that bears the name of, and is linked to, a natural object such as an animal or a plant or an artefact, or even a natural phenomenon such as a river, that is associated with a set of moral, physical, and behavioral attributes, a living expression of certain qualities that transcend their own existence, rather than an individuality, with which it is possible to maintain a personal relationship (as in animism). Here we can see another notion of space entirely. The classical example is provided by the indigenous Australian “dreamtime,” a single word used to sum up many different kinds of experience. In this experience of experience, primeval beings emerged from the depths of the Earth from specific sites. Some embarked on journeys that left their marks on the landscape and behind them they strew many of the existing beings of today, all manner of humans, plants, and animals, each with its respective totemic affiliations. These primeval beings might be human in terms of their behavior, language, and social codes, but they also have the attributes of plants or animals and they are the origin of stocks of spirits laid down at the sites where they themselves disappeared. “Dreaming” isn’t just
ancient history, for when the beings departed they left a legacy of spirits, routes, and rituals that continue to affirm their presence in the present. The paths continue to thread their way through the landscape, rather like the maps of underground and subway systems with which we are now so familiar, and indigenous Australian peregrinations continually reaffirm them. They express a living relationship with the land, with “country,” understood as an animate entity: “The country may be mother or grandfather, which grows them up and is grown up by them. These kinship terms impose mutual responsibilities of caring and keeping upon the land and people.... For many indigenous Australians, person and place, or ‘country’ are virtually interchangeable” (Arthur, cited in Nicholls 2014, 4). Indeed, such cultural differences as these mean that different human beings may experience the basics of space quite differently. These differences, both biological and cultural in nature, can be quite extreme. Work in cognitive anthropology shows just how extreme. For example, the work of Steven Levinson (2003) on certain indigenous Australian and Mexican groups shows that, because they tend to use absolute rather than relative frames of reference, not only do they have very good senses of direction – they are able to point the right direction to a place without demur and past events are directionally anchored in great detail – but they genuinely perceive cardinals such as up and down and left and right in very different ways.

Western cultures often think of technology as the primary determinant of spatial perception. That is important, of course. When new technology of various kinds arrives, space can be perceived in ways that were not possible before. We have noted the case of maps and measurement, but there are many other examples of how technology changes spatial perception. Take the faculty of vision. The invention of spectacles is an obvious but often overlooked example. The invention of oil paints, crucial to the invention of impressionism, is another. A further example is provided by artificial lighting. Night time is no longer another country, dark and forbidding. Thanks to reliable and constant artificial illumination produced by large industrial power networks the space that we might inhabit, the “sphere” to use Sloterdijk’s term, has expanded its orbit. The process began in Britain, which became a gas-lit society when the first public street, Pall Mall in London, was lit with gas in 1807. Electric lighting arrived in 1878 but did not find its way into homes on a large scale until after World War I. Artificial light has now spread all over the world, producing new apprehensions of how and what can be seen (Otter 2008). But we should not overestimate this process of enlightenment: for many people in the world the dark is still dark. For example, in India in 2012, the largest electrical blackout in human history left 600 million people without power and therefore without light. But discussing the blackout, the economist Amartya Sen wryly noted that the media had neglected an important fact: “Two hundred million of those 600 million people never had any power at all.”

But our apprehension of space is not just about simple advances in technology. It also follows from accompanying shifts in how people perceive the world, each of which has a spatial dimension – what is considered to be inside or outside, what is considered to be public and private, what is considered to be full or empty, what is considered to be a whole or a part, what is considered to be general or particular, what is considered to be different or the same, what is considered to be near or far, what is considered to be small or large, what is considered to be center or periphery, what is considered to be where or nowhere, what is considered to be separate or juxtaposed, what is considered to
be still or moving. These shifts, which can be
domestic or global in scale, produce new spatial
orders, new placings, new spatial signposts. But
dimension is perhaps too weak a term. What is
meant is what is meant by life: the way things
are. These shifts can be very general cultural
currents, such as that European complex of arts,
sculpture, and building that became known as
the Renaissance. They can be artistic move-
ments such as Impressionism or Cubism. But
sometimes they stem from just a few small points
of change that become general.

A good example is provided by Pablo Picasso
(Clark 2013). Picasso pushed at the bounds of
space all through his career. He tried to identify
new ways of thinking about inside and outside,
which acknowledged the domestic interior that
had become a key feature of the inner and outer
of European bourgeois life and its representa-
tions in paintings, and increasingly challenged its
ascendancy. Thus, he tried to identify new organs
that linked bodies in different ways, both inside
and outside conventions of what counted as a
room. For example, he conjured up ways of mak-
ing sexuality surprising, unfamiliar – even fright-
ening – by draping bodies over and around spaces
so that intimate interiors could become loud
exteriors. In his later career, he also tried to ques-
tion what we mean by objects by constantly buf-
feting the common notions of proximity so as to
produce new “inhuman” mixtures. For example,
he disrupted the pure lines through which space
could flow unobstructed, the certainties of
geometry that allow us to place and contrast our-
selves and to adhere, and the pressure of surfaces
and boundaries produced by the containerized
nature of so much representation of room. In
doing so, Picasso operated on what might be
regarded as the “truth” of space, trying to paint
or sculpt what “really” existed. He provided
new kinds of reaching out, new kinds of limits,
new means of looking back, new animations
that have allowed us to produce a new visual
vocabulary of space: in other words, he produced
a new cultural “floor” to spatial perception.

The new geology: exploring the space
of the Anthropocene

Our technological and cultural perception of
locating and knowing space is changing, then,
as we lay down layer upon layer of infrastructure.
The world is threaded with roads and cables,
undergirded by pipes and tunnels, saturated by
wireless signals, loaded down with all kinds of
built infrastructure, and heated up by all manner
of energy sources. It is crisscrossed by airline
routes, lit up by the innumerable street and
other lights mentioned above, and shaken by all
manner of artificial sounds.

Geography was often thought to be an offshoot
of geology. But the question arises as to what
happens when human beings begin to change
the planet to such a degree that they start to
create their own geological epoch by building
one vast ants’ nest which extends both down into
the ground and up into the air. We might see
human beings as creating a new space, one with
its own atmosphere, its own dynamics – and
its own problems. This new era is creating a
distinct geology. When an alien explorer looks
back at the Earth from millions of years in the
future, she or he or it will be able to discern a
whole stratum based on the detritus of human
habitation, not just buildings but all manner of
objects and even clothes – which could well be
interpreted as external coverings periodically
discarded as they grow too tight to fit a growing
organism. Although human cities may not yet
be as impressive as biological cities, such as
coral reef, in their scale and longevity, or the
nesting sites of the now extinct passenger pigeon
mentioned earlier, each host of pigeons weighing
down the trees in their millions and covering a space as large as Manhattan (Strycker 2014), still humanity is catching up fast (Zalasiewicz 2009). Furthermore, human cities are giving rise to exactly the same spatial promiscuity with regard to minerals and metals as has already been noted with flora and fauna.

The geological record will also show other marks and, most particularly, climate change and mass extinctions. Humans have undoubtedly begun to change the chemical composition of the atmosphere. At the same time, humans are producing a mass extinction, on the same scale as the catastrophic extinctions caused by asteroid impacts, as they wipe out species directly or simply leave them marooned and so condemned to fade away. “It is estimated that one-third of all reef-building corals, a third of all freshwater mollusks, a third of sharks and rays, a quarter of all mammals, a fifth of all reptiles, and a sixth of all birds are headed toward oblivion” (Kolbert 2014, 17).

Then how we experience space begins to be mediated to the second or third degree by infrastructure. Take the case of sound. In the past, the soundscapes of cities left room for sounds emanating from natural sources. Church bells might produce a periodic cacophony, the noise of horse-drawn traffic might create a low roar at certain times of the day, and various shouts and bursts of music interspersed the daily round. But there were periods of quiet and many acoustic spaces in which sound still consisted of the wind and birdsong (Glennie and Thrift 2009). Now, things are very different. Places where the only sound is natural sound are few and far between— a British professor of acoustic engineering tried to map them. In the United Kingdom, you have to go far into a remote Northumbrian bog to find the quietest place. Cities are chock full of noises that form their own associative landscapes intensifying and fading as we move around—from the sound of aircraft overhead through the hum and honking of traffic to the snatches of music and conversation, each with its own arc (Gandy and Nilsen 2014). Meanwhile, the world has become so beset by noise that great tits are forced to sing faster and higher in the urban din, and robins have taken to singing at night when it is quieter. Shipping noise disturbs the breeding of whales and dolphins: whales are having to sing louder and louder—and in some cases have given up entirely (Cox 2013). Equally, there are radio quiet zones around a few large radio telescopes to prevent interference from radio waves. The main reason why we can’t get away from all this noise is infrastructure.

Infrastructure consists of all of those objects that allow human beings, cars and trucks, water, electricity, radio signals, information, and the like to flow from one place to another, to become mobile, to circulate. Mainly they consist of continuous conduits of one form or another but, increasingly, as wireless has become more common, these conduits have broadened out into signals transmitted from and received by masts, although the principle remains much the same.

The point is that the Earth’s surface has become an anthropic stratum hundreds of kilometers high and at least 3 km low that is a bit like a Swiss cheese in its makeup, a stratum through which pipes and cables crawl, under which tunnels and boreholes and mineshafts bore down into the Earth, on which all kinds of reservoirs and power sources hold sway, and over which airplanes and satellites and wireless signals fly back and forth.

So generic is this infrastructure that we take it for granted, at least until it goes wrong; think of the burst water main or the power cable brought down by an ice storm. Equally, we forget that it has its own history. We have already touched
upon systems of lighting with their pipes and cables. But take another example, this time from transport infrastructure: the humble elevator upon which tall buildings rely for sustenance. Although records of elevator design date back to Roman times, elevators (or “ascending rooms”) were first commonly used in the nineteenth century when hydraulic, steam, and electric power were all used as sources of lift. In 1852, Elisha Otis introduced the first safety elevator, which prevented the cab from falling if the cable suspending it broke. The first such passenger elevator was installed in 1857 in a building that still stands in the SoHo neighborhood of Manhattan. The first office building to have passenger elevators, the Equitable Life Building, was completed, again in New York City, in 1870, and prefigured the growth of the late-nineteenth-century commercial “skyscraper” (a term first used then) and the consequent transformation of the skyline of many cities. The adoption of elevators had many consequences, apart from creating recognizable “downtowns.” For example, before the use of elevators, most residential buildings were limited in height to about seven stories. The wealthy lived on the lower floors, while the poorer residents lived on the higher floors, and were thus required to climb many flights of stairs. As exemplified by the modern penthouse, the elevator reversed this stratification (Bernard 2014). Now, as buildings have become ever taller (with a tower 1 km high planned in Saudi Arabia), so elevators have become increasingly complex. Of course, they need to be faster (with speeds of up to 18 m/s) but they also need to include sky lobbies where passengers can change lifts to reach higher floors, and means of increasing capacity such as double-decker lifts or multiple cabins in the same lift shaft.

So ubiquitous is infrastructure such as elevators – New York has at least 64,000 according to the city’s buildings department – that this infrastructure has become an accepted feature of the landscape: airports, railway stations, service stations – and elevators – have all become stock scenes of human conduct, places where we expect certain classes of drama – meetings and farewells, temporary sojourns where it is possible to eat or refuel, places to gather and disperse, uneasy encounters and serendipitous meetings – to play out against a background that is made as predictable as it can be, from the identical architecture to the uniforms. A French anthropologist, Marc Augé (2009), once called them “non-places” but as a description that is very far off the mark. Rather, they are “by-places,” which depend on the journeys of people and things for and as their existence.

Transport infrastructure has all kinds of other effects. Most particularly, in allowing people to move, it allows all kinds of communities to spread out across the world. All of the diasporas that have arisen from population movement are striking in their extent. In large part, the history of countries such as Australia and the United States is the history of wave upon wave of diasporic communities. Migration has been a constant condition of human history but it has picked up in pace and volume since the nineteenth century as movement has become easier and less hazardous. All kinds of discontinuous diasporic spaces have been created, many based on simple economic incentive but some the result of concerted state and state-related action such as ethnic cleansing (Osterhammel 2014). But movement is also born out of other imperatives – such as tourism, religious observance (consider the hajj), and all manner of other motives.

Governing space

In most societies around the world we have come to believe that space can be governed or owned.
We have come to believe that space should bear our indelible mark, the mark of “territory” (Elden 2013). We do not belong to places, as the indigenous Australian thinks. No, they belong to us. We contain them rather than they contain us. The question arises as to why and how this container style of thinking, with all of its physical accoutrements, from fortresses to barbed wire, from passports to border posts, from fences to electronic surveillance, has come about, and how we have arrived at a world in which spaces are able to be stabilized sufficiently that when we draw lines around them, the lines not only stick but become important icons in their own right.

The answer is multiple, but one undoubted answer is through the gradual growth of the modern state. We should not exaggerate the powers of the state, of course, whether they consist of organized violence or bureaucratic practices or legal codes or shared norms or ideologies. Indeed, it could be argued that in many countries states didn’t do as much as has often been argued until relatively recently in the historical record and in large parts of the world they still don’t. Other structures, such as organized religion, have been powerful and have continued to exert heft. Part of the reason for this exaggeration of states’ powers (for example, the idea that states create one type of agent) comes from the tendency to portray states as unitary authorities bringing one space under the sway of one will, but that is an illusion. The production of state action is distributed among many authors and material artefacts in acts of collective governance that are always spread across many different types of space, each responding differently even as they add up to something greater than the sum of the parts. Even when the state is engaged in the greatest of great projects, which look as if they are all central diktat and have no local room for maneuver, whether they be the Pyramids or the Three Gorges Dam, the expertise needed to produce the project is never to be found only at the “center,” whether that center is a temple or an anonymous set of offices. It depends greatly upon the skills of the artisans and workers who are there on site. Indeed, without this initiative from below, not much will happen, and the conjuring act is to allow input from below while ensuring that power and direction remain at the upper levels. Much of the bureaucratic weight of empires and other state forms relies on getting this balancing act right through devices such as addresses, which exactly locate a destination, files and paperwork more generally, manuals, offices (with their double meaning) and waiting rooms, examinations, general notions of conduct and habit, and even styles of communication (from the flowery language of the courtier to the “plain” prose style of the civil servant), each of which shapes people and space to the state’s will by manipulating the efforts needed to access and exert power. Connecting and governing are two sides of the same coin (Joyce 2013).

Equally, that weight depends upon producing a space in which the state seems to be a constant companion. Ordering and governing space depends upon naming places, localities, topographical features, regions, and larger areas too, such as various kinds of world region. It depends upon delineating borders. It depends upon producing uniform and continuous spaces through the use of standardized units of measurement. So the whole profession of geography as it appeared in the nineteenth century, with its own research methods, terminology, career paths, academic departments, textbooks, and journals, depended upon a practice of exploration that was in part precisely concerned with what could often be the simultaneous location and naming of places, a kind of “worlding,” establishing new borders or asserting old ones and producing quotidian spaces of reckoning. In Britain, for example, what had been the practice of military
mapping of Scotland and then England gradually turned into a more general national mapping agency, the Ordnance Survey, founded in 1791 although called by this name in print only from 1810 (Hewitt 2010). In turn, its cartographic practices moved out into parts of the British Empire such as India. But, ironically perhaps, practices that were conceived with military means in mind were subsequently appropriated for civilian purposes, not least tourism and hiking, which are associated with freedom of movement rather than binding state grids. A similar process happened in countries such as the United States where state mapping began as a means of inventorying the rapid expansion of the nation, usually via a characteristic grid form, but became something less utilitarian as time went by.

All of this state activity had to be held together by practices of connection and, just as importantly, nonconnection such as secrecy: secrecy is a key feature of state power. States need to keep things out of sight (Galison 2003; Paglen 2010), and that means walling off spaces from public view or only allowing unequal access. This practice may be at odds with modern views of citizenship, which rest upon the idea of greater mutual visibility between state and citizens, but the fact remains that modern states keep a good deal secret, just as the states of yore did with their invisible ink and strings of secret intelligencers, tightly guarded documents, and the pouches of diplomatic couriers. The intricate patchwork of secret spaces expanded mightily in World War II and now includes defense facilities, many government buildings, and bunkers. It also includes unequal knowledge of individual citizens of the sort that is promoted by the apparatuses of files, constant electronic surveillance, and finally, the actual removal of knowledge from public view as promoted by the practice of classification. The net result can sometimes seem baroque: currently, around 4 million people hold some measure of clearance to view classified documents in the United States and 33 million documents were newly classified in 2001 – a figure which has almost certainly increased since then (Galison 2003).

Of course, different states hold such geographies of connection and nonconnection together differently. To begin with, just look at the evidence of maps. They often loudly declare not just that this is “my space” but also that a particular space is central – and other spaces are not. Over a long period of time, imperial era Chinese maps have been the perfect example of this statement (Hostetler 2001; Smith 2013). Imperial era Chinese maps tended to look and feel quite different from Western maps in that they were not gridded and devoted much more space to written text, given that in China written words counted above visual images in terms of the weight given to their representational authority. In these maps, China is always the pivot, and other lands are gathered around at a much smaller scale as a fringe of tributary relationships. When the Jesuits produced maps of China and the world from their perspective, they were attacked for dislodging the “Central Kingdom” from its rightful position at the center of things. Equally, the incentive to seek out knowledge of such foreign spaces seems to have been marginal since China was so clearly the important space. Thus, “Chinese mapmakers understood the utility and appeal of accurate measurement, and their colleagues in astronomy developed sophisticated instruments that made possible the projections and coordinate systems that Westerners associate with Ptolemaic cartography. But throughout most of the imperial era, they found no compelling reason to conceive of the world as spherical, nor did they see any merit in drawing all maps ‘to scale’” (Smith 2013, 87). China was where it was at.
This example may be an extreme case of the state’s spatial narcissism but it is hardly unusual. Wars, legal cases, and boundary disputes are all fought as though only some can have rights to a piece of space and others should be excluded—or even deleted from existence so that they can never make claims on the state again. So it is that between 1776 and the present the United States could seize about 1.5 billion acres from North America’s indigenous peoples, an area 25 times the size of the United Kingdom, with a consequential decline in the population of indigenous peoples. It is worth remembering that as late as 1750 these peoples had still constituted a majority of the North American population.

But it is important to understand that we live at what is probably the high water mark of a particular kind of state, the nation-state, a spatial form that can be dated to the Treaty of Westphalia of 1648, which both formalized and then normalized this particular kind of political geography, although it did not set it in train, as some would have it. But today political geography is driven by all manner of exceptions to the idea of a set of contiguous nation states legitimated by legal sovereignty over “their” space and by constitutions that abjure any other way of thinking, and which are able to claim the right to indulge in armed conflict with one another as a result. Indeed, this form is, if anything, becoming defined by the host of exceptions to it: all of the other institutional bodies whose spaces do not coincide. These spaces are legion and include those of the numerous international and subnational bodies, global cities such as London, New York, and Shanghai, various ecological enclaves, diasporic communities, global brands, special economic zones, massive computational networks that share files with abandon, logistical networks, the footprints of satellite surveillance, criminal networks and clans, financial markets with their server farms and special offshore domains, and goodness knows what else. This tendency has only been accelerated by the multiple networks of information technology, which allow all kinds of new addresses to come into being: land, then sea, then air, and now—cloud. The difference is that we have built this composite space of address and its forms of participation, via server farms and data centers, millions of miles of cable, the wireless frequency spectrum, and, by 2020, an estimated 1.9 terawatts of power (placing the cloud, if it were a nation-state, as the fifth largest consumer of electricity in the world). With it we have formed a world in which not only can we communicate but so can things, and not just with us but with each other, so heralding what might become a post-Anthropocene (Bratton 2014).

Perhaps we shouldn’t be too surprised by the increasing diversity of institutional spaces. Before the seventeenth century, millions of acres weren’t strictly owned by any one person or institution. Rather, they were subject to a patchwork of rights. Through history, people have held “rights of common” to carry out activities (to pasture animals, to fish, to take wood for fuel, to take sand and gravel, and so on) in and on particular pieces of space. Originally, these spaces were appurtenances to other privately held space but, over time, they have come to be understood as “public,” a word which has its own geographical history. Thus, the idea of a common was exported by the Puritans to North America: famous examples include New Haven Green in New Haven, Connecticut (the Puritans were said to have designed the green so that it was a large enough space to hold the number of people who they believed would be spared after the Second Coming of Christ: exactly 144,000), Cambridge Common, and Boston Common, all of which were converted into parks.

But the idea of ownership is not just the preserve of the state, as the examples of many spaces
held in common make clear. It also comes from the notion of an economy, in which the practices of exchange have become the be-all and end-all. Like the state, the economy, especially the global capitalist economy, isn’t a natural construction. It has arisen over many centuries from interactions that have become increasingly regularized by a network of practices, specialist laws, and regulations, by brute enforcement by empires, by colonial adventures, and now, by large multinational corporations that can span the world and create their own owned spaces, both in and out of any one state jurisdiction.

Trading space

If we turn to the economy, then, there is another way in which space has become objectified – as a traded commodity available for exchange, as “land” that can be “owned” and then “valued.” It is an obsession that is deeply rooted in history – some of the first known maps are probably records of land ownership – and has produced for millennia an uneasy equilibrium between those who believe in common land and those who believe in privately owned land. At least part of that debate comes from what seems to be a very human need to close off access, so as to make space “mine” and give it secure title (Linklater 2014). Notice the quotation marks around the words “land” and “owned” though: in these days people very often assume that one must mean the other, but there are still many instances of land that is owned in common or in trust and therefore cannot be trespassed upon. Thus, it has been estimated that nearly 15% of the Earth’s surface has been preserved for conservation in areas such as National Parks. In some countries – such as Scotland, for example – there are universal access rights to most land and inland water (although there are exceptions) and there are still common grazing rights in a number of areas of England such as the Lake District. But it is also clear that the majority of land and what is distributed over it is privately owned in some way and has an explicit economic value, especially if it is thought that the Earth has now effectively been domesticated for human use by the economy, and that “wild” nature is no more and can be replaced by human-designed ecosystems. The planet’s main purpose is to be friendly to humans by accumulating wealth through trade in commodities, including land, so that humans can be, well, more wealthy.

Everyone talks rather glibly about this process of trade and commodification as a “world economy,” but such an entity exists as a definite object only in the imagination and in theoretical texts: what actually exists are numerous overlapping spatial networks of people and things set up to allow predictable exchanges to take place on a continuous basis (Thrift et al. 2014), exchanges of consumer goods, money, and remittances, and pleasurable tourist experiences certainly, but also of slaves and trafficked women, international criminals and drug runners, and all manner of pollution.

These networks are vast historical accretions. Take the case of the seas. Nowadays trade has become a maritime infrastructure in its own right, an infrastructure dependent upon a forest of rules and regulations that range from the international law of the sea to the humblest health and safety inspections and regulations. Then there are 100 000 freighters on the seas at any one time carrying nearly everything we eat, wear, and work with, crewed by an itinerant population numbering in the hundreds of thousands (George 2013). Then there are the ports, full of specialized equipment ready to load and unload the containers, which are the basic grammar of maritime trade (Levinson 2006). Then, of course, there
is all the trade carried out by road, rail, and air, which cannot be mentioned in any detail here.

But this over-the-seas world of trade has not just magicked itself into existence. It has come about as a result of definite historical processes. To govern spaces such as the sea means being able to define, measure, recognize, and enforce boundaries and thus control movement by means such as cartographic, population, and navigational data, understood as tools and not just as a representation of power. To understand this trading space, we can return to the map – after all, the power of the map is its ability to qualify movement – and specifically to the famous Selden map of China, bequeathed to the Bodleian Library in Oxford in 1654 by an English lawyer, John Selden (Brook 2013; Batchelor 2014). For etched into the history of this unique 16 2/3-square-feet map of China we can also find the classic signifiers of bounded territory – the nation-state, the rule of law, and the corporation – and the consequent enhanced ability to control movement. At the time Selden owned the map, the British state was experimenting with new models of bureaucracy that would bind it closer together as a coherent space. The map was in the ownership of Selden, one of the pioneers of the project, to allow nations to own the sea through a dense skein of maritime law, an autonomous legal and mercantile framework that would allow maritime trade to flourish unencumbered, a project that had become vital as “ships in their tens of thousands were sailing from every port of Europe and Asia” (Brook 2013, xxii). Seas could be closed off – the title of one of Selden’s works was The Closed Sea – and taken in to a coherent space that could support the growing global ambitions of “empires,” but with the monarchy becoming the symbol of coherent state authority and not just a political settlement. Finally, there was the joint-stock company, the progenitor of which, significantly, was called the Cathay Company, founded by Sebastian Cabot in London (Cabot was the son of John Cabot, the Italian navigator and explorer whose discovery in 1497 of parts of North America under the commission of Henry VII of England is commonly held to have been the first European encounter with the mainland of North America since the Norse visits in the eleventh century). Significantly, Cabot had also partnered with Clement Adams to publish London’s first printed world map. The joint-stock company was not just a tool that allowed the risks of long-distance maritime trade to be taken on board, but also a means for producing fiscal and commercial autonomy from the burgeoning state and so establishing the mixed authority between state and economy that we now take so much for granted. Some of these ideas quite clearly came from an awareness of the sovereign boundary definition going on in Ming China, with its dependence on notions of counting population and on technical achievements such as the compass.

In turn, trade has become the means by which we understand the world. It is a part of how we are. That has been the case for a long time, of course. For example, Europe has been a trading zone since at least 9000 BCE. But instead of amber, soapstone, and shells brought overland or by sea and made into necklaces, bangles, and the like (Cunliffe 2011), our very bodies are now maps of global trade. Shirts, tee-shirts, and blouses from Thailand and China, coats from Malaysia, glasses and contact lenses from Germany, watches from Switzerland, shoes from the United States: each of us is a lesson in exchange, a world in miniature. We live in places chock full with stuff that has transited from other places and still contains those places’ echoes. This fact is underlined not just by the constantly changing retail landscape with its standard grammar of shops and malls and warehouses, but by much less imposing but
equally crucial intermediary locations such as Chungking Mansions in Hong Kong, where cheap goods are sold (Mathews 2011). That is before we get to the afterlife of all these things as they pass to other owners as second-hand goods, accumulate in garages and attics, or end up being recycled or cast aside in garbage dumps where they recreate value as waste – and create records for future archaeologists.

Indeed, this roundelay of trade has produced what some have called a junkyard planet (Minter 2013). Much but by no means all of what we produce goes into landfill. Cans, computers, and cars rarely end up in landfills. Indeed, automobiles are nearly 100% recycled. No surprise then that the global recycling industry has a turnover of $500 billion a year, roughly equal to the gross domestic product of Norway. It is an industry which forms a trading complex in its own right since it consists in large part of the complex movement and exchange of goods such as paper and cardboard, iron and steel, aluminum and copper, from countries such as the United States over the sea to countries such as China – reflecting exactly an imbalance in trade. The United States consumes and throws away much more than it manufactures. China, meanwhile, is both the largest exporter of new goods to the United States and the largest importer of US recyclables. In turn, all kinds of places are linked together.

They are linked in other ways too. For example, new goods are crucial but getting them or inventing them is no easy matter. Let’s return to the topic of secrets. When a new product or service is invented it immediately becomes a matter of how easy it is to steal it away from its originator in a complex geographical game of push-me-pull-you. For example, nowadays great attention is paid to Chinese economic espionage around the world, but it is worth remembering how active the United States was in illicitly appropriating mechanical and scientific innovations from the British in the nineteenth century, often with the encouragement of the US government (Ben-Atar 2006). Keeping ideas at home was a British national priority: Britain had strict laws against the export of machines, and skilled workers were banned from emigrating, so American industrial spies were lionized. The British were hardly blameless either. In 1848–1849, in one of the most successful acts of industrial espionage ever carried out, the East India Company, tiring of the Chinese monopoly on tea, which meant that one out of every five chests of tea manufactured in China was being purchased by Britain, sent the botanist Robert Fortune to China where, heavily disguised, he stole both the technique for processing tea leaves and a large collection of tea plants that were subsequently conveyed to India to be grown, thus breaking the Chinese stranglehold on the global tea market forever (Rose 2002).

But trade isn’t only the to and fro of what we regard as “material” goods. There is also trade in language and more generally in meanings – in signs that work across a series of different sensory registers (such as vision, sound, and movement) and different means of registering them (such as books or recordings or films) which are constantly mobile and changing – and although they may exist within predefined systems of meaning, such as textual or filmic conventions, they tend to overflow them. Take the case of language: we move about constantly so language is always in movement, constantly mutating: the “most fundamental fact about human communication is its variability” (Levinson 2003, 318). It can be moved about through the myriad interactions of “ordinary” conversation, with its encyclopedia of verbal and nonverbal cues, including particular ways of organizing and distributing spatial information, but equally it is moved about through all the means of expression that are currently
available: music, dance, all manner of texts, movies, and television, and latterly the Internet, with its new variants of communication. In turn, when signs are combined with bodies and emotions they produce deep and fast-flowing cultural currents that we still struggle to describe, even as we feel them as the compasses that set our behavior. These cultural currents wax and wane and join with other currents in all kinds of combinations. Take just the case of music (Byrne 2012). It’s a set of cultural baggage etched in sound — tempos, melodies, means of collaboration (from rock groups to orchestras), different kinds of instruments and contexts (such as bars and clubs, opera and concert halls, arenas, or outdoors), different ways of amplifying sounds (from cathedrals to microphones), and emotional reactions — which has traveled all around the world, just like any other traded goods, through a mixture of passion and economic calculation: geography and music are now inseparable. Part of the reason for music’s power as a set of signs is that it is closely allied to the makeup of particular spaces but can now also transcend them thanks to technologies of recording — the first sound recording was made in 1878 — which have themselves acted as means of producing new kinds of music while they have passed music around and around and made it possible to intersperse musical genres to an even greater extent through techniques such as sampling and the influence of all manner of new digital formats.

To conclude: cityspace

This is where cities come in, as the chief conductors of all the spatial transactions that define the human planet, from the to and fro of state intelligence through the vagaries of economic exchange to simply acting as founts of creativity. Rather late in the day to write about cities, you might think, in any account of space, but, then again, maybe not. Cities have always been seething multitudes, billions of interactions pulling together states and economies through great networks of influence and exchange. But now cities are growing in size and number to the point where the planetary condition is becoming the urban condition. Cities are becoming states and economies in their own right as a growing share of the world’s activity flows across national borders, both cementing and challenging a container view of space. That said, this pervasive urban condition is much too complicated to be described by concepts such as “planetary urbanization” — the variation in what cities are like and why they exist is too great for such simple-minded cut-throughs to say much at all — but what cities allow is for senses of connection to be both strengthened and subverted. Cities are not merely quantitative amplifiers but also, because of their great complexity, they are generators of qualitative change. They both hold things together and allow things to diverge: everything can become a stakeholder and so everything is put in relation and at stake (Bratton 2014). Cities are where questions and questioning chiefly emerge, and there are plenty of questions to be asked, many of them precisely concerned with how cities will survive in an era of climate change, population growth, energy deficits, lack of fresh water and clean air, and sometimes grotesque inequality: after all, so far, the Anthropocene has been a “filthy undertaking” (Vince 2014, 3).

At their worst, cities can be murderous entities casting people carelessly aside. But at their best, they will allow us to die another day by finding the answers we need to the questions we cannot avoid. The time will come when we realize that just having and owning means that we won't be heir to much at all. The planet will take it all back. Let's hope we can avoid such a bitter inheritance.
But to avoid that inheritance means that we must find new ways of sensing and representing space, ways that recognize that to love something, you do not have to govern it or own it or trade it. We can’t have it all. That’s a fact. It’s not just “our” planet. Mutuality needs to replace mastery. We need to become responsible earthlings before the Anthropocene becomes simply an obscene blot on the geological record (Ellsworth and Kruse 2013). Geography, the guardian of difference, can map out the long and no doubt painful road to what could be a shimmering redemption.

Membership: 950 (as of 2013)
President: Carmen Delgado
Contact: carmen.delgado@unican.es

Description and purpose

The Asociación de Geógrafos Españoles (AGE) is a group of geography teachers, researchers, and professionals whose main aim is to promote and advance geographical science and its applications in Spain. In addition, it aims to promote wider public knowledge and a greater understanding of geography. Since its foundation it has been mainly involved in promoting scientific meetings, coordinating the activities of Spanish geographers, and collaborating with other national and international associations. Given the wide variety of topics related to geography and ever greater thematic specialization, the association has set up fourteen working groups.

Current activities or projects

The association hosts the Congresos de Geógrafos Españoles (Congress of Spanish Geographers), a biennial congress, the most recent being held on October 23, 2013, in Palma de Mallorca. AGE also organizes annual meetings for the fourteen working groups as well as annual seminars on “Geography Teaching in Secondary Education,” the last one was held on July 6, 2013, in Getafe (Madrid).

Brief history

In the mid-1970s an emerging need for organizing scientific activities and to solve common matters encouraged academic geographers to found the Asociación de Geógrafos Españoles (AGE) in 1975 during the IVth National Geography Conference. The first president of the association was Professor Jesús García Fernández.

AGE has maintained relations with the Associação Portuguesa de Geógrafos (Association of Portuguese Geographers), which has resulted in the Iberian Colloquiums on Geography, held alternately in Spain and Portugal. AGE has also signed permanent agreements with geographical associations from other countries,
such as the Institute of British Geographers and L’Association Française pour le développement de la Geographie. AGE holds the presidency or the vice-presidency of the IGU Spanish Committee in rotation.

AGE’s administrative bodies comprise the general assembly, which is an annual meeting of all members, and the board of directors, which is in charge of implementing the program of activities put forward by the general assembly. The board of directors is elected for a four-year term and is partially re-elected every two years. The board of directors comprises the President, the secretary, the treasurer, and eight board members. The working groups are governed by specific committees.

Description and purpose

The purpose of the Real Sociedad Geográfica is to promote the production and dissemination of geographical knowledge with particular attention to subjects of relevance to contemporary social, political, and economic life. The focus of studies is on Spanish lands and the peoples linked to Spain by language and other reasons. The society organizes and participates in conferences, courses, and workshops; undertakes state-funded research projects; publishes a journal, books, and other special publications; and has a major collection of books and maps.

Journals or major publication series

Current activities or projects

The primary activities of the society are courses, conferences, workshops, and exhibitions, which are either conceptual (about the nature of geography), territorial (about the different lands and nations), or about geographical tools (cartography, GIS, and remote sensing).

Boletín de la Real Sociedad Geográfica is the Society’s primary journal which has been published as far back as 1876 (except during the Spanish Civil War), being the oldest geography journal in Spain, with papers by eminent geographers, historians, and scientists. The society has also published around fifty books and other special publications relating to its activities.

The society has a large bibliographic and map collection which is stored at the Spanish National Library in Madrid including over 11,000 books, 12,700 booklets, 150 journals, and several thousand maps dating back to the mid-eighteenth century.

Brief history

The society was founded in 1876 as the Sociedad Geográfica de Madrid and renamed the Real Sociedad Geográfica in 1901. Among the first members were prominent people in the public and scientific sphere including politicians, military cartographers, engineers, and planners.

At that time, geography was a discipline of great political relevance offering a scientific and academic basis for international relations as well as for domestic development. Thus, the society started its activities immersed in a political climate of colonial expansion, national unifications, industrial imperialism, and also
urban and infrastructure developments. In particular the society was involved in exploration and discovery in Africa and Asia including Guinea, Morocco and the Sahara, and Eastern Africa.

Another chapter was the collaboration and merging with other scientific and exploration associations such as Sociedad Española para la Exploración de África and Sociedad Española de Africanistas y Colonialistas (later the Sociedad de Geografía Comercial), all of which were absorbed by the Sociedad Geográfica.

The society organized several important scientific meetings such as the Congreso Español de Geografía Colonial y Mercantil (1883) and the Congreso Geográfico Hispano Portugués Americano (1892, 1914, 1921), which included representatives from the geographical societies on the American continent.

Spain, represented by the Real Sociedad Geográfica (RSG), was one of the seven founding countries of IGU in 1922, which many other associations have joined right up until the current IGU’s Spanish Committee.

Spain: Sociedad Geográfica Española (SGE) (Spanish Geographical Society)

Founded: 1997
Location of headquarters: Madrid
Website: www.sge.org
Membership: 1500 (as of December 31, 2013)
President: Juan José Herrera de la Muela
Contact: sge@sge.org

Description and purpose

The Spanish Geographical Society (SGE) is a nonprofit organization aimed at encouraging the rediscovery of Spanish history throughout the world by Spanish people, promoting geographical and social awareness of different peoples, creating an understanding of, and human contact with, different cultures and ways of life, and becoming the driving force behind projects that serve investigation, science, art, and the revitalization of geography and traveling as a personal discovery, using the means available in the twenty-first century. The society was appointed “Of Public Interest” by the corresponding government department in 2012.

Journals or major publication series

Several titles published on Spanish exploration across the world. http://www.sge.org/

Current activities or projects

The SGE works actively to organize conferences, courses, seminars, periodical gatherings, trips, cultural tours, slideshow projections, exhibitions, travel book releases, and other events open to the general public with a special preference for members.

Each year, the SGE gives out awards in eight categories related to its objectives.

The society maintains an editorial activity by publishing specially ordered books on subjects relating to exploration, travel, and geography. One of the primary concerns of the SGE is the recovery of ancient geographical books and expanding a comprehensive library and documents department at the society’s headquarter.

Brief history

The SGE was founded on October 12, 1997, through the initiative of a mixed group of people with a common interest in geography and traveling. It already comprises more than 1500 members and boasts the participation of geographers, travelers, writers, anthropologists, ecologists, biologists, people professionally involved with tourism, and many other people with an interest in the society’s goals as stated in its articles of association.

The SGE has its headquarters at the Instituto Geográfico Nacional in Madrid.

The SGE’s goals are to promote the study and understanding of our environment, to promote geographical knowledge by all available means, and, above all, to make public modern geographic science while also investigating
the adventurous side of Spanish geographic discoveries throughout history.

The society publishes its own magazine every four months in collaboration with some of the most prestigious travelers, geographers, and investigators in the country.

For the past 13 years the SGE has awarded different prizes (National, International, Enterprise, Trip of the Year, Image, Communication, Investigation, and Honorary Member) to several distinguished representatives of these fields in a ceremony which is attended by members of the SGE and by outstanding representatives of the cultural and social world and the media.

The society keeps in touch with different societies all over the world as well as Spanish geographers’ associations in order to encourage collaboration projects with university departments within this discipline. The SGE also collaborates with Spanish universities and will continue to increase contact with other groups of investigators (sociologists, biologists, city and town planners, etc.).

Spain: Societat Catalana de Geografia (SCG) (Catalan Society of Geography)

Founded: 1935
Location of headquarters: Barcelona
Website: http://scg.iec.cat
Membership: 429 (as of June 16, 2014)
President: Josep Oliveras-Samitier
Contact: scg@iec.cat

Description and purpose

The objectives of the SCG are to promote research in all geographic areas and specialties, to spread knowledge among the population, and to collect and publish the scholarly and popular works of its members and other interesting authors. The SCG gives preeminence to items that deal with the geography of Catalonia, but it is open to the dissemination of knowledge from other regions, geographical problems, and foreign authors. It is a member of the EUGEO (Association of European Geographical Societies) and of the Spanish Commission of the International Geographical Union (IGU). SCG members are mostly professional geographers.

Journals or major publication series

Current activities or projects

The SCG publishes, since 1984, a biannual journal of geography (Treballs de la Societat Catalana de Geografia). It also publishes a collection of books on topics in geography by ancient and modern authors as well as foreign and domestic authors. The SCG’s website gives information of the activities that are carried out, the history of the Catalanian geography, and work of people dedicated to it. The SCG maintains another website giving information on tools and resources for teaching geography (http://ensenyament-geografia.espais.iec.cat).

Spatial analysis

Levi J. Wolf
Alan T. Murray
Arizona State University, USA

Spatial analysis is an expansive term that has been defined a number of different ways. Primarily, spatial analysis is the process of generating useful knowledge to answer questions about order, pattern, and structure inherent in spatial problems (Anselin, Murray, and Rey 2013). Structure and pattern arise from tangible questions emanating from spatial systems. Spatial analysis techniques seek to facilitate answering these questions through the application of formal mathematical, statistical, and/or computational methods. The domain has a long history of focusing on geographic issues and problems, where generating useful knowledge/insights can help policymakers, stakeholders, managers, and the broader scientific community.

By engaging problems that arise from geographic interactions, spatial analysis is faced with ever evolving questions and problems. This tightly couples spatial analysis techniques to empirical questions. Understood in this way, spatial analysis is the process of describing, characterizing, understanding, creating, and visualizing latent order, pattern, and structure associated with geographic phenomena. As the questions and problems change, so do the methods needed to address them. Spatial analysis therefore reflects many diverse perspectives, each with slightly different goals, concerns, and methods. However certain traits are common across spatial analysis domains and perspectives.

The most common of these traits are a consistent use of abstraction, mathematical expression(s), a quantitative or empirical focus, and an aim for broader spatial understanding.

Spatial analysis involves the use and application of statistical, mathematical, and/or computational methods that account for or exploit order, pattern, and structure, providing insights about how spatial processes work and may be managed. These methods and tools are widely used, both within geography and in other domains. As many problems across domains have some geographic component, spatial analysis is often an interdisciplinary point of contact between geographers, spatial scientists, and decision-makers. Spatial analysis provides unique, powerful, and incisive ways to generate useful knowledge because it involves the use of quantitative methods as part of a process.

Distinguishing traits

Spatial analysis is a unique domain that exists at the crossroads of many different disciplines and methodological perspectives. In addition, spatial analysis frequently offers one view out of many on a problem or question. While there are numerous domains that attempt to understand order in the world, spatial analysis is different in many ways. The questions that spatial analysis addresses are quite different from other types of aspatial questions. In addition, geographic data contain information that spatial analysis techniques can exploit in novel ways. Therefore, the way data are stored, analyzed, and displayed must reflect this information, as structure, order, and pattern inherent in geographic data are a central
Spatial analysis questions all share these common traits and confront similar difficulties. As spatial analysis perspectives are all united by a goal to provide useful knowledge about the order inherent in spatial data to answer questions, contextual factors shape the character of spatial analysis. Therefore, discussing these common themes, how they arise, and how they contribute to answering questions about spatial systems shows the unique geographic context of spatial analysis.

Spatial data by design reflects the fact that observations have geographic meaning. In particular, observations have geographic position on the surface of the Earth defined by coordinates in two or three dimensions. Thus, patterns in the proximity of observations frequently contain information about underlying spatial processes. However, there is frequently more information associated with each observation than its position alone. These “attributes,” essentially the traits associated with each observation, are important. If attributes are ignored, significant amounts of information are discarded. To handle the unique pairing of position and attribute information, spatial analysis must be sensitive to potential variation in patterns of both attribute(s) and location. Thus, spatial analysis techniques tend to be quite different from other analytical techniques because the data express information in a distinctly geographic way.

Spatial representation of observations is unique for geographic data. In spatial analysis, many different types of pattern may be present in data. However, some cannot be identified or visualized using traditional means such as histograms or distributional charts. The fact that the data contain spatial specificity also provides more information than just the nonspatial attributes alone, and requires unique systems of representation. Thus, storage, visualization, and mapping are quite important for spatial analysis. Often, many different “views” of data must be considered, each capturing a different aspect of the structure in the data. Spatial analysis techniques frequently rely on visualization and the use of multiple views, particularly when mapping, distinguishes spatial analysis from other domains.

Because spatial data are novel, demands on information systems that process spatial data are different from traditional database infrastructures. Because position and spatial configuration express special kinds of structure, reference frames for geographic data preserve geometric or topological relationships. As such, spatial analysis requires different technologies to handle and retrieve data. These systems are called geographic information systems (GIS). Because spatial analysis is often strongly coupled with explicit GIS functionality, discussion of spatial analysis is sometimes equated to GIS operations. This is an incomplete view. While spatial analysis may include GIS functionality, it goes beyond capabilities offered through the use of GIS. Basic tools in GIS for handling representation, storage, and display of spatial data are important, but come nowhere near to providing a complete picture of the breadth and depth of spatial analysis as a domain of inquiry.

Unique structures in spatial data abound (Anselin, Murray and Rey 2013; Murray 2010b). Common concerns focus on the structure of spatial dependence between observations’ attributes or their locations, the spatial heterogeneity of this dependence in space, and problems with the observational scale or framing of the data. Spatial dependence is a central concern for spatial analysis techniques. It manifests when the...
geographic location or measured properties of data rely on the spatial configuration of the data. That is, spatial dependence occurs when spatial relationships between observations change or affect the configuration, behavior, or value of observations themselves. Spatial heterogeneity manifests when the behavior of spatial dependence changes in space. As measuring and understanding the structure of spatial heterogeneity involves studying the spatial dependence of the data, it follows that understanding spatial heterogeneity also requires special treatment.

Handling frame and scale effects requires special attention as well. These effects stem from direct limitations on processes of observation, representation, and the conceptualization of spatial processes. Frame effects, in the context of spatial analysis, are encountered when changing the area of focus for a spatial question changes the results. This implies that all of the work done to characterize and explain pattern and order within the problem frame may not have external validity. Because spatial heterogeneity is often the rule rather than the exception, these issues challenge spatial analysis results. Similarly, scale effects manifest when a question’s scope or extent is either reduced or expanded, but stays centered at the same spot. These can be thought of, more generally, as a kind of frame effect, as the dependence on spatial frame is scaling uniformly rather than translating in space. In addition, this relates to well-known aggregation effects such as Simpson’s paradox and the modifiable areal unit problem, where the significance or character of structure in data changes significantly depending on how it is grouped.

With all of these concerns, it is clear that spatial problems are distinct from other types of problems. As such, spatial analysis has contributed significantly to the body of useful knowledge on dealing with geographic issues and problems. Spatial analysis is also well poised to continue doing so due to the unique traits of the encountered problems. Again, spatial analysis generates useful knowledge to answer geographic questions. It does so by making latent order and structure in spatial data clear through formal mathematical, statistical, or computational methods. Spatial analysis is distinct because spatial structure in geographic data is different: the ways which spatial problems are framed, measured, expressed, and solved are often more fundamental concerns than in other analysis perspectives.

### Analytical approaches

As mentioned, spatial dependence or heterogeneity effects, in addition to problems of scale and frame dependence, are novel issues characteristic of spatial analysis and are challenging to handle appropriately. In light of all of these concerns, spatial analysis perspectives are unique. The aim is to generate useful knowledge to answer questions involving spatial data. The large diversity in spatial analysis approaches is a response to the many needs of managers, stakeholders, policymakers, and scientists using geographic data. Spatial analysis is often strongly use-oriented, so abstractions that are useful for answering some questions may not be helpful for others. The varying perspectives in spatial analysis still aim to make inherent structure, pattern, or order apparent while generating useful knowledge, but often they seek to answer different questions or do so in different ways. It is important to note the many communities of practice that have developed in spatial analysis; their concerns often appear disparate. However, each perspective shares in the same aim common to spatial analysis discussed above, that of generating useful knowledge to answer questions about latent structure, pattern, or order in spatial data.
Focus on applied problems has long been central to spatial analysis. Commonly cited as one of the first cases of a coherent spatial analysis perspective, John Snow’s 1854 analysis of cholera outbreaks around the Broad Street pump in London is noteworthy (Snow 1855). By considering spatial dependence of cholera cases in relation to water pumping sites, Snow used spatial logic to advance the then-controversial germ theory of disease. In this vein, later spatial analytical efforts developed new tools by focusing primarily on derived useful knowledge: Von Thünen (1875) and spatial models of economic rents developed by studying urban land markets, Weber (1909) and location models of economic distribution structures, and McHarg (1969) and proximal relationships using overlay and map algebra for examining land-use systems. Later advancements made in the mid- to late twentieth century hinged on the same focus on tools for producing useful knowledge, and were empowered by the rise of digital computation. Computing access and pervasive data collection facilitated spatial analysis intertwined with GIS (Goodchild et al. 2000), but also into common day-to-day life experiences. This integration, particularly due to availability of inexpensive digital computing and abundant data, has driven development of quantitative tools for spatial analysis. Newer spatial analysis perspectives retain this overarching quantitative focus on spatial dependence, heterogeneity, and frame/scale effects, yet with more computing power, data, and nuance than before.

With this in mind, current spatial analysis perspectives seek to satisfy slightly different goals while generating useful knowledge. Modern spatial analysis has also retained the quantitative and computational traits developed during the latter twentieth century. Current techniques in spatial analysis retain the strong linkages to problem-based reasoning established throughout its history, and the development of new techniques often occurs when particularly difficult or poorly behaved real-world problems arise. Some of the more prominent spatial analysis methods include: exploratory spatial data analysis, spatial regression, spatial optimization, and geosimulation. These methods are discussed in some detail here.

**Exploratory spatial data analysis**

One popular perspective in spatial analysis is exploratory spatial data analysis (ESDA), emphasizing the discovery of latent trends. These approaches avoid imposing predictive hypotheses on data before analysis. Work applying ESDA approaches does not aim to confirm prior expectations about how a process behaves but interacts with the data in ways that generate new questions and provide grounds for new hypotheses. Discussion and application of ESDA can be found in Anselin and Bao (1997), Fotheringham, Brunsdon, and Charlton (2000), Murray et al. (2001), and Murray (2010b), among others. ESDA techniques characterize the geographic distribution of the data by searching for spatially interesting phenomena that violate expectations of spatial heterogeneity or independence. Frequently, ESDA includes inherently visual components, relying somewhat on natural pattern-seeking capabilities of the human mind to validate or initiate the application of methods or statistical tools. Visualization and methods to support searches for pattern or disparity in data are central concerns of ESDA approaches.

ESDA techniques are centered on examining spatial dependence in data and determining whether or not spatial dependence is heterogeneous in space. Without imposing particular models, ESDA techniques tend to focus on uncovering structure and order in data through examination of “neighborhoods” around observations. Measures of nearness
Spatial analysis

frequently incorporate aspects of contiguity, proximity, and spatial interaction. Based on this, ESDA techniques seek to uncover locales that are unusual with respect to general patterns of spatial dependence.

Depending on the type of spatial data involved, ESDA techniques can operate differently. The mechanics of individual techniques vary significantly depending on the spatial support. However, ESDA techniques often consider changes in spatial dependence over the entire problem space or look for specific locales that defy the broader observed trends. ESDA techniques often are flexible with respect to the scale of the processes involved. “Global” measures that characterize the behavior of the entire problem space and “local” measures that examine a subset of the geographic space both are prevalent. Regardless of the scale, visualization techniques that pair multiple views of the data in different formats provides a more flexible and incisive way to understand the patterns in the data across time, space, and scale.

Spatial regression

Spatial regression aims to describe the geographic structure and distribution of the data by focusing on modeling conditions of spatial dependence and heterogeneity using formal mathematical structures. Detailed discussions of the various approaches can be found in Anselin (2003, 2010), and Pace and LeSage (2009). Spatial regression models estimate the value of a given attribute in space using information about the relationships between attributes, with spatial dependence being one of many potential factors. By determining which factors are statistically significant in influencing the observed location or attributes of features, spatial regression provides incisive empirical models for understanding spatial variation.

Spatial regression techniques account for many different kinds of structure and pattern in geographic data. Because of sensitivity and flexibility, spatial regression techniques are used across many different problem domains and spatial data types. A common type of spatial regression is the spatial lag model. This model assumes that the value of an attribute under study is likely related to the value of its neighbors. By considering spatial variance as its own direct effect, this model specification is quite sensitive to spatial dependence between observations and their neighbors. However, another regression model type uses regularities in the error terms to structure estimations. These models, called spatial error models, suggest that the errors in the trait to be estimated vary systematically in space rather than the values themselves. Another kind of spatial regression model divides the problem area into distinct regions and estimates the values in question differently in each new subregion. These spatial regime regression strategies allow the analyst to vary the expected structure of spatial dependence across the problem space in a systematic way. Other techniques, such as conditional autoregressive models or simultaneous autoregressive models, allow spatial information to be incorporated into regression models, albeit through different conditioning processes. These techniques are frequently used, and play a central role in spatial regression.

Because of their flexibility and the diversity of model specifications, spatial regression can be applied to many diverse problem types. Spatial regression techniques provide valuable insight into the structure of spatial dependence and can take into account issues of modeling spatial heterogeneity. With spatial regression techniques, hypotheses concerning potential relationships between explanatory variables can be formulated and evaluated. This power is useful for examining spatial processes. As such, spatial regression
SPATIAL ANALYSIS

techniques provide a unique set of methods to predict and estimate attributes in the sample space and provide a unique contribution to answering spatial questions.

Spatial optimization

Spatial optimization shares spatial regression’s focus on modeling order and structure. But, instead of examining or specifying the order and structure inherent in data, optimization approaches tend to focus on modifying current systems and predicting how they will then behave. Optimization techniques have long been part of spatial analysis, and applications and discussions of common spatial optimization techniques are provided in Tong and Murray (2012), Murray (2010a), and Church and Murray (2009).

A few common concerns for spatial optimization are how objects are located, service and trade, organizational structure orientation or alignment, and system flow. Common applications of spatial optimization include location of emergency facilities, land-use problems, districting or assignment problems, and urban planning. Spatial optimization models are useful when three aspects of a problem can be identified: a goal or objective, a set of decisions to make in order to achieve the goal, and usually (but not always) a set of constraints that restricts decisions. Optimization models are then constructed from these pieces to reflect latent order in the spatial relationships or aspatial structures in the data.

Of course, relationships between components of a spatial optimization model may not be obvious. Dealing first with the goal, spatial optimization is most useful in cases where there is some desired outcome to be achieved. Often, policymakers or modelers designate these objectives in advance. They reflect concerns about the desired end-state of the model. Narrowly, objectives can be thought of as some desirable property that the analyst uses to discover a better structure or configuration of the system under study.

Second, some decisions about how to achieve the objective must be made. For example, in a production distribution system, spatial decisions could affect what warehouse supplies which stores, what roads are selected to ship material or finished goods, or where a factory should be located. Decisions are formally expressed in the problem structure. These “decision variables” are related to each other through the objective and through the constraints on decisions discussed later. The value of these decision variables expresses information about how the system must be configured in order to achieve the objective. The kinds and complexity of decisions that are modeled in the spatial optimization literature is incredibly diverse. This is because decision variables are designed to reflect real-world choices and are specified for a specific problem instance.

Finally, spatial optimization problems typically have some kind of constraints that prevent simple satisfaction of the objective. Often, there are limiting factors that restrict a system’s performance, particularly with respect to a given objective. For example, common constraints on the performance of businesses, consumers, governments, or city planners are budgets, regulations, or laws. Constraints reflect these factors. They also link the decision variables to limiting factors in meaningful ways. Constraints encode information about the problem, as aspects of the inherent spatial order of a system are identified and codified in mathematical language. Unconstrained problems do exist, though, and are sometimes quite difficult to solve. Aspatial factors frequently come into play in spatial problems, so constraints on spatial optimization models are also designed to incorporate these various concerns. However, in general, constraints incorporate both spatial and aspatial information.
into a problem, making spatial optimization techniques useful across many domains.

Once these three components are specified and put together into the optimization problem, appropriate solution techniques are applied to find a useful answer to the question modeled. Solution techniques can either be exact or heuristic. Exact solution techniques use the problem’s special mathematical properties to generate a solution that is guaranteed to be optimal. The fact that solutions found by exact methods carry this guarantee is useful, but exact techniques are often difficult to discover and slow to execute given the complexity of many problems. Heuristic strategies, however, are developed individually for different problem instances. These techniques typically find acceptable solutions quickly, but cannot demonstrate how good the solution is with respect to other, undiscovered solutions. Regardless of the specific tool, though, solution techniques serve to link the output of the optimization procedures to the original question posed by the spatial optimization model. Questions of spatial dependence and heterogeneity are captured in the construction of the model and affect their solutions. This focus on making decisions about some system while accounting for its spatial structure and relationships makes spatial optimization approaches quite distinct from other spatial analysis perspectives and heightens their ability to contribute useful knowledge to spatial questions.

Geosimulation

The final, broad perspective in spatial analysis discussed here is spatial simulation, or geosimulation. These techniques aim to provide insight into “what-if” questions about the future configuration of spatial systems. Discussions of geosimulation techniques and applications can be found in Beneson and Torrens (2004) and Ward, Murray, and Phinn (2003). Geosimulation is often most relevant when attempting to figure out what will happen given some set of decisions to be made or rules to be followed. These approaches aim to simulate the emergent behavior of complex geographic systems. Through modeling small-scale interactions between elements of the system, the behavior of the entire system can be understood. Geosimulation techniques focus on exploring hypothetical, “what-if” configurations of existing geographic systems. This aim provides a unique toolset to spatial analysis more generally: simulating spatial order given some current set of known behaviors provides the ability to examine potential scenarios that may occur given a particular course of action.

To construct geosimulations, analysts decide on hypotheses about how parts of a spatial system should behave given a certain set of suppositions. These rules describe the multiple states any individual component of the spatial system can occupy at some time. They also govern the transitions between states in time and control how elements affect their neighbors. Consensus in current scholarship drives the development of these rules. However, these suppositions can also be structured in order to examine possibilities on the research frontier, where no clear consensus about the states or behaviors of a system exists. In these cases, suppositions and their attendant rules allow analysts to examine many possible scenarios about the future given different rules of interaction. Once the data are codified and the rules of interaction are formalized, the simulation begins by using the rules to simulate a new configuration given some observed initial configuration. Simulated elements act according to simple rules, but can generate complex emergent patterns of spatial dependence and heterogeneity. This process of applying the rules to the dataset continues until
some kind of termination criteria, designated in advance, is reached.

Evaluating a geosimulation is, in some ways, trickier than evaluating the output of other spatial analysis tools. Using simulated data, the original hypothetical questions can be answered. However, it is difficult to validate the rules used to simulate new data, as they depend on domain knowledge about the system being simulated. When simulations are primed on different hypotheses about what drives the system’s behavior, differences between simulated scenarios can provide support for or against causal or descriptive hypotheses. Analogous to the hypotheses testing or generating present in other spatial analysis techniques, geosimulation techniques are varied in their aims to confirm hypotheses or generate new questions based on simulated output of potential scenarios. It is precisely these “what-if” cases where geosimulation provides powerful insight into the unique structure of the initial data, and how it may affect future derived data. Geosimulation’s utility in answering questions at the frontier of research, in situations where more traditional causal or predictive models are too immature or too rigid, serves a unique yet essential niche in spatial analysis’ pursuit of useful knowledge to answer spatial questions.

**Common themes**

Given these primary analytical thrusts in spatial analysis, recognizing the common themes between approaches helps to tie the domain together. Spatial analysis techniques are incisive and powerful in the face of unique geographic issues due in large part to a few traits common across many spatial analysis perspectives. By focusing more generally on order, pattern, and structure inherent in the phenomena around us, spatial analysis aims to generate useful knowledge that answers questions about geographic systems. The different perspectives on spatial analysis share common design choices that make it possible to achieve powerful, general insights. These general traits are abstraction, mathematical expression, a focus on quantitative or empirical questions, and a drive for broader spatial understandings. Essentially, these themes characterize the factors that differentiate spatial analysis methods from other perspectives. While these approaches have their merits, spatial analysis makes these tradeoffs to ensure unique, powerful insights into many different problem domains.

Abstraction is a long-used design technique to reduce complexity or improve clarity of complex problems or questions. In spatial analysis, abstraction is employed as a way of uncovering structure in data. By removing or ignoring smaller, confounding detail, it may be possible to understand the problem more clearly. Extraneous or unneeded information may be ignored and the analyst can focus only on the important, central aspects of a system’s structure. As a tool for designing inquiry, abstraction also works well with the other aspects of spatial analysis, namely mathematical expression and drive for general explanations. Thus, through intelligent application of abstraction, spatial analysis techniques generate strong and robust results.

Abstractions are integral to many different kinds of techniques, so spatial analysis’ use of them is not, by itself unique. However, abstraction in spatial analysis typically enables expression of the problem in mathematical language. This kind of abstraction is necessary to exploit special mathematical structures in spatial problems. By pairing the use of abstraction to remove unnecessary or irrelevant detail and mathematical expression to be explicit about the details remaining, structure and pattern in the important traits of a problem become clearer. Mathematical structure abounds in the systems
humans encounter. Whether by design or as a product of analysis, these structures often illustrate regularity in a problem. Because the mathematical characterizations of problems are often easier to express, understand, and control, these structures can be used to make complex geographic problems more accessible.

Because spatial analysis aims to answer questions that arise in dealing with spatial systems, it is empirical in focus. This means that spatial analysis is often concerned with the tangible, measurable, and quantifiable. However, this does not mean that spatial analysis fails to handle issues of uncertainty or vagueness. Many methods have been developed to deal with the unknown or unknowable factors that affect geographic questions. Because geographic questions frequently involve the limitations of formal expression, measurement, and quantitative tools, spatial analysis is acutely aware of where focus on known, observable factors is not sufficient. Spatial analysis, while frequently engaging issues of uncertainty is often quantitative and empirical.

Finally, approaches in spatial analysis all exploit order inherent in geographic data. By understanding and exploiting the unique mathematical structures of geographic data, broader understandings of how space and location affect geographic processes are possible. As such, spatial analysis techniques tend to exploit order common across many problems, rather than unique to a single instance. This means that the frontier in spatial analysis research is often split into two pursuits. One involves the efforts to develop stronger tools to hit stubborn special cases that resist more general solutions. The other deals with the examination and characterization of commonalities in spatial structure across problems. As such, spatial analysis work often moves freely between theoretical work on general structures and applied work on particular geographic problem instances.

Overall, these four traits are common across spatial analysis approaches. They describe the core of what differentiates spatial analysis from other geographic perspectives and other data analysis approaches. Each is tightly related to the other, as some design choices amplify the effectiveness of others. Abstraction helps mathematical expression remain concise and specific. Mathematical structures lend themselves to empirical or quantitative approaches. Geographic data, carrying the unique problems and possibilities associated with spatial information, is amenable to quantitative analysis when sufficiently and effectively abstracted from irrelevant detail. Together, a quantitative focus, use of efficient abstraction, mathematical expression and structure, and a search for broader spatial understandings of geographic processes drive the success of spatial analysis methods.

Future trends

As a domain, spatial analysis approaches have been useful across many problem domains throughout time. However, spatial analysis faces a few central challenges. Good overviews of spatial analysis’ potential challenges and opportunities exist in Goodchild et al. (2000), Anselin (2010), or Murray (2010b). However, techniques that handle uncertainty, intensify spatial analysis’ past interdisciplinary linkages, and are scalable over the pervasiveness and size of modern geographic data collection are often cited as central areas of development for spatial analysis.

With respect to the size and pervasiveness of geographic data, concerns about “big data” abound. Efficient computational techniques to manage the increasing size and scope of geographic data are needed. With computation getting cheaper and microelectronics getting smaller, data are recorded at astounding rates...
SPATIAL ANALYSIS

and with startling pervasiveness. Intensive data generation and its pervasive scope present unique challenges for spatial analysis. Discussions of big data reflect these concerns and spatial analysis will continue to be central to the analysis of data, regardless of its size. However, current analysis techniques sometimes are too slow when presented with large datasets, and systems of geographic data representation can break down when attempting to visualize extremely dense sets of observations. Developing better tools, computational methods, and visualization strategies will be central to emerging spatial analysis research.

As geographic data that are broader in scope and more in-depth are collected, the relevance of spatial analysis increases across disciplines. Many social problems and scientific questions concern objects with some kind of geographic representation: location is a ubiquitous trait. With better, wider coverage of geographic data, spatial analysis is well poised to answer questions about geographic systems in the future. Spatial analysis is certainly positioned to play a major role in future interdisciplinary science applications. Its historical role in tying together disparate domains in order to solve intractable problems in geographic contexts will likely continue as research focusing on commonalities in order, structure, and pattern continues. Across domains, calls for spatially integrated social science (Goodchild et al. 2000) or intensification of geographic methods in the natural sciences reinforce the centrality and importance of spatial analysis methods and, more generally, reasoning about geographic problems in a quantitative fashion.

Concerns about the size, pervasiveness, or speed of computational tools may prove irrelevant, though, if more fundamental issues about uncertainty are left unaddressed. Often, geographic measurements are uncertain. This can be due to measurement uncertainty, where the exact dimension, position, or trajectory of an object is difficult to observe reliably or precisely. It can also be due to representation issues, where the methods to represent an object’s geographic properties are not sufficiently descriptive or lack some dimension needed to fully understand the object. Uncertainty can also be caused by a lack of information about the problem itself. Concerns posed by the emergence of “big data,” essentially concerns about what to do with massive and pervasive datasets, are mirrored by questions about what to do in cases where the data is not “big” enough, and components needed to apply spatial analysis approaches are either missing or estimated. Handling uncertainty, particularly how it can affect core assumptions or suppositions needed for analysis, is a central concern for spatial analysis work going forward.

Another important trend is the proliferation of spatial analysis tools. Spatial analysis has traditionally been a domain reflecting concentrated technical skill, using powerful insights derived from mathematics to exploit and characterize latent order, pattern, and structure in geographic data. Many commercial GIS packages now contain basic spatial analysis functionality. Yet, many lack the appreciation and understanding of spatial analytical traditions more broadly and their relationship to central issues in statistics, mathematics, and issues of representation in geography. As such, development of spatial analysis tools focuses both on utilizing pervasive and cheap computation to provide new functionality, but also must make it easier to effectively apply this functionality. By improving CyberGIS and the quality of open spatial analytical software, the quality and accessibility of spatial analysis techniques will be improved. Improving the power and usefulness of spatial analysis techniques in conditions of pervasive data and uncertainty in data will certainly be difficult. Accomplishing this while remaining accessible to end users and
generalizable across many problem cases, though, will assuredly be quite the task.

Spatial concepts

Karl Grossner
Stanford University, USA

The term “concept” has been defined in several ways. From the perspective of cognitive science, concepts are mental constructs about the nature of material and abstract things, and the relationships that obtain between them. The words we use in communication – and some would add in reasoning – refer to concepts, and their meanings are shared between individuals to a greater or lesser degree. There is little agreement among the philosophers, linguists, and psychologists who study the nature of concepts as to how such mental representations and lexical concepts precisely relate to language, thought, and activity.

An important branch of geographic information science (GIScience) studies such ontological issues from several perspectives, motivated by the need for better analytical software, better navigational devices, and better geographical education. Spatial information theory has emerged in the past two decades as a blending of interests from researchers in many fields, including geography, cognitive psychology, computer science, and linguistics. The biennial Conference on Spatial Information Theory (COSIT) has become an important meeting ground and publication venue for this multidisciplinary community of interest.

The creation of geographic information and knowledge follows from the gathering of observational data from human senses and mechanical sensors. Understanding the progression of representations involved at each stage of this process is important from both scientific and social theoretic points of view. Because geographic knowledge informs important policy and geodesign decisions, it is essential we understand the sources of error and bias in measurement and interpretation. The need for development of semantic reference systems as an essential complement to existing spatial and temporal reference systems has been described by Kuhn (2003) and has motivated considerable research activity on geographical ontologies.

Spatial concepts and spatial reasoning lie at the heart of geography as a multifaceted academic subject, and the professional practice of geography – one that began with the fundamentally spatial tasks of measuring Earth features and describing their spatial relations. Geography’s numerous subfields are often classified at the highest level in terms of conceptual or methodological duals: physical and human, quantitative and qualitative, space and place. As the intellectual traditions of geography have multiplied and grown more varied over two millennia, space and spatiality have remained integral to each. However, geographers’ conceptions of space are by no means uniform. There has, for example, been considerable debate on whether geography is a “spatial science.”

Space, space–time, and place

Broadly speaking, there are in geography two distinctive views of space: first, as a fundamental attribute of reality that is, with time, the mathematically describable context for natural phenomena; second, as a count noun standing for human conceptual constructs borne of
individual experience and societal factors such as power relations. Within the first view, there are distinctive conceptual frames: that of an absolute, Newtonian space as “container,” normally associated with Euclidean geometry, and that of relative space within which distance may be geometric or derived from other relations. The term “place” is often used to refer particularly to the human experience of space. Description affords analysis, and the concepts discussed below are by and large those enabling mathematical and formal-logical spatial analyses.

In modern physics, space and time are understood to be joined as the unbounded continuum of space–time, a four-dimensional reality wherein all phenomena are events. Certainly, to exist in a location with certain attributes is to exist there in that state for some period of time. However, those dynamics are not necessarily a focus in any given investigation. Other branches of science, including geography, have sought to develop four-dimensional representations, but have found it generally useful to hold time apart from the spatial dimensions in a “three plus one” model.

The spatial concepts enumerated here should be understood to have an important temporal dimension even where time is not mentioned explicitly.

**Universality and ubiquity**

Although geography is thoroughly spatial, the most fundamental of spatial concepts are by no means exclusive to geography. There are distinctive disciplinary perspectives on many, and some spatial terms (i.e., lexical concepts) can have multiple meanings. For example, surface normally refers to the physical bounds of an object, particle, or organism. In oceanography, surface topology is used to map currents and study climate. Materials scientists study the physical properties and chemical interactions of surfaces as interfaces between phases of matter. The calculations and design choices of structural engineers depend in part on surface stress properties of building materials. The term “surface” also refers to the mathematical description of a two-dimensional field, which is an important analytical construct in geography among many other fields. Finally, surface is also used to mean, “that which is superficial or most readily perceived” in any domain.

This example illustrates the way that many core spatial concepts have both a basis in physical reality and important metaphorical meanings in the physical and social sciences, in engineering and other design fields, and in the humanities. Johnson (1987) has argued convincingly that the ubiquity of metaphorical spatial conceptual language stems from the human bodily experience of physical interaction with the world, and proposed corresponding cognitive structures, termed image schemas, that represent for example the concepts and experience of containment, path, force, counterforce, and center-periphery.

**Spatial concept taxonomies**

There has been a growing impetus to enumerate spatial concepts and to organize them in one or more taxonomies, both within and outside of disciplinary perspectives. The motivations for this include (i) designing instruction in academic subjects such as geography, geoscience, chemistry, and engineering; (ii) designing training to improve spatial reasoning ability at all developmental and educational levels more generally; (iii) developing more usable software for professional practice, including geographic information systems (GIS); and (iv) making useful links between the above requirements
and basic research in cognitive psychology and education.

For education

Scientific instruction proceeds through grade levels with the introduction of concepts and conceptual frames of increasing complexity, seen for example in *Benchmarks for Science Literacy* (American Association for the Advancement of Science 1993). Hierarchies of complexity for spatial concepts in geography have been developed by at least two research groups. In one case (Golledge, Marsh, and Battersby 2008), five concept/task tiers are identified: primitive, simple, difficult, complicated, and complex; single examples of concepts for each of those levels are location, distance, adjacency, scale, and interpolation. In a second case (Jo and Bednarz 2009), three levels are identified: primitive, simple-spatial, and complex-spatial; single examples of concepts for these are, respectively, location, distance, and distribution.

For software design

Spatial analytical software and GIS enable the application of computational methods to research questions by means of specific models and algorithms. These are often instantiated as modular software programs (“tools”) applied individually or in sequence upon spatial data. Choosing the correct tool or tools to use for answering a particular question, from a library of hundreds, is problematic. This problem could be mitigated by organizing such tool libraries according to some spatial conceptual logic, preferably informed by cognitive studies and our improving understanding of hierarchical concept complexity. The structure for such organizing models could range from simple thesauri specifying broader, narrower, and related relations, to formal ontologies.

For improving spatial ability

There has been considerable psychological research on spatial cognitive ability in the past several decades, and there is now a common understanding that spatial ability is not monolithic, but rather multifaceted, making it more realistic to speak of multiple spatial abilities. That is, there are distinctive components involved, and individuals may be differentially competent at each. Recent research has shown that performance at some spatially demanding tasks can be improved by training and other interventions (e.g., Newcombe and Frick 2010).

A taxonomy adopted by cognitive psychologists (Newcombe and Shipley 2014) is based on two conceptual divisions. The first is between concepts concerning the internal structure of objects and those concerning objects’ locations in the world. The second is between static representations of such structure and position, and their dynamic nature and representation. This suggests four broad categories of spatial skills, which may be extended to concepts: intrinsic-static, intrinsic-dynamic, extrinsic-static, and extrinsic-dynamic (Figure 1). It should be noted that many spatial concepts do not fit neatly within a single category. For example, clusters are defined by spatial relationships within a reference frame, and have identity as objects unto themselves, with structural characteristics such as density.

Developing a universal taxonomy of spatial concepts has proven to be difficult, as spatial concepts seem to defy narrow classifications. This suggests multiple taxonomies will be useful, for different purposes. This entry does not attempt a strict ordering; rather, it enumerates a number of the fundamental spatial concepts in narrative fashion within the broad thematic groupings that follow.
Divisions of size and scale

The term “scale” has several related but distinct meanings. As a noun, it refers to a particular range of sizes or magnitudes. In an adjective phrase, scale is often used to mean relative or absolute size on one such scale, for example “large-scale” or “human scale.” The same entity may be considered large or small on different scales; even large ponds are small-scale water bodies.

When we say that each scientific, engineering, and artistic field is concerned with phenomena at some range of scales, we mean in some cases absolute size on the scale of all things, and in others the projective psychological scales of perception and representation (Montello 1993). Half a county can be viewed in the frame of an airplane window, and a two-dimensional projection of the entire Earth represented at a very small scale (a high ratio, or small representative fraction) to fit on a single sheet of paper. The “landscape” of a molecule can be scaled by a microscope to fill our field of vision.

There are disciplinary associations with particular scales, and disciplinary subdivisions can be scale-based. For example, distinct branches of physics concern phenomena at subatomic,
atomic, molecular, and astronomical scales. Chemistry concerns the dynamics of matter, principally at atomic and molecular scales. Industrial designers create tools and other mechanical devices at scales ranging from handheld objects to large vehicles. Architects design at the scale of buildings – single structures, ensembles of buildings, and the spaces within and between them. Many fine arts, including painting, sculpture, and dance, are intrinsically spatial, producing visual and/or kinetic forms; artistic scales in human terms can range from the figural (smaller than the human body) to vista (larger than the body but apprehended from a single location).

At the next larger scales we find geographers and planners, seeking scientific explanation and designing settlements and settlement systems in environmental space, which “is usually thought to require the integration of information over significant periods of time,” and geographical space, which “cannot be apprehended directly through locomotion; rather it must be learned via symbolic representations such as maps or models …” (Montello 1993, 315).

Fundamental spatial concepts

Given that no universally accepted taxonomy of spatial concepts has been developed to date, much less a formal ontology, the following geographically oriented groupings are presented. Definitional statements have been synthesized from geographic textbooks and dictionaries.

Spatial primitives

The most basic of spatial concepts are studied in classical physics, topology, and mereology (part–whole relations). These are primitives in a sense, from which we derive more complex concepts and principles. As noted earlier, many primitive concepts are used metaphorically in reasoning about spatiality as well.

Objects (bodies) in the universe are constituted by matter, giving them mass. Objects thus have physical extension and time-indexed spatial location. They are bounded – that is, there is a division between object and not-object – and they may be composed of smaller objects or have features considered as parts. Objects are subject to external forces, including from gravitational fields, and can move in space. That is, they change position with respect to each other or to a reference point, according to laws first described by Isaac Newton.

The relative position of objects (and their abstract representations as points, lines, and areas) can be described in the primitive non-metric terms of topology. These include concepts of containment and connection. Relevant cognate terms include adjacency and neighborhood.

Location

Arguably, the most fundamental of spatial concepts for geographers is location, and like many spatial terms, its definition is problematic. The terms location, position, and place are often used interchangeably, along with site and locale. They are “near-synonyms,” as each commonly appears in definitions of others. Each can be viewed as one kind of answer to the question, “where?” Geography seeks to explain the why of where, which requires first establishing location, as well as is practicable, by means of spatial descriptions. Geospatial data describe at minimum the location of some phenomenon and its class or category. As noted earlier, whereas all entities with spatial extent also have temporal extent, many geospatial data sets are either encompassed within a single temporal frame or divided into time-indexed “snapshots.”
SPATIAL CONCEPTS

Geographic locations in this broad sense can be represented mathematically in the so-called absolute terms of coordinates on a grid of two to four dimensions \((x, y, z, t)\), where \(t\) is time) having an arbitrary origin, or in relative terms of distance and orientation (or bearing) related to other locations. Relative locations are also frequently described in topological or otherwise nonmetric terms, including vague natural language such as “just north of.” Strictly speaking all locations are relative, whether to coordinates on an abstract grid and its possibly arbitrary origin, or to other entities. The reference origin of geographic coordinate systems is an estimated center of the Earth.

The location, position, site, or locale of a thing might be represented solely in mathematical terms or with additional attributes deemed essential to a particular investigator or perspective. For example, site and locale suggest important containment or environmental relationships.

In the most general terms, a place is a location about which we have something to say (Haggett 2001). However, the qualities of a place are understood by many geographers to include not only metrical location, but also (or alternatively) individual or collective human experiences there (Tuan 1977).

Distance

Euclidean distance is essential to metric descriptions of location and is thus a first-order concept one step removed from that primitive. Distances are the essential measure of spatial distributions (patterns), and therefore the basis for identification of clusters, spatial association, and centrality.

An important related concept for geographers, cost distance, is another example of the mutability of spatial concepts and their important value in reasoning more generally. Geographers have noted for many decades that metric distance is but one way of describing how far one thing is from another, effectively. The 12 miles between two locations across a plain and the 12 miles traversing a mountain have radically different meaning in human and economic terms of cost in physical effort and in elapsed time. Janelle (1968) developed the concept of time–space convergence to reflect the shrinking effect that transportation and communication technologies have upon the effective or functional distances of commerce and everyday life.

Representation

Our reasoning about spatial phenomena, and spatial concepts like their absolute or relative location, involves representation in several respects. When converting directly or remotely sensed data of counts and measurements into the mental, mathematical, physical, and graphical representations we call geographic information, we are reasoning about representations of concepts and not the phenomena themselves.

Two distinctive conceptual representations of space – those of objects and fields – inform representational strategies and methods. In simplest terms, the object view of space is that of “an inert container populated by objects” whereas the field view posits, “a ‘plenum’ characterized by a ubiquitous field” (Couclelis 1992, 70). These are analogous to a similar division in physics, and correspond to choices of vector and raster data formats in a GIS.

Several concepts pertaining to spatial representation derive from the object-field division and inform the digital maps geographers and cartographers make. We most commonly model physical objects geometrically in terms of points, lines, areas, and volumes. Fields are most often represented as matrices of uniformly sized rectangular cells corresponding to a particular spatial resolution, each with a single value for
a given attribute. Fields can also be derived from point data by means of spatial interpolation and represented in vector form as, for example, triangulated irregular networks (TINs).

One of the most important representational techniques for viewing and analyzing spatial data involves the overlay of spatially aligned datasets in order to merge or compare them visually and computationally.

Pattern and process; form and function

A cornerstone activity of both physical and human geographers is the identification of patterns of spatial distribution and their explanation in terms of the underlying processes that produce them. An analogous activity, more particular perhaps to physical geography, is the description of spatial form and its explanation in terms of processes, function, or human purpose. Spatial patterns concern the extrinsic spatial relations between objects of interest, including events as commonly understood (e.g., crime or earthquakes). In contrast, spatial form concerns intrinsic properties of objects and entities considered as objects, including indistinctly bounded features of a larger object (e.g., a mountain and the Earth), or collections of component objects themselves (e.g., wells in an oil field, or streams in a watershed). This flexible and scale-dependent conception of objects means the division between form and pattern is not crisp, as we have seen in several imprecise classifications discussed already.

A number of fundamental spatial concepts are common to the discovery and description of form and patterns; some of these have been mentioned previously. The form of a geographic object or feature is described in terms of its size and shape, as delimited by its boundary, and by its structure – the number and arrangement of component parts or features. Many geographic phenomena have a fractal nature. That is, their structure is self-similar at any scale of observation. We see this when viewing higher and higher magnifications of crystals, for example. Clouds, river networks, and coastlines are said to have fractal qualities.

Patterns in the spatial distribution of geographic phenomena can be reified as the human-defined analytical objects, regions and clusters. The concept of region is normally defined as an area having one or more characteristics distinguishing it from surrounding areas; however, regions can be purely spatial (e.g., northern) and are not always geographic (e.g., anterior). The identification of particular geographic regions can be controversial because their defining criteria – characteristics considered and quantitative thresholds – are often subjective. Like objects, regions are bounded, although regional bounds are more often indistinct, or fuzzy.

Clusters are spatial distributions defined by an abnormal concentration (i.e., high density) of some phenomenon within a study area. Although clusters are often abstracted to aggregations of points, the phenomena can be large geographic features as well, such as a cluster of islands. Clusters may define regions: for example, Tornado Alley is an informally bounded region of the United States where tornados have historically occurred most frequently.

Spatial context

Observations of natural phenomena occur within a reference frame, which forms the context for their description and analysis. The concepts of scale and granularity are closely related to reference frames. For example, what constitutes a cluster at one scale and within a particular reference frame can appear as an even or random distribution in another. The well-known modifiable areal unit problem arises from the
SPATIAL CONCEPTS

often times arbitrary choice of bounds used for aggregating point data.

Objects of study – whether things or occurrences – are almost always impacted by their surroundings, that is, their neighborhood, setting, or environment. Elements of relevant spatial context can include adjacent and nearby things, network connections at any distance, the bounds of a study area, and areal divisions within it. All are important factors influencing the results and interpretations of scientific studies.

Tobler’s “First Law of Geography” (1970) asserts that attributes of things that are near each other tend to be more similar than attributes of things that are far apart. Such similarity is assessed and confirmed by measures of spatial dependence and spatial autocorrelation. Because location and proximity are often omitted from statistical models, assumptions of independence for observational data are in many cases a fallacy.

Networks, connection, and interaction

Networks are the essential structural form of many human artifacts, from roads and railway systems to utilities infrastructure such as pipelines and power grids. Network structure appears throughout nature at many scales, for example in watersheds, circulatory systems, proteins, lightning, and neurons. Abstract network representations consisting of nodes and edges are an invaluable method of representing connectivity and interaction of all kinds. The analysis of social and professional networks has become a significant methodology in fields ranging from the history of science, to sociology, to business marketing. Nodes might correspond to individuals, groups, and publications or other products. Edges can correspond to friendship, co-authorship, affiliation, or production.

Spatial relations in all networks are at minimum topological ones of connectedness. If a network is geographically embedded, its nodes correspond to geographic locations. Its edges may as well, but with more or less resolution. That is, in some cases the geographical paths between nodes are either unknown or incidental. A common example of this is the representation of flows, where the attributes of interest are the source, target, class of substance, commodity, or activity and its aggregated magnitude for some period.

Many generalized spatial measures are relevant to all networks, whether geographically embedded and physical, or entirely abstract. These include size, density, connectedness, clustering coefficient, and node or edge centrality.

Spatial dynamics

Patterns of spatial distributions and of connectivity are intrinsically dynamic. They are the product of processes that transpire over time and their properties are time-dependent. The qualities, magnitude, and identity of many things in the world are in continual flux, and so a significant proportion of our scientific observations, measurements, and analyses seek to explain spatial change. Physical objects and Earth features change form, position, and orientation. Their identity can be changed by splitting and merging events, and by changes to essential attributes. A prime example is the changing shape, size, and nature of geographic features at the Earth’s poles, as influenced by climate. These types of spatial change extend to non-physical geographic features such as cities and countries, as well as to regions, which can be defined by any number of physical and social variables.

Concepts involving the spatial dynamics of movement are relevant in many fields and at most scales. Many have precise meanings in physics and chemistry, and alternate but similar or metaphorical meanings in other fields. In
physics, diffusion refers to a heat exchange process where a high concentration of a finite number of particles spreads throughout a solution in a random walk motion. In geography, diffusion can refer to the spread of a concept or practice from one or more locations to many more, but with some distinct differences: the paths taken by individuals are unlikely to be deemed random, and processes like dispersion and migration do not always entail some finite quantity dispersing elsewhere. Rather, geographic diffusion suggests probabilistic or deterministic dispersion and increasing magnitude. The term “flow” in the physical sciences refers to the continuous movement of matter (normally fluids) in a stream-like fashion. It is also used routinely and metaphorically in geography and many other fields in reference to nonmaterial things like ideas, and to nonfluids, such as commodities and currency in trade activity.

Spatial context

Sara McLafferty
University of Illinois at Urbana–Champaign, USA

Spatial context refers to the geographic setting in which events and processes occur. It comprises nearby places and the environmental, social, and geographical characteristics of those places. For a person, the relevant spatial context might include the person’s home and the surrounding neighborhood, along with locations that are important in daily life, such as the locations of work, school, friends, and family. The spatial context for a city might include the state or country in which the city is located, nearby towns and suburbs, and natural features in the neighboring area. Thus, spatial context is a relational concept that reflects the interactions between an entity and its nearby environment. The term “spatial context” is often used interchangeably with terms like “geographical context,” “neighborhood context,” and “place;” however, terms like neighborhood context and place include an important perceptual and experiential dimension – how people experience their local settings. In contrast, spatial context emphasizes the spatial properties of the setting, including its geographic size and relative location, and the proximity and density of environmental characteristics.

Three elements make up the spatial context for a particular topic: (i) the entity – the person, organism, location, or object of interest; (ii) the geographic setting or environment in which the entity is situated; and (iii) a set of rules or processes that govern the relationships between entity and environment. In defining a person’s spatial context with respect to health-care access, the entity is the person, the relevant environment comprises the locations of health-care providers, and the processes linking the two consider issues such as the person’s ability and willingness to travel, access to transportation, and providers’ referral networks, services offered, and outreach efforts. These processes determine the size and geographical characteristics of the spatial context.

Interest in spatial context first appeared in geography in the mid-1960s, when economic and political geographers like Julian Wolpert and Kevin Cox investigated how the spatial settings in which people live influenced their decision-making on questions like which crops to plant and how to vote. Interest in spatial context also emerged among behavioral geographers whose work examined the important question of how the spatial distributions of retail and service opportunities affect people’s decisions about where to travel for everyday activities. At the same time, urban and transportation geographers began to analyze spatial context through research on the spatial and temporal characteristics of activity spaces, the spaces in which people’s daily activities unfold. However, these early efforts were constrained by limited computing resources and difficulties in managing and analyzing the complex geospatial data needed for measuring spatial context.

These barriers began to fall during the 1980s, when geographic information systems (GIS) provided, for the first time, tools for rapidly measuring and analyzing spatial contexts and for categorizing and updating their social and environmental characteristics. A host of innovative spatial–contextual methods and approaches grew out of the GIS revolution, and their development....
SPATIAL CONTEXT

continues apace. At the same time, researchers in fields spanning the natural, social, behavioral, and health sciences are embracing the concept of spatial context and recognizing its significance, conducting empirical research on the implications of spatial context for issues ranging from animal behavior to geopolitical conflict to obesity. The remainder of this entry emphasizes advances in spatial context methods, models, and applications since the 1980s.

Identifying spatial contexts

A wide range of methods have been developed for identifying and estimating spatial contexts and most methods can readily be implemented using geospatial data and GIS. Given a set of one or more discrete entities – for example, people, locations, residences, or zones – the goal is to identify a spatial context for each entity. Typically, the spatial context is estimated as a discrete zone extending around the entity; however, alternative approaches have also been developed.

One of the simplest measures of context is spatial membership: location inside or outside a geographic zone. For example, location within a specific kind of climate zone might affect the presence of particular animal or plant species; similarly, living in a particular state in the United States influences access to benefits from the Medicaid program. Determining spatial membership is straightforward in GIS using point-in-polygon operations.

Another class of methods focuses on contiguity – the topological relationships between spatial objects. Spatial context for a zone can be defined as the set of neighboring zones, zones that share a common border, a principle known as rook contiguity (Figure 1a). To include diagonal neighbors, that is, zones that share a common point, the queen contiguity rule is used. In some cases, the spatial context that is relevant for a zone may extend beyond adjacent zones, especially in places where the zones are small in size. These larger areas of influence can be modeled by using higher-order definitions of contiguity: second-order contiguity encompasses all zones that are contiguous to a first-order contiguous zone (Figure 1b). As the order of contiguity increases, the geographic size of the spatial context increases, implying that the geographical setting or zone of influence for a place extends over a wide area. Defining spatial context based on contiguity is straightforward when the spatial data of interest are recorded for zones (polygons). If the data are recorded for points, Theissen polygons can be used to convert the data from point to polygon format, and then identify spatial contexts based on polygon contiguity.

Distance-based methods are widely used in identifying spatial contexts. The spatial context for an entity is defined as all places located within a particular maximum buffer distance of the entity. For example, a one-kilometer buffer distance from an individual’s home is often used to define the spatial context that can be reached by walking (Figure 1c). Although many studies have relied on Euclidean distance for measuring spatial context, a growing trend is the use of network buffers, which involves computing distance or travel time along a transportation network. Spatial contexts identified this way are irregularly shaped, following the contours of the transportation network. More complex metrics that incorporate transportation access and cost have also been developed.

A crucial issue in using distance-based methods to identify spatial context is the choice of buffer distance. By determining the radius or maximal extent of the modeled spatial context, buffer distance critically affects the results of spatial contextual research investigations. Studies show significant changes in model results as the buffer distance varies (Spielman and Yoo 2009).
Moreover, researchers typically use the same buffer distance for an entire study area or study population; however, the relevant spatial context is likely to differ among entities based on their social, geographical, and economic positions. For example, evidence suggests that the distances and times people are willing and able to travel vary greatly based on social characteristics such as age, gender, income, and rural/urban location.

Distance and contiguity methods represent the spatial context for an entity as a discrete, bounded zone: places are designated as either inside or outside the spatial context and only places within are important. In reality, most spatial contexts have fuzzy boundaries that reflect varying influences across space. Geographers have turned to field-based methods to represent the fuzziness of spatial contexts. Kwan (2000) generated spatial contexts for individual people via kernel density estimation of their daily activity locations (Figure 2). Spatial context is depicted as a continuous surface of varying intensity, in which peaks represent locations where daily activities are concentrated and valleys areas with few or no daily activities. Similar approaches have been used in representing animal’s home ranges – their spatial contexts – based on locations recorded by GPS monitoring devices. Field representations of context have also been important in modeling the social and environmental characteristics of spatial contexts, such as: ethnic/racial segregation; spatial accessibility of jobs, services, and resources; and environmental quality. Representing these characteristics as continuous fields enables examination of how the intensity of risk, access, and exposure vary within spatial contexts.

There is growing interest in space–time contexts, contexts that change dynamically over time. Such contexts are critically relevant for representing the environments that people experience as they move about in everyday life and
throughout their life course. The uncertain geographic context problem highlights the fact that spatial contexts are uncertain, reflecting myriad individual decisions and contextual influences, and that contexts change dynamically over time (Kwan 2012), with critical implications for research design and research findings. Interest in space–time contexts dates back to the work of Hägerstrand on time geography, and Hägerstrand’s space–time prism concept has been used to represent contexts as they unfold over time (Miller 1991). Activity locations, and the pathways connecting them, comprise the space–time context. Similar approaches are employed by researchers studying environmental influences over the life course based on individual migration data. For all of these space–time approaches, it is important to incorporate accurate data about the environment at each relevant time and place – a challenging task.

Today, GPS–enabled cell phones and other devices can be used to track individual movements in real time, providing highly accurate representations of space–time context that can be used in studying topics like exposure to environmental hazards, access to healthy/unhealthy food environments, and risk and protective environments for substance use (Zenk et al.}
These technologies are quickly decreasing the need to model spatial and space–time contexts, providing a strong empirical foundation for retrospective contextual representation. However, privacy and confidentiality restrictions and the high cost of data acquisition often limit application of these approaches to relatively small samples, and methods for analyzing the vast and complex “big data” obtained from GPS–enabled devices are still in their infancy. Still, analyzing these “experienced” space–time contexts presents tremendous opportunities for research in areas ranging from health sciences to ecosystem dynamics to environmental risk and vulnerability.

Spatial context, spatial analysis, and modeling

The notion of spatial context lies at the heart of many recent advances in spatial analysis and modeling. Developments in local spatial statistical analysis and modeling rest on the fact that spatial context matters (Lloyd 2011). Local spatial analysis methods involve the calculation of statistics or models at each location (entity) within an area, and the computations are made within the entity’s spatial context. The local Moran’s I statistic for location j, for example, represents the well-known Moran’s I statistic computed within the local spatial context of j. Location j’s spatial context is modeled by a vector of spatial weights that define j’s proximity to other locations. Spatial weights matrices express contextual relationships among all locations within a study area, and these matrices are foundational for all local spatial analysis methods, including spatial and spatiotemporal hotspot detection, spatial filtering and kernel density estimation, and geographically weighted regression. Development and application of these methods grow out of the key recognition that processes vary over space in response to environmental, social, and geographical characteristics of local spatial contexts. Efforts at downscaling global climate models, for example, clearly acknowledge the significance of spatial context.

The multiscalar dimensions of spatial contexts are also being incorporated in spatial analysis and modeling. Multilevel models represent contextual influences that exist at multiple geographical scales, such as the household, census tract, state, and country. In hierarchical models, these scales are neatly nested, so that each lower-level unit falls completely within a corresponding upper-level unit. Efforts are underway to develop methods for modeling non-hierarchical, multilevel, spatial contextual effects, although overlap of spatial effects across levels poses conceptual and methodological challenges. Spatial multilevel models – those that incorporate spatial associations beyond those represented by hierarchical spatial units – are also attracting attention.

Development of context-aware models reflects heightened awareness of spatial context among spatial analysts and modelers. Context-aware models involve constant updating of model parameters and outcomes based on changing conditions at a particular time and place. Methods like agent-based modeling enable researchers to represent the dynamic relationships between individuals and their local contexts, with contextual characteristics affecting behaviors and those behaviors simultaneously affecting spatial contexts. These methods have been used effectively in modeling the spatiotemporal spread of disease, impacts of habitat change on endangered species, and other complex, dynamic phenomena.

An important, but less studied implication of spatial context for spatial analysis and modeling is its constraining effect on model results. For many empirical research studies, the spatial configuration of environmental and social factors
forms a template within which data collection and sampling take place. That template limits the kinds of relationships and patterns that can be observed. For example, in a city in which the residential locations of high- and low-income groups are evenly intermixed, it is impossible to locate services to geographically advantage one group over the other: inequity cannot be observed in such a spatial context. This point was recognized in the 1970s and 1980s, when behavioral geographers observed that people’s revealed spatial preferences are influenced by the spatial configuration of opportunities and when empirical studies demonstrated the effect of this spatial constraint on measures of statistical association. Recent work suggests that the topological properties of spatial contexts are related to the properties of spatial models and tests (Farber, Paez and Volz 2009).

Impacts of spatial context on social and environmental processes

The past two decades have seen an enormous expansion of empirical research on spatial contextual effects. A wide range of phenomena are influenced by spatial context, including social outcomes such as employment and incomes, crime, and health and well-being, as well as environmental phenomena such as animal behaviors, natural hazards, and vegetation types and distributions. Because all living things depend on the environment for their survival, all are strongly influenced by spatial context. The diversity of topics makes it difficult to summarize empirical findings on contextual effects. Evidence shows, for example, that attributes of geographical and ecological context strongly influence species–area relationships at multiple scales (Drakare, Lennon, and Hillebrand 2006). Studies of people’s employment outcomes in cities indicate that unemployment and incomes are strongly shaped by the local availability of jobs, while at the same time reflecting individual and household characteristics such as gender, age, and ethnicity/race (Preston and McLafferty 1999). Research in these diverse fields emphasizes that the influence of spatial context differs from place to place, at multiple scales, and among entities (e.g., people, species), reflecting the dynamic connections between them.

In understanding how spatial context affects a particular outcome variable, it is essential to think through the processes that link context and outcome, so that context can be modeled appropriately. For human health studies, at least three processes are thought to connect outcomes and spatial contexts: exposure to environmental agents, such as pathogens or toxins in air and water; access to local economic and social resources, including parks and recreational facilities, stores offering healthy foods, job opportunities, and social support; and access to health-care services (Macintyre, Ellaway and Cummins 2002). Each of these processes has different implications for defining spatial context: analyzing environmental exposure requires detailed data on people’s indoor and outdoor locations and the intensity of environmental agents at those times and places. Researchers are increasingly using mobile environmental monitoring devices and dense sensor networks to record the spatial contexts of people’s environmental exposures. In contrast, access to health care is affected by human decision-making and mobility, availability of services, and political and economic forces that affect the array of services available and people’s abilities to use them. In this case, researchers model spatial context based on potential access to health care and incorporate important interpersonal variations.

The dynamic and relational qualities of spatial contexts present challenges for empirical
research. Contexts affect entities, but entities simultaneously affect contexts, making it difficult to disentangle their effects. Moreover, people and animals actively select contexts based on personal preferences, resulting in the important issue of selection bias. Although methodologies exist for addressing selection bias, these methods may not be feasible for particular kinds of research problems. Finally, even when selection into particular contexts is not based on preferences, there are often strong social or environmental forces that channel people into particular contexts, sharply limiting the opportunity to observe all types of people in all geographic settings. In the United States, for example, racial residential segregation implies that African Americans only live in a very limited subset of residential contexts, which confounds our ability to distinguish the independent effects of race and segregation.

In summary, it is widely recognized that spatial context matters in fields spanning the social and environmental sciences. At the same time, developments in GIS, spatial analysis methods, and geospatial technologies have greatly advanced the ability to model spatial contexts and explore their complex effects. Already, fundamental shifts in spatial contextual analysis are being witnessed, including the increased monitoring of contexts in real time using GPS-enabled mobile devices and environmental sensing networks, and heightened attention to methodological challenges, such as the uncertain geographic context problem, selection bias, and the constraining effects of spatial contexts on model estimates. Understanding how spatial contexts both constrain and enable lives and livelihoods, and how those, in turn, shape spatial contexts, presents exciting opportunities for research across the social and environmental sciences.

SPATIAL CONTEXT

Spatial crowdsourcing

Cyrus Shahabi
University of Southern California, USA

Smartphones are ubiquitous: we are witnessing an astonishing growth in mobile phone subscription that surpassed 4.35 billion worldwide at the end of 2009 (ABI Research 2010) and reached 6 billion in 2011, which is 87% of the world population. By 2013, Gartner, the world’s leading information technology research and advisory company, predicted that mobile phones would overtake PCs as the most common web access device worldwide. Meanwhile, the mobile phone’s bandwidth is constantly increasing: from 2.5G (up to 384 kbps) to 3G (up to 14.7 Mbps) and recently 4G (up to 100 Mbps) (Sauter 2011). Hence, the multiplication of the above two factors plus the constant progress and increase of smartphone’s sensors (e.g., video cameras) suggest an exponential growth in data collection and sharing by smartphones. That is, every person with a mobile phone can now act as a multimodal sensor collecting and sharing various types of high-fidelity spatiotemporal data instantaneously (e.g., picture, video, audio, location, time, speed, direction, and acceleration).

Exploiting this large volume of potential users and their movability, a new mechanism for efficient and scalable data collection has emerged: spatial crowdsourcing (Kazemi and Shahabi 2012). Spatial crowdsourcing requires workers (e.g., willing individuals) to perform a set of tasks by physically traveling to certain locations at particular times. Spatial crowdsourcing has applications in numerous domains such as journalism, tourism, intelligence, disaster response, environmental monitoring, and urban planning. To illustrate, consider a citizen-journalism scenario depicted in Figure 1, where a news agency (i.e., requester) is interested in collecting pictures and videos of demonstration areas from various locations of a city. With spatial crowdsourcing, the requester issues a query to a spatial crowdsourcing server (SC-server). Consequently, the SC-server distributes the query among the available workers in the vicinity of the events. Once the workers document their events with their mobile phones, the results are sent back to the requester.

Taxonomy

To start, a taxonomy is defined for spatial crowdsourcing (Figure 2). First, spatial crowdsourcing is classified based on workers’ motivation. Next, two modes of task publishing in spatial crowdsourcing are defined. Finally, the workers are classified into two groups based on whether or not they have constraints.

A major challenge in any crowdsourcing system is how to motivate people to participate. Four levels of worker motivation have been identified by Quinn and Bederson (2011), including pay, altruism, fun and implicit. To simplify, spatial crowdsourcing can be classified based on the motivation of the workers into two classes: reward-based and self-incentivized (Figure 2). With reward-based spatial crowdsourcing, every spatial task has a price (assigned by a requester) and workers will receive a certain reward for every spatial task they perform correctly. Examples of this class include Field Agent (www.fieldagent.
Figure 1  Ten locations of disasters. Ten tasks to be assigned (t1–t10) and three available workers in the immediate vicinity (w1–w3).

SPATIAL CROWDSOURCING

net/) and Gigwalk (http://gigwalk.com/). With self-incentivized spatial crowdsourcing, workers volunteer to perform the tasks or usually have other incentives rather than receiving a reward, such as documenting an event or promoting their cultural, political, or religious views. An example of this class is the University of California, Berkeley, traffic project (http://traffic.berkeley.edu/), in which more than 5000 users have voluntarily installed traffic software onto their phones and report traffic information.

Next, two task publishing modes in spatial crowdsourcing are defined: worker selected tasks (WST) and server assigned tasks (SAT). With the WST mode, the SC-server publishes the spatial tasks and online workers can choose any spatial task in their vicinity without the need to coordinate with the server. One advantage of the WST mode is that the workers do not need to reveal their locations to the SC-server since they can choose any arbitrary task in their vicinity autonomously. However, one drawback of this mode is that the server does not have any control over the allocation of spatial tasks. This may result in some spatial tasks never being assigned, while others are assigned redundantly. Another drawback of WST is that workers choose tasks based on their own objectives (e.g., choosing the k closest spatial tasks to minimize their travel cost), which may not result in a globally optimal
Spatial Crowdsourcing

Figure 2 A taxonomy of spatial crowdsourcing.

Assignment. An example of the WST mode is provided by Alt et al. (2010), in which the workers browse for available spatial tasks, and pick the ones in their neighborhood.

With the SAT mode, the SC-server does not publish the spatial tasks to the workers. Instead, any online worker sends his location to the SC-server. The SC-server, after receiving the locations of all online workers, assigns to every worker his nearby tasks. The advantage of SAT is that, unlike WST, the SC-server has the big picture and, therefore, can assign to every worker his or her nearby tasks while maximizing the overall task assignment. However, the drawback is that the workers should report their locations to the server for every assignment, which can pose a privacy threat. Examples of this mode of spatial crowdsourcing are provided by Kazemi and Shahabi (2012) and Kazemi and Shahabi (2011). In Kazemi and Shahabi (2011), a framework for small campaigns is proposed, where workers are assigned to their nearby sensing tasks.

Finally, in the case of SAT, we divide the workers into two groups based on whether or not they have constraints. With workers without constraints, the server has full flexibility on how tasks should be assigned to the workers. This means that workers only send their locations to the server, and the server assigns every spatial task to its nearby worker (Kazemi and Shahabi 2011). With workers with constraints, the server needs to satisfy the constraints while assigning the tasks. An example of spatial constraint is that every worker only accepts spatial tasks in a spatial region (i.e., his working region).

Task assignment

The main challenges of spatial crowdsourcing are due to the large-scale, ad hoc, and dynamic nature of the workers and tasks. First, to continuously match thousands of spatial crowdsourcing campaigns, where each campaign consists of many spatiotemporal tasks, with millions of workers, an SC-server must be able to run efficient task assignment strategies that can scale. Second, the task assignment must be performed frequently and in real time as new tasks and workers become available or as tasks are completed (or expire) and workers leave the system. Third, while in small campaigns the workers may be known and trusted, with spatial crowdsourcing the workers cannot always be trusted. In fact, some skeptics of crowdsourcing go as far as calling it a “garbage in, garbage out” system due to the issue of trust. Finally, individuals with mobile devices need to physically travel to the specified locations of interest. An adversary with access to these individuals’ whereabouts can infer sensitive details about a person (e.g., health status and political views); thus, protecting worker location privacy is an important concern in spatial crowdsourcing.

In the following it is shown that the combination of the abovementioned challenges renders the spatial crowdsourcing problem unique, where
SPATIAL CROWDSOURCING

the solutions proposed for similar problems cannot thoroughly address its task assignment problem.

The first class of similar problems is called volunteered geographic information (VGI) with the goal of generating geographical information provided voluntarily by individuals. Most real-world examples of VGI are limited to adding contents to a prebuilt map such as Wikimapia (www.wikimapia.org/), Google Map Maker (http://www.google.com/mapmaker/), or Open Street Map (www.openstreetmap.org/). As opposed to spatial crowdsourcing, with VGI applications there is no need for the worker to be present at any specific location in order to perform the task (even though being at a location can still improve the accuracy of the performed tasks; for example, in disaster regions the Red Cross may use Open Street Map because it is far more accurate than Google maps since people voluntarily report broken streets or bridges). As the name suggests, VGI is more self-incentivized, whereas in spatial crowdsourcing workers are assigned tasks by the SC-server.

Another class of similar problems, called participatory sensing, exploits mobile users to collect and share data using their sensor-equipped phones for a given campaign. Some applications of participatory sensing in the real world include traffic monitoring, urban planning, disaster response, and urban air pollution. Most studies on participatory sensing focus on small campaigns with a limited number of workers. However, with spatial crowdsourcing the focus is on devising a scalable, generic, and multi-purpose crowdsourcing framework, similar to Amazon Mechanical Turk, but spatial, where multiple campaigns can be handled simultaneously. Therefore, the main challenge with spatial crowdsourcing is to devise an efficient approach to assign tasks to workers given the large scale and dynamism of the environment.

Some recent studies in spatial matching do focus on efficiency and use the spatial features of the objects for more efficient assignment. Spatial matching is a one-to-one (or in some cases one-to-many) assignment between objects of two sets where the goal is to optimize over some aggregate (sum, max, etc.) function of the distance between matched objects. These studies assume that a global knowledge about the locations of all objects exists a priori and the challenge comes from the complexity of spatial matching. However, spatial crowdsourcing differs due to the dynamism of tasks and workers (i.e., tasks and workers come and go without our knowledge), and so the challenge is to perform the task assignment at a given instance in time with the goal of global optimization across all instances. Moreover, the fact that workers need to travel to task locations causes the landscape of the problem to change constantly. This will add another layer of dynamism to spatial crowdsourcing that renders it a unique problem.

One can consider the task assignment problem in spatial crowdsourcing as a matching problem between tasks and workers, which makes it similar to the classic matching problem. In particular, the online matching problem is the most relevant variation to spatial crowdsourcing as it captures the dynamism of tasks arriving at different times. However, once the number of tasks assigned to one worker is more than one, the online matching problem cannot capture the true cost of performing tasks. More specifically, the cost for a worker to perform a task mainly corresponds to the time it takes for him or her to travel to the location of the task. Thus the cost of a task is not a fixed value but is dependent on the user’s location before performing the task. The execution of a set of tasks is therefore the distance of the shortest path that starts from the worker’s current location and goes through the locations of all the assigned tasks. On the other hand, with online
matching the overall cost for one worker would be the sum of the distances between the worker and each assigned task.

Modeling the assignment cost as the shortest path visiting the location of multiple tasks brings another class of problems to attention. In this context the assignment problem in spatial crowdsourcing becomes similar to the traveling salesman problem (TSP) and the vehicle routing problem (VRP). The goal of VRP is to minimize the cost of delivering, using a fleet of vehicles, goods located at a central depot to customers who have placed orders for such goods. The online versions of both TSP and VRP have been studied to some extent where new locations to visit are revealed incrementally. Since there is only one salesman in the standard version of TSP, this entry focuses on VRP. Different variations of VRP have been studied, yet there are still some differences between task assignment in spatial crowdsourcing and these variations. In VRP, a server can pay a penalty and deny visiting a location; however, in spatial crowdsourcing the goal is to maximize the number of assigned tasks so the worker does not have the option of denying a task. Furthermore, with VRP, all servers start from the same depot whereas in spatial crowdsourcing each worker can have a different starting location. Moreover, with VRP there are a fixed number of servers whereas in spatial crowdsourcing the same type of dynamism for tasks can apply to the workers. That is, workers can be added (removed) to (from) the system at any time.

Now some preliminary approaches to solve the task assignment problem of spatial crowdsourcing are summarized. The first approach to task assignment problems is to simplify the issue by focusing only on a given instance of time and ignoring the dynamism of the environment. In this case, task assignment can be modeled as a matching problem, which can be reduced to the maximum flow problem (Kazemi and Shahabi 2012). In this study, the constraints of workers have been taken into consideration. Each worker has two constraints, including a spatial region \( R \) and the maximum number of acceptable tasks \( \text{max}T \) (see Figure 3). The spatial region \( R \) is the area represented by a rectangle, in which the worker can accept spatial tasks. The other constraint, \( \text{max}T \), is the maximum number of tasks that the worker is willing to perform at the given time instance. Therefore, the optimization goal is to maximize the number of assigned tasks while conforming to the constraints of the workers, referred to as maximum task assignment instance (MTA instance).

It has been shown (Kazemi and Shahabi 2012) that the MTA-instance problem is reducible to the maximum flow problem. Thereafter, one can use any algorithm that computes the maximum flow to solve the MTA-instance problem. One of the well-known techniques in computing the maximum flow is the Ford–Fulkerson algorithm.

Next, Kazemi and Shahabi (2012) extended the maximum task assignment (MTA) problem by taking into account the time dimension. That is, MTA considers multiple instances of task sets.
Spatial Crowdsourcing

and worker sets over time. Also, each task has an expiration time and thus needs to be completed before the deadline. Therefore, the goal of MTA is to maximize the total number of assigned tasks over all time instances. Solving MTA could be straightforward if the SC-server was clairvoyant, knowing what tasks and workers would arrive or leave in future. Three alternative solutions to the MTA problem have been proposed by Kazemi and Shahabi (2012). The first approach, called greedy (GR), follows the local optimization strategy by maximizing the task assignment at every time instance. The second approach, called least location entropy priority (LLEP), improves the overall task assignment by prioritizing spatial tasks located in worker-sparse areas (i.e., places with low location entropy). The assumption is that spatial tasks are more likely to be performed in the future if they are located in worker-dense areas. In this approach, each task is associated with a certain cost, which is the entropy of the task location. Accordingly, tasks with lower costs have a higher priority, since they have a smaller chance of being completed. Thus, the goal is to assign the maximum number of tasks during every instance of time while the total cost associated to the assigned tasks is the lowest. This problem is reducible to the minimum-cost maximum-flow problem, which can be solved by using the Ford–Fulkerson algorithm to compute the maximum flow and then minimizing the cost by applying linear programming. With spatial crowdsourcing, the travel distance of the workers is also important. The third approach, namely nearest neighbor priority (NNP), incorporates the travel distance of the workers into the task assignment by assigning higher priority to the tasks with lower travel distance. Therefore, a similar solution to that of LLEP but with a different cost function (i.e., travel cost) can be applied to solve this problem.

Trust

One challenge with spatial crowdsourcing is that the human workers are not equally trusted and hence it is important to verify the validity of the results provided by these workers. This problem was studied in Kazemi, Shahabi, and Chen (2013), where every worker was assumed to have a reputation score indicative of the probability that they would perform a task correctly. The concept of a reputation score is similar to any reputation system used by Internet markets such as eBay. Moreover, each spatial task is assumed to have a confidence value (i.e., a necessary criteria set for expected answers) which states that the answer to that spatial task is only accepted if its confidence is higher than a certain threshold. Hence, the problem is to maximize the number of assigned tasks while satisfying the confidence of every task, referred to as the maximum correct task assignment (MCTA) problem.

Figure 4 illustrates an example of a trustworthy spatial crowdsourcing system with a set of spatial tasks \( T = \{ t_1, \ldots, t_{10} \} \) and a set of workers \( W = \{ w_1, w_2, w_3 \} \). The desired level of confidence of the tasks and the reputation scores of the workers are shown in two different tables. An example of an assignment is to assign \( t_2 \) and \( t_3 \) to \( w_1 \), since they have a smaller chance of being completed. Thus, the goal is to assign the maximum number of tasks during every instance of time while the total cost associated to the assigned tasks is the lowest. This problem is reducible to the minimum-cost maximum-flow problem, which can be solved by using the Ford–Fulkerson algorithm to compute the maximum flow and then minimizing the cost by applying linear programming. With spatial crowdsourcing, the travel distance of the workers is also important. The third approach, namely nearest neighbor priority (NNP), incorporates the travel distance of the workers into the task assignment by assigning higher priority to the tasks with lower travel distance. Therefore, a similar solution to that of LLEP but with a different cost function (i.e., travel cost) can be applied to solve this problem.

However, there may be tasks whose confidence values are too high to be matched by the reputation of any single worker. Therefore, Kazemi, Shahabi, and Chen (2013) proposed having tasks performed redundantly by multiple workers. The idea of redundant collection is to increase the reputation score on the content. That is, multiple workers with different reputation scores can solve the same task so that their aggregated score
satisfies the required confidence for the task. Consequently, an exhaustive approach needs to compute the aggregate reputation score (using a typical decision fusion aggregation mechanism, such as voting) for all possible subsets of the workers, which renders the problem NP-hard (by reduction from the three-dimensional matching problem (Kazemi, Shahabi, and Chen 2013)). Therefore, a number of heuristics have been proposed to achieve close to optimal performance but with a cost close to that of a GR approach, by exploiting the spatial properties of the problem space.

**Privacy**

Another challenge with spatial crowdsourcing is to protect worker location privacy while still using an SC-server as a broker to assign tasks to workers. Location privacy has been studied before in the context of location-based services. Several solutions (Gruteser and Grunwald 2003; Ghinita et al. 2008; Mokbel, Chow, and Aref 2006) have been proposed to protect location-based queries, that is, given an individual’s location, find points of interest in the proximity without disclosing the actual coordinates. However, in spatial crowdsourcing, a worker’s location is no longer part of the query, but rather the result of a spatial query around the task location. This makes the problem more challenging, and previous solutions do not offer satisfactory results. In addition, some work considers queries on private locations in the context of outsourced databases, in which the data owner entity and the querying entity trust each other, with protection being offered only against intermediate service provider entities. This scenario does not apply in spatial crowdsourcing since there is no inherent trust relationship between requesters and workers.

A framework for location privacy in spatial crowdsourcing was proposed in To, Ghinita, and Shahabi (2014). With this framework, worker locations are first pooled together by the data owner (i.e., cell service provider, or CSP) and sanitized according to differential privacy (DP) (Qardaji, Yang, and Li 2013; Cormode et al. 2012). Thereafter, the SC-server only has access to the sanitized data. However, using DP techniques introduces two challenges. First, the SC-server must match workers to tasks using noisy data, which requires complex strategies to ensure effective task assignment. Worker location data are sanitized at the CSP using the private spatial decomposition (PSD) approach (Cormode et al. 2012). PSD is a sanitized spatial index, where each index node contains a noisy count of the workers rooted at that node. Particularly, this study devises a mechanism to create a worker PSD by extending the adaptive grid technique (Qardaji, Yang, and Li 2013). On top.
SPATIAL CROWDSOURCING

of the noisy data, to ensure that task assignment has a high success rate, the authors developed analytical models and task assignment strategies that consider task completion rate, worker travel distance, and system overhead. Second, by the nature of the DP protection model, fake entries may need to be created in the worker PSD. Thus the SC-server cannot directly contact workers, not even if pseudonyms are used, as establishing a network connection to an entity would allow the SC-server to learn whether an entry is real or not, and breach privacy. To address this challenge, a geocast mechanism was introduced for the task request dissemination. Geocast is a routing and addressing method, which is used to deliver information to a group of destinations in a network identified by their geographical locations. Once a PSD partition is identified by the analytical model outlined above, the task request is geocast to all the workers within that partition. Geocast introduces system overhead that needs to be carefully considered in the framework design.

Conclusion

Participatory sensing and crowdsourcing have each been shown to have major societal impacts in various areas: from disaster response when organized information collection systems fail, to citizen news dissemination when mainstream media are censored, to community data collection at large scales when centralized data collection approaches are deemed too expensive (e.g., Google map community), to human-reliant data processing tasks used in order to improve query answering in databases when either queries are subjective or information required to answer queries is missing. Spatial crowdsourcing is a natural next step to scale single-campaign, customized participatory sensing to the generic, multipurpose, scaled-up platform of crowdsourcing. Given the increasing popularity of mobile phones, their continuously increasing bandwidth, power, and sensory features, and the consistent drop in their price, the growth of spatial crowdsourcing is inevitable.

With crowdsourcing, there are many obvious social implications, for example, spatial crowdsourcing can be abused to collect illegal information. There are also orthogonal technical challenges that are not discussed here, for example, with “trust,” the quality of the collected data was not discussed – a worker may have a good reputation but his or her sensor may be broken or wrongly configured (e.g., flash turned off) and he or she may collect garbage. Alternatively, one may consider the expertise of the workers in order to assign them tasks. Note that a worker’s expertise is different and orthogonal to his or her reputation. Another interesting extension is to consider the allocation of rewards to tasks to incentivize workers. The challenge is how to assign a reward to each task in order to maximize the number of completed tasks.

In addition, this entry only focused on server-assigned approaches to spatial crowdsourcing where the server has all the information and matches workers to the tasks. Alternatively, we can consider a scenario where the server publishes all its tasks and workers autonomously select the tasks in their vicinity. This approach would result in local optimization of the task assignment problem because each worker acts alone and selfishly without considering the global objective. However, this approach has the advantage of being more privacy friendly as the workers do not need to share their locations with the server.

In sum, spatial crowdsourcing is a fruitful area of research with many challenging problems and a strong connection to real-world application scenarios benefiting from further research.

SPATIAL CROWDSOURCING

Spatial data infrastructures

Max Craglia
European Commission Joint Research Centre, Italy

Background

A spatial data infrastructure (SDI) is an Internet-based facility to search, find, access, and share location-specific information. The term “spatial” is generic and may refer to any space, from the microscale to the cosmos. In practice, however, the term is often used as a synonym of “geographic” or “geospatial,” that is, space that refers to the earth’s surface, or near-surface. A widely used definition of an SDI is the one adopted in President Clinton’s Executive Order 12906 of 1994 that established the National SDI in the United States: a framework of “technology, policies, standards, and human resources necessary to acquire, access, store, distribute, and improve utilization of geospatial data” (Clinton 1994).

The development of SDIs started in the 1990s following the rapid diffusion of geographical information systems (GIS), and the increased availability of spatial data in digital format. The transition from mainframe computers and dedicated workstations (in the 1970s and 1980s) to desk-top personal computers (in the 1990s) made it possible for thousands of organizations across the world, in both public and private sectors, to start using GIS and to develop applications in many areas, such as urban planning and management, land management, environmental assessment, risk management, and logistics. Initially, each organization had to acquire hardware, software, and data either by digitizing paper maps or by buying digital data from third parties. Most of the use of these data was internal to each organization. As the use of the Internet also spread rapidly in the 1990s, it became possible to publish and share spatial data through this medium. This was a significant step forward but also exposed the limitations of uncoordinated developments in which each organization developed its own applications without consideration of the interoperability of systems or data, making reuse by other organizations very difficult and costly. SDIs were initially developed to address these limitations and to provide a framework for a more coordinated sharing of spatial data based on agreed standards.

Over the past 25 years, most countries in the world have embarked on the development of SDIs, initially driven by the public sector at a national level, but increasingly also at subnational and local levels. The private sector is also a key player, not only as provider of hardware and software (and sometimes data) but also as a user of SDIs and GIS to develop services and applications for both private and public sector clients, in what is often referred to as the location-based industry (or location-based services).

Key components

Most SDIs have developed along similar lines and have the following components.

- **Metadata**, which are structured descriptions of the datasets available through the SDI.
Typically, this also involves the adoption of an existing metadata standard or the definition of an agreed upon way to document available resources.

- A catalog of the metadata records and a set of Internet services used to search, discover, view, and access the data, which are held not in a centralized data store but in a distributed network of data providers. In the United States’ National SDI, this set of services is called a clearinghouse. In other SDIs, this term is not used but the essence is still the same: support for users to search and find what they are looking for, and for data providers to publish their data and related descriptions. Again standards are implemented to ensure that the services can be used effectively across multiple technological platforms.

- Core data sets or framework data are frequently used across multiple applications, and are prioritized in the SDI to be documented and made accessible. The United States’ National SDI, for example, identified seven framework themes: digital orthoimagery, geodetic control, elevation, transportation, hydrology, government boundaries, and cadastral or land ownership information. The European SDI discussed later is much more ambitious with 34 core data themes.

- A set of policies must govern data access and reuse. This is a key component of any SDI because the heterogeneity of policies related to data access and reuse has been, and often continues to be, a key stumbling block to users. In a few countries data can be used with no restrictions at all, in some it can be used with few restrictions (e.g., for non-commercial purposes), whilst in others data must be purchased at high cost and reuse is severely restricted. Compounding the problem of different policies across countries, and even organizations in the same country, is the fact that policies are sometimes not clear, discriminatory, or poorly developed. Users wishing to integrate data from multiple sources with different policies will then encounter the complex problem of restrictions stacking up and compounding each other, making use of the derived data very difficult.

- Coordination of the infrastructure is absolutely crucial, as the essence of an SDI is based on distributed sources of data (and services) from multiple contributors. To build an effective infrastructure it is necessary to get these multiple contributors to agree on standards, protocols, policies, and funding mechanisms to deploy and sustain the operations of the infrastructure. These agreements are by no means easy to forge and sustain, as each partner has to derive a benefit in the endeavor, and the benefit has to be perceived at all levels from senior management down to the technical staff who implement standards and protocols in their daily work. Underpinning the implementation of an SDI with a legal framework it sometimes is helpful to get the attention of senior management and have some leverage to support coordination. It is, however, not a sufficient condition to guarantee success.

A practical example from Europe

Whilst many countries in the world are building an SDI, one of the most complex examples is the Infrastructure for Spatial Information in Europe, INSPIRE, because this SDI, focused on environmental applications, spans 28 countries in 24 languages, and has a strong focus on harmonizing the data necessary to underpin environmental policy across 34 different thematic domains (EC 2007).
The purpose of INSPIRE is to support environmental policy and overcome major barriers that affect the availability and accessibility of geospatial data. These barriers include:

- inconsistencies in spatial data collection: spatial data are often missing, incomplete or, alternately, the same data are collected twice by different organizations;
- lack of or incomplete documentation of available spatial data;
- lack of compatibility among spatial data sets that cannot, therefore, be combined with others;
- incompatible SDI initiatives in Member States that often function only in isolation;
- cultural, institutional, financial, and legal barriers that prevent or delay the sharing of existing spatial data.

The key elements of the INSPIRE Directive that have been developed to overcome these barriers include:

- metadata to describe existing information resources, so that they can be more easily found and accessed;
- harmonization of key spatial data themes needed to support environmental policies in the European Union (EU);
- agreements on network services and technologies to allow discovery, display, downloading of information resources, and access to related services;
- policy agreements on sharing and access, including licensing and charging;
- coordination and monitoring mechanisms.

INSPIRE addresses 34 key spatial data themes organized in three groups (or Annexes to the Directive) reflecting different levels of expected harmonization, and a staged phasing (Box 1).

The legal framework of INSPIRE has two main levels. At the first, there is the INSPIRE Directive itself, which sets the objectives to be achieved and asks the EU Member States to pass their own national legislation establishing their SDIs. This mechanism of European plus national legislation allows each country to define its own way to achieve the agreed objective, taking into account its own institutional characteristics and history of development.

The drawback of having 28 different “flavors” of INSPIRE is that making the system work is undoubtedly more difficult. For this reason, the Directive envisages a second level of legislation, the implementing rules, which are more stringent because they must be implemented as is, and do not require follow-up national legislation. Therefore, INSPIRE envisages technical implementation rules in the form of formal legal acts for metadata, harmonization of spatial data and services, network services, data and service sharing policies, and monitoring and reporting measures to evaluate the extent of the Directive’s implementation and to assess its impact. Each of these regulations needs the approval of the Member States and of the European Parliament. The first implementing rules were approved in December 2008 for metadata, while the last set of implementing rules to specify the data models of Annex III data themes and for the interoperability of spatial data services were approved in 2013.

INSPIRE has several characteristics that make it particularly challenging. The most obvious is that it is an infrastructure built in 28 different countries using 24 languages. The requirements for multilingual services and interoperability among very different information systems and professional and cultural practices are, therefore, very demanding. This means, for example, that existing standards, where they exist, must be tested in real distributed and multilingual settings.
In the best scenario, all works well, but for a European-wide implementation there is a need to translate the standards and related guidelines into the relevant languages (the standards by the International Standards Organization, ISO, and the Open Geospatial Consortium, OGC, are typically in English only). In other instances, testing has demonstrated that the standards are insufficiently mature, or leave too much room for different interpretations, and thus require further definition or individual bridges to make different systems interoperate. This can be seen in the results of tests on distributed queries in catalogs that used the same specifications; the results identified a number of shortcomings that required the development of an adaptor for each catalog, which in a Europe-wide system with thousands of catalogs, would obviously not scale. In harder cases still, there are no available standards, and therefore they have to be created. This applies, for example, to the specifications required for the interoperability of spatial datasets and services, which is a central feature of INSPIRE.

To understand the context, it is worth remembering that each country in Europe has its own heritage and traditions, which also include different ways and methods for collecting environmental and geographic data, different traditions on how to analyze and visualize them, including different coordinate reference systems (sometimes more than one in each country), projections, and vertical reference systems. These different traditions mean that it is not enough for an SDI in Europe to help users find and access data; it is also necessary to understand
the meaning of what we are accessing to make appropriate use of it. This means, in turn, that it is necessary to develop not only translation tools to help overcome the “natural” language barriers but also agreed reference frameworks, classification systems and ontologies, data models, and schemas for each of the data themes shown in Box 1, against which the national data can be transformed or mapped. This is necessary because it is not possible to ask the Member States and their national and local organizations to re-engineer all their databases. Thus, the approach adopted is to develop agreed European models and systems of transformation (on-the-fly or batch), so that the level of interoperability necessary for key European applications can be achieved.

The approach sounds simple but putting it into practice and sustaining it over a long period is very complex, as it required seven years of work to develop an agreed methodology (the generic conceptual model) and tools, mobilize hundreds of experts in different domains, and deliver and test the specifications for the datasets falling in each of the themes identified in the Annexes of the Directive. A visit to the INSPIRE website (http://inspire.jrc.ec.europa.eu/index.cfm) in the data specifications’ sections demonstrates the large amount of work involved. There are thousands of pages of specifications and, not to be forgotten, tens of thousands of comments that had to be addressed individually during the stakeholder consultations.

The organizational model put in place to develop INSPIRE is one of its more interesting features, drawing significant attention also from outside Europe. In essence, it is a substantial exercise in public participation, the likes of which is most unusual in policy-making. From the outset it was recognized that for INSPIRE to be successful and overcome barriers to data access and use, it was necessary for the legislators, implementers, and practitioners in the Member States to come together and agree on a shared understanding of the problem, and of possible solutions. Therefore, an expert group with official representatives of all the Member States was established at the beginning of the process in 2001, together with working groups of experts in the fields of environmental policy and geographic information to formulate options and forge consensus. The INSPIRE proposal was subject to an extended impact assessment to identify potential costs and benefits, before it was opened for public consultation. The revised proposal was then debated by the Council and European Parliament over a three-year period before final adoption in 2007. This process in itself is a good example in democracy but the more interesting aspect is the way in which interested stakeholders continue to participate in ongoing activities required to develop the INSPIRE implementing rules (i.e., the follow-up legal acts and detailed technical guidance documents).

To organize this process, two mechanisms were put in place: the first is to engage the organizations at European, national, and sub-national levels that already have a formal legal mandate for the coordination, production, or use of geographic and environmental information (the so called legally mandated organizations or LMOs). The second mechanism aims to facilitate the self-organization of stakeholders, including spatial data providers and users from both the public and private sectors, into spatial data interest communities (SDICs) by region, societal sector, and thematic issue. Through these mechanisms, hundreds of organizations and thousands of experts across Europe have volunteered to contribute to the development of the technical specifications, and their testing.
The complexity of this participatory approach is certainly innovative, not only in relation to the developments of SDIs but also more generally to the formulation of public policy at the European level. The outcome produces both consensus-based policy and the development and maintenance of a network of stakeholders that make it possible to implement a more effective distributed European SDI. Participation is high, but it requires considerable effort. In particular, maintaining the momentum of the process, the commitment of hundreds of organizations, and thousands of experts, and building a relationship of trust across multiple levels of governance is a difficult challenge. Without this social network, however, it would not have been possible to develop INSPIRE. An interesting outcome of this process is that the network is now used by the Member States to help them implement their technical infrastructures, and to share expertise, funding, and technical components across multiple Member States.

The INSPIRE example is notable because it highlights a general lesson that applies to any SDI: SDIs are about data, technology, and standards but would not work without a strong social infrastructure underpinning the technical one. This social dimension will become even more important as SDIs coalesce into other data infrastructures in the public and private sectors (e.g., the recent open data initiatives taking shape around the world) and the general public becomes not just a user but also a producer of information and data, which then can be integrated with official data. Technology is rapidly shifting towards mobile devices and open applications, thus challenging the established patterns of relationships among the traditional public sector players (mapping agencies, geological agencies, land and property organizations), value-added integrators, and users. The increased availability of data from high-resolution satellites and sensor networks sending constant streams of terabytes of data per day, coupled with unstructured data from mobile devices and social networks, will change the way data and information are organized and processed, but geographical location will remain as one of the key organizing principles of data streams. In this respect, SDIs will continue to be important whatever shape they take in the future.

Spatial database

Markus Schneider

University of Florida, USA

Definition

In various application disciplines, such as geography, the earth sciences, and geographical information systems (GIS), there is a need to manage large volumes of spatial or geometric data, that is, data related to space. Geographic data are a special category of geometric data. According to the old vector/raster debate, data related to space can be subdivided into spatial objects (vector view), which have features such as identity, location, extent, and relationships to other objects, and image data (raster view), which are available as digital bitmaps and can be stored, manipulated, and retrieved as discrete entities. Because of the fundamentally distinct nature and dichotomy of the two kinds of data, the requirements and techniques for dealing with spatial objects are rather different from those for dealing with raster images. This entry will only deal with spatial objects that are kept in spatial databases, not with images that are kept in image databases. In some sense one can say that spatial databases and image databases are complementary. A spatial database system (Rigaux, Scholl, and Voisard 2002; Shekhar and Chawla 2003) is a full-fledged database system with additional capabilities for handling spatial objects. A spatial database system should not be special purpose systems only. Since in practice spatial objects always occur in connection with nonspatial, alphanumerical data, a spatial database system should be a full-fledged database system with additional capabilities for handling spatial objects. Feature 2 stresses that special data types are needed for spatial data. In the two-dimensional (2-D) space, we distinguish point, line, and region objects, each of which have different properties. Feature 3 relates to special operations that are needed.
for processing spatial objects. Examples are the computation of a region object as the result of the intersection of two region objects, the calculation of the length of a line object, and the determination of the convex hull of a large number of point objects as a region object. Feature 4 deals with special Boolean functions that allow one to check topological properties or cardinal directions. For example, one can check whether a line representing a river is located with in a region representing a state, or whether the city district Brooklyn is southeast of the Central Park. Feature 5 requires a special query language that allows a user to pose spatial queries that are evaluated by the spatial database system. Feature 6 refers to the implementation of the aforesaid concepts and aims to achieve a high performance of geometric computation in a database context. This especially requires methods from computer science and computational geometry (de Berg et al. 2008; Preparata and Shamos 1993). Spatial join techniques support connecting spatial objects from different database tables through some spatial predicate in a more efficient way than combining all tuples from individual tables (Cartesian product) and filtering the combinations that fulfill the predicate. Spatial index structures (Samet 2006) avoid scanning the whole set of spatial objects in order to identify those objects that are located in a particular area. This entry will exclusively focus on the conceptual features in points 1 to 5 and neglect the implementation features in point 6.

Historical background

In the late 1970s, an interest arose in storing geometric data in databases in order to support spatial and geographic applications. The success and efficiency of relational database technology for standard alphanumerical applications, which is rooted in its simple data model, its structured query language (SQL), and its well-understood underlying theory, has led to many proposals to transfer this technology directly to geometric applications and to explicitly model the complex structure of spatial data in database tables. But this turned out to be a very unfavorable approach since the consequence is that the user conceives spatial data in tabular form, just the same as standard data, and that a spatial object is represented by several or even many tuples and possibly even spread over several databases tables. An example of such a relation schema is

$$\text{RelName}(id : \text{real}, x_1 : \text{real}, y_1 : \text{real}, x_2 : \text{real}, y_2 : \text{real}, \text{type} : \text{string}, <\text{other information}>)$$

where $x_1, y_1, x_2,$ and $y_2$ are the coordinates of a point or a line segment. The flag type indicates whether a tuple describes a point, a single line, a line segment of a line, or a line segment of a polygon. The value $id$ denotes the object identifier. A line object with several line segments has now to be represented by several tuples, each of which describes a single segment. One can show that an adequate representation of a polygon needs three tables.

This approach has revealed a number of fundamental drawbacks. Since all lines and polygons are decomposed into a set of line segments (tuples) scattered over one or more relations, a spatial object is not treated as an entity or unit but only corresponds to several tuples. This is different compared to values of standard data types such as integers or strings. A second drawback is that the approach forces the user to model complex spatial objects in flat, independent tables. Since the representation of spatial data occurs on a very low level and is exclusively based on standard domains such as integers, strings, and reals (while the user has originally intended to deal with points, lines, or polygons (regions)), an adequate treatment of spatial data is impeded. Although the facilities of the query language of a database management system (DBMS) are available, they
are only of limited use. Since such a language is based on standard domains and has no concept of spatial data types, it cannot provide and support any meaningful geometric operations.

**Spatial data types**

The numerous deficiencies of the approach of modeling spatial data as database tables have resulted in the assessment that this approach is unsuitable to manage spatial data in a clean and efficient manner and that a high-level view of spatial objects is essential. This has led to the design and implementation of special data types called spatial data types (Schneider 1997). Data types, in general, are a well-known concept in computer science (e.g., in programming languages or in database systems). A data type defines a set of homogeneous values and the allowable operations on those values. An example is a type integer representing the set of 32-bit integers and including operations such as addition, subtraction, and multiplication that can be performed on integers.

**Spatial data types** or geometric data types provide a fundamental abstraction for modeling the geometric structure of objects in space as well as their relationships, properties, and operations. They form the foundation of spatial databases. One speaks of spatial objects as values of spatial data types. Due to the inherently complex structure of spatial objects, spatial data types have been designed as abstract data types (ADTs). This enables them to (i) provide a high-level view of spatial objects since the internal data structure of a spatial object is invisible to the user, (ii) offer a high-level usage of spatial operations and predicates because the underlying geometric algorithms are hidden from the user and results of geometric computations and properties of spatial objects can only be obtained by calling these (abstract) operations, and (iii) be used as attribute data types in a database schema in the same way as standard data types such as integer or string. Spatial data types have a conceptually complex structure and can be defined for the 2-D space and the three-dimensional (3-D) space. But spatial databases nowadays mainly support 2-D spatial data. In the 2-D space we distinguish the spatial data types point, line, region, spatial network, and spatial partition. Note that different implementations (e.g., software packages) may adopt different terms for each of these spatial data types, but the underlying concepts are universal. If we are only interested in the locations of a spatial object, we use a point object. A point object represents a finite number of locations, that is, single points. For example, the locations of all lighthouses in Florida can be kept in a point object. A point object is called simple (Figure 1a) if it only contains a single point; otherwise, it is called complex (Figure 1d). If we are interested in the areal extent of a spatial object, we call it a region object. A region object consists of a finite number of disjoint components (except for common single boundary points) called faces, possibly with one or more disjoint holes (except for common single boundary points). Examples are an air-polluted zone or Italy with its mainland and offshore islands as faces and the Vatican as a hole in the mainland. A region object is called simple (Figure 1c) if it only contains a single face without holes; otherwise, it is called complex (Figure 1f). If we are interested in the linear extent of a spatial object, we call it a line object. A line object consists of a finite number of disjoint components called blocks, each of which contains a finite number of curves. Examples are the ramifications of the Nile Delta or the geometry of a street network. A line object is called simple (Figure 1b) if it consists of a single block with a single curve; otherwise, it is called complex (Figure 1e). The generality of the aforementioned spatial data
Spatial Database

types in terms of multicomponent spatial objects is important since only this property ensures that the spatial data types are closed under geometric set operations such as geometric intersection, geometric union, and geometric difference. That is, applying a geometric set operation to two spatial objects of the same spatial data type will lead to a resulting spatial object of the same type.

Even more complex spatial data types are spatial networks and spatial partitions as the essential components of maps. They represent spatial connectivity structures, that is, the individual spatial objects in them fulfill certain topological constraints toward each other. A spatial network (Figure 2a) can be viewed as a spatially embedded planar graph which consists of a set of point objects representing its nodes and a set of nonintersecting line objects describing the geometry of its edges. Examples are highways, rivers, public transportation systems, power lines, and phone lines. A spatial partition (Figure 2b) is a set of region objects fulfilling the topological constraints that any two regions either meet or are disjoint. The neighborhood relationship is of particular interest here since region objects may share common boundaries. Examples are states, school districts, crop fields, and land parcels. Both spatial networks and spatial partitions are not purely geometric structures since their components (line objects, region objects) are annotated with thematic data such as state name, unemployment rate, and parcel identifier.

Three-dimensional data types have so far not been implemented and provided in spatial databases. But increasingly geoscience applications are interested in 3-D data representations and geometric computations. They will require data types such as surface, for example, to model the shape of landscapes, and volume, for example, to represent urban areas, clouds, hurricanes, and temperature zones.

Spatial operations

Spatial objects as values of spatial data types are processed by spatial operations. A spatial operation is defined as a unary or binary function with spatial argument objects, that is, it takes one or two spatial objects as operands and returns either spatial objects or scalar values as results. Spatial operations are especially important for spatial query languages into which they are embedded and which allow new kinds of powerful queries
that were impossible before. In the following we provide an overview of the most important spatial operations and consider them in the 2-D space. They can be classified into the following categories: (i) spatial predicates returning Boolean values, (ii) spatial operations returning constituents of a spatial object, (iii) spatial operations returning numbers, (iv) spatial operations returning spatial objects, (v) spatial operations on sets of spatially referenced objects, and (vi) spatial selection and spatial join.

A spatial predicate is applied to two spatial objects and returns a Boolean value that represents the validity of a spatial relationship. A spatial relationship is a relationship between two spatial objects and characterizes their relative position to each other with respect to different aspects. They can be classified into the following subcategories: (i) topological relationships, (ii) directional relationships, (iii) spatial order and strict order relationships, (iv) metric relationships, and (v) fuzzy relationships. Their importance for spatial databases consists in their use as filter conditions in spatial joins and spatial selections.

Topological relationships such as \textit{intersect} and \textit{disjoint} describe purely qualitative properties of the relative positions of spatial objects toward each other. They rest on topological properties for their description and include concepts such as continuity, adjacency, overlapping, interior, boundary, connectivity, and inclusion. There is no dependence on a distance function, since topological relationships are not distance-preserving. An essential property is that they are preserved under continuous topological transformations including all affine transformations such as translation, rotation, and scaling. They enable the user, for example, to ask for land parcels that are \textit{adjacent} to a hazardous waste site, to explore the \textit{overlapping} of a river floodplain with a proposed highway network, or to determine for a collection of cities and states which city is located \textit{within} which state. They belong to the most formally investigated spatial relationships. The goal has been to formally determine sets of topological relationships that characterize all topological situations between two spatial objects and are mutually exclusive. The most well-known models for achieving this are the 9-intersection model (9IM) (Egenhofer and Franzosa 1991) and the Region-Connection-Calculus (RCC) (Cui, Cohn, and Randell 1993). Figure 3 shows the eight topological relationships \textit{equal}, \textit{disjoint}, \textit{coveredBy}, \textit{covers}, \textit{intersect} (\textit{overlap}, \textit{cut}), \textit{meet} (\textit{touch}, \textit{adjacent}, \textit{neighboring}), \textit{inside} (\textit{within}), and \textit{contains} between two simple region objects as they have been identified by both models.

Topological relationships have been investigated for all combinations of simple spatial objects as well as all combinations of complex spatial objects of the spatial data types \textit{point}, \textit{line}, and \textit{region} (Egenhofer and Franzosa 1991; Schneider and Behr 2006). Table 1 shows their numbers based on the 9-intersection model.

The large number of topological predicates for each combination of complex spatial data types makes it difficult for the user to distinguish, remember, and handle them. Topological cluster predicates (Schneider and Behr 2006) have been defined that group similar topological

relationships together based on user-defined and/or application-specific rules.

*Directional relationships* also describe purely qualitative properties and check the *cardinal directions* between two spatial objects. More precisely, we distinguish *absolute directional relationships* such as *north* and *southwest* with respect to a given reference or coordinate system from relative directional relationships such as *rightOf* and *leftOf*. Absolute directional relationships are especially important for geographical applications. Users may, for example, ask for all hurricanes that have ever been west of Florida, the general direction of the whale routes in the Gulf of St Lawrence, or all land parcels that are located to the west of the parcels of power stations. The background for the interest in the latter query could be that due to west winds these parcels are endangered by the hazardous influence of air pollution.

*Metric relationships* such as *inCircle* and *inWindow* use distance measurements in order to test if a spatial object lies within the scope of a predefined circle or rectangle, respectively.

*Spatial order and strict order relationships* are based on the definition of order and strict order. As a rule, each order relation has an inverse relationship. For instance, *behind* is a spatial order relationship based on the order of preference with the inverse relationship *inFrontOf*. Other examples are the pairs *above*/*below* and *over*/*under*. Also, the pair *inside*/*contains* can be regarded as a spatial order relationship.

*Fuzzy relationships* such as *nextTo*, *close*, *near*, or *far* are vague distance relationships. While users are able to cognitively interpret their meaning, it is difficult to formally define these predicates.

*Spatial operations returning constituents of a spatial object* allow the user to extract components of a spatial object that are conceptually known to the user but not directly accessible at the user’s level; they can only be accessed through operations. Examples are *xCoord* and *yCoord* to obtain the x-coordinate and y-coordinate of a single point as real numbers, *getSegment* to get access to a segment of a line or region object, and *getFace* to get access to a face component of a region object.

*Spatial operations returning numbers* comprise spatial operations which compute a metric property of a spatial object and return a number as a result. The operation *area* returns the area of a region object, and the operation *perimeter* yields its perimeter. The operation *length* calculates the total length of a line object. The operation *dist* determines the minimal Euclidean distance between any two spatial objects. The operation *diameter* computes the largest Euclidean distance between any of its components. The operation *direction* computes the angle between any two spatial objects as a real number in the range $0 \ldots 359°59’59”$. The results of all operations enumerated so far are real numbers. The operation *noOfComponents* (cardinality) yields the number of components (points, blocks, faces) of a point, line, or region object as an integer number.
Spatial operations returning spatial objects take one or two spatial objects as arguments and return single spatial objects as results. Two subcategories can be distinguished: (i) object construction operations which construct new objects from two or more existing objects, and (ii) object transformation operations which transform a single spatial object into a new spatial object.

Object construction operations as the first subcategory include geometric union, intersection, and difference operations and are applied to two point, two line, or two region objects. These operations fulfill closure properties. This means that if they are applied to two objects of the same spatial data type, they always yield an object of the same spatial data type. For example, to find out which part of a school district is exposed to an air-polluted area, we can geometrically intersect both region objects and will obtain a region object as a result. For the intersection of line objects we have the special case that they can also intersect in a collection of points, that is, in a point object. Two region objects might meet and share a collection of single boundary points represented as a point object. In both cases the operation commonPoints computes this point object. Two region objects may also meet and share a common boundary line. The operation commonBorder determines this common boundary as a line object. The operation intersection can also be applied to two objects of different spatial data types and yields an intersection object of the spatial data type of lower dimension.

The operation convexHull (Figure 4) constructs the convex hull of a point set (point object) and is defined as the smallest convex polygon enclosing all points. It is, for example, deployed to find the diameter of a point object, that is, the maximum distance of any two points of the point object. The diameter will always be the distance between two points of the convex hull.

The operation closest takes a complex point object $p$ and a reference point object $r$ as input values and yields a complex point object whose points are from $p$ and nearest to the points in $r$ (Figure 5).

The operation $mBB (box, mBR)$ computes the minimum bounding box (aka minimum bounding rectangle) that bounds a spatial object and is axis-parallel to the selected reference frame (coordinate system). The operation centroid computes the arithmetic mean, that is, average, position of all the points in the spatial object. The operation contour (aka boundary, border) produces the boundary line of a region object as a line object. Such a line object contains the outer cycles and hole cycles of all region object components (faces). The operation vertices (aka boundary, border) returns the end points of a line object as a point object. The operation choose produces an “arbitrary” point on or inside each component of a line object or a region object. This is useful when such an object is to be approximated by a single point for each component as a representative. The operation interior is applied to a line object, identifies all outer, encompassing
cyclic structures, and represents them as a region object. The effect is that all cyclic and acyclic structures within these outer cyclic structures are removed. For example, if $R$ is a region object, then the term $\text{interior(\text{contour}(R))}$ can be used to remove all holes in $R$. Another variant of the operation $\text{interior}$ takes a point object and a line object as operands and produces a region object that comprises a set of smallest faces where each face surrounds a point of the point object and has a boundary that is part of the line object. That is, if $R$ is a region object, then the term $\text{interior(choose}(R), \text{boundary}(R))$ is equal to $R$.

Object transformation operations as the second subcategory comprise operations such as $\text{extend}$, $\text{rotate}$, and $\text{translate}$. The operation $\text{extend}$ (also called $\text{buffer}$, $\text{buffer zoning}$, or $\text{region expansion}$) takes a spatial object $s$ and a real number $r$ as operands and creates a polygonal outer region which is a spatial expansion of $s$. Parameter $r$ indicates the expansion distance from $s$ (Figure 6). If $r$ is negative, a shrinking operation on a region $s$ is computed and leads to an inner region. The operation $\text{rotate}$ rotates a spatial object around a point; the operation $\text{translate}$ moves a spatial object by a defined vector.

Spatial operations on sets of spatially referenced objects support the manipulation of spatial connectivity structures such as spatial partitions, that is, subdivisions of space (such as school districts), and spatial networks, that is, spatially embedded graphs (such as road networks), which are associated with thematic data (such as the number of students or road names). As such they are very complex since, in contrast to the operations of the other categories, these operations have to cooperate with a DBMS data model (relational, object-oriented, complex object, etc.). They do not manipulate individual spatial objects but collections of spatial objects with special topological properties and annotated with thematic data. They take a set of spatially referenced objects as arguments and produce a new set of spatially referenced objects as a result.

The operation $\text{overlay}$ is one of the most frequently used spatial operations in a GIS and allows a user to transparently lay two partitions modeling different thematic topics on top of each other and to combine them geometrically.
Two variations of the operation overlay.

Figure 7 Two variations of the operation overlay.

into a new partition of disjoint or adjacent regions. Two different interpretations of the overlay mechanism are given in the literature (Figure 7). In the first interpretation (overlay₁), the resulting object set contains one new region object obtained as the intersection of a region object of the first partition with a region object of the second partition. Since the plane need not be completely covered by regions, it is possible that a region object of one partition does not intersect any region object of the other partition. In this case it will not be part of the resulting partition. In the second interpretation (overlay₂), also taken into account are those parts of region objects that do not intersect any region object of the other partition.

In this case it will not be part of the resulting partition. In the second interpretation (overlay₂), also taken into account are those parts of region objects that do not intersect any region object of the other partition.

The operation superimposition allows the spatial objects of a partition to be superimposed on another partition and parts of the other partition to be to covered and erased (Figure 8).

The operation fusion (merge, generalization) takes as input a spatial partition and a set of thematic (i.e., nonspatial) attributes that are a subset of those attributes associated with all region objects of the spatial partition. As output it creates a new spatial partition that geometrically merges the region objects of the input partition on the basis of the equality of the values of the reduced attribute set and that associates the corresponding values of the reduced attribute set to each obtained region object. Figure 9 shows a partition of districts with their land use. Each district is marked with an identifier \( d_i \) and its crop cultivation. The task is to compute the regions with the same land use. For this purpose, the set of attributes \{identifier, crop cultivation\} is reduced to the set \{crop cultivation\}. This has the effect that single districts with the same land use are merged by geometric union to a complex district possibly consisting of several faces. Further, neighboring districts with the same crop cultivation are geometrically merged by erasing the common boundary line between them. Each hatched area \( d_i \) on the left side of Figure 9 is part of an object describing a district. On the right side, after the application of the operation fusion, all areas belonging to the same group \( g_i \) form a single region object and are hatched in the same way. District boundaries are not distinguished any more. To be feasible, the fusion operation requires that region objects are defined as many-component objects with holes.

The operation cover (sum) yields a single region object as the geometric union of all region objects of a spatial partition (Figure 10).

The operation windowing allows one to retrieve those regions of a spatial partition whose intersection with a given (rectangular, polygonal, circular) window is not empty (Figure 11). An example of windowing is a query where the window is defined as a circle with center \( p \) and radius \( r \) and where we ask for all objects whose distance from a given point \( p \) is less than \( r \).

The operation clipping selects those parts of a partition which lie inside a given rectangular window (Figure 12).
The operation \textit{voronoi} is based on a well-known structure from computational geometry. For a given set $S$ of points in the plane, the Voronoi diagram (also called Thiessen diagram) associates with each point $p$ from $S$ the region consisting of those points of the plane that are closer to $p$ than to any other point in $S$ (Figure 13). The resulting set of regions forms a spatial partition. Usually, some regions of a Voronoi diagram are infinite, namely those belonging to the points on the convex hull of $S$. But if we assume a rectangular reference frame that surrounds all points in $S$, the operation \textit{voronoi} constructs the Voronoi diagram for the points inside this rectangle.

An important task of spatial predicates is to serve as filter conditions for \textit{spatial selection} and \textit{spatial join} operations. Let $S$ be a set of database
objects or database tuples, each of which contains a spatial object. A *spatial selection* filters out all those database objects of S whose spatial object fulfills a selection condition given either by a spatial predicate or by a comparison expression that contains a spatial operation with a numerical result as a constituent part. For example, having stored data about the US states, one could ask for all those states with an area less than 66000 square miles.

*Spatial join* operations represent database operations that combine two sets of database objects on the basis of the fulfilment of a spatial predicate; they construct a new database object as a concatenation of the two argument database objects. For example, given a set of city objects with their geometric point locations and a set of state objects with their regions, one could ask for all those city names and state names where the city location is located in the state region. This is an example of an *inside join*.

In the literature, the term “spatial join” is not used in a uniform way. Some authors equate the term with the spatial join intersection operation, that is, where the spatial predicate in the join condition is restricted to an intersect predicate. Other authors do not distinguish between spatial selection and spatial join operations. Another example is an *overlap join* where the filter condition checks the intersection of two region objects. An example is a query that finds out all counties that were affected by hurricane Katrina.

### Spatial query languages

Spatial query languages serve as a communication interface between the spatial database system and the user. By adding spatial data types, operations, and predicates, they are often extensions of SQL, which is the standard query language for relational databases. Spatial queries allow the user to get the spatial information of interest. A few examples will illustrate this. Consider the map of the 50 states of the United States. Each state has its thematic attributes, such as name and population, as well as a geometry which is described by its region. Such a region has an internal complexity since it can have holes (such as enclaves) and can consist of several components (such as mainland and islands). Cities have a name and a population and are geometrically represented as points, that is, we are here interested in their location and not so much in their extent. Let us assume the two relational database tables *states* and *cities* whose schemas are given as

**states**(sname: string, spop: integer, territory: region)
**cities**(cname: string, cpop: integer, loc: point)

Each table schema consists of attributes (such as *sname* or *loc*) that describe properties of database objects or tuples (such as *states* objects or *cities* objects), and each attribute has a data type such as *string* or *integer*. The two spatial data types *point* and *region* are used to represent the spatial objects of cities and states, respectively. They are attribute data types in the same way as the types

---

**Figure 13** The operation *voronoi*. 
**SPATIAL DATABASE**

*string* and *integer*. The difference is that spatial data types have an inherently complex structure. The internal structure is made deliberately invisible to a user and can only be accessed by high-level operations. A query could ask for all pairs of city names and state names where a city is located in a state. This can then be formulated as a spatial join.

```sql
select c1.sname, c2.sname, dist(c1.loc, c2.loc) as distanceBetweenCities
from cities c1, cities c2
where c1.cname <> c2.cname
```

This query uses the metric operator *dist* to compute the minimum Euclidean distance between two point objects. The next query determines all neighbor states of Colorado and is another example of a spatial join.

```sql
select s1.sname, s2.sname
from states s1, states s2
where s1.territory meets s2.territory and s2.sname = 'Colorado'
```

This query make use of the topological predicate *meets*. A further query lists all states with at least one neighboring state and sorts this list according to the number of neighboring states.

```sql
select s.sname, count(s1.sname) as noOfNeighbors
from states s, states s1
where s.territory meets s1.territory
order by count(noOfNeighbors)
```

This query first combines each state tuple *s* with each other state tuple *s1* if their territories are adjacent. Then it groups all resulting tuples that have the same state name *s.sname* together, uses the SQL aggregate function *count* to total its neighboring states *s1.sname*, and outputs the state names sorted in ascending order by the number of neighboring states. Our last query asks for those states that have only one neighboring state.

```sql
select s.sname
from states s, states s1
where s.territory meets s1.territory
having count(s1.sname) = 1
```

Here, by using the SQL *having* clause, only those groups that consist of only one tuple are admitted for further consideration. They describe states with only one neighboring state. The reader is invited to determine whether this query has a solution and, if so, what the solution is.

Spatial problems confronting policy, business, and planning arenas are often complex and “wicked” in nature, in that they are hard to specify and have no easy, satisfactory solutions (Jankowski et al. 1997). Yet, decisions still need to be made. This dilemma – decision-making in the face of uncertainty, ambiguity, and incomplete information – has formed the foundation for spatial decision-support systems (SDSS) research and development (Densham 1991). This dilemma has also guided the development of SDSS from workstation, expert-oriented, and single-user systems to web-enabled, multi-user systems that can be used in settings as diverse as participatory planning (Jankowski et al. 2006) to on-the-ground, real-time decision-making for land management (Arciniegas and Janssen 2012), routing, and many other applications. The rationale for ongoing SDSS development is exemplified by the estimate that 80% of data used by managers are spatially dependent, meaning that many high-stakes decisions have integral spatial components.
SDSS researchers and practitioners have decided to address have shaped the current status of SDSS research and understanding.

Background and history

Sugumaran and Degroote (2011) divided the history of SDSS into the three overlapping phases. In the 1980s, researchers and practitioners merged the notions and technologies of geographic information systems (GIS) and decision-support systems (DSS), and subsequently developed prototypes. During the 1990s, the SDSS community integrated new technologies into SDSS and applied the technology to new disciplines and in novel use cases, such as group and collaborative contexts. By the start of the 2000s, SDSS were being implemented more widely, particularly with the advent of web-based SDSS and the subsequent deployment on mobile technologies. While these phases are not definitively demarcated points in time, they can serve as a general frame of reference for considering the broad trends within SDSS research and development.

During the introductory phase of SDSS, researchers developed conceptual frameworks and subsequent prototypes for command-line desktop or workstation users. Patrick Mantey and Eric Carlson were likely the first to document an SDSS in the 1970s and 1980s, though they did not use the term “spatial decision-support system.” Their work focused on the geodata analysis and display system (GADS). Developed by IBM, GADS allowed noncomputer users to interact with spatial data. Another similar system, the generalized planning system (GPLAN), used spatial data in a decision-support system. The system allowed users to iteratively analyze and plan land use while considering the impacts on water quality. For the first time in 1985, Hopkins and Armstrong used the term “spatial decision-support systems” to describe an analytic and cartography framework, and by 1989, the terminology of spatial decision-support systems was becoming more widely used, particularly in the geographic and land information systems literature where prototype applications were being described. This last point illustrates the long connections between SDSS and land-use analysis and planning. Generally speaking, wider adoption was hindered during the introduction phase by expert knowledge requirements, and the high technology costs related to computation, memory, and data storage.

Computer hardware and software advances in the 1990s encouraged SDSS development, which spurred greater deployment for new use cases. Specifically, three things enabled SDSS expansion: (i) less expensive, higher-powered desktop computers, (ii) easy-to-use graphical user interfaces (GUIs), and (iii) more accessible software development environments. Because SDSS became easier to develop and use, they could be more widely researched and adopted. Commercial GIS packages such as the Environmental Systems Research Institute’s (ESRI) ArcInfo and ArcView, MapInfo, IDRISI (now known as TerrSet), TransCad, along with open source GIS such as Geographic Resource Analysis Support System (GRASS), played important roles in advancing the usability of GIS and encouraged the development of SDSS.

Accompanying these new software packages were easy-to-use application development languages such as Arc Macro Language (AML). These new languages enabled experts to more easily incorporate and create problem-specific models, and allowed researchers to address one of the core limitations of utilizing GIS as SDSS (Densham 1991). The proliferation of GUIs also enabled collaborative or group
SDSS by overcoming some of the limitations of single-user SDSS and command-line interfaces.

Theoretical developments in participatory planning processes and collaborative decision-making accompanied technical developments. For example, Jankowski et al. (1997) developed and implemented a group SDSS that utilized multicriteria decision modeling combined with consensus-building techniques. The general framework, called Spatial Group Choice, was originally used to support a habitat restoration project, but was also shown to be applicable to areas as diverse as healthcare and transportation system design. Looking ahead to the potential proliferation of SDSS, where experts would not always be able to guide use, researchers saw a need for automated expert-guided decision systems. Such systems, developed using expert knowledge, relied on extensive sets of if-then-else statements that would guide users through a problem context. As GIS and ICT advanced, and the Internet emerged through the late 1990s, researchers began turning their attention to the potential that existed for web-based SDSS, though the vision wouldn’t be fully realized until the 2000s (Sugumaran and Degroote 2011).

The number of SDSS publications grew substantially in the 2000s as GIS became more usable and increasingly applied to specific problem domains. Use of web-based SDSS enabled increased accessibility and cross-platform flexibility in addition to an efficient mechanism for data storage, administration, and distribution. Specific web-mapping platforms emerged in the late 1990s and early 2000s such as ESRI’s ArcIMS (Arc Internet Map Server), the University of Minnesota’s MapServer, and GeoMedia WebMap, though these platforms supported limited analysis capabilities. In many respects, the 10 years of web-based SDSS development from 2000 to 2010 mirrored the desktop developments of the 1990s. In terms of content, web-enabled SDSS often focused on environmental or conservation impacts of land use, and often employed elements of multicriteria decision analysis, but also included examples of identifying potential store locations and route finding. Web-enabled tools for spatial data storage, processing, and analysis could be built using many different development platforms, such as Extensible Markup Language (XML), Web Services Description Language (WSDL), Simple Object Access Protocol (SOAP), Universal Description, Discovery and Integration (UDDI), and ESRI’s ArcGIS. The rise in web-based services marked the beginning of service-based SDSS, and provided an opportunity for modular, problem-specific instantiations of user-friendly SDSS.

Currently, web-based and distributed SDSS continue to advance in their capacities for usability, mobility, and computational power. With the rise of cloud computing technologies, many SDSS follow a server-side data storage and processing architecture where users interact with data visualized through a web browser or lightweight application, and then send processing requests to a central server that can handle large volumes of data (Wang et al. 2013). New distributed server frameworks such as Spatial-Hadoop (http://spatialhadoop.cs.umn.edu) and other “big data” infrastructures are enabling users to “mash up” data and perform analysis through a web browser with processing occurring off-device (Wang et al. 2013). The trajectory of SDSS fits into the larger trajectory occurring within GIScience (i.e., CyberGIS; Wang et al. 2013) as demand increases for real-time, flexible spatial data analysis and visualization. Example use cases include the monitoring of and responding to social media for disaster relief. This move in GIScience corresponds with the general trend toward remote
monitoring and dynamic management of the “Internet of Things” that consists of critical infrastructures and services such as the power grid or emergency response systems, as well as consumer household products. Additionally, as the trajectories of planning and business continue toward collaborative processes, researchers are exploring how to maximize participation through new input/output devices such as large touch screens (Arciniegas and Janssen 2012).

SDSS as sociotechnical systems

Taking the broadest definition, an SDSS consists of a technical component (i.e., hardware and software) and a stakeholder component (i.e., users; Jankowski 2008). These two components form a sociotechnical system that can function in many different ways, and therefore, can be described in many different ways, which is aptly illustrated throughout the SDSS literature (Densham 1991; Jankowski 2008; Sugumaran and DeGroote 2011).

Technical components

The technical component of an SDSS combines the spatial capacities of geographic information systems with analysis, modeling, scenario evaluation, and other decision tools to support a user or group of users in a spatial decision-making processes. As data availability has improved, and technology has become less expensive and easier to use, more people in a greater diversity of domains have begun to use SDSS, which mirrors the general trajectory of GIS and ICT (Sugumaran and DeGroote 2011). From a hardware perspective, this trajectory has meant a shift from individual workstations and personal computers to collaborative touchscreens and mobile and cloud-based SDSS models (Arciniegas and Janssen 2012). Software has also undergone a revolution, transitioning from single-user software to web-based applications that run through Internet browsers supported by large-scale, cyberGIS infrastructures (Wang et al. 2013).

Spatial decision-support software components are typically quite diverse, and rely on various configurations, depending on the specific decision problem. The various software components for an SDSS can be (i) embedded, where the system components are hard-coded together and share common data structure, storage, and user interface, (ii) tightly coupled, where components share a common user interface, have separate data structures or storage, but may still be hard-coded together, or (iii) loosely coupled, where inputs and outputs are used from component to component, but may be transferred by an analyst or user (Jankowski 2008). Embedded and tightly coupled components can happen on individual systems, but are increasingly happening server-side through web portals.

The core of an SDSS is the database that houses vector, raster, and tabular forms of data. Depending on the scale of the SDSS implementation, databases can be housed on individual workstations or on a centralized server. If the data are housed on a centralized server, data processing can occur either client-side on users’ devices, or server-side. The latter is often preferable for web-based applications given the greater computing power of servers. Data interoperability has long been a major challenge within GIScience; however, new data synthesis efforts combined with easy-use portals could substantially decrease this problem. Examples of such projects include TerraPopulus (Minnesota Population Center 2013), the Integrated Public Use Microdata Series (iPUMS; Minnesota Population Center 2013), the Globe Project (globe.umbc.edu), NASA’s socioeconomic data center (SEDAC), DataOne (www.dataone.org), the University of
Wisconsin’s Center for Sustainability and the Global Environment (http://nelson.wisc.edu/sage), and commercial data warehouses such as ESRI’s Living Atlas of the World. However, having large amounts of data readily accessible creates new concerns surrounding data accuracy, uncertainty, and appropriate use, particularly if such data are being used in high-stakes decision processes (Sugumaran and DeGroote 2011).

Models used in SDSS can take many forms, ranging from simple land suitability models, to complex dynamic equilibrium, agent based, spatial analysis, or multicriteria optimization models. Simple distance measures, overlays, buffers, and land suitability modeling capabilities often come with common GIS packages (Jankowski 2008). Dynamic equilibrium and agent-based models often require add-on packages or extensive programming in GIS-specific languages in order to implement (Parker et al. 2003; Shook, Wang, and Tang 2013). However, additional modeling with GIS add-on packages is often a primary requirement of creating a fully functioning SDSS. Spatial analysis functionality encompasses a large range of spatial statistics applications, and can be used to explore empirical or modeled data. Multicriteria optimization modeling can involve all of the previously mentioned models, and seek a mathematically optimal outcome across multiple variables (Malczewski and Rinner 2015). Model selection will depend heavily on the specific purposes of the SDSS.

Visualization within SDSS mostly consists of two-dimensional maps and charts, but with new computing advancements, three-dimensional visualization is becoming more feasible. Visualization of data should enable users to simply and quickly weigh the tradeoffs and synergies for the relevant variables across the different decision situations (Jankowski 2008). One of the reported benefits of using maps as a central means to visualize data is that decisions can be made more quickly; however, decision performance can decrease as problem size and data dispersion increase and data aggregation decreases (Keenan 2006). As a result, experts are often more accurate than nonexperts in using maps for decision-making, which means that education and training are key in order for nonexperts to successfully use maps for decision-making.

User interfaces for SDSS have ranged from command-line and mouse and keyboard interfaces, to large touch tables for group collaborative work. While command-line and mouse and keyboard interfaces may be preferable for the expert working alone, they can present barriers to group interaction. As a result, large touch tables and screens have been deployed. In one example, Arciniegas and Janssen (2012) describe the use of a large touch-enabled screen laid flat as a table. The tool can sense which of four users is touching it, and allows for simultaneous usage. Such tools enable increased face-to-face collaboration and decision-making by removing the computer from the primary center of focus, but still provide a shared map interface.

Domains as diverse as transportation engineering, city and regional planning, water resources management, agriculture, and forestry have adopted SDSS, with users ranging from individuals to large groups across a variety of levels of technical expertise. New commercial tools, such as ESRI’s ArcGIS Online, CityEngine, and Geodesign tools, along with open source Javascript libraries, such as Leaflet and D3, are likely to continue to increase disciplinary use of SDSS as applications become easier to build, deploy, and maintain, and less expensive to rapidly develop. However, “big data” applications will likely remain time-, money-, and expertise-intensive, though with the advent of
modular and reproducible “big data” SDSS, this may not be the case.

Social component

Decision-making involves the selection from two or more potential options (Jankowski 2008). How individuals and groups move through the decision process has been theorized in various ways, each of which has strengths and weaknesses when considering the implications for SDSS technical and process design. Antunes et al. (2014) describe three complementary views of models for the decision-making process: sequential, dynamic, and continuous (for more information, see Decision analysis). Each theoretical model is likely to have tradeoffs and synergies, given a specific SDSS application context. Stakeholder expertise, as stated above, plays a significant role in what creates an effective SDSS for an application context. Regardless of the theoretical model that an SDSS will be designed with, iterative development and user testing will be required.

Design considerations

A major goal of human–computer interaction is anticipating user needs for information (Jankowski et al. 2006). In practice, doing so requires iterative development of an SDSS. Development processes are discussed at length in the human–computer interaction literature. There are many factors to consider when designing an SDSS, including software and hardware costs; the deployment hardware platform and the respective operating system; user or group technical abilities and their respective user interface needs; the availability, suitability, interoperability, and usability of different models; and model data requirements and types (Jankowski 2008). Determining what the “best” choices are in each of these categories will be entirely dependent upon the context in which the SDSS will be used, and the unique opportunities and limitations this context offers. Uran and Janssen (2003) reviewed the SDSS literature and asked a simple question: Why are some spatial decision-support systems not used? They guided their evaluation of various SDSS by five questions.

- How are alternative scenarios or decision pathways specified?
- How do users get from the start of a decision pathway to the finish?
- How is the output of the process presented?
- How is evaluation of the results supported?
- Does the SDSS function as it is supposed to?

To answer these questions, they compared across multiple case studies and found that SDSS provided little to no support for aspatial or spatial evaluation of the scenario outputs, which they think may have caused low levels of adoption in the Netherlands.

Sugumaran and Degroote (2011) provide six additional questions that are directly related to the five listed above and which they believe are often overlooked in the implementation of SDSS.

- What software system should be used? Which is best?
- What aspatial and spatial models would address the decision problem?
- Are the user interfaces easy to use? How should these be developed?
- How are outputs validated and evaluated?
- What technologies should be used?
- Do sufficient resources exist to create an SDSS?
Because of the very nature of ill-structured spatial decision problems, even if these questions are answered, the task of successfully implementing an SDSS and the accompanying workflow or stakeholder process is socially and technically complex. However, with advances in both open source and proprietary software, the complexity of technically designing SDSS is becoming simpler.

Spatial econometrics

Xinyue Ye
Kent State University, USA

The small volume entitled *Spatial Econometrics* by Paelinck and Klaassen (1979) is considered to be the first comprehensive attempt to set the stage for spatial econometrics. Anselin (2010) also stresses the importance of the seminal book on spatial analysis by Berry and Marble (1968), which outlines the quantitative revolution in geography. These efforts are followed by the inspiring work of Anselin (1988), which is the first book in spatial econometrics formally establishing the theoretical and methodological framework. It warrants notice that the methods illustrated in Anselin (1988) mainly deal with cross-sectional data. In the past three decades, spatial econometrics has witnessed marvelous development in terms of theoretical thoughts, applications, and software development beyond the methodological toolbox of applied econometrics (Anselin and Rey 2012).

According to spatial econometrics, any individual or collective decisions would rely on the decisions made in the neighboring spatial units, indicating that an explicit accounting for spatial effects is required (Arbia 2011). Spatial effects are classified into two major aspects, namely, spatial dependence and spatial heterogeneity. Spatial econometrics lies at the heart of research in regional economics and quantitative geography, which calls for a set of tools to model the interaction and measure the spillover effects among a group of spatial units with particular attention to location, spatial structure, and spatial processes (Anselin 2010). Spatial econometrics has provided the methodological foundation for regional and urban econometric models. By analyzing recent developments, Anselin (2010) argues that spatial econometrics is among the mainstream of applied econometrics and social science methods, reflecting a fast-growing need to incorporate spatial effects into operational urban and regional models through spatially explicit variables. This growth can also be attributed to synergies between applied economics and geographic information science (GIScience), as well as to the adoption of spatial econometric methods owing to a growing list of software (Goodchild et al. 2000). The ultimate success of spatial econometrics will be determined by the extent to which domain scientists can access, adopt, and utilize them in order to incorporate additional advances in research inquiry for specific research questions (Arbia 2011). In other words, wider scientific and open source communities lead to a brighter future for spatial econometrics and interdisciplinary collaboration (Anselin 2010). Anselin and Rey (2012) also argue that replication mechanisms, collaborative environments, and computing power can fundamentally change the qualitative and quantitative nature of spatial econometric work. Spatial econometrics studies spatial interdependence both in a spatial perspective and in a more general socioeconomic sense. It provides new theoretical perspectives to empirically verify models of social and spatial interaction, such as peer effects, neighborhood effects, spatial spillovers, and network effects (Anselin 2010).
Interestingly, the role of space and geography in socioeconomic dynamics is also evidenced by the World Bank Development Report of 2009 devoted to economic geography, and the 2008 Nobel Prize in Economic Sciences awarded to Paul Krugman, in part in recognition of his achievements on spatial economics and new economic geography. The last two decades have witnessed a growing literature of empirical studies on socioeconomic dynamics (Anselin and Rey 2012). Some dominating applications include, but are not limited to, income growth, regional convergence, industrial concentration, regional labor markets, land use, housing, voting behavior, and political trends. The availability of large georeferenced event datasets along with high-performance computing technology has raised fundamental challenges and opportunities for mainstream social science research on whether and how these new trends in data and technology can be utilized to collect thematic information and help understand socioeconomic dynamics, in order to enhance and advance the research in social, economic, and behavior sciences in general (Arbia 2011). Such large-scale data analytics will stimulate the development of new computational models. In turn, these newly developed methods are adopted in real-world practice, forming a positive feedback loop. Enabling such space–time analysis over cyber-infrastructure is particularly useful for spatial econometrics, where this positive feedback loop will allow researchers and practitioners to test their models faster and scale them to a larger dataset, therefore producing more policy-relevant results. Such research bridges emerging advanced computing infrastructure and computing technology with socioeconomic analysis, which is among the burgeoning efforts seeking the cross-fertilization of multiple fast-growing interdisciplinary communities (Anselin and Rey 2012).

Definition and adoption

Taking into the account the fact that the spatial perspective is generally ignored by econometricians, Paelinck and Klaassen (1979) delineate five fundamental principles to guide the formulation of spatial econometric models in their pioneering work. These five rules include the role of spatial interdependence, the asymmetry in spatial relations, the explanatory factors in other locations, the differentiation between ex post and ex ante interaction, and the explicit modeling of space and topology. In particular, these rules highlight the importance of a realistic specification of space in econometric models. Indeed, this seems to be a natural progression resulting from the increasing availability of empirical data with locational information. Spatial econometrics goes on to develop into an emerging paradigm for spatial modeling of socioeconomic data, but with limited adoption among econometricians and economic geographers. The situation in the late 1980s and early 1990s was that applied spatial econometric work was constrained by the lack of appropriate spatial data analytical software (Anselin 2010). Though a few methods had been developed by individuals, they were not generally available to the wider community. In addition, extensive documentation and tutorials were required to gain sufficient adoption of methodological development and empirical practice, which were missed at this stage. Anselin (1988, 8) compares spatial econometrics to standard econometrics, stating that spatial economics models should deal with “the specific spatial aspects of data and models in regional science that preclude a straightforward application of standard econometric methods.” In his book, Anselin stresses the estimation and specification testing methods. Specifically, the domain of spatial econometrics is defined as “the collection of
techniques that deal with the peculiarities caused by space in the statistical analysis of regional science models” (Anselin 1988, 7). To promote spatial econometrics studies, much effort has been spent on developing spatial econometric scripts or a set of routines in the context of existing commercial statistical software. The availability of spatial econometric software is a key driver in the adoption and dissemination of spatial econometrics throughout the social sciences (Anselin 2010). In contrast to the abundance of mainstream econometric packages and tools, this limitation has been considered a major impediment for the adoption of a spatial perspective in empirical work. SpaceStat is the first truly self-contained spatial econometric analysis tool, used to illustrate the estimation methods and test statistics in Anselin (1988) based on GAUSS routines. Hence, the approaches from Anselin (1988) have become empirically feasible. The commercial sector has not lagged behind. This has been very quickly followed by the commercial specialized package S+Spatialstats. Since version 9.2, the Environmental Systems Research Institute’s (ESRI) ArcGIS geographic information system (GIS) software has contained the functionality for spatial autocorrelation analysis and geographically weighted regression.

In the early definitions of spatial econometrics, the scope of the field is largely limited to urban and regional modeling, which fails to anticipate the enormous growth of geospatial technologies and data analytics toward both conceptual and empirical studies in many social sciences (Anselin 2010). Anselin (2006) removes the limiting context of urban and regional modeling by broadening the scope of spatial econometrics from the cross-sectional setting to the space–time domain as “a subset of econometric methods that is concerned with spatial aspects present in cross-sectional and space–time observations. Variables related to location, distance and arrangement (topology) are treated explicitly in model specification; estimation; diagnostic checking and prediction” (Anselin 2006, 902). A set of specialized toolboxes have been yielded, with a variety of flexibility and scalability, within the commercial software environment (such as Matlab and Stata), as freestanding software, and through open source ventures such as Python and R (Bivand, Pebesma, and Gómez-Rubio 2008; Anselin and Rey 2012). Free spatial econometric software GeoDa consists of a graphical user interface allowing exploratory spatial data analysis and spatial regression to be carried out. The history of the open source movement is much younger, but its impact on the GIS world is impressive through the creation of a powerful community of collaborators and peer review resources. The Open Source Geospatial Foundation (OSGeo) projects that support spatial data handling have a large developer community with extensive collaborative activities, possibly due to the wide audience and publicly adopted Open Geospatial Consortium (OGC) standards. In comparison, spatial econometric analysis is often field- and data-specific. Therefore, the analysis routines are often written by domain scientists with specific scientific questions in mind and are not of a collaborative nature. To date, only a handful of open source spatial econometrics tools exist. The R open source statistical programming framework contains the spdep (spatial dependence: weighting schemes, statistics, and models) and sphet (estimation of spatial autoregressive models with and without heteroskedastic innovations) packages among others (Bivand, Pebesma, and Gómez–Rubio 2008). The Python Spatial Analysis Library (PySAL) deals with a range of spatial analysis and spatial econometric codes in the open source Python language (Rey and Anselin 2007).
A space–time perspective has been increasingly relevant in the investigations of socioeconomic phenomena. More and more data available for spatial econometric research are characterized with space–time labels, such as historical census data provided by governments, environmental observations recorded by sensors, or volunteered geographic information through social media. With the increasing availability of spatiotemporal data, a gradual shift has been identified from the analysis of synchronic cross-sectional spatial data to that of diachronic spatial panel data (Arbia 2011). Paralleling this is the development of the theoretical foundation and methods dealing with panel data. There is also a crucial need to better understand the fundamental processes behind the spatial and space–time correlation.

The evolution of the definition and scope of spatial econometrics over time reflects a major migration of the field from the margins in applied urban and regional economic analysis to the mainstream social sciences (Bivand, Pebesma, and Gómez-Rubio 2008; Anselin and Rey 2012). Arguably, early work on theoretical and methodological advances in the 1970s and 1980s is mainly published in regional science and quantitative geography journals. The situation has changed dramatically. Spatial econometrics has become a recognized subfield in many handbooks of econometrics. In recent years, the interest in spatial analysis in general and spatial econometric modeling in particular has witnessed an almost exponential growth and a rapidly expanding application in increasingly diverse scientific disciplines (Goodchild et al. 2000; Bivand, Pebesma, and Gómez-Rubio 2008). Consequently, the related publications are wide-ranging and appear across a variety of scientific journals. The presence of spatial econometrics in these mainstream compendia has facilitated its interdisciplinary popularity and acceptance in both theoretical development and empirical practice (Arbia 2011). In addition, the open source movement in spatial econometrics blurs the line between a scholar’s role as software user and as collaborative producer (Anselin and Rey 2012).

**Spatial dependence, spatial heterogeneity, and spatial models**

Ignoring the spatial relationship among geographic observations is analogous to disregarding the ordering of time-series data. While similar to correlation in the time domain, the distinct nature of spatial dependence requires a specialized set of techniques. There is a fundamental difference between spatial series and time series due to the feedback and simultaneity originating from spatial interaction (Arbia 2011). Importantly, there is no straightforward extension of time-series methods to two-dimensional geographic space. In addition, the spatial relationship is more difficult to define because it needs to be derived from a specific ordering, such as measures of potential, distance-decay functions, and spatial arrangement. Furthermore, the spatial dependence may decrease to zero beyond a given threshold of distance that separates two spatial units. For instance, it is expected that the spillover effect will be stronger on closer neighbors, and that it will vanish as distance increases.

In general, spatial effects are present in two ways: spatial dependence and spatial heterogeneity (Arbia 2011). In spatial dependence, the structure of the correlation between random variables at different locations is determined by the relative position of the observations in geographic space. Spatial dependence is a direct result of Tobler’s first law of geography, which states that “everything is related to everything else, but near things are more related than distant things.” Anselin (1988) argues that
this spatial dependence is the rule rather than the exception, which conflicts with the usual assumption of independence among observations. Spatial dependence can also originate from measurement error. Spatial dependence exists if the cross-sectional correlation is nonzero, following a certain spatial ordering.

In the spatial lag model, the spatial autocorrelation appears in the dependent variable, indicating that the spatial units influence one another; this is also the case in time series when the lagged variable influences the contemporaneous one. By contrast, when the spatial autocorrelation appears in the error term the model is known as a spatial error model. It indicates that the neighbors are subject to the same random shock. Spatially lagged variables can be included for the explanatory variables, leading to so-called spatial cross-regressive models. In addition, different combinations of these models are possible, yielding a rich array of spatially explicit models such as the spatial Durbin model (Anselin 2010).

The Global Moran’s I and Local Moran’s I are applied to measure spatial autocorrelation. Global spatial autocorrelation analysis mainly concerns the spatial distribution characteristics of the values for some property of spatial units in the entire region, and it can analyze the overall regional spatial associations and spatial differences by the calculation of the Global Moran’s I. The formula is shown in equation (1), where

\[
I(d) = \frac{\sum_{i}^{n} \sum_{j \neq i}^{n} w_{ij} (x_i - \bar{x})(x_j - \bar{x})}{s^2 \sum_{i}^{n} \sum_{j \neq i}^{n} w_{ij}}
\]  

\(s^2 = \frac{1}{n} \sum_{i=1}^{n} (x_i - \bar{x})^2, \quad x_i\)

is the observation at spatial unit \(i\), \(\bar{x}\) is the arithmetic mean value of \(x_i\), and \(w_{ij}\) is the spatial weighting value. The value of the Global Moran’s I ranges from −1 to 1. A positive value for \(I(d)\) indicates spatial clustering of similar values, whereas a negative value indicates spatial clustering of dissimilar values between a focal region and its neighbors.

The local spatial autocorrelation analysis deals with the distribution pattern of the values for some property of spatial units in the heterogeneous space, and it can measure the local spatial correlation between each focal region and its surrounding regions. Local Moran’s I was first proposed by Anselin (1995) as a local indicator of spatial association. The formula for the Local Moran’s I is shown in equation (2), where \(x_i\) is the observation at spatial unit \(i\), \(W\) is the spatial weight matrix, \(w_{ij}\) indicates the interaction between spatial unit \(i\) and \(j\), shown in equation (3). If \(I_i\) is significantly greater than 0, it indicates that spatial inequality between the given location \(i\) and its surrounding regions is significantly small, and vice versa.

\[
I_i = \frac{(x_i - \bar{x})}{s^2} \sum_{j}^{n} W_{ij} (x_j - \bar{x})
\]

\[
\bar{x} = \frac{1}{n} \sum_{i=1}^{n} x_i, \quad s^2 = \frac{1}{n-1} \sum_{i=1}^{n} (x_i - \bar{x})^2
\]

The specification of spatial heterogeneity can be classified as either discrete heterogeneity or continuous heterogeneity. The former consists of a prespecified set of spatial regimes, while model coefficients and other parameters might vary across regimes. Continuous heterogeneity specifies how the regression coefficients change over space, either following a predetermined functional form such as the spatial expansion method, or as determined by the data through a local estimation process such as geographically weighted
regression. The statistical literature specifies spatial heterogeneity as a special case of random coefficient variation. The treatment of spatial heterogeneity initially focuses on further elaboration of the expansion method. However, the most important development in this respect is the advent of geographically weighted regression as a way to model parameter variability across space.

An important distinguishing characteristic of spatial econometrics is the need to explicitly deal with the spatial structure of the observations: their spatial arrangement, or topology. Spatially lagged variables are weighted averages of observations for the neighbors of the focal spatial observation. An important aspect is the definition of neighbors, which is typically carried out through specification of a spatial weights matrix, the key concept in this regard. This aspect requires the use of spatial data structures that do not fit within the architecture of the standard econometric software. This neighbor structure not only forms the basis for the specification of spatial dependence in the econometric model but also leads to a series of computational issues that set spatial econometrics apart from traditional approaches (Anselin 1988).

As an elegant conceptual structure expressing the spatial extent of the influence of the focal spatial unit, the spatial weights matrix $W$ is of dimension $n \times n$. Each nonzero element $W_{ij}$ indicates whether the locations $i$ and $j$ are neighbors. It conceptually defines the underlying relationship between units of observations. In addition, it can also give a measure of relative strength of the interaction between these two units, which is named the “power” of the influence. The spatial data structure needs to be accessed in order to derive or extract the adjacency structure of polygons, or to compute various distance metrics from point coordinates. The neighbor structure of the observations can be mainly defined in two ways. The first type (contiguity-based spatial weight matrix) identifies a relationship based on shared borders. The second type (distance-based spatial weight matrix) establishes a relationship based on the distance separating observations. The selection of a spatial weight matrix can be either ad hoc or data-driven. The purpose of involving a spatial weight matrix is to take the spatial effects into account in the spatial analysis and modeling. In most cases, the selection of the spatial weight matrix is conducted before running the model, usually based on past experience. The spatial weight matrix is first introduced to treat the correlation between geographical units. The aim is to define how close or remote neighbors depend on each other, which has been extended to economic, social, cultural, and demographic distance or neighborliness (Villano, Fleming, and Moss, 2016).

Regarding contiguity-based spatial weight matrices, there are three types of contiguity: rook contiguity, bishop contiguity, and queen contiguity. Rook contiguity means that two polygons share a common border, while bishop contiguity indicates that two polygons share a

![Figure 1](image_url)  
**Figure 1** Contiguity-based spatial weight matrix.
common node. Queen contiguity is combination of rook and bishop contiguity. Figure 1 demonstrates how rook, bishop, and queen contiguity are defined. Lattice 1 has two neighbors, Lattice 2 and Lattice 3, in the context of rook contiguity, while Lattice 4 is the only neighbor of Lattice 1 if bishop contiguity is applied. Under queen contiguity, Lattice 1 is contiguous to all three other lattices. Regarding the power of influence in these contiguity structures, each neighboring lattice exerts the same influence. Such spatial weight matrices are widely used in applications where the polygons contain the attributes.

The specification of the contiguity-based spatial weight matrix is defined as shown in equation (4).

\[
W_{ij} = \begin{cases} 
1, & \text{if } i \text{ and } j \text{ are neighbors} \\
0, & \text{if } i \text{ and } j \text{ are not neighbors}
\end{cases} 
\tag{4}
\]

where \( W_{ij} \) is the \( i,j \)th element of \( W \).

Distance-based spatial weight matrices are mainly used in the context of point data or where the use of polygon data is not appropriate. A typical specification of the relationship in the \( W \) matrix is shown in equation (5), where \( d_{ij} \) indicates the distance between two points \( i \) and \( j \). The term \( \theta \) represents the power of the influence, which can be considered as the transportation friction. It can demonstrate a variety of spatial decay effects when the parameter \( \theta \) is assigned different values. The term \( a \) is the threshold to define the extent of influence. The selection of such a value largely depends on the extent of the conceptualized neighborhood of a focal unit. After the selection of spatial weight matrix, row standardization is needed. Such a process will make each row sum to one.

\[
W_{ij} = \frac{1}{(d_{ij})^\theta}, \quad \text{if } i \neq j \text{ and } d_{ij} < a \\
W_{ij} = 0, \quad \text{if } i \neq j \text{ and } d_{ij} \geq a, \quad \text{or if } i = j \tag{5}
\]

The general spatial model follows (Anselin 1988), as shown in equation (6), where \( Y \) represents a \( n \times 1 \) vector of dependent variables, \( \rho \) is the coefficient of the spatially lagged dependent variable, \( X \) is an \( n \times k \) matrix of independent variables, and \( \beta \) is a \( k \times 1 \) vector of parameters associated with \( X \). The \( \epsilon \) term represents an \( n \times 1 \) vector of disturbances, \( \lambda \) is the coefficient of the spatial autoregressive structure for the disturbance \( \epsilon \), and \( \mu \) is an \( n \times 1 \) vector of disturbances. The disturbance \( \mu \) is normally distributed with a general diagonal covariance matrix \( \Omega \). The diagonal elements serve as a function of exogenous variables with a constant term. \( Z \) is an \( n \times r \) matrix of exogenous variables with the constant term. \( \alpha \) is an \( r \times 1 \) vector of coefficients related to the terms.

\[
\begin{align*}
Y &= \rho W Y + X \beta + \epsilon \\
\epsilon &= (I - \lambda W)^{-1} \mu \\
\mu &\sim N(0, \Omega) \\
\Omega_{ii} &= h_i(Z \alpha) \tag{6}
\end{align*}
\]

A series of spatial models can be derived from this general spatial model and are demonstrated in Table 1.

### Comparative space–time dynamics

Comparison is at the heart of human behavior and reasoning. Comparative analysis is a method used to observe and interpret the world, including spatial and temporal characteristics of places. A powerful analytical framework for identifying spatial econometrics research gaps and frontiers is fundamental to the comparative study of spatiotemporal phenomena throughout the social

sciences. Increasingly easier development processes facilitate the explosion of related routines with powerful scripting language environments such as R and Python (Bivand, Pebesma and Gómez-Rubio 2008; Rey 2009). However, duplicated efforts exist and many critical gaps remain unexplored. Ye and Rey (2013) argue that methodological duplicates and gaps exist due to the lack of systematic exploration of the space–time dataset. The multiple dimensions and scales of socioeconomic dynamics pose numerous challenges for the application and evaluation of public policies in the comparative context. However, the definitions of the unit of analysis and the unit of observation should be distinguished before the structure of the space–time dataset is characterized.

In addition to their relationship in space, things near in time or in statistical distribution are more related than distant things. There is a growing consensus that all dimensions of the data should be handled together instead of them being treated independently (Anselin 2012). Hence, ignoring the interdependence across space, time, and statistical distribution leads to overlooking many possible interactions and might cause biases in the analytical results (Rey and Ye 2010). To reveal these relationships, the distributions of space, time, and attributes should be treated in the context in which a measurement is made, instead of specifying a single space or time as the context. The “distribution” in space (the dimension of space) refers to the spatial distribution of attributes while the “distribution” of attributes (the dimension of statistical distribution) implies the arrangement of attributes showing their observed or theoretical frequency of occurrence. In addition, the “distribution” of time (the dimension of time) signifies the temporal trend of attributes (Rey and Ye 2010).

Besides the dimensions in analyzing data, it is also important to recognize the issue of scales of data and analysis. Four scales are taken into consideration. The unit of analysis at the individual scale signifies the geographical location of an attribute (A1 in Table 2), the temporal label of an attribute (A5 in Table 2), or the rank of an attribute (A9 in Table 2). The unit of analysis at the local scale explores a group of units which is formed by the focal observation and its neighboring observations in one of these three dimensions. A focal state and its neighboring states, for example, can be considered as a unit of analysis from the perspective of the spatial dimension (distribution) at the local scale (A2 in Table 2). A focal year, the previous year, and the following year can be considered as a unit of analysis from the perspective of the temporal dimension at the local scale (A6 in Table 2). A focal rank and the two immediate higher/lower ranks can be considered as a unit of analysis from the perspective of the statistical dimension (distribution) at the local scale (A10 in Table 2).

A mesoscale analysis studies a group of entities which shares similar feature(s) in spatial, temporal, or statistical distributions. In other words, the local-scale analysis differs from the mesoscale analysis in how a subset of data is retrieved for analysis. The former emphasizes that the rest of the subset are “near things” to the focal element while the latter does not have this constraint. Hence, the latter usually has a
larger subset (larger in space and lengthier in time) as the unit of analysis than the former does. The spatial distribution of rich states, for example, can be considered as a unit of analysis from the perspective of the spatial dimension (distribution) at the mesoscale (A3 in Table 2). All the years since a policy has been implemented can be considered as a unit of analysis from the perspective of the temporal dimension at the mesoscale (A7 in Table 2). An income quartile can be considered as a unit of analysis from the perspective of the statistical dimension (distribution) at the mesoscale (A11 in Table 2).

The analysis at the global scale examines the distributions of all the regions, times, or attributes. Spatial distribution of all the incomes, for example, can be considered as a unit of analysis from the perspective of the spatial dimension (distribution) at the global scale (A4 in Table 2); all the years can be considered as a unit of analysis based on the temporal dimension at the global scale because space–time dynamics research is very sensitive to the selected starting and ending years (A8 in Table 2); the statistical distribution of all the incomes can be considered as a unit of analysis based on the statistical dimension (distribution) at the global scale (A12 in Table 2).

Limiting attention to only one of these dimensions or scales may result in a misguided or partial understanding of economic growth dynamics.

The unit of analysis is the major entity that is being analyzed in the research, while the unit of observation is the basic entity described by the data. The unit of analysis is the “what” that is being studied, and is designed by the researcher. Nevertheless, the unit of observation is determined by the way the dataset is collected, which cannot be fully controlled by the researcher. In most studies, the difference between the unit of analysis and the unit of observation is not emphasized, but it is important to recognize this difference for comparative space–time analysis. Because the unit of analysis involves the issues of scales and levels of aggregation of data, it is critical in designing data analysis tasks. Various spatial partition schemes often lead to different types of units of analysis, which in turn generate different perspectives of the same data. Hence, it is valuable to consider all possible perspectives before formulating research questions. All possible temporal configurations should also be considered. Monthly unemployment counts (the unit of observation), for instance, can be aggregated into quarterly or yearly periods.

Many types of units of analysis can be generated when both spatial and temporal partition schemes are considered. Unemployment issues, for instance, can be analyzed at the county level using monthly counts, or at the state level using yearly counts.

Most empirical studies are motivated by only a few well-defined research questions. Then, the researcher chooses the appropriate analytical methods while also obtaining the data needed for application of the methods. Only at the end of the process does the analyst interpret and evaluate the results. These traditional research methods and procedures, however, tend not to be very useful in systematically revealing patterns and trends in complicated space–time datasets. This is because the intermediate stages in a process are not observed or analyzed. Typically, the analyst has to get acquainted with the data before formulating novel questions. Rey and Ye (2010) develop a framework based on Table 2 that leads to a general task topology for socioeconomic data by integrating spatial, temporal, and statistical distributions at individual, local, meso-, and global scales. One research question can thus engender many follow-up research questions. This framework allows the behavior of a dynamic system to be reconstructed from a group of units of analysis. The key aspect of the work is to integrate the three dimensions of a space–time dataset into a four-scale environment. Taxonomy of methods can then be built by combining any two approaches at any two scales.

Big spatiotemporal data and computation

A growing research community of spatiotemporally integrated social science has emerged aimed at analyzing spatial patterns and geographical dynamics, and maximizing the potential of massive data to improve human wellbeing. Big spatiotemporal socioeconomic data will become increasingly available in the near future, allowing the possibility for individuals’ space–time economic behavior in space and time to be modeled and for the results of such models to be used to gain information about economic trends across spatial scales (Arbia 2011). For instance, the US Census Bureau’s Longitudinal Business Database provides annual records for every private sector establishment from 1976, which involves about 4 million establishments and 70 million employees each year. However, as the space–time data accumulate, the rich details of space–time complexity in social science remain largely unexplored because of many binding constraints for scientific advancement, such as the challenge of intensities of data computing and very large georeferenced dynamic databases (Anselin and Rey 2012). Computation has been playing a central role in the development of econometrics, in terms of both theory and applications (Bivand, Pebesma, and Gómez-Rubio 2008). In addition, the unique characteristics of spatial data bring extra challenges, such as data summarization, numerical optimization, simulation-based estimation, and nonparametric/semiparametric estimation (Anselin and Rey 2012). The following notions will become unrealistic in the big data setting: the standard sample–population paradigm, spatial stochastic process, spatial stationarity, and the statistical significance test (Anselin 2010). Many current space–time statistics and simulations can only deal with a limited amount of data due to computation constraints. Hence, more advanced computational techniques are needed to handle the complex large-scale space–time interactions through deploying modern accelerator technology and hybrid computer systems.

Cyberinfrastructure has enabled both physical and social scientists to collaboratively tackle sophisticated problems across various
domains. Many studies have been undertaken to empower space–time analytical models with high-performance computing techniques. These methods generally take advantage of multicore central processing units (CPUs), many-core graphical processing units (GPUs), or Intel® Many Integrated Core (MIC) architecture. In social science research, quite a few studies have been conducted to speed up agent-based modeling and land-use planning. The cyberinfrastructure poses challenges to the existing spatial econometric packages largely relying on the single-CPU realm. Anselin and Rey (2012) envisage a spatial econometrics workbench as a framework for supporting spatial econometric research in the cyberscience era, taking into account that cyberinfrastructure offers the potential of lowering the hardware and software costs facing the applied spatial econometrician. Timely analysis using spatial econometrics models will open up a rich empirical context for social sciences and policy interventions, and will be critical for quantifying the impact of socioeconomic policies.

However, there are no easy ways to directly equip these existing spatial econometric models, estimators, algorithms, and data structures with high-performance computing capacities in the cyberinfrastructure, because most of the analytical and processing functions need to be rethought and rewritten. There is a critical need to examine their particular computational requirements and how they may map to specific types of parallelization. At the same time, the characteristics of a problem determine to what extent and how conveniently a certain algorithm can be parallelized (Ye and Shi 2013). New algorithms have begun to use the new features in computational languages supporting parallelization (such as MatlabMPI, Stata/MP, and the parallel packages in R) in the context of rapidly changing computing technology, such as distributed computing, cloud computing, and the use of handheld devices (Anselin and Rey 2012). In addition to technical solutions of embracing high-performance computing, a major challenge is to deal with the conceptual questions raised by massive datasets and the complex dynamics underlying the existence of spatial interaction (Anselin and Rey 2012).

Spatial epidemiology
Daniel J. Exeter
The University of Auckland, New Zealand

Spatial epidemiology refers to research that analyzes and describes the geographical distribution of health and wellbeing, in relation to sociodemographic, environmental, and behavioral risk factors (Elliot and Wartenberg 2004). Epidemiologists aim to better understand the social and environmental patterns and processes of diseases. In addition, epidemiologists are particularly interested in the distribution of disease events over time, and investigate such patterns across large geographic regions such as administrative districts or counties. By contrast, many spatial epidemiologists focus their attention on small areas, whose populations are less than 5000 residents, in an attempt to identify the spatial distribution of disease, exposure to toxins, and health outcomes and disease clusters. Spatial epidemiologists maximize the use of population, environmental, and disease data represented as points or areas in their analysis.

There are many ways to classify the techniques used in spatial epidemiology. The most common, however, are in terms of broad applications: disease mapping; geographical correlation studies; and clusters, clustering, and surveillance, which are addressed in turn below. Methods used by conventional epidemiologists and statisticians involve performing analyses that make the assumption that results obtained for one area are independent of other areas in the study (this being the converse to Tobler's First Law of Geography, whereby geographic entities are all related, but entities in close proximity to each other are more related than distant entities; Tobler 1970). In the grouping of the spatial epidemiological approaches discussed below, there is also a general transition from the use of conventional epidemiological techniques (e.g., age-standardized rates) to more advanced approaches (e.g., local spatial clustering) that are designed to respect Tobler's First Law of Geography.

Disease mapping

Early examples of spatial epidemiology include John Snow’s dot maps that were developed to investigate the cholera outbreak in London (UK). Snow mapped every case of cholera at the household level upon the local street map and there were more cases in households that were serviced by a contaminated water source. This rather primitive dot map led to the discovery in the 1850s that cholera was a waterborne illness. Similarly, Alfred Haviland’s mortality maps of heart disease and cancer used routine data sources such as the mortality statistics and the census populations in the 1870s, extending the influential work of early pioneers such as William Farr. Today, disease maps represent a major stream of spatial epidemiological research, displaying standardized rates of disease to adjust for differences in population structure of residents within regions included on the map. Disease maps can rapidly highlight geographical patterns that would otherwise be hidden in a table, and are commonly used for hypothesis generating and as the first step in exploratory spatial data analysis. Disease mapping can also
be used to show results from statistical modeling, demonstrating whether disease rates in a given area are statistically significant compared to the average rate for the study area (i.e., the mean), or by grouping disease rates according to standard deviations from the mean. Moreover, the increased availability of commercial and open-sourced geographic information system (GIS) software has led to the rapid development of disease mapping at the local (e.g., small census areas or block-groups in the United States), regional (county), and national (state) or international scales.

Researchers mapping spatial patterns of disease for small areas are confronted with a number of challenges, including cartographic design, the modifiable area unit problem, and also the “small number” problem, where some places have no, or few, disease events and/or a low population at risk of contracting the disease. This is a substantial problem in places beyond the urban fringes, which raises the subsequent problem associated with thematic (choropleth) mapping: localities with smaller populations often have the largest areas on the map, thus distracting the user from potentially more important results in the more populous communities. Disease rates can be very unstable when calculated for small geographical areas or relatively rare diseases. Overcoming the small number problem may be achieved by increasing the size of the regions being mapped, for example, from census areas to electoral districts. Alternatively, spatial epidemiologists may choose a spatial smoothing process such as Kernel Density Estimation (KDE) or a statistical smoothing approach (e.g., Empirical Bayes Estimation) to reduce the extreme values. Kernel density estimation transforms point data (e.g., an outbreak of measles) to a continuous data surface of disease risk. Varying the size of the search area or bandwidth used in the KDE process results in different depictions of risk. Thus an ideal representation is a surface that demonstrates spatial variability that exists within the data with precision while removing extreme values or “noise” from the dataset. Empirical Bayes Estimation is used to smooth areal data (e.g., heart disease mortality rates by region) by removing some of the random error in the rates to produce smoothed relative risks of disease for each area, and has the greatest impact (i.e., data are smoothed the most) in areas with a low population at risk.

Geographic correlation studies

Disease maps can present a visual summary of disease patterns, but there is often a need to investigate the patterns further and, if possible, to identify potential causes or circumstances underlying those patterns. Ideally, we would have individual-level measurements of exposure to environmental determinants of health (e.g., exposure to air pollution) in addition to disease outcomes and individual risk factors (smoking, drinking) for all patients in a population, but such information is often difficult, impractical, or impossible to obtain for investigation. Therefore spatial epidemiologists compare the spatial distribution of disease with the geographical variations in environmental or lifestyle exposures. These studies are often referred to as geographic correlation studies and this literature aims to develop or test hypotheses regarding the etiology (causes) of disease. By way of example, the INTERSUN project (World Health Organization 2003) used a geographic correlation study to determine the relationship between solar ultraviolet (UV) irradiance and the consequences of UV radiation exposure in terms of skin, ocular, and immunological diseases.

The use of GIS in public health research and by various agencies in the past decade has contributed to the considerable growth in this
SPATIAL EPIDEMIOLOGY

field of spatial epidemiology. As a result, the measurement of exposure variables such as access to food outlets or other community resources has been used to explore associations with obesity and other chronic illnesses. Broadly, these studies have reported that with increased availability of health-promoting facilities within close proximity to an individual's home, the population is less likely to be obese. The widespread availability of digital information for populations and the ease with which individual-level information can be obtained via Global Positioning System (GPS) sensors and other smart technologies have also facilitated the use of multilevel modeling techniques to investigate geographic correlations between exposures and health outcomes.

Spatial clustering, disease clusters, and surveillance

In spatial epidemiology, a disease is said to be “clustered” if spatial variation in risk remains after controlling for known confounders (Pfeiffer et al. 2008). There is a multitude of cluster detection techniques available for both point and areal data, and these can be categorized according to the nature of the clusters identified. Global clustering methods identify the presence of a cluster in a study area, but do not identify the specific location(s) of the clusters. Rather, methods such as Ripley’s bivariate k-function use point data and provide a single value indicating the degree of clustering, which can then be tested for statistical significance. Local clustering methods are commonly referred to as hotspot analysis tools, and use point data to identify the location and geographical extent of one or more clusters in a study region. Focused-cluster detection is a form of local analysis in which local clustering techniques are used to detect clusters around a specific point, such as a cancer cluster around an industrial pollutant site. The Geographical Analysis Machine (GAM) was developed in the 1980s (Openshaw et al. 1987) and was used to seek clusters of leukemia in the United Kingdom. The GAM used a fine grid over the study area upon which circles of varying radii were generated. For each circle, the GAM calculated the observed and expected number of cases. Circles with higher-than-expected values were retained for visual inspection, but a significant limitation of the GAM was its multiple testing. Kulldorff’s spatial scan statistic, packaged as SaTScan™, extended the GAM to overcome the multiple-testing limitation and has been extensively used in many aspects of human and animal health research to detect local clusters of disease. Currently, SaTScan is the most common local clustering approach used in the spatial analysis of disease data published in epidemiology journals (Auchincloss et al. 2012), and can be used to investigate temporal, spatial, and spatiotemporal clusters. In addition, the space–time permutation model in SaTScan may also be used in public health offices as a surveillance tool. By linking into routine disease notification registers, the software can prospectively detect an elevated risk or occurrence of disease and trigger early warning surveillance systems.

Moran’s I and Geary’s C statistics are commonly used “global” clustering techniques for use with areal data. These statistics measure the spatial autocorrelation between two variables and use a matrix of nearest neighbors defined in terms of adjacency or distance. This matrix is used to ensure that closest neighbors are assigned greater weight than more distant neighbors. In a similar way to the k-function test for point data, these provide an indication of spatial autocorrelation for the dataset overall. Local clustering techniques for areal data include Getis and Ord G* statistic, and the local Moran’s I statistic is commonly referred to as Local Indicators of
Spatial Association (LISA), which detect clusters by calculating the association for a value (i.e., disease rate) for one area and values in its adjacent areas.

Regardless of the methods used, the quality of the data used in analyses is vital. Spatial epidemiologists must address the challenge of depicting spatial processes as accurately as possible, while ensuring that the confidentiality of patients is preserved. This concern is especially the case for spatial point-pattern analyses. Aggregation of the data from individual events to administrative units poses problems related to the scale and aggregation effects of the modifiable areal unit problem (MAUP), in addition to the risk of the ecological fallacy.

The recent growth of “big data” (a collection of data too large for storage in traditional databases or analysis using conventional data processing software) and the increasing availability of spatially referenced data present a bright future for spatial epidemiology. The development of electronic health records may provide opportunities for obtaining more accurate residential histories of (anonymized) patients and their lifestyle risk factors of disease. These may then be used to enhance explanatory variables in disease clustering and the validity of results from geographical correlation studies.

Spatial feature classes

E. Lynn Usery  
US Geological Survey, USA

Spatial feature classes are the basic result of human cognition and categorization of geographic phenomena. Categorization and classification are basic to human knowledge and understanding and form a basis of scientific investigation. For geographical phenomena, humans categorize the world into identifiable, discrete entities whether these entities occur naturally or are human-constructed. Spatial feature classes are defined as categories of geographic phenomena that are uniquely identifiable and distinct. Based on cognitive category theory, this categorization typically occurs cognitively at a most basic level (Rosch et al. 1976) and for geographic phenomena that level corresponds to features commonly represented on cartographic abstractions of geographic space or maps (Usery 1993). Thus, spatial feature classes, such as roads, streams, hills, cities, and structures, are a basic level of human cognition that cartographers have used for thousands of years in constructing maps that communicate effectively about geographical phenomena.

Digital representation of geographic phenomena also requires use of this basic level of abstraction and fortunately, as geographic information systems (GIS) were developed, the basic features traditionally used on maps were replicated as digital representations. It is the purpose of this entry to present the concepts and history of spatial feature classes, which form a part of the representation and theory of geographic information. The second section, “History,” provides a history of spatial feature classes from concepts of geographic regions and cartographic generalization processes (particularly selection) to the use of points, lines, and polygons as feature classes in commercial GIS software. The third section, “Standardization of spatial feature classes,” describes attempts at standardization of spatial feature classes based on the design of feature lists and feature attribute catalogs, and examines specific standards that were developed, some of which are still in use. The fourth section, “A theory of spatial feature classes,” documents research to develop a theory of geographical phenomena or spatial feature classes. The fifth section, “The rise of ontology in spatial feature classes and feature class semantics,” details the rise of ontological concerns in geographic information science and presents a basis for feature class semantics dependent on feature identity, attributes, and relationships to other features and provides a basis for the current (2016) geographic feature vocabularies being developed for the Semantic Web. A final section draws conclusions and posits a future of spatial feature classes in relation to changing technology and new approaches to geospatial data collection, storage, and distribution.

History

The concept of a class of spatial features spans the temporal range of geography, the earliest attempts being to define a basic set of entities or phenomena in geographic space. Dividing the Earth into areas of water and land develops a coarse set of spatial feature classes with members of oceans and continents, respectively. Further division leads to feature classes of smaller spatial extents such as seas, countries, mountains,
valleys, and others. Although such attempts at categorization of geographical phenomena date from earlier times, near the beginning of the twentieth century geographers made concerted efforts to define a set of natural geographic regions (that is, features) but because these regions were cognitively generated, much controversy ensued. Through the work on definition of geographic regions, geographers developed the concept of a region that is neither an object nor self-determining, but rather an intellectual concept, an entity for the purpose of thought, created by the selection of characteristics that are relevant to an area of interest and by the disregard of all characteristics considered to be irrelevant (Whittlesey 1954). The selection in the statement is equivalent to selection in the generalization process of creating a map at a particular scale, that is, one selects features of interest for a particular scale and disregards others. Since the term “feature,” as used in current geographic information science (GIScience) and as used in this entry, is defined as “a geographical entity and its object representation” or “a digital representation of a real world entity or an abstraction of the real world,” and possesses “a common set of attributes and relationships,” (Guptill et al. 1990), it corresponds exactly to the intellectual concept of a geographical region. Although regions are commonly thought of as areal phenomena, the strict definition allows point, line, area, volume, or pixel and voxel representations of the geometry as with features. Thus, the current concept of a feature class in geographic information science has long roots in geography through its association with the region concept. More importantly, feature classes are intellectually generated based on physical geographic characteristics and human cognition, which involves classification and category concepts as explored in cognitive psychology and GIScience (Usery 1993).

Since the early models of geographic phenomena and space were created from the map model, spatial feature classes abstracted basic geometry from that model in the form of points, lines, and polygons for geographic phenomena, and picture elements (pixels) for geographic space. Feature classes were represented either as layers of point, line, or area objects or as a raster layer of pixels. These are the fundamental processing components of GIS. Thus, for the first 30 years of GIS, these geometric elements formed the basis of spatial feature classes, and commercial software implementations of GIS termed these basic geometric elements as features. These geometric elements rarely corresponded to real geographic entities as cognized and named by humans. They provided a basis for geometric and analytic processing that supported multifarious applications, such as site location, land-use planning, corridor analysis, land management and monitoring, and many others.

Standardization of spatial feature classes

As the development of spatial databases became a primary activity associated with GIS, there was a need to catalog spatial feature classes as well as their associated attributes and relationships, although little was achieved on relationships for many years. Since primary mapping activities rested with national mapping organizations, such as the US Geological Survey (USGS), responsible for topographic mapping in the United States, the Defense Mapping Agency (DMA, now the National Geospatial-Intelligence Agency (NGA)), responsible for providing maps of the rest of the world to the US Department of Defense, the National Oceanic and Atmospheric Administration (NOAA), responsible for coastal mapping and charting, the US Census Bureau, responsible for maps to support the decennial
census, and others, in the 1970s these organiza-
tions began developing digital cartographic
databases primarily from existing maps as a
base to support GIS analysis and operations.
Key components of those databases were the
geographical entities selected and represented,
albeit as geometric elements of points, lines, and
areas, which became feature classes.

The early results of these efforts led to car-
tographic feature coding (Wood and Douglas
1984) with extensive lists of point, line, and area
objects annotated as geographic features. For
example, the USGS created Digital Line Graph
(DLG) data with more than 200 feature codes or
feature types that represent various classes of data
such as roads, railroads, streams, and others with a
seven-digit numeric code, the first three digits of
which are the major code for the class of feature,
and the last four digits a minor code denoting the
attributes associated with the feature. It should
be noted that this early use of numeric codes
rather than actual names was primarily due to the
technological limitations of computer program-
ing in languages, such as FORTRAN, that
supported numeric data processing much better
than alphabetic names. As a case in point, a road
symbolized on a USGS 1:24 000-scale topo-
graphic map as a “Primary route, class 1, symbol
undivided” is coded as 1700201. The 170 is the
major code for the class of roads and the 0201
is the minor code specifying the exact symbolic
attributes of the cartographic feature. Most map-
ing organizations developed catalogs of feature
codes and, with the associated geometric data
that were digitized from maps and annotated
with these codes, constructed base geographic
data layers for the GIS software available at
the time. Examples of such cartographic fea-
ture codes include the USGS DLG, the DMA
Feature Attribute Coding Standard, Canada’s
Department of Energy Mines and Resources
National Topographic Database, South Africa’s
Proposed Standard for Exchange of Digital
Geo-Referenced Data, and many others.

Because many of these catalogs of feature codes
were cartographic or geometric in nature and
lacked exact correspondence to real geographical
phenomena, researchers in GIS in the 1980s and
1990s began to develop alternative models of
spatial feature classes. The development of the
Topologically Integrated Geographic Encoding
and Referencing (TIGER) system by the Cen-
sus Bureau created one of the first systems to
code spatial feature classes, such as census tracts
and minor civil divisions, which correspond
to enumeration units rather than cartographic
representations or geometric elements. It was
also during this time that theoretical work
to determine human understanding of spatial
feature classes began.

The USGS developed Digital Line Graph–
Enhanced (DLG-E), where the enhancement
was representation of real-world spatial feature
classes (Guptill et al. 1990). A major part of the
DLG-E research effort was examining topo-
graphic maps and determining feature classes,
developing rigorous definitions of the spatial
feature classes, then associating the attributes and
relationships of those features to provide a set
of objects that could be used in GIS. The final
developed feature list for DLG-E appears in its
entirety in Guptill et al. (1990). Simultaneous to
the research around DLG-E, and with some of
the same researchers and a similar methodology
for defining features (Rugg 1988), the Spatial
Data Transfer Standard (SDTS) was being devel-
oped and promoted. SDTS was created from
the merger of the Federal Geographic Exchange
Format (FGEF), which was designed to support
exchange of geographical data among Federal
agencies and developed by the Federal Inter-
agency Coordinating Committee for Digital
Cartography, with the standard prepared by the
National Committee for Digital Cartographic
Spatial Feature Classes

Data Standards (NCDCDS). NCDCDS was led by the American Congress on Surveying and Mapping operating on grant funding from the USGS. The SDTS specification became a standard under International Standards Organization (ISO) 2011 and originally was published in *The American Cartographer*, in 1988, with an implementation specification published in *Cartography and Geographic Information Systems* (Morrison and Wortman 1992). The final version of SDTS is available from the USGS (2014). SDTS includes 202 different entity types (spatial feature classes) and accounts for 1203 included terms, which are alternate methods of naming these entity types. For example, “access way” and “alley” are included terms of the entity type Road.

Although significant resources had been expended to develop SDTS and define a common set of spatial feature classes, there was little use of the standard that had been developed. The complexity of SDTS was daunting to the casual user and dedicated professional GIS users opted for simpler de facto standards based on vendor domination. For example, by the late 1990s, the dominant transfer format for spatial data of vectors was Esri’s shapefile, originally developed as a display format for ArcView GIS. The primary transfer format for raster data was Tagged Interchange File Format (TIFF). Although SDTS failed to be adopted as a universal standard, its development led to the recognition of the need for a theory of geographic information in which spatial features held a prominent role. Research on such a theory had begun in the 1970s and 1980s and gained significant momentum in the 1990s with the recognition of GIScience as a separate discipline. As a discipline, GIScience needed its own subject matter and that subject matter is space carved into spatial feature classes. Using theory as a basis, the design and development of spatial feature classes moved toward ontology and the definition of a geospatial vocabulary for use in semantics processing, particularly for the Semantic Web.

A theory of spatial feature classes

Research in spatial data models and the fundamental basis of human cognition of spatial phenomena led the development of a theory of geographic phenomena and spatial feature classes (Mark 1993; Usery 1993). Berry (1964) developed a conceptual framework of a geographical matrix to account for all possible types of spatial analysis. In his matrix, the columns represent locations and the rows represent measurement of a variable or theme. Time was added as a perpendicular dimension to the rows and columns. With such a matrix, each cell value corresponds to a geographical fact, the occurrence of a single attribute at a single location at a specific time. This concept of a geographical fact corresponds to the description of a geoatom provided by Goodchild, Yuan, and Cova (2007) exploring a general theory of geographic representation in GIS. The basic dimensions of the geographical matrix and of spatial feature classes are space, theme, and time (Table 1), of which one of the three dimensions is fixed, a second is controlled, and the third is measured. This view is supported in GIS since most data sources are maps and maps usually fix the time, control the theme, and vary the spatial location. The concept of the geographical matrix and the analysis methods it presented became a cornerstone of GIS design, development, and implementation.

Goodchild (1987) examined spatial analysis concepts based on data models for point, line, area, and grid cell objects represented in GIS software packages at the time, and the types of analysis he defined can all be mapped to the types defined by Berry (1964). These observations
concerning the fundamental basis of geographic phenomena, and the possible types of analytical operations, led to a set of requirements for any theory of geographic phenomena and any implementation of such a theory in terms of analytical needs. These requirements are that any theory must account for geographical entities (features) and their attributes and relationships along the three dimensions, space, theme, and time, and allow for implementation of the types of analyses observed by Berry (1964) and Goodchild (1987).

Toward generating such a theory, defining spatial feature classes becomes a major consideration. Such classes are defined with attributes and relationships along the three dimensions of space, theme, and time (Table 1, Usery 1996). Yuan (1996) preferred the term “domain” to “dimension” and developed a three-domain model. Spatial feature classes must also be composed of one or more geographical facts or geoatoms. This theory, supported by work in cognitive psychology on category theory, in geography by work on geographic regions and spatial analysis, and in cartography by work on abstraction and generalization, provides the basis for the development of a multidimensional representation of geographic phenomena.

It has been shown that features commonly defined as mappable geographic entities fit category theory’s basic level of cognition for geographic phenomena (Rosch et al. 1976; Usery 1993; 1996) and that formalization of these entities in systems design can be achieved through interaction concepts such as metaphor and object semantics. Theoretical work on human cognition indicates the use of metaphor is an appropriate mechanism to relate geographic knowledge. Alternative conceptions of space, including Euclidean, physical, sensorimotor, perceptual, and cognitive, can be distinguished and represented as algebraic group structures. Interface design requires formalization of interaction concepts, one of which is metaphor. Metaphor domains are formalized by algebras, morphisms, and image schemas. Usery (1993) examined category theory as a basis of defining basic level geographic features which correspond to mappable features, such as roads, streams, hills, and valleys.

While components of a basic theory of geographic entities or features and human understanding through metaphor and algebraic concepts are well illustrated, the theory is incomplete and the path to implementation is not clear. One of the missing parts of the theory is how one feature relates to another (the relationships shown in Table 1). These relations are extremely important and often form the basis of geographic applications. Early in the study of computer-based representation of geographic phenomena, Freeman (1975) defined 13 different spatial relationships: left of, right of, beside, above, below, behind, in front of, near, far, touching, between, inside, and outside. Peuquet (1986) refined Freeman’s work and stated that all spatial relations

SPATIAL FEATURE CLASSES

can be defined in terms of three primitives: direction, distance, and Boolean set operations (and, or, not). She further developed some implementation methods for these set operations using a raster GIS database. More recent work has focused on defining the fundamental bases of spatial relations and the operations allowed.

The thematic and temporal relationships of Table 1 are not addressed directly and receive attention only when spatial concepts, such as topology, can be applied to the thematic and temporal dimensions. The definition of geographic entities or features requires definition of all attributes and relationships of the entity. With the development of the World Wide Web and the Semantic Web, with its inherent semantic structure and logic and inference capabilities, the definition of spatial feature classes has become an exercise in ontology design, development, and engineering.

The rise of ontology in spatial feature classes and feature class semantics

Spatial feature classes are human conceptualizations and, whether occurring naturally, such as hills, valleys, streams, and mountains, or as a result of human engineering, such as roads and buildings, it is the human mind that gives meaning to the spatial feature class. Spatial feature classes are determined in a human cultural context and cannot be separated from human culture and associations. The study of spatial feature classes is an examination of what exists in reality and thus leads to a study of ontology of geographic information. GIScience researchers began to examine ontological concepts of geospatial phenomena in a quest to establish robust theoretical foundations for geographic information science. Whereas the early work with identifying spatial feature classes for use in GIS and the developments of feature lists and standards, such as SDTS, were really ontological efforts developed by data gathering organizations for operational use, the earliest conceptual and theoretical work on spatial feature classes identified specifically as ontology in the GIScience discipline occurred in the late 1990s. For example, Smith and Mark (2001) empirically tested subjects to identify geographic categories. Among their findings, the term geographic feature conveys concepts of mountains, hills, valleys, and other natural physical entities, whereas geographic object is most often associated with a map, globe, compass, or atlas. For human-engineered geographic features, such as roads, bridges, boundaries, and cities, the common association is with something shown on a map, rather than the term “geographic feature.”

Using ontology to construct a set of spatial feature classes has become the norm in GIScience. The proliferation of ontology tools and the existence of the Semantic Web and linked data activities since 2001 led to the use of ontology and semantics as methods for defining and accessing spatial feature classes. In the post-2001 timeframe, the Ordnance Survey developed an ontology which includes topographic and administrative spatial feature classes. The USGS has also developed an ontology for The National Map. The primary activity of Geospatial Vocabulary Camps (GeoVoCamps) is to crowsource or collaboratively build small ontologies or design patterns that are generic geographic features that can be reused. Examples include path, point-of-interest, and others. The focus of many of these efforts is to build a set of spatial feature classes with semantics that account for attributes, relations, and interactions of one spatial feature with another. It should be noted that these ontologies are domain ontologies of classes and rarely include instance data of actual geographic features in real-world locations. There also
are efforts to provide instance-level data and develop procedures for use and interaction of those instance data (for example, see Usery and Varanka 2012).

Conclusions

The concept of spatial feature classes is now an integral part of an ontology of geographic information. The design and development of lists of spatial feature classes is an ongoing effort and will continue as long as there is a need to define, identify, and interact with geographical entities in the real world. Defining classes allows assignment of members to those classes and provides a mechanism to use instance-level data with coordinate representation and the many levels of attributes and relations built into the spatial feature class ontology. A major effort today in defining spatial feature classes is occurring through crowdsourcing the effort through GeoVoCamps. With new sensors, including humans with geolocation devices, providing geographic data of many different kinds through crowdsourcing, the definition and assignment of data to spatial feature classes are being crowdsourced as well.

SPATIAL FEATURE CLASSES

Spatial filtering
Victor Mesev
Florida State University, USA

Spatial filtering is a data frequency manipulation technique designed to improve geographical feature interpretation. An independent $n \times n$ moving window (filter, mask, or kernel) is used to suppress or enhance spatial frequencies between local neighboring data values of a separate target dataset. For example, high frequencies indicate rapid changes of values between neighboring cells or pixels (values that represent the edges of features, such as buildings, coastlines, or roads), while low spatial frequencies indicate more gradual changes between neighboring values (values that represent more homogeneous features, such as the areas within deciduous forests, wheat fields, or lakes). Spatial filters are also used to improve data quality by removing, or at least minimizing, striping and noise, which are unexplained variations in data frequency and are, on the whole, unrepresentative (or unexpected) of spatial patterns and trends. Spatial filtering is part of statistical or quantitative analysis in geography. Many types of spatial filters are available in current geographic information systems and image processing software, but two main groups of spatial filters are those used for (i) data manipulation of remotely sensed imagery, including digital photogrammetry, and (ii) data manipulation of spatial data in response to the effects of spatial autocorrelation.

Spatial filtering of remotely sensed image data is known as spatial convolution, and the objective is to improve feature interpretation by visually smoothing or sharpening the image. Convolution uses windows of typically $3 \times 3$, $5 \times 5$, $7 \times 7$, or $9 \times 9$ fixed arrays that multiply pixel brightness (or digital numbers) by moving systematically across the entire raster data image and altering the pixel corresponding to the central cell of the window (hence the use of odd numbers only). For example, when using a $3 \times 3$ window, each pixel in the target image is assigned a new number based on the coefficient of the nine cells in the window (Gao 2009):

$$DN_{OUT} = \frac{1}{W} \sum_{i=1}^{d} \sum_{j=1}^{d} w_{ij} DN(i,j)_{IN}$$

where, $DN_{OUT}$ = convoluted output pixel value; $DN(i,j)_{IN}$ = pixel value in the input image at location $(i,j)$; $i$ ($i = 1, 2, 3$) = row index; $j$ ($j = 1, 2, 3$) = column index; $w_{ij}$ = value of the cell at location $(i,j)$ in the window; $W$ = sum of all window elements; and $d$ = window size (in this case 3).

There are essentially three types of spatial filters used in photogrammetry and remote sensing: low pass filters that de-emphasize the spatial frequencies of neighboring raster pixel values, high pass filters that enhance spatial frequencies of neighboring values, and edge enhancement filters that also sharpen the contrast between the spatial frequencies of neighboring pixel values, but in a vertical, horizontal, or diagonal direction (Jensen 2004; Gonzalez and Woods 2008). The images in Figure 1 illustrate the visual effects on a remotely sensed image by applying the mean low pass spatial filter, the high pass smoothing or sharpening the image. Convolution uses windows of typically $3 \times 3$, $5 \times 5$, $7 \times 7$, or $9 \times 9$ fixed arrays that multiply pixel brightness (or digital numbers) by moving systematically across the entire raster data image and altering the pixel corresponding to the central cell of the window (hence the use of odd numbers only). For example, when using a $3 \times 3$ window, each pixel in the target image is assigned a new number based on the coefficient of the nine cells in the window (Gao 2009):

$$DN_{OUT} = \frac{1}{W} \sum_{i=1}^{d} \sum_{j=1}^{d} w_{ij} DN(i,j)_{IN}$$

where, $DN_{OUT}$ = convoluted output pixel value; $DN(i,j)_{IN}$ = pixel value in the input image at location $(i,j)$; $i$ ($i = 1, 2, 3$) = row index; $j$ ($j = 1, 2, 3$) = column index; $w_{ij}$ = value of the cell at location $(i,j)$ in the window; $W$ = sum of all window elements; and $d$ = window size (in this case 3).

There are essentially three types of spatial filters used in photogrammetry and remote sensing: low pass filters that de-emphasize the spatial frequencies of neighboring raster pixel values, high pass filters that enhance spatial frequencies of neighboring values, and edge enhancement filters that also sharpen the contrast between the spatial frequencies of neighboring pixel values, but in a vertical, horizontal, or diagonal direction (Jensen 2004; Gonzalez and Woods 2008). The images in Figure 1 illustrate the visual effects on a remotely sensed image by applying the mean low pass spatial filter, the high pass
Figure 1  Visual effects on a remotely sensed image by applying filters: (a) original image; (b) mean low pass spatial filter applied; (c) high pass Laplace edge enhancement filter applied; (d) Sobel linear edge enhancement filter (in the vertical direction) applied.  

Laplace edge enhancement filter, and the Sobel linear edge enhancement filter (in the vertical direction). The mean low pass filter has a window with an array of values all set to 1, or in this case set to $1/9$, which when multiplied with the central pixel brightness value results in a reduction in spatial frequencies of values between neighboring pixels. In contrast, the window for the high pass Laplace filter has 0 and $-1$ values surrounding a central value of 4. The effect is to sharpen spatial frequencies in the image data by computing the derivative from the gradient of the spatial frequencies. Occasionally, the directional alignment of geographic features is of interest, and using linear edge enhancements can accentuate the visual contrast of buildings and roads aligned in, say, a vertical direction. For that to happen, the Sobel filter may have values set to 1 in the left column of the window and values of $-1$ in the right column.

Spatial filtering is termed linear when the output image is a function of some weighted average (a linear combination) of pixel brightness values. This process of evaluating the weighted neighboring pixel values is called 2-D convolution filtering. Another linear spatial filter technique designed for remotely sensed image data is Fourier analysis, which statistically separates the image into its spatial frequency components (known as Fourier transforms) by a summation of a series of sinusoidal terms of varying spatial frequencies (for a statistical formulation of the Fourier transform see Jensen 2004). The technique is able to maintain fidelity when combining (or fusing) multiple images at a lower spatial resolution with the high spatial resolution properties of panchromatic-sharpened images, which has the effect of reducing the storage space necessary for the images (Civco and Witharana 2012). In contrast to convolution techniques, another means of applying linear
Spatial filtering to remotely sensed images is by correlation; this is used to measure the similarity between images (a technique known as pattern matching).

Linear spatial filters are far more amenable to numerical analysis, but nonlinear filters are able to restore image data values, reduce noise levels, and, unlike linear filters, do not simultaneously blur edges. The simplest nonlinear spatial filter is the moving median, which is used for removing striping noise in an image (including raster digital elevation models) by ranking the pixels in the neighborhood from lowest to highest, and then selecting the median value. Nonlinear filters are not additive; repeated application of a median filter is not equivalent to a single application of a median filter using a different size of window. By making repeated use of a nonlinear smoothing filter with a small window, it is sometimes possible to improve on noise reduction while at the same time retaining fine details that would be lost if a larger window was used. In terms of accentuating the contrast of edges using a nonlinear process, the minimum and maximum values in a window are typically used in a range filter, or as in a Roberts’s filter, the sum of the absolute differences of diagonally opposite pixel values (Gonzalez and Woods 2008).

In general statistical analysis, spatial filters are used to isolate the underlying spatial effects of geographical variables from the effects of temporal and spatial autocorrelation.

This second main group of spatial filtering techniques measures the lack of independence between adjacent observations across geographical space. Essentially, this is the measurement of the effects of spatial autocorrelation, either using Moran’s \( I \) correlograms to explore spatial patterns in data, or to verify the presence of latent predictors in a multiple regression at different scales. In addition, the Getis and Griffith approach uses an eigenfunction decomposition based on the geographic connectivity matrix used to compute a Moran’s \( I \) statistic (Getis and Griffith 2002). Eigenvector-based spatial filtering can be used to analyze geographical patterns in many different applications (Diniz-Filho and Bini 2005). In addition, numerous other techniques have attempted to incorporate the temporal component of data, as well as the spatial aspects, when studying stochastic error characteristics in a time-series process (Getis and Griffith 2002).

Spatial interaction is a generic term for any form of movement or transmission over space that results from a decision-making process. Movement implies a physical relocation of an object or a person from one location to another, whereas transmission implies a nonphysical interaction such as communication. In both cases, a key concept of spatial interaction is that there is a transfer between an origin and a destination – in the case of movement, this transfer is a physical entity such as a good or a person; in the case of communication, the transfer is of information. To make this clearer, examples of spatial interaction include commuting flows; shopping trips; recreational visits; airline passenger movements; visiting relatives; attending sporting events, concerts, or religious services; migration; freight movements; going to school; telephone calls; and various forms of social networking involving location. In short, spatial interaction involves many of the important things we do as human beings. The only types of movement or communication that are not included within the definition of spatial interaction are those types of movement or communication that do not result from a choice, such as storm tracks, water-flows, the diffusion of pollution, forced migration, and the spread of forest fires. All of these involve movement of one type or another but the movement does not result from a spatial choice process.

Consequently, spatial interaction is arguably one of the most important topics within geography because it encompasses so many different and important types of human behavior. For instance, the types of questions that can be answered through an understanding of spatial interaction include the following.

1. Is there sufficient demand to establish a profitable air service between two cities? What frequency of air service will meet demand?
2. Is the investment in a new rail service, road system, or bridge cost effective given the expected demand?
3. What will be the effect on traffic patterns of building a new shopping center?
4. What will the effect on housing demand be throughout the city if a new employment center locates in place X?
5. From which schools does a university draw more (or fewer) students than would be expected given the locations and sizes of the schools?
6. Where is the optimal location for a new supermarket?
7. How sensitive are various types of movements to changes in travel costs?
8. What differences in travel behavior are there between different types of individuals? Does where you come from affect how far you are likely to travel?
9. Are we becoming less constrained by space over time?
SPATIAL INTERACTION

11 What makes some areas attractive (or unattractive) to migrants?
12 Would it be better to offer a specialist type of medical service in one hospital rather than another based on demand?
13 Where does the catchment area of one retailer end and that of a competitor begin?
14 How will the location of a new store affect demand at existing stores?
15 How many people can be expected to attend a mobile breast cancer screening service in a given location?

As Olsson states (1970, 233): “Under the umbrella of spatial interaction and distance decay, it has been possible to accommodate most model work in transportation, migration, commuting and diffusion, as well as significant aspects of location theory.”

Despite the diversity of types of spatial interaction, there are several tenets in common across all these areas.

1 A choice has to be made from a set of alternatives at different locations.
2 The choice is discrete, that is, only one alternative is selected.
3 The alternatives have fixed spatial locations.
4 There are many factors that affect this choice and these factors are context-dependent. That is, what determines a consumer’s choice of store will not be the same as what affects a migrant’s choice of destination.
5 However, regardless of what are the exact determinants of choice, no matter what the context, an individual somehow evaluates alternatives and trades off poor scores on one attribute with good scores on other attributes in order to select one particular alternative.

6 An important attribute of the choice process, common to all types of spatial interaction, is the spatial separation between an origin and a destination (often measured by distance but can also be thought of in terms of cost or time). Generally, we are more reluctant to interact with places farther away than we are with nearer places, all things being equal.

What do spatial interaction data look like?

Spatial interaction data denote the propensity of movement or communication between a set of origins (labeled $i$ here) and a set of destinations (labeled $j$ here), as depicted in Figure 1, where $M_{ij}$ represents the number of interactions or flows between $i$ and $j$. The propensity of flow could equally be denoted by a probability of movement between $i$ and $j$ representing the likely actions (decisions) of an individual, but for the sake of convenience here $M_{ij}$ is used as an aggregate number of interactions between an origin $i$ and a destination $j$.

In this situation there are $m$ origins and $n$ destinations so that we have an $m \times n$ interaction matrix. The sum of the interactions across a row, $O_i$, represents the total flow out of an origin and the sum of the interactions down a column, $D_j$, represents the total flow into a destination. The overall total interaction in the system is denoted by $M$ where:

$$M = \Sigma_i \Sigma_j M_{ij} = \Sigma_i O_i = \Sigma_j D_j$$

A spatial interaction matrix such as that in Figure 1 can be disaggregated in many ways, such as over time, over space, and by person type. For example, it is possible to have a separate matrix of shopping trips for car owners versus
Figure 1 A typical spatial interaction matrix.

non-car owners; for weekdays versus weekends; and for one city versus another.

Spatial interaction models

Geography can be defined as the study of spatial processes. In human and environmental geography, spatial processes are the actions and decisions that lead, at least in part, to the data that are measured to describe the social and physical environments. In order to better understand these processes, it is useful to formulate and calibrate models of the real world. In terms of spatial interaction, this is done through the formulation of spatial interaction models – mathematical models that relate the propensity of interaction between an origin \( i \) and a destination \( j \) to attributes of origin \( i \), attributes of destination \( j \), and some measure or measures of the separation between \( i \) and \( j \). The particular attributes of origin \( i \) and destination \( j \) deemed relevant to describing variations in interaction propensity depend on the type of interaction being examined, but, in general, people speak of the “push” and “pull” of places, or how the attributes of an origin would be those describing the “propulsiveness” of the place and the attributes of a destination would be those describing its “attractiveness.”

In terms of shopping behavior, for example, origin propulsiveness might be measured in part by population, income levels, and car ownership rates and destination attractiveness might be measured by store size, average price levels at a store, parking facilities, or other relevant factors. What constitutes relevant propulsiveness and attractiveness measures is something of an art form based on a mix of experience, guidance by the existing literature, common sense, and statistical testing.

A very simple spatial interaction model with only one origin propulsiveness attribute, \( v_i \), and one destination attractiveness attribute, \( w_j \), and one measure of spatial separation taken to be the distance between \( i \) and \( j \), \( d_{ij} \), is:

\[
M_{ij} = k v_i^\alpha w_j^\theta d_{ij}^\beta
\]

where \( k \) is often referred to as the intercept (a scaling parameter with no behavioral value and its value is not generally of much interest); \( \alpha \) indicates the sensitivity of the flow from \( i \) to \( j \) to the propulsiveness of origin \( i \) as measured by \( v_i \); \( \theta \) indicates the sensitivity of the flow from \( i \) to \( j \) to the attractiveness of destination \( j \) as measured by \( w_j \); and \( \beta \) indicates the sensitivity of the flow between \( i \) and \( j \) to the spatial separation between \( i \) and \( j \). This last parameter is sometimes referred to as “the disutility of distance” or “the friction of distance” or “distance decay.” It will almost always be negative, indicating that, other things being equal, as the distance between an origin and destination increases, interaction will decrease. That is, we are more likely to patronize a store which is 100 m away from our home than one which is 10 km away, other things being equal.

One very important and useful reason for calibrating a spatial interaction model is to obtain estimates of the parameters in the model to obtain information on the determinants of
interaction. For example, it might be interesting to examine how the parameter estimates vary by type of interaction, by the type of people interacting (i.e., calibrating separate models for different groups of people perhaps based on characteristics such as age, income, and gender), over space, and over time (either as transportation access and incomes vary over time or diurnal variations, such as during rush hour versus during regular traffic conditions). For example, Figure 2 depicts a situation in which $\beta$, the distance-decay parameter, is becoming less negative over time, indicating that distance is becoming less of a deterrent to interaction over time, presumably as transportation systems evolve and/or people’s ability to pay for transportation increases.

Arguably the distance-decay parameter, $\beta$, is the most interesting element of a spatial interaction model, as it measures the inherent ability of individuals to overcome the friction or distance (alternatively, the disutility of traveling). This parameter provides a means of quantifying variations in the ability to select from a wider set of destinations by individuals; for example, between those who own cars and those who do not own cars, or between younger migrants and elderly migrants, or between people with access to rapid transit and those without. Similarly, estimates of this parameter over time allow the degree to which traveling longer distances has become easier to be quantified, allowing the growth of cities, the decentralization of retailing away from city centers, and the growth of mega-malls. Indeed, the concept of distance decay is fundamental to understanding the evolution of urban areas, retail systems, patterns of migration, and most facets of regional and urban planning.

There are numerous examples of empirical applications in which variations in the parameter estimates obtained in the calibration of spatial interaction models have been reported; a useful overview of these can be found in Fotheringham and O’Kelly (1989). It is important to note that such comparisons are possible because the parameters of the model described above are power functions, and hence are scale invariant. For instance, in some studies an exponential function of distance has been employed so the model calibrated is then:

$$ M_{ij} = k v_i^\alpha w_j^\theta \exp(\beta d_{ij}) $$

In this case, for example, the estimate of $\beta$ depends on the units in which distance is measured.

The spatial interaction model given above is perhaps the simplest possible model that yields useful information on the processes generating the observed flows between origins and destinations. More complex forms are generated by (i) adding additional origin and destination attributes and (ii) by using more complex mathematical model forms. For instance, consider the investigation of shopping trips where the focus is on uncovering attributes of stores that make them attractive or unattractive to consumers. Here, it is possible to use the known volumes of outflows from each origin and concentrate solely on assigning these flows to the various destinations based on the characteristics of these destinations (including, importantly, how far each potential destination is from an origin). In
which case, the appropriate spatial interaction model has the form:

\[ M_{ij} = O_i w_j d_{ij}^{\beta} / \Sigma_j w_j d_{ij}^{\beta} \]

where \( O_i \) is the observed (known) outflow from origin \( i \) and the situation is restricted to where there is only one destination attractiveness attribute in the model, \( w_j \), for convenience, but it is recognized that further attributes with associated parameters can be easily added. This model is often referred to as a production-constrained spatial interaction model because the sum of the predicted outflows for each origin, \( \Sigma_j M_{ij} \), must equal the observed volume, \( O_i \). In essence, this model allocates a share of the total flows from an origin to each destination based on the relative attractiveness of each destination where relative attractiveness is defined by the term \( w_j d_{ij}^{\beta} / \Sigma_j w_j d_{ij}^{\beta} \). This model is hence particularly useful in retailing studies where the aim is to identify those store attributes that have a significant impact (both positive and negative) on consumer store choice. It can also be used to determine the optimal location of stores by finding the location which will maximize \( \Sigma_j M_{ij} \), the predicted total inflow into a destination. (Further retailing applications of this model can be found in Fotheringham 1988 and Fotheringham and Trew 1993.)

Alternatively, if the focus of the analysis is on analyzing residential choice, given that it is known where individuals work for the purposes of understanding housing demand, then the following spatial interaction is appropriate:

\[ M_{ij} = D_j v_i d_{ij}^{\beta} / \Sigma_i v_i d_{ij}^{\beta} \]

where \( D_j \) is the observed total flow into destination \( j \) and a share of this total is allocated to each origin based on the relative propulsiveness of each origin as measured by the term \( v_i d_{ij}^{\beta} / \Sigma_i v_i d_{ij}^{\beta} \). This model is often referred to as an attraction-constrained spatial interaction model because the sum of the predicted flows into each destination, \( \Sigma_j M_{ij} \), is constrained to equal the known total inflow into each destination, \( D_j \). Apart from identifying those features of an origin that lead to large outflows, a useful application of this model is in predicting housing demand given a change in the employment structure of an area such as the opening or closure of a large factory. By varying one or more values of \( D_j \), the effect of these changes on housing demand in each origin can be assessed by computing \( \Sigma_j M_{ij} \), the predicted total outflow from each origin.

A fourth type of spatial interaction is one in which the focus is to simply predict flows between origins and destinations given that the total outflows from each origin and the total inflows into each destination are known. Such a situation arises, for example, in urban transportation planning, where the total number of employees living in each neighborhood and the total number of jobs in each destination zone is known and the aim is to allocate flows from each origin to each destination under different scenarios. Essentially, this is a situation where the row and column totals of the matrix in Figure 1 are known but the cell counts are unknown. In this case, the appropriate model form is referred to as a doubly constrained spatial interaction model where

\[ M_{ij} = A_i O_i B_j D_j d_{ij}^{\beta} \]

where

\[ A_i = [\Sigma_j B_j D_j d_{ij}^{\beta}]^{-1} \]

and

\[ B_j = [\Sigma_i A_i O_i d_{ij}^{\beta}]^{-1} \]

The terms \( A_i \) and \( B_j \) are known as balancing factors because they ensure that the following two conditions are met:

\[ \Sigma_j M_{ij} = O_i \text{ for all } i \]
The former states that the sum of the predicted interactions from each origin will equal the known total outflow from each origin and the latter states that the sum of the predicted inflows into each destination will equal the known total inflow into each destination. Hence, the model is useful for assessing the impact of changing road conditions within a city. A change can be represented by an increase or decrease in the distance between $i$ and $j$, or between a set of origins and destinations, and the model can be used to predict a new flow matrix under this change. It is thus useful in transportation planning to assess the impacts of new transportation infrastructure such as building a rapid transit line or a new crossing over a river.

The four models just described can be derived from a common general form (Alonso 1978) and can be seen as four particular outcomes from an infinite number of possible models, as shown in Figure 3, which is derived from the formula:

$$M_{ij} = k v_i A_i^{\alpha-1} w_j B_j^{\gamma-1} d_{ij}^{\beta}$$

where

$$A_i = \sum_j w_j B_j^{\gamma-1} d_{ij}^{\beta}$$

and the destination-specific, attraction-constrained model is:

$$B_j = \sum_i v_i A_i^{\alpha-1} d_{ij}^{\beta}$$

So that:

- if $\alpha = 1$ and $\gamma = 1$, the model is unconstrained;
- if $\alpha = 0$ and $\gamma = 1$, the model is production-constrained;
- if $\alpha = 1$ and $\gamma = 0$, the model is attraction-constrained;
- if $\alpha = 0$ and $\gamma = 0$, the model is doubly constrained.

Consequently, it is possible to think about spatial interaction models derived from this general framework where the values of $\alpha$ and $\gamma$ are between zero and one. Such models can be considered as “quasi-constrained” or “relaxed” spatial interaction models, which may be useful in situations where the constraints on either or both the outflows from each origin or the inflows into each destination are not known with certainty (Fotheringham and Dignan 1984).

Finally, the form of spatial interaction models described thus far assumes that each model is calibrated using all the data from the full interaction matrix depicted in Figure 1. In such applications, one estimate of each parameter in the model is obtained reflecting general relationships across all origins and destinations. However, to obtain much more detailed information on the determinants of interaction, the models can be calibrated separately for each origin and each destination in the system so that the parameters are specific to each origin or to each destination. For example, an origin-specific, destination-attractiveness model has the form:

$$M_{ij} = O_i w_j^{\theta(i)} d_{ij}^{\beta(i)} / \sum_j w_j^{\theta(i)} d_{ij}^{\beta(i)}$$

and the destination-specific, attraction-constrained model is:
Theoretical foundations

There have been at least four attempts, of increasingly behavioral validity, to provide a theoretical basis for the form of spatial interaction models described above. These are described with an approximate evolutionary timescale in Figure 4.

The earliest form of spatial interaction was termed a “gravity” model because it was developed as an analogy to Newtonian laws of gravity that the force of gravity between two objects increased as the masses of the objects increased, and decreased as the distance between them increased. This simple analogy, part of a broader trend of importing concepts from physics into social science, termed social physics, served well to predict population movements between cities but was clearly devoid of any behavioral context save from a vague notion of distance having a frictional effect on movement.

In the 1970s, an attempt was made by Wilson (1975) to put spatial interaction on a firmer theoretical footing by demonstrating how the models could be developed by reference to the principles of entropy maximization – essentially finding the most likely set of origin–destination flow counts in Figure 1 given constraints on the row and column totals. However, although it was possible to derive spatial interaction models via this method from first principles, the behavioral foundations were really no stronger than in the previous social physics era. Indeed, the development of spatial interaction models through an entropy maximization framework could be viewed as an alternative type of social physics.

The behavioral foundation of spatial interaction models was given a boost by McFadden’s (1974) derivation of choice models via a utility maximizing framework. For the first time, models such as the production- and attraction-constrained models could be seen as the outcome of choice processes in which individuals selected one alternative from the set of all alternatives that maximized their utility. However, this development, although extremely insightful, was essentially aspatial in that it ignored the spatial arrangement of potential destinations and treated the choice of a destination in exactly the same manner as individuals chose a brand of coffee. It remained for Fotheringham (1983, 1986) to add a spatial component to McFadden’s choice axioms by recognizing that individuals faced with large numbers of alternative destinations arranged in space did not always, and indeed could not always, evaluate all the alternatives available to them to make a choice. An example would be
a person selecting a residence in a large city and being faced with thousands of possible houses or apartments. Consequently, Fotheringham recognized that people were likely to make spatial choices hierarchically, first selecting an area or spatial cluster of alternatives and then selecting one alternative from this subset having evaluated only the alternatives in this subset. This led to the development of the competing destinations model which has the form:

$$M_{ij} = O_{ij} w_j^\theta d_{ij}^\beta c_j^\varphi / \sum_j w_j^\theta d_{ij}^\beta c_j^\varphi$$

where $c_j$ is the degree of competition faced by destination $j$ from all other destinations and is generally defined in terms of some measure of the proximity of $j$ to all other destinations, preferably weighted by the attractiveness of each destination such that high values of $c_j$ reflect a destination in close proximity to other destinations and low values a destination that is relatively isolated. The parameter $\varphi$ indicates the effect of this competition on destination selection and is generally negative, indicating that as a destination has greater competition from nearby destinations, it attracts fewer flows, all things being equal.

**Summary**

The term spatial interaction encompasses many important components of social systems, including, but not limited to, commuting patterns and residential choice; shopping trips and the location of stores; the efficient and equitable location of facilities such as medical services; transportation demand; the impact of new services and facilities on existing demand; the analysis of social networking data such as twitter contacts; the analysis of communications; and the growth of cities. By reversing the modeling component, spatial interaction models have also been used to predict the locations of ancient settlements and to derive measures of the relative attractiveness of recreational areas and other destinations (Fotheringham et al. 2000). Indeed, it is difficult to comprehend properly the growth of cities and the distribution of population without an understanding of spatial interaction and its determinants.

Consequently, it can be argued that spatial interaction is one of, if not the most important subject areas in geography. Indeed, it can easily be argued that human geography would not exist without spatial interaction and distance decay. Hence, it is essential that geographers continue to conduct research that improves both the understanding of the processes leading to spatial interaction and the ability to model and predict patterns of spatial flows.

Spatial modeling: Voronoi diagrams

Christopher Gold
*University of South W ales, UK*
*Jiaotong University, China*

In the context of this entry, a spatial model is a conceptual model of the space under consideration, and a data structure is the way it is stored in the computer. The Voronoi diagram is a particular, and very useful, spatial model.

The Voronoi diagram (also called a Dirichlet tessellation or a set of Thiessen polygons) is a partition of a metric space such that we associate all locations in that space with the closest object in that space, based on the specified metric. Thus each object is the generator of a cell or tile and the set of tiles covers the space or map. In the simplest case we are given a set of points \( S \) in the Euclidean plane, which are the Voronoi generators. Each generator \( s \) has a Voronoi cell \( V(s) \) consisting of all points closer to \( s \) than to any other generator. Voronoi cells can be defined for metrics other than Euclidean, such as the Manhattan distance, and for other surfaces than the plane, such as the sphere. Voronoi cells can also be defined by measuring distances to objects that are not points.

We will first discuss spatial models, then some appropriate data structures, and conclude with some applications of the Voronoi/Delaunay approach, to illustrate its utility and flexibility.

Objects and fields

The way we think of space varies considerably depending on the application, the type of data, and our own presuppositions. One well-accepted distinction is between a set of spatially located “objects” such as buildings and a continuously varying value – a “field” – such as temperature. Another useful distinction concerns our navigation within this world: are we a “plane” flying above, or a “boat” acting within this space and interacting with it – this would mostly, but not necessarily, apply to the “object” model.

A “field” is continuous, but not necessarily smooth: it could consist of a tessellation with constant values in each cell – “blocks.” An “object” model would have empty space between at least some of the tiles, and does not necessarily have any obvious spatial relationships between them.

A famous debate between Newton and Leibnitz concerned whether space was “real” and could be measured (Newton) or only existed as the spatial relationships between objects (Leibnitz). The first led to Cartesian coordinate systems and raster spatial models, and the second led to graph theory and networks. (We can of course have two-dimensional (2D) and three-dimensional (3D) Cartesian space – and other dimensions – but other metric spaces are possible, including “city block metric” where distance must be measured along the axes only.) We may also have spatial embedding, when a lower dimension structure may be embedded in a...
higher dimension – for example a terrain surface embedded in 3D space, a road embedded in 2D space, or a node embedded in a one-dimensional (1D) road. (All of these examples imply that the higher-dimensional space is not necessarily fully occupied: that is, an arbitrary query at any location in the bounding space will not always return a value.)

The simplest form of spatial relationship between a pair of objects is adjacency: if their boundaries touch (presupposing that only one object may occupy any particular location) then a relationship – an edge of a graph – may be recorded. In a field model the whole space – within some bounded region – is filled and all objects (tiles) have recorded neighbors. In an object model this will, at most, be only partially true, meaning that navigation within that model cannot be guaranteed.

The Voronoi spatial model attempts to remedy that deficiency: objects are expanded until all boundaries meet, “holes” in the space are filled in, and a complete set of spatial adjacency relationships are obtained: the object model becomes a field. As with fields, a response is available at any spatial location, and as with the object model, the “name” of the object and its spatial properties may be obtained directly (unlike traditional raster fields, where the object must be reconstructed from grid cell attributes). Only one change needs to be considered: instead of obtaining “the object at this location is …,” we get “the object closest to this location is ….” As we will see, this is often what we wanted to ask in the first place.

**Dominance**

In its simplest form, an object (often a point) dominates all spatial locations closer to it than to any other point: this is its dominance region – think perhaps of predators who protect their territory with greater ferocity closer to their lair; there will be a boundary between two territories at an equal distance from the lairs. This boundary is the perpendicular bisector of the line between these generators. For three generators – and three boundaries – there is a single location equidistant between the three, at the center of a circle touching the three generators, where the three boundaries meet. (For collinear generators and boundary cases it is often easier to place them on a sphere rather than a plane. In 3D the separating boundaries are planes, with four meeting at the circumcenter.) Adding additional generators produces a complete tessellation of the space, termed a Voronoi diagram (VD). The collection of the edges connecting generators sharing boundaries is termed the Delaunay triangulation (DT). (In the plane the DT forms a set of triangular regions except where four or more generators are cocircular, in which case that region may be arbitrarily subdivided into triangles without losing any of the useful properties.)

**Planar graphs, duality**

A graph consists of a set of nodes and connecting edges. The most common type is a “planar graph”: here the graph is embedded in the plane and no edges cross. (To be precise, no edges have to cross – taking a planar graph and pushing the interiors of some edges across other edges does not make it nonplanar – this is only a geometric change, and pure graphs have no geometric properties.) Graphs may be undirected or directed: undirected edges may be traveled in both directions, and directed edges are like “one-way streets.” Edges may also have weights: these describe the “cost” of traveling them, for example travel time on a road segment.
Planar graphs may also have faces (regions) defined by closed loops of edges. The Euler-Poincaré formula states that for a planar graph $V + F - E = 2 - 2G$, where $V =$ # vertices (nodes), $F =$ # faces (regions), $E =$ # edges (arcs) and $G =$ the genus (# holes in the manifold). The rules for “planar” graphs hold for closed surfaces (2-manifolds): a plane or sphere has $G = 0$, a doughnut has $G = 1$. The exterior of a graph is also a region: think about drawing the graph on a balloon, and looking at it from behind.

In order to walk around the edges of a face we need to know the “next” edge around each vertex, which adds “topology” to the original graph. If we know this we can navigate in the graph, for example around polygon faces (Figure 1). This is normally difficult when only given digitized edges, but easy when using the Voronoi diagram.

If we start with a set of regions (adjacent countries perhaps), put a “capital city” within each, and connect the capitals whenever two countries have a common boundary, we create a “dual” graph. This dual graph is also composed of vertices and edges: the vertices represent the original regions and the edges were defined to cross the original region boundaries. Itselves a planar graph, the dual graph has regions, which are the duals of the junctions of the boundaries of the original countries. Both the primal and the dual graphs follow Euler’s formula. The important point to note is that, in any number of dimensions, every entity has a matching (paired) entity in the dual – and vice versa, as the dual of the dual is the original graph. As both the primal and the dual structures are graphs, standard graph theory algorithms may be applied to traverse the graph efficiently, detect closed regions (polygons) if given the edge order, as in Figure 1, and estimate flow in networks. This is also true for Voronoi/Delaunay graphs, as Figure 2 shows.

Imagining that Figure 2 represents an elevation map, with values at the data points, it can be visualized in two ways. In the first way it is now common to represent terrain as a TIN – a triangulated irregular network. In this case the surface would be composed of a set of flat, sloping, triangular plates: along the boundary between a pair of triangles they share common elevations. Alternatively, each Voronoi cell could be considered as a block having the data point elevation.

**Figure 1** Ordering of edges around polygons, and around vertices.
There are many ways that triangles may be constructed from a set of data points. The method now almost universally accepted is to construct the DT, as it has some very valuable properties. First, the definition maximizes the minimum angles of the triangles, reducing the chances of having long skinny ones. Second, the solution is unique: no matter the order in which the points are inserted the resulting triangles are the same. (The exception to this is when there are four or more cocircular points: any set of interior triangle edges may then be chosen.)

The incremental algorithm is the most common approach, as it is simple and robust, although not the fastest. It can be very simply described: (i) create a boundary triangle large enough to contain the whole map; (ii) perform a “local search” to find the triangle enclosing each new data point (initially the boundary triangle); (iii) split this triangle into three, with edges connecting each of its vertices with the new point; (iv) test each pair of triangles having a common edge, and decide whether to “switch” this diagonal for the other alternative; (v) test all edges whose adjacent triangles may have been changed by all this, and switch if necessary; (vi) go back to step ii and repeat for each new data point (Figure 3) (Lawson 1977). A “local search” may be performed by testing each edge of some initial triangle against the desired location, moving to an adjacent triangle if the location is outside, and repeating the process until the location lies on the interior of each of the three edges (Gold, Charters, and Ramsden 1977).

Many tests could have been done at step iv but the one that guarantees that the minimum angle in the triangle pair is progressively maximized, and that a finite number of switches (averaging six for each point insertion) is required, is based on the Voronoi/Delaunay duality. Voronoi “bubbles” created by the dominance method meet at a triple junction, which is the center of a circle (the circumcircle) touching the associated triangle’s three vertices. If a new point is placed inside this circle then this center, and its associated triangle, will be destroyed. Thus for each triangle to be tested, the three exterior vertices (associated with its adjacent triangles) must be checked to see if they fall inside its circle (Shewchuk 1997). If they don’t the triangle is good, otherwise the common edge between the two triangles must be switched and the tests repeated. It can be shown that this converges rapidly. The Delaunay triangulation test is based on the underlying Voronoi model. This is a basic example of the importance of the interlinking of the primal and dual graphs; we will see many more.

Parenthetically, the circumcenter is the interior point furthest away from the three triangle vertices – so an examination of the circumradii of all the Voronoi vertices on the map will locate the largest available empty circle (Figure 4).
null
Spatial models

We previously imagined that the terrain model of the given elevation data points of Figure 2 could be expressed as a set of flat triangular plates. However, we could equally have imagined that it was represented by the set of Voronoi cells, each with the height of the generating data point: this gives us an alternative spatial model, which is equally useful – we have a “block” world, to go along with our previous “slope” world (Figure 5).

This is what, in this entry, we mean by a “spatial model.” The most common is the raster, a field model where the partition is based on the coordinate system, not the data distribution. There are others; for example, a typical choropleth map or a road network, where the relationships between the entity types may be different: in a road network the only connectivity is between individual segments, and the only navigation queries are from segment to segment, whereas the Voronoi approach is a “space-filling” model, where adjacency relations between all 2D cells are available.

The hierarchical Voronoi diagram

It is conventional knowledge that one of the disadvantages of the VD is that there is no hierarchical structure available, so that search of very large datasets is slow. Various kinds of searching may be performed (Figure 6). One solution can be found based on Christaller’s work (see the discussion in Gold and Angel 2006) where he examined town and village distributions and their respective hinterlands. He did not attempt to insert lower-level village zones of influence within the higher-level zones for towns. He inserted the center of the zone – the village location – instead. Clearly points can
easily be inserted within a town’s higher-level index zone and, similarly, lower-level points can be located within a village zone.

The hierarchical Voronoi problem can thus be solved by using high-level Voronoi cells as index cells for the next level of points, letting their cells be secondary indexes for the third level points, and so on. In searching for a particular location, a local search (as described above) is performed at the top level until the enclosing cell is found, along with a pointer to some point in the next level down (if any exist). This is repeated on this second level, and on the third level, and so on, until a closest point is found at the base of this search tree. This speeds up the theoretical time for the walk (and hence the whole incremental algorithm), and any desired index level may form the basis for separating the map “sheets” and storing them in separate portions of the hard drive.

2D Spatial data structures and the quad-edge

A “spatial data structure,” on the other hand, as opposed to a “spatial model,” is a technique to allow the representation of a particular spatial model within the computer. Since the Delaunay TIN terrain model is well known, a triangle-based data structure is often used: here a topological element consisting of a triangle, with pointers to the three vertices and to the three adjacent triangles, is often used (Gold, Charters, and Ramsden 1977). This, however, has several disadvantages: it cannot be used to navigate from one triangle to the next without checking which edge it has in common with the starting triangle; and it cannot directly represent the dual (Voronoi) structure. The first issue can best be resolved by using an edge-based structure such as the winged-edge or half-edge (Baumgart 1972), which permits direct pointer-based navigation from one element to the next throughout the whole map. The second issue may easily be achieved by using the quad-edge data structure (Guibas and Stolfi 1985), which combines two half-edges in the primal structure (e.g., the Delaunay) with two in the dual structure (e.g., the Voronoi). This is particularly valuable when both the primal and the dual spatial models are required for an application.

An early data structure for modeling 2-manifolds (e.g., closed surfaces in Computer Aided Design (CAD) systems) was the winged edge. Each data element is an edge, with four pointers to the adjacent edges in the structure, to permit navigation from one edge to the next. It has a particular problem, in that when moving to a new edge – perhaps round a face – it is not clear which way it is oriented. A vertex check is required in order to find which end of the new edge connects to the old. An improvement is the half-edge, where each edge is “split down the middle” and each half-edge has a vertex pointer, a “next” pointer to the following edge around the relevant face, and a pointer to the other associated half (Figure 7). This permits navigation without stopping to ask which end or face is required.

The quad-edge data structure incorporates the half-edge structures of both the primal (e.g., Delaunay) and the dual (e.g., Voronoi) into one. Figure 8 illustrates this: although it appears complex, it is merely one primal plus one dual half-edge pair linked by a “Rot” (R) pointer with four rotating values – one may navigate from the Delaunay structure to the Voronoi one simply by following R. (N is the pointer to the next edge around a vertex or face, V points to a vertex, and S – not shown – points to the other associated half-edge.) This is particularly
Applications of the Simple DT/VD

Single cell analysis

It has been found that, when the primary objective is the total volume of a resource, such as coal seams or rainfall, the sum of the volumes of the individual Voronoi cells provides a more reliable estimate than attempting to interpolate a smooth surface: assuming that the value at any location equals that of the nearest data point avoids many awkward conditions. An example is the thickness estimation of formations, such as coal, based on drill-hole observations. Rather than estimating the upper and lower surfaces and subtracting them, summing the thickness value times the cell area, for each cell, may give a more consistent overall volume estimate. The same holds true for total rainfall estimation based on rain gauges – as originally suggested in Thiessen (1911).

A related, and common, problem is that of point density mapping. This is usually attempted by counting circles – counting how many points fall within a given circle, and then moving it and trying again: a very small circle, or a very large one, would give implausible results. Noting that point density (points per unit area) is the reciprocal of the Voronoi cell area (area per unit point) greatly simplifies this process.

Context

It can be argued that one of the main problems of spatial analysis – the knowledge of the neighborhood of an object – can be effectively managed by using the Voronoi diagram. In this entry we call this the “context” of the object.

Thus the context – the neighborhood – of the point $P$ in the red cell in Figure 9 is the set of (green) Voronoi neighbors: any minor perturbation of $P$, or even its deletion, will only affect
the green cells. (Conversely, if \( P \) was not initially there, its insertion will only affect the green cells.) This structure resolves the “post-box” problem – to find the nearest point (post box) to any spatial location – as each Voronoi cell contains all the spatial locations closer to its generating point than to any other. This is also the basis for nearest-point interpolation: occasionally – especially in some remote sensing processes – a pixel should take the value of its nearest data point, rather than averaging a set of neighbors, which would blur the boundaries required for object recognition. The VD directly provides this function.

For the simple VD of point datasets the context may well be expressed as the DT: each Delaunay edge states that another vertex is a Voronoi neighbor to the central one. Thus vertices may be visited in any desired order by following the DT edges. One particular property is often useful: the minimum spanning tree (MST) of a set of points is a subset of the DT edges. The MST is the shortest graph (tree) that connects all the points – although there may be others that are equally short. In geographic terms, it would be the shortest total length of road that would connect all the villages.

The VD could, in theory, be created by growing “bubbles” at an equal rate from each of the data points until all spatial locations are filled. This models a large number of natural processes: examples are turtle shells, crocodile skins, mud and basalt cracks, and many more. Of clear geographical interest is the example of many types of forest growth: the trees try to crowd each other out, thus the Voronoi cell area approximates the crown size, which approximately estimates the tree volume.

This approach may also be useful for the extraction of the boundaries of clusters of unlabeled points – and may serve to give them cluster labels if required.

As previously indicated under “spatial models,” a terrain surface may be thought of as a DT, as a VD, or as both together. A prime example of this is runoff modeling, whether of a raster grid or of irregular Voronoi cells. Finite-difference modeling, where a quantity of water moves from each cell to its downhill neighbors during each iteration, is an excellent example of this: it needs both a “bucket” and a “slope.” The bucket, of some known area, serves to contain the water; the slope indicates the downhill velocity. But adjacent buckets have vertical boundaries! (see Figure 5). Thus, even for simple raster algorithms, there are primal and dual concepts involved – the square bucket, and a slope imagined to be between the centers of adjacent grid cells. The Voronoi runoff model is identical, except that the geometric structure of the Voronoi edges and the Delaunay edges must be explicitly preserved. Then, for each time step, the water transfer is calculated from the slope of the Delaunay edge, the area/volume of the Voronoi cell, and the common edge between an adjacent cell pair (Dakowicz and Gold 2007).
Labeled skeleton – grouped context

The Voronoi diagram clearly gives a good estimate of the context of an individual tree in a forest: its constraining neighbors are found directly. It is similarly useful for “labeled maps,” where each Delaunay vertex, or Voronoi cell, is given a label rather than a continuous variable such as elevation. Preliminary geological mapping is a good example: in many areas the geologist has to hunt to find identifiable outcrops that are not covered with overburden, and label them as to the rock type. As nothing is known in the covered regions, the best guess is the closest observed outcrop – hence the Voronoi cell can form the basis for the initial map-coloring exercise. This is still interpolation, although the variable being plotted is not continuous.

To improve the results of such geological maps, boundaries between cells with identical classifications may be suppressed. We refer to this as the “labeled skeleton” to distinguish it from the “geometric skeleton” described below, where the skeleton boundaries are derived without manual point labeling. Estimated geological boundaries are not required between outcrops of the same rock type, so a simple pruning of the Voronoi boundaries will give a preliminary geological map that may be amended by additional geological knowledge. Thus the original simple context becomes a grouped context, with a complex Voronoi boundary around each contiguous set of similarly labeled outcrop regions, as in Figure 10 (Gold 1999).

A similar approach has been found very useful in some major map digitizing projects, such as soil or forest maps and reports, where a large number of contiguous polygons need to be digitized and the underlying map is sufficiently complex that simple scanning will not suffice. In this case the cursor is “rolled” round the interior of each polygon (perhaps with the aid of a small central dot) and a polygon label assigned to each of the points (Figure 11). This is repeated for all polygons on the map. When discarding all Voronoi boundaries between points with the same label – between adjacent points on the polygon interior – the boundaries between the polygons remain – in many
cases with enough precision for the application. Efficient algorithms exist for this extraction and aggregation process (Gold, Nantel, and Yang 1996).

An interesting point is worth noting: because the original set of Voronoi boundaries is topologically connected, and because the same is true for contiguous aggregates of cells, the boundaries between the polygons are guaranteed to be topologically complete, even taking account of digitizing errors such as forgetting a polygon. This is particularly useful in the processing of scanned maps when using the geometric skeleton, as described below.

The geometric crust and skeleton

Before the widespread use of computers, Blum (1967) discussed a method for describing irregular (“biological”) shapes. Using optical defocusing techniques he showed that if “waves” are created — perhaps by synchronized vertical oscillation of a set of generators — the boundaries between the merging wave sets formed equidistant “skeletons” (also called medial axes) between them. For point generators these form the Voronoi diagrams described above. For complex shapes, such as polygon boundaries, the skeleton may be used to describe the polygon’s shape (see Figure 12). Note that both endo- and exoskeletons are produced. Skeleton points are equidistant from at least two closest points on the polygon boundary: in fact they are Voronoi vertices whose circumcircles touch the boundaries. In addition, he suggested that these circumradii could be used to assign heights to the skeleton points: a larger circle gives a greater height (Gold and Dakowicz 2005).

Polygon boundaries are commonly defined as a series of points. If the VD/DT is constructed from these, and they are sufficiently close, then a subset of the Voronoi edges will form the skeleton and a subset of the Delaunay edges will form the “crust” or connected boundary of the polygon. As primal/dual structures, each Voronoi edge will have a matching Delaunay edge, and vice versa. It can be shown that for each edge pair either the Delaunay edge will be part of the crust (and the Voronoi edge can be ignored), or the Voronoi edge will be part of the skeleton (and the Delaunay edge ignored). This can be determined by a simple test: create a circumcircle from the two Delaunay vertices and one of the Voronoi vertices — if the second Voronoi vertex is inside the circle then the Voronoi edge is part of the skeleton (and the Delaunay edge is ignored), otherwise the Delaunay edge is part of the crust (and the Voronoi edge is ignored) (see Figure 13; Gold and Snoeyink 2001).

We will illustrate this with a scanned outline of a maple leaf (Figure 14). The left-hand part shows all the Voronoi and Delaunay edges together; the central part shows the resulting crust and skeleton when the above rules are implemented — note that no Delaunay edges cross Voronoi ones, and vice versa. Note also that the skeleton suggests the locations of the veins within the leaf.

There is one obvious criticism: the skeleton is notably “hairy.” This is because small perturbations in the digitized boundary points produce triangles with small circles that are far away from the true skeleton. The answer is to perturb each boundary point until the tip of each hair retracts to its parent in the skeleton; there is no tolerance involved. The right-hand part shows the smoothed version (Gold and Thibault 2001). This process can also be applied to arbitrary curves or networks, as well as polygons, as illustrated by the river network in Figure 15.

This clearly gives the impression of delineating the watersheds around each river segment. Applying Blum’s height transform to the skeleton points — height equals distance from the
Figure 12  Blum’s skeletons of irregular shapes, and his height transform.
Figure 13  Crust/skeleton testing.
river – implies a 45° slope everywhere, although this may be scaled as desired: not a bad initial approximation. Figure 16 gives a perspective view of the resulting TIN model.

However, we may go further. Each of the data points along the river has its own Voronoi cell: the region whose rainfall would run off downhill and meet the river close to that point (see Figure 17a). In addition, the crust – a subset of the Delaunay edges – gives the connectivity of the river segments and thus the flow of the accumulated runoff. The right-hand figure gives a static view of the overall total flow: approximate, but useful as an initial estimate for flood-risk analysis, despite its large assumptions about geological and surface homogeneity (Gold and Dakowicz 2005).

A related problem concerns terrain interpolation from contours – an old, but still important, data source. A good TIN may be produced by triangulating points on adjacent contours, but problems arise if all three vertices fall on the same contour: “flat” horizontal triangles result, as in Figure 18.

This affects ridges, valleys, peaks, and pits, although common sense can often estimate the desired result. Here again the skeleton helps to fill in the blanks. Skeleton points between contour levels contribute little, but those between points on the same level indicate, as for rivers, the ridge or valley lines (Figure 19a). The problem is to estimate their heights: Blum’s height transform will not do, as there is no overall fixed slope, but we may assume constant slope within a particular valley segment, for example. If this assumption is reasonable, then we may again take advantage of the already-existing circumcircles centered on the Voronoi skeleton points. First estimate the local slope at a skeleton junction whose circumcircle touches two contour levels, and then propagate this slope along all of the valley’s skeleton points – if we know the slope then we can estimate the skeleton height based

Figure 14  VD/DT; crust/skeleton; smoothed crust/skeleton.
Scanned map processing

A final example of the use of the simple incremental VD/DT algorithm and the geometric skeleton is the processing of scanned maps: due to the probable presence of unclosed loops we cannot use the labeled skeleton. Instead, we perform edge detection on the map image, generating boundary points between “black” pixels formed within the interiors of the line artwork and “white” pixels elsewhere. We then construct the VD/DT, and the crust and skeleton, and smooth it. The results for simple text are shown in Figure 20.

The resulting endoskeletons, with their particular loops and branches, provide an initial stage in character recognition. The exoskeletons express the relationships between the characters. If we repeat the exercise for a scanned cadastral map the result is as shown in Figure 21.

This provides the framework for further detailed analysis (Gold 1997). First, the skeletons form the centerlines of the initial line work – and if this was topologically connected then so are they, so in most cases the topological digitizing of property boundaries is automatic. Second, individual skeletons of the “white” regions identify separate map components – in this case mostly buildings and text. Third, the skeletons show the adjacency relationships between these components: the placing of a building within a property, the association of individual characters to form a word or number, and the placing of these labels within a property or building. (Note that all skeleton segments have an associated, and perpendicular, Delaunay edge connecting the two components.) Other applications can easily be envisaged.

Interpolation: the dynamic algorithm

Many traditional surface interpolation methods are based on the weighted-average technique: some set of neighbors to the query point are obtained, some kind of weighting function is calculated (where the weight decreases with the...
metric distance between the neighboring point and the query point), and a weighted average of these neighbors is used to estimate the height of the query point. Various difficulties can arise, especially with supposedly precise data. The biggest of these is that the selection of the set of neighbors is not directly related to their spatial distribution, usually being based on the metric distances, and thus the weighting functions can not readily take account of this distribution: ideally neighbor weights should decrease to zero precisely when that point ceases to be selected as a neighbor, and should reach 100% when the query point and the neighbor coincide. This is not easy to achieve.

An alternate approach is to take account of the Voronoi neighbor relationships – where these include a newly inserted query point, as in Figure 22; the weights are the areas stolen from the original neighbors (Sibson interpolation, natural neighbor, or sometimes area-stealing: Sibson 1982; and Gold 1989). This has two advantages: weights decrease to zero precisely when a data point ceases to be a neighbor, and, as the query point approaches a neighbor, that neighbor’s contribution approaches 100% and the others’ decrease to zero. It can be shown that this approach is “smooth” throughout, except at the data points themselves.

This is really an example of an order-2 Voronoi diagram, where the “weights” are the areas of
those regions closest to the query point and second-closest to the original data point. It may be thought of as the hospital-districting problem: what the consequences would be if the central hospital was incapacitated by fire — or, conversely, if a new one was built at the query point (Okabe et al. 2000).

Figure 23 shows the results of using this interpolation approach on our contour dataset with added skeleton points: the surface is smooth except at the data points — an interpolated point can never have weighted neighbors that only come from one direction. This is also valuable for other anisotropically distributed datasets, such as airborne surveys, ships’ traverses, or, in vertical sections, oceanographic soundings and temperature profiles. In all these cases Sibson interpolation guarantees contributions from a
Often forgotten is that, for many real-world problems, the surface slope is even more important than the elevation – think of insolation or vegetation analysis. However, the above methods may be modified for this purpose by replacing the elevation at each data point by a (usually planar) function. This is then evaluated at the query point. This produces a nearly – but not quite – smooth surface overall (Dakowicz and Gold 2003). Interestingly, if the same approach is applied directly to the TIN model itself, using only planar interpolation, the results are surprisingly good (see Figure 24). (One empirical way to check the surface quality is to interpolate the heights of a random set of points, and use these as the basis for finite-difference runoff modeling, as described earlier: irregularities in the surface will show up as patches of water, or dry areas, at various time steps.)

In summary, interpolation first of all needs the definition of a meaningful set of neighbors, second, a weighting function based on the spatial point distribution, and third, slope estimates.

However, Sibson interpolation needs the addition, and deletion, of individual points; complete set of neighboring data points (Gold and Condal 1995).

[Figure 21 A scanned cadastral map and its topological relationships.]
The kinetic Voronoi diagram

If a Voronoi generator $P$ is moved slightly its Voronoi boundaries with its neighbors will be perturbed. If it is moved sufficiently far then one of these boundary segments will disappear as $P$ moves far enough away – or a new boundary will appear as $P$ moves towards a new neighbor. These are “topological events,” where the diagonal of a pair of adjacent Delaunay triangles is switched to the other configuration. The key idea is that the Delaunay condition – every triangle’s circumcircle must be empty – must be preserved. The moving point $P$ is tested to see if it enters the circle of an adjacent triangle immediately exterior to those with $P$ as a vertex – or, alternatively, if it leaves a circle formed by three contiguous neighboring points of $P$. If so, $P$ gains – or, alternatively, loses – a Delaunay neighbor and the process may be repeated as $P$ moves through the mesh. In Figure 27, $P$ moves towards $Q$ (going from $a$ to $b$) or else away from it (from $b$ to $a$). Care must be taken if two points collide, as all Voronoi generators must have distinct locations.

The kinetic VD has various applications. In Free-Lagrangefluid flow modeling each Voronoi cell represents a fixed “packet” of fluid, which is pushed around by external forces as well as by its neighbors. Thus a smaller cell area implies a greater cell height – for example of water. In another application – a marine geographic information system (GIS) – moving points represent ships, and fixed points the coastline, permitting navigation decisions based on adjacency (Figure 28; Goralski and Gold 2007).

Complex objects

When looking at the scanned map application of Figure 21 it is evident that we are using many
points to represent basic objects. Much work has been devoted to finding a way of working with other kinds of Voronoi generators. Practical algorithms for the line-segment Voronoi diagram, for example, have involved many years’ labor as there are many degenerate configurations where generators meet, nearly meet, or intersect (Held 2001; Gold and Dakowicz 2006). This is unfortunate, as it is, in practice, a very valuable tool. The algorithms involved are complex, and only one – based on the moving-point VD – will be outlined here. We will start by looking at an alternate model based on the DT.
point is preserved it will have all of the historical adjacency relationships of the generating point. If some point $e$ is split off from one data point, moved to another and then merged, we could preserve its track as a triangle edge, even if its properties were no longer Delaunay. From this we could construct, for example, the outline of a house using the “constrained Delaunay triangulation” (Figure 29).

This is used fairly frequently in GIS but it has a particular difficulty: the constrained edges have a dual role, as they must represent objects as well as express the relationships between objects (which the other triangle edges do). This can cause problems. An alternative, but more complex, approach is for these trailing edges to be entities in the map layer itself, rather than in the topology layer formed by the triangles. This requires that the data structure be changed, with the trailing edge being represented by two half lines: this allows the representation of the Voronoi region on each side of the line (Gold and Dakowicz 2006).

Figure 30 shows the Voronoi regions for a set of buildings, which are compound objects.
constructed of points and line segments. Each point, and each half-line, has its own cell, and these are connected by the dual triangulation (not drawn). It is therefore easy to assemble all the connected component parts of each building, as well as their interior cells. Note that the exterior cells together give the Voronoi region of the building as a whole, and the boundaries between the buildings form the skeleton – being the line of maximum distance between them, which is necessary for many navigation problems.

This approach demonstrates that the Voronoi diagram answers most questions about the spatial context of map objects. Worthy of note is that the fundamental query when pointing at a map – “What is here?” – is modified to “What is closest to here?” in the Voronoi approach. Clicking anywhere on the map returns the appropriate response.

Partitioning the map into these proximal regions converts a set of map objects into a “field” – a continuous coverage that always returns a valid response to the fundamental query. In addition, certain other queries may be greatly simplified: buffer zones, for example, can be trivially constructed. By definition they are the map portions within a specified distance of the closest generator. Since all map locations are already assigned to the closest generator, then the “clipped context” is those portions of each proximal region that fall within the specified distance (Figure 31).

It is worth noting that for some applications it is easier to estimate the Voronoi diagram in the...
Figure 32  A unified spatial model based on the VD/DT.
raster domain, and perform the above analyses in that mode. However, such approaches are only approximate – depending on the limitations of raster/vector conversion and the approximation of the Euclidian metric in raster space – and are not rotation invariant (Li, Chen, and Li 1999).

**A unified spatial model**

Throughout this survey there has been one theme: many aspects of 2D spatial analysis may be conveniently expressed in the VD/DT framework. Indeed, it could form the framework for a general spatial data structure that is appropriate for most of the usual geographical data types, and with a common underlying algorithmic basis. Figure 32 illustrates this unified spatial data model for GIS (Dakowicz and Gold 2012).

**Beyond 2D**

Finally it should be remembered that we really live in a 3D world. While the construction of 3D complex objects is still very much a research topic, the 3D point VD/DT is achievable, and is of considerable utility for 3D interpolation problems in such fields as geology and oceanography (Ledoux and Gold 2008). Going further afield, a quick search will discover applications at every scale, from the structure of molecules to the structure of the universe. It is clear that many more applications are waiting to be found.

Spatial optimization

Arika Ligmann-Zielinska
Michigan State University, USA

Spatial optimization uses mathematics to find solutions to spatial decision problems that seek the best arrangement of locations under strictly defined conditions. It is a branch of spatial multicriteria decision analysis, which centers on designing a collection of spatial options and judging how close each of these options satisfies a given set of objectives (Malczewski 1999). Two broad types of problem are considered. First, the decision may involve choosing a location for a particular activity or facility. Second, the problem may focus on selecting an activity for given locations. Either way, space is the essential component of the decision problem, and the best solution offers the optimal design of space under given conditions. Spatial optimization has been used as a prescriptive (normative) tool in a wide variety of geographic applications, including land-use patterning for planning, locating public or private facilities, transit scheduling, moving goods efficiently, finding the shortest path, redistricting schools and voting areas, improving emergency response, locating landfills, designing parks and reserves, and finding the closest facilities, to name a few.

Formalization of spatial optimization concepts and methods in geography can be traced back to Garrison (1959), who applied linear programming to locating manufacturing plants and to solving transportation problems involving the movement of goods from supplying centers to receiving places. Church and ReVelle (1974) presented a general location-allocation model of maximum population coverage of selected services given limited number of facilities. Harvey, Hocking, and Brown (1974) applied a traveling-salesmen algorithm (which determines the shortest route among several locations) to geographic space structuring. Notable publications on spatial optimization include Haggett (1965), Scott (1971), Ghosh and Rushton (1987), Church (2002), Church and Murray (2008), and Tong and Murray (2012).

Any optimization problem consists of decision variables, objective functions, and constraints. The essential element that distinguishes spatial optimization from other optimization problems is the explicit representation of space in the decision variables and functions used to solve the problem. The general formulation of a spatial optimization problem is shown here. Given a set of geographic decision variables \( x \in X \) representing locations:

\[
\text{Optimize} ( f(x) )
\]

subject to a number of conditions \( n \) in the form:

\[
g_n(x) \leq c_n \quad (2)
\]

\[
g_n(x) \geq c_n \quad (3)
\]

\[
x \geq d \quad (4)
\]

where \( c_n \) is a limit value for the \( n \)-th condition, specified as an upper bound (inequality 2) or a lower bound (inequality 3).

Geographic decision variables represent locations that are most often defined using \((x, y)\) coordinate pairs. They can also be defined using three or
four dimensions, especially if the optimization involves time in addition to space (Shirabe 2004). Decision variables can be formalized using any data model, including vector points (Church, Scaparra, and Middleton 2004), lines (Harvey, Hocking, and Brown 1974), polygons (Williams and ReVelle 1996), or raster pixels (Ligmann-Zielinska, Church, and Jankowski 2008; Cromley and Hanink 1999). Function 4 puts technical constraints on the decision variables setting them within a specific range of real or integer values. Geographic decision variables are often binary (Williams and ReVelle 1996), where \( x_i = 1 \) indicates a selected site, and \( x_i = 0 \) signifies a rejected site. The variables can be discrete or continuous, with the latter offering an almost infinite number of possibilities to choose from. For example, a mobile phone tower site selection problem may involve a finite set of candidate locations, or may consider any point in the area of interest. Variables are weighted by coefficients that indicate their relative importance, such as the magnitude of impact, the importance associated with a site, the cost of traversal, or the benefits of selecting a particular site. In general, coefficients are derived from attributes associated with a site or computed based on a relationship between locations. Following the example, if a pair of terms \( 2x_j, 8x_k \) represents the cost of mobile tower installation for two different sites, location \( x_j \) is four times less expensive than location \( x_k \). Furthermore, if \( 200x_{lj}, 50x_{lk} \) stand for distances between an existing tower, l, and the proposed towers, j and k, respectively, tower k would be situated four times closer to l than j.

The term \( f(x) \) is called an objective function, which represents a statement about the desired direction of achievement of a particular decision goal. For example, if the problem is to find the least expensive location to build a new mobile phone tower, the direction of achievement (i.e., optimization) is to minimize the cost. However, if the decision-maker wants to identify a location that serves the largest number of mobile phone users, the direction of achievement is to maximize population coverage. Formally, assuming that the solution to the problem is represented as \( S \), maximization requires that \( S \geq f(x), \forall x \in X \), whereas minimization assumes that \( S \leq f(x), \forall x \in X \). A solution to the optimization problem consists of the optimal value of the objective function and the corresponding values of the decision variables. Due to the complex nature of geographic decision-making, the vast majority of applications use multiple objective functions that reflect the ecological, social, political, economic, legal, and demographic aspects of the problem. In the case of mobile phone tower siting, for example, there may be simultaneous interest in minimizing land acquisition costs and maximizing the coverage of mobile phone users. Multiple objectives are often conflicting, and it is rarely possible to find a solution that optimizes all of them. Instead, multiobjective problems produce a suite of optimal solutions that are noninferior, that is, they cannot be improved on one objective function without degrading another objective (Church and Murray 2008). Noninferior solutions represent tradeoffs among the conflicting objectives and the final choice is often made based on other intangible decision factors.

Constraints (inequalities 2 and 3) are conceptually equivalent to the objective functions because any decision criterion can be either an objective or a constraint. For example, the cost of tower installation can be minimized, or can be set to not exceed a certain threshold. What makes constraints different from the objective function is that they confine the solution space to feasible results, meaning that only the decision variable values satisfying all constraints are considered as potential solutions. Inequality 2 represents cost constraints where lower values are preferable, and
inequality 3 represents benefit constraints where higher values are considered preferable.

Decision criteria used to formulate objective functions and constraints may denote costs (due to activities including engineering, construction, maintenance, transportation), stocks and flows (associated with the amount of goods stored or moved between places), and surpluses (such as monetary and nonmonetary benefits), among others. Most notable, however, are those criteria that reflect topological and nontopological spatial relations, dependencies, and interactions, including distance, pattern, adjacency, connectivity, shape, overlap, containment, and space partition (Tong and Murray 2012; Shirabe 2005).

Addressing distance (proximity) is ubiquitous in spatial optimization applications, such as measuring the shortest path between police stations, the distance traveled from home to work, the fastest route between cities, or the minimum distance necessary to get to the nearest hospital. When operationalizing proximity, it is important to select appropriate distance metrics. The simplest are Euclidean (straight line) and Manhattan (grid) distance measures but, for practical purposes, complex networks of roads, pipelines, power lines, and so on are often utilized. Proximity is usually computed using physical measures (like distance in kilometers), but other types of metrics like travel time are also common. It may be formalized as an objective function (e.g., the shortest path) or as a constraint (e.g., for every residential block, a tornado shelter must be within 10-min drive). Public and private facility location as well as routing are representative applications of distance relations (Church and Murray 2008; Church, Scaparra, and Middleton 2004).

A different type of problem arises from an explicit evaluation of pattern – the spatial distribution of locations, which can be clustered, random, or dispersed. Following the mobile phone tower example, the decision may require the towers be spread relatively uniformly, so that the overall areal coverage of the service is maximized. Conversely, land acquisition for residential development may require clustering of parcels to minimize various infrastructure construction and maintenance costs. Pattern is measured using a variety of approaches borrowed from spatial statistics (average nearest neighbor, spatial autocorrelation, hot-spot analysis), geostatistics (density calculation), and fragmentation statistics (perimeter:area ratio, fractal dimension index). Classic applications include facility dispersion, land patterning, and backup facility siting (Church and Murray 2008).

Clustering often requires addressing issues of adjacency and connectivity. Adjacent or touching spatial objects, referred to as neighbors, share a common boundary. Connectivity (contiguity) is the capacity to move from one spatial object to another without interruption. Both characteristics necessitate a well-defined topology in the underlying data model, so that the geometric intersection of the spatial entities can be evaluated. Contiguity is required in network analysis, and measured as a path between network nodes connected through arcs. Contiguity is enforced using various approaches like evaluating network flows, using dual graphs, optimizing ratio between perimeter length and area of the selected polygons, or evaluating adjacency of spatial units (Ligmann-Zielinska, Church, and Jankowski 2008; Williams and ReVelle 1996; Aerts et al. 2003). A closely related spatial decision criterion is the geometric shape of the solution. Some reserve delineation applications (such as setting aside land for a specific animal or plant species) may require circle-like patches, whereas some habitat corridors may benefit from elongated configurations. Adjacency and connectivity are encountered in a wide array of problems, such as those involving urban growth and land-use planning, nature reserve design, right-of-way
SPATIAL OPTIMIZATION

corridors, transportation network planning, traffic flow management, and evacuation planning.

Other forms of spatial overlap, including intersection and containment, are also common in spatial optimization problems. Polygon intersection can be used in problems that involve service overlap. Critical real-time situations often require some redundancy in service provision (Curtin, Hayslett-McCall, and Qiu 2010). For example, for regions characterized by a high elderly population, some level of overlap could be enforced between two medical emergency service areas, in order to ensure a fast response during peak hours. Intersection can be operationalized using standard spatial analysis methods including point, line, and polygon-on-polygon overlay. Containment is present when one spatial object lies completely within another object. It is commonly used in applications that delineate service areas with focus on the maximum coverage of the target population (retail outlets, banks, hospitals) or in the siting of emergency facilities (Church and ReVelle 1974).

Spatial optimization has long been employed to problems of space partition for administrative, legislative, and other regionalization and zonation purposes (Garrison 1959; Church and Murray 2008). Representative examples include the design of school and voting districts. Partition of space is typically based on population counts (the number of students in a city or voters in a region) and requires no overlaps between districts.

Solution methods to spatial optimization problems are grouped into exact and heuristic categories (Church and Murray 2008). Exact methods evaluate all feasible options and always result in a unique optimal solution, or, in the context of multiobjective decision problems, a unique collection of noninferior solutions (Ligmann-Zielinska, Church, and Jankowski 2008; Aerts et al. 2003; Eastman et al. 1995; Church, Scaparra, and Middleton 2004). They use analytical methods and, therefore, guarantee that the identified solution is indeed the best for the specific mathematical problem. Common methods include enumeration, linear programming, and integer programming with branch and bound (Tong and Murray 2012). Enumeration is a complete search strategy where all feasible solutions are listed and evaluated in order to identify the best option. While enumeration is a simple approach, it becomes unfeasible for problems with a large number of discrete solutions, and impossible for problems with an infinite number of solutions. Linear programming uses a system of linear equations to calculate the optimal function value. While commonplace and relatively efficient, linear programming is of limited use for problems that cannot be formulated with linear functions. Integer programming with branch and bound is used in problems with discrete integer variables by using a divide-and-conquer approach, where the problem is split into smaller and more tractable subproblems. Unlike linear programming, integer programming with branch and bound does not easily handle large numbers of variables.

In contrast to exact approaches, heuristic methods involve rules-of-thumb and ad hoc procedures that result in near-optimal solutions. Since they can handle complex nonlinear functions with a large number of variables in a way that exact methods cannot, they are often an attractive alternative for solving spatial optimization problems. Common approaches include simulated annealing (Aerts and Heuvelink 2002) and genetic algorithms (Tong, Murray, and Xiao 2009). The major drawback of heuristics is that it does not guarantee a truly optimal solution, which may be acceptable in problems that do not exclusively optimize monetary objectives or involve irreducible uncertainties,
such as maximizing ecological suitability in a reserve selection problem or minimizing travel time for a transportation problem. Exact and heuristic methods have been compared in a number of studies (Williams and ReVelle 1996; Church and ReVelle 1974; Harvey, Hocking, and Brown 1974).

While most spatial optimization methods are derived from aspatial approaches, spatial optimization problems offer their own unique challenges, such as the mathematical abstraction of ill-defined spatial problems and integration of optimization with GIS (Tong and Murray 2012). With the ever-increasing complexity of the real-world problems, often defined by fuzzy spatial boundaries and complex measures of social and natural landscapes, it becomes more and more difficult to express variables, objectives, and constraints in a rigid mathematical format. Another problem lies in selecting the appropriate scale of analysis and the representation of the decision variables as points, lines, polygons or more complex entities. Other more conventional yet still important challenges include problems of accuracy and error, and various aspects of uncertainty in spatial data and measurement.

GIS plays a pivotal role in addressing spatial optimization problems (Malczewski 1999; Church and Murray 2008; Cromley and Hanink 1999). It serves as a repository of data used to initialize the variables, a geoprocessing engine that allows operationalization of the spatial properties and relationships of objective functions and constraints, and as a tool for visualizing the results. GIS integration challenges result from the constantly growing amount of spatial data and the higher resolution of the available datasets. As a consequence, the size of optimization problems is surging, requiring computationally efficient solution algorithms that work in real time and can simultaneously handle multiple objectives.

Spatial organization and structure

Jiaoe Wang
Chinese Academy of Sciences

Spatial organization is a complicated concept which can be roughly matched to the whole object and subject of economic geography as a scientific discipline, and also figures in different geographic traditions across the world. The idea that geography is the study of spatial organization was emphasized by Edward J. Taaffe (1974). This view sits alongside human–land relations and area studies, and, along with earth science, these are the four geographic traditions suggested by William D. Pattison (1964). Apart from general geographic knowledge about where to locate, spatial organization helps people understand how to organize geographic space (in which space is seen as property or territory) to satisfy their needs and demands. Meanwhile, generalizations about spatial structure can be made due to the existence of similar spatial patterns or landscapes, enabling understanding, prediction, and a capacity to influence human behavior (Morrill 1974).

Spatial organization relates to many research themes examined at different scales, including the distribution of agricultural activities (such as the Corn Belt), industry layout (such as steel factory layout), services location (such as geography of retail shops), the distribution of human settlements, central place and urban systems, the distribution of infrastructure layout, movements of people, and land-use patterns in cities. Undoubtedly, the most interesting part for geographers is the analysis of the structure and organization of cities, as well as the development of urban systems, due to the high population densities and the existence of dynamic socioeconomic activities.

The spaces in which human activities take place are usually studied at three research scales: global, regional, and local. Meanwhile, space can also be considered abstractly as comprising three geometric elements: points, lines, and surfaces. As such, spatial organization patterns can be classified statically into three types: contiguous structures (including uniform regions and functional regions), discrete structures (such as settlements and network cities), and integrated structures that combine both. Contiguous structures are constituted by spatially continuous surfaces (areas or zones) with a functional center (functional regions) or on the basis of similarity in some respect (uniform regions). For example, urban regions and industrial regions are functional regions, but agricultural regions are typical of uniform regions. Discrete structures are constituted by network elements (mainly points and lines) that comprise, for example, transportation-economic complex axis and pole-axis systems. However, some geographic systems are usually a combination of contiguous and discrete structures. This kind of system is called an integrated structure. One example is the major function-oriented zone, proposed by Chinese economic geographers for promoting coordinated regional development and reshaping in an orderly way the spatial structure by regulating territorial functions. The major function-oriented zone includes four major functional categories: optimized development areas; key development areas; restricted development areas; and prohibited development areas. These four
area types are identified on the basis of their different major functions and roles in urbanization and industrialization, ecological construction, grain production, and protection of natural and cultural heritages.

Chronologically, the research of spatial organization and structure could be coarsely divided into four periods: (i) early development in geography (pre-1920s); (ii) emergence of spatial organization as a focus of geographical research (1920s–1940s); (iii) quantitative revolution (1950s–1970s); and (iv) new challenges since the 1980s.

Early development in geography (pre-1920s)

Geography has traditionally sought to examine the spatial organization of human activities and the principles that account for them. Immanuel Kant (1724–1804), a prominent philosopher, proposed that the geographical and historical sciences extend humans’ knowledge, in which geography focuses on space, while history deals with time. An outstanding German geographer, Alfred Hettner (1859–1941), stated that geography was a spatial or chorological science that studied the relationships of diverse phenomena in terms of space or areas. Richard Hartshorne (1899–1992), however, interpreted earlier research as making geography a largely descriptive and interpretative study of areal differentiation and an important part of area studies.

As a matter of fact, geographers have implicitly engaged practically in spatial thinking from an early stage. Two important activities are worth mentioning. One is the design of maps by cartographers to show the locations of villages, mountains, and forests. In order to record every-thing on the map as clearly as possible, symbols representing soil, climate, vegetation, and so on, were used with different sizes, frequencies, spacing, and directions expressed in an orderly spatial structure, even if cartographers themselves did not recognize it. As such, maps were used to express how humankind’s homelands were organized, but with little deep thinking. The other is the work done by historiographers, urban planners, and sociologists, who observed the unique patterns of city shapes as well as inner-city communities, and put forward some related concepts such as Scoria’s linear cities, Howard’s garden cities, and Galpin’s agricultural community.

During this period, German economist Johann Heinrich Von Thünen (1783–1850) and geographer Johann Georg Kohl (1808–1878) initiated the groundwork for location theory. In 1826, Von Thünen published The Isolated State, in which he presented a land-use model, with concentric rings of land use around a central market: an inner ring of intensive agriculture gave way successively to rings for forest, extensive agriculture, ranching, and waste (Haggett, Cliff, and Frey 1977). Von Thünen’s land-use model was closely related to the more recent bid rent theory developed to explain urban land use. Soon afterwards in the 1840s, Kohl developed representation of a settlement pattern from empirical observations, where the settlements were symmetrically arranged along corridors with hierarchies and scales in a planar graph, which looked like a tree. Kohl depicted the vertical and horizontal landscapes of a city, with a declining trend horizontally in the density of economic activities and population from the city center to the peripheries (Berry and Rees 1969) and vertically in the height of buildings, with different uses of the floors of multistory buildings.

Besides Von Thünen and Kohl, economists Wilhelm Launhardt (1832–1918) and Alfred Weber (1868–1958) separately made excellent progress analyzing the location of industries. In 1909, Weber published the Theory of the Location
of Industries, where he formulated a least cost theory which tries to explain and predict the location of industries at a macro scale. The point was to minimize the cost of transportation and labor by analyzing three factors: the material input, labor, and agglomeration economics. These three factors are usually regarded as mechanisms driving the formation of spatial structures.

Emergence of spatial organization as a focus of geographical research (1920s–1940s)

Most European and American countries underwent rapid urbanization in the nineteenth and/or early twentieth century due to the diffusion of successive industrial revolutions. On the one hand, urbanization implied a change of lifestyle and a redirection of research from the countryside to cities. On the other, human beings’ capacity to change the earth’s surface was greatly increased by the emergence of new technologies during this period. For example, the Fordist revolution based on an industrialized and standardized form of mass production rapidly pushed automobiles into people’s daily life (Knox and McCarthy 2005), greatly influencing urban patterns and structures. Great changes in urban areas gradually led to a decline of academic interest in environmental determinism, while socialists and geographers gradually became interested in how to organize space to promote rapid urban population growth.

City growth

Although human–land relations were advocated by a geographer, Harlan H. Barrows (1877–1960), the initial research on the spatial organization of human activities in cities was done by the Chicago School, and in particular by Robert E. Park (1864–1944), Rodericke D. McKenzie (1865–1941), and Ernest W. Burgess (1886–1966) from the perspective of human ecology.

Burgess proposed a descriptive urban land-use model in 1925 that divided cities into six concentric zones expanding from downtown to the suburbs: central business district (CBD), factory/industry zone, zone of transition, working-class housing zone, residential zone, and commuter zone. This model represented the tendency of a city to expand outwards and for land use to change as a result of competition and the growth and relocation of population with different levels of income and belonging to different social groups.

Homer Hoyt (1895–1984) modified the concentric zone model of city growth, presenting a sector model in 1939 through a study of residential areas in the North American context. In this model, transport had directional effects on land uses. As such, various socioeconomic groups tended to expand outward from the city center along railroads, highways, and other transportation arteries. Meanwhile, the city grew in wedge-shaped patterns or sectors emanating from the CBD and centered on major transportation routes.

Following Burgess and Hoyt’s monocentric city model, Harris and Ullman (1945) introduced a multiple nuclei model with more effective generalization of urban land use. Through case studies in London and Chicago, Harris and Ullman found that the spatial structure of large cities was organized with irregular sectors and multiple separate CBDs, which were shaped by different degrees of accessibility, land use, and regional specialization. Satellite settlements are typical examples and follow neither the concentric zone theory nor the sector theory.
Functional regions

Functional regions are usually organized around a center, or focal point, with the surrounding areas linked to that center through systems, associations, and activities. Actually, functional regions were first put forward in the 1920s, when McKenzie argued that the spatial distribution of human beings and institutions was a result of evolution and dynamic functional interrelationships, with all of the elements organized around centers or points of dominance. McKenzie identified the boundaries of US metropolitan regions through the analysis of daily newspaper circulation. At the global scale, the world evolved from fragmented places into a highly linked and centralized pattern during the 1920s and 1930s. Europe and the United States were the world centers and possessed large cities, while oriental and tropical areas were underdeveloped and located on the fringes of the world.

Meanwhile, geographers firstly focused on visualizing the landscapes of functional regions and describing their characteristics through field investigations. For example, a popular approach involved the preparation of atlases depicting land cover and land use and the way they changed. The mosaic of land-use patterns reflected the relationships between agricultural crops and natural conditions in geographic space. However, Robert S. Platt (1891–1964) emphasized the limitation of an atlas, which cannot reflect the relationships (e.g., retail, entertainment, trade, and migration) between different regions. Then the synthetic map appeared with an overlapping and cobweb-like complex structure, focusing on communications in a region (Hanson 1997). The identification of functional regions is a particularly important way of examining the world from a geographic point of view.

Settlements and central place theory

Settlements, as the space in which most human activities are carried out, are the main research field in studies of the spatial organization of regions. The first statement of the rank-size rule on city population was given by Felix Auerbach in 1913, and was written as:

\[ p_i = p_1 / i \]

where \( p_1 \) is the population size of the largest city, and \( p_i \) is the population size of the city ranked \( i \) in the series 1, 2 \( \ldots \) \( n \), in which all cities in a region are arranged in descending order by population (Haggett, Cliff, and Frey 1977). The rule did not receive much attention until the 1920s, when Alfred J. Lotka (1880–1949) restated it, and the 1940s, when it was popularized by the sociologist George K. Zipf (1902–1950). Today, the revised rule, Zipf’s law, a special case of Pareto distribution, is still widely used by geographers to describe how urban systems are organized.

An examination on the rankings of cities at the global scale was first completed by a geographer, Mark Jefferson (1863–1949), who compared the first-, second-, and third-largest cities by population size for 50 countries of the world and found that in most countries the population of the largest city was much higher than that of the next largest. This phenomenon is also known as the law of the primate city, which was defined by Jefferson as being at least twice as large as the next largest city and more than twice as significant. Today, both the rank-size rule and the law of the primate city are still important approaches for statistically analyzing the structure of urban systems.

Central place theory was proposed by Walter Christaller (1893–1969) in 1933 and is a milestone for studying the organization of human settlements. Christaller asserted that settlements simply functioned as central places providing
services to surrounding areas, and built the central place theory with a case study in southern Germany. Central places and their market areas form a hierarchy in which the demand and supply of goods and services of different kinds are (spatially) equilibrated. The larger the settlements are in size, the fewer in number they will be. With quite a lot of assumptions, Christaller deduced that settlements would tend to form a hexagonal lattice, which was the most efficient pattern to serve areas without any overlap. Soon after, in 1940, the German economist August Lösch (1906–1945) expanded on Christaller’s work. Unlike Christaller, whose system of central places began with the highest-order center and focused on maximizing consumer welfare, Lösch began with a system comprising the lowest-order (self-sufficient) farms and created an ideal consumer landscape where the need to travel for any good was minimized and profits were equalized. The central place theory proposed by Lösch was regularly distributed in a triangular-hexagonal pattern. After that, Harris and Ullman (1945) focused their research on investigating the influences of transportation and specialized function on the structure of central places. Central place theory provides an integrated explanation of the number, size, and location of human settlements, and is a comprehensive approach to understanding the spatial organization of urban systems (Hanson 1997).

Quantitative revolution (1950s–1970s)

Starting in the early 1950s, a quantitative revolution occurred in the social sciences as well as in its subdisciplines. Instead of focusing on what made places different, geographers looked for what they had in common and searched for spatial order or rules using deductive and inductive mathematical and quantitative methods (Isard 1956; Berry and Marble 1968; Haggett, Cliff, and Frey 1977). Emphasis was placed on the measurement and mathematical/statistical representation of all elements of the landscape, such as population, industry, market, trade, cities, and land use. A geographer, William Bunge, even insisted on using the science of geometry to interpret space. Most of this research concentrated on the analysis of spatial organization, the structure of cities, and the organization of systems of cities.

Urban structure

Urban structure is recognized as an integration of urban form and spatial interaction as well as organization rules (e.g., land rent). Urban areas are complex regions aggregating arrangements of land use, social groups, and economic activities. In the 1950s, social area analysis and factorial ecology were pioneered by urban ecologists to explain urban structure. These methods were used to examine residential differentiation in preindustrial and postindustrial urban areas and identified a city’s discrete divisions with their distinctive social traits in terms of three underlying dimensions (ethnic status, family status, and economic status) (Berry and Rees 1969). These studies showed, however, that urban structure varied from one city to another, indicating and intertwining of concentric zones and sectors with disturbed mosaic areas.

There are many models of population and land use developed to explain urban organization rules. Colin Clark proposed the first urban population density model in 1951, written as:

\[ y = Ae^{-bx} \]

where \( x \) represents the distance from the city center and \( y \) represents the density of the residential population, which time series and spatial
tests suggest usually follows an exponential function.

In 1964, William Alonso (1933–1999) put forward the bid rent model, which is an extension of the Von Thünen model. The Alonso model states that each land user (including commercial, industrial, and residential) will compete with one another bidding for land, and that land rent is a function of distance to the CBD. The bid rent curve of commercial land use is the steepest, followed by industrial and then residential land use. Based on Clark and Alonso’s work, in 1967 Edwin S. Mills (b. 1928) incorporated a transportation component into land-use models. In 1964, Ira S. Lowry drew on gravity principles in developing the Lowry model to examine the relationships between transportation and land use. This model opened the way to a large volume of work on the modeling of cities. In adapted forms this model is still in use today.

Systems of cities

Central place theory was first tested by John E. Brush (1919–2007) in the early 1950s with an empirical study in southwestern Wisconsin. Then Walter Isard (1956) improved the spatial and regional frameworks of economics through the development of a more adequate general theory of location (including central place theory) and space economy. Thereafter, geographers Brian J.L. Berry, Michael F. Dacey, and John B. Parr and economist Martin J. Beckmann, among others, carried out case studies to re-examine the statistical rules of central place theory and the rank-size rule. Megalopolis, a type of region playing a special role in the organization of urban systems with frequent and close connections, was defined by Jean Gottmann (1915–1994) on the basis of a study of metropolitan areas on the northeastern seaboard of the United States. In the 1960s, G. William Skinner (1925–2008) examined periodic markets and social structures in underdeveloped areas, such as in traditional rural China, and proposed a modification of central place theory.

Different from the static pattern and relations of central place theory, a four-phase model of transportation expansion and the growth of cities was proposed in 1963 by Edward J. Taaffe, Richard L. Morrill, and Peter R. Gould, with case studies in underdeveloped areas such as Western Africa. The first phase consists of a scattering of small ports and trading posts along the seacoast with limited hinterlands. In the second phase, hinterland transportation costs are reduced for certain ports with the emergence of major lines of penetration, and inland trade begins to concentrate in these ports. In the third phase, lateral interconnection begins to move out as feeder lines develop both from the ports and from nodes and subcenters along the penetration lines. In the fourth phase, a transport network and the urban system is formed with a set of high-priority linkages between the largest centers. This four-phase model describes the evolution of the transportation system as well as urban systems from a spatial organization perspective (Haggett, Cliff, and Frey 1977). In developed areas, the coastal transport route usually helps to integrate the port-cities into a megalopolis.

In 1970, James E. Vance (1925–1999) proposed a mercantile model for explaining the trading-settlement structure of regions between North America and Europe, in which transportation and trade roles shaped settlements. Designed to address the deficiencies of Christaller’s endogenetic central place theory, in which the growth of settlement systems derives from an increase in internal demand for traded goods, Vance’s mercantile model is exogenous, in that central place networks evolve in the context of externally based transportation-trading systems. Vance argued that long-distance trade ties resulted in the
formation of new settlements, initially serving as trading entrepôts or “points of attachment,” and that the number of settlements derived from political and transportation conditions. If successful over time, these new settlements became established wholesale centers with their own hinterlands. Subsequent empirical studies have confirmed that the mercantile model applies well to cases of trade-led expansion of settlements in North America as well as in the other parts of the world. Central place theory is suitable for explaining at all times and places a settlement structure centered on the provision of services in an endogenous, closed economic system. Once the system is opened up by long-distance trade or penetration from outside and there is exogenous growth, the mercantile model takes priority over the central place model in shaping the major lineaments of settlement.

New challenges since the 1980s

The economic development of major industrial countries of the world was heavily affected by two energy crises in the early and late 1970s and a related “Fordist” economic crisis. At that time a new international division of labor started to emerge as companies took advantage of developments in transportation and communication technologies as well as the fragmentation and locational flexibility of production, greatly influencing movements of people, commodities, and information. These distant and dynamic interactions in a network society gave rise to what Manual Castells called “spaces of flows,” as a way to “reconceptualize new forms of spatial arrangements under the new technological paradigm.” This concept led to a great deal of research re-examining the organization of space on different geographic scales, with cities in space (networks) as well as cities as places (regions) acting as the critical hubs and nodes in the space of flows.

Global system

At the global scale, transnational corporations began to relocate their production processes from developed countries to developing countries, searching for the cheapest locations to manufacture and assemble components, giving rise to global production or value chains. Commodities, services, financial capital, and technologies moved and diffused globally, and producer services, including business, legal, finance, insurance, and management services, developed very fast. Both the headquarters of transnational corporations and advanced producer services were inclined to concentrate in certain cities. A world city network accordingly emerged from the global space of flows, although world cities were recognized much earlier by Patrick Geddes (1854–1932) in research on Europe.

John Friedmann and Goetz Wolff (1982) first pointed out that the command-and-control functions of global cities were concentrated in corporate headquarters, from which global businesses were run. Then Friedmann (1986) identified a core–periphery pattern and divided world cities into four categories: primary core cities; primary semiperiphery cities; secondary core cities; and secondary semiperiphery cities. At a global scale, New York, Chicago, Los Angeles, Tokyo, London, and Paris belonged to the group of primary core cities. Saskia Sassen coined the term “global city” in 1991 and emphasized that the concentration of advanced producer services in large cities helped them to assume advantageous positions in the global economic system and dominate it. Although both Friedmann and Sassen identified New York, London, and Tokyo as the leading cities in the world economy, neither was quite clear
about the structure of the global system. Peter J. Taylor (2004) identified world cities as well as the world city system with the analysis of inter-city relations in networks. Until recently, the spatial structure of the global system has been evolving into a more uneven structure.

Regional system

Regional integration has resulted in an interlocking network and urban agglomerations as network cities have emerged. A network city evolves when two or more previously independent cities with potentially complementary functions strive to cooperate and achieve significant scope economies aided by fast and reliable corridors of transport and communications infrastructures. The economic area bounded by the cities of Paris, Milan, Munich, and Hamburg in the European Union has become an integrated region with network cities as well as world cities.

China, as a developing country, has seen major changes in its spatial structure over the past few decades. Following the start of the reform and opening-up policies in 1978, a “T”-shaped development model was proposed by economic geographers under the guidance of the pole-axis theory, where socioeconomic activities were mainly concentrated in the eastern coastal area and the Yangtze River area (Lu 1998). Since the late 1990s, the Chinese government has adopted a series of development strategies, such as the Western Development Strategy, Revitalizing the Old Northeast Industrial Base Plan, and the Rise of Central China Plan, in order to reduce inequalities in spatial development. In 2010, the Chinese central government released the Major Function-Oriented Zoning Plan as the guideline for optimizing the territorial development pattern. Under the plan, the whole country is reorganized into a complex and integrated regional system, and the urban system is distributed as “two vertical and three horizontal” axes with different hierarchies of urban agglomerations. The Yangtze River Delta, the Pearl River Delta, and the Jing-Jin-Ji area are undoubtedly the leading hierarchies of urban agglomerations.

Local system

At the local level, human behavior has its most obvious and significant spatial impacts on urban areas. Since the late 1970s, both counterurbanization in developed countries and urbanization in developing countries have progressed simultaneously and finally ended with the strengthening of large cities. In 2010, people living in cities accounted for 50% of the world’s population.

In the large cities in developed countries, people moved from urban areas to suburbs or rural areas as a reaction to overcrowding, traffic congestion, air pollution, and so on in the inner city, and the population of large cities dropped quickly. Meanwhile, with the prevalence of information and communication technologies, the urban form was splintered in terms of land use, and the galactic metropolis came into being, with a salient landscape – the growth of the edge city as a part of urban agglomerations. Since 2008, re-industrialization and the relocation of industries have appeared due to the impact of the global financial crisis. Mobility, interactive relations, and inclusive environments are making urban communities more diverse.

In most developing countries urbanism is in an upgrading stage, according to the urbanism theory proposed by Ray M. Northam in 1975. For example, 47% of China’s population lived in cities and towns in 2010. The equivalent figures in India and Egypt were 30% and 43%, respectively. With large influxes of population from rural areas to cities, local systems are diverse due to their development history (e.g., a colonial
past), culture (e.g., Islam), economy, and other factors. For example, the combined industrial and residential communities in Chinese cities have gradually disappeared due to the adoption of a market-oriented housing policy since the 1990s and a change of focus in city development from the inner city to the outer city, as in most Western countries. Today, however, many municipal governments in China have realized the importance of renewing the historical areas in the inner city in terms of cultural heritage conservation, modifying urban structures. In addition, the emergence of Desakota regions has been examined in many countries of Asia. The Desakota region is a region with an intense mixture of agricultural and nonagricultural activities that often surround a core city or stretch along corridors between large city cores (Knox and McCarthy 2005).

Spatial organization is one of the most important research themes in the science of geography and has played an increasingly important role in understanding and examining changes in the organization of human activities on the earth’s surface, particularly in urban structures, systems of cities, and functional regions at different scales. The patterns of spatial structures vary with different organizational models: contiguous structures, discrete structures, and integrated structures. The study of spatial organization and structure, however, is facing new challenges in seeking to understand how to organize geographic space to satisfy human beings’ needs and demands in an interdependent, uneven, and diverse world.

SPATIAL ORGANIZATION AND STRUCTURE

Further reading

Spatial resolution

Peter M. Atkinson
University of Lancaster, UK
Queen’s University, Belfast, UK
University of Southampton, UK

This entry considers the topic of spatial resolution from a geography and environmental science perspective. As this is an encyclopaedia of geography, the entry is written at a general level for a wide audience, including the general public. For a more detailed consideration of the topic of spatial resolution, readers are referred to the book by Zhang, Atkinson, and Goodchild (2014).

Geography is inherently spatial in nature. Topics studied range from a spectrum of environmental phenomena and challenges, including understanding environmental processes through paleoecology, geomorphology, hydrology, biogeography, landscape ecology, and spatial epidemiology, through to social and economic analyses. In all cases, the focus is on the spatial environment, human spatial constructs, and the interplay between them (socioecological interactions). For certain subdisciplines this extends to interactions between humans, animals, and environment, for example in the fields of conservation biology and One Health. Increasingly the focus of geography is also being extended to the temporal dimension, without losing its spatial underpinnings, resulting in space–time geographical inquiry. Such space–time investigation has been a natural part of some subdisciplines for a substantial period for example paleoecology, but is only just being enabled in others.

In all of the fields of inquiry noted, there are two basic ways of knowing about the real world. The first and most fundamental is “measurement.” In the context of research, this can mean measurement followed by induction of a hypothesis that explains potentially some unexpected observation, and measurement designed within the frame of an experiment (and control) such that the difference in outcomes is a function only of the experiment. It should be obvious that here measurement has been placed into the inductive and deductive scientific research methodologies, respectively. Abstraction of ideas is also possible.

The second route to understanding is “modeling,” which involves the fitting of logical and mathematical constructs to data to generalize their information content, and also, through their application, to constrain what can possibly be true given the data and the model; that is, to predict. Here, the model, no matter how poorly, encapsulates our understanding of the processes in the real world (usually directly, but also indirectly, for example through statistical models), and differences between predictions and observations allow potential refinement of our understanding. The focus of this entry is measurement, but models are also invoked that capture and test our understanding of spatial resolution.

Spatial resolution may seem an unrelated concept to the topics discussed so far, but it will be seen that all measurement and all models are dependent on it. Spatial resolution is a fundamental concept in geography, in science, and in our everyday lives. How strange, then, that until recently it has rarely been considered. Spatial resolution is now introduced in the context of remote sensing.

Spatial resolution has gained interest as a subject of investigation in geography primarily as a result of the advent of remote sensing.
SPATIAL RESOLUTION (Atkinson and Tate 2000). Spatial resolution is a term associated with images, including remotely sensed images, and commonly it is used to refer to the pixel size, where the pixel is generally a grid cell in an image, is square, and, crucially, has a specific size represented as the length along one side of the square. The choice of spatial resolution in remotely sensed imagery is important because it determines the information content of the image. Thus, via the launch of early satellite sensor systems such as the Landsat multispectral scanning system (MSS) (with a spatial resolution of 79 m), the Landsat thematic mapper (TM) (with a spatial resolution of 30 m), and the National Oceanographic and Atmospheric Administration’s (NOAA) advanced very high resolution radiometer (AVHRR) (with a spatial resolution of 1.1 km), the term spatial resolution was popularized among scientists. More recently, digital cameras and online services such as Google Earth™, which allow rapid zooming in and out of geographical images and data, have brought the concept, and the meaning, of spatial resolution to the general public.

The two sensor systems described above (Landsat, 79 m and 30 m; AVHRR, 1.1 km) illustrate a key issue in the design of satellite sensors: a trade off has to be made between spatial resolution, spatial extent, and temporal revisit frequency. Landsat TM has a swath of about 185 km and a revisit frequency of 16 days. NOAA AVHRR has a swath of about 2600 km and a revisit frequency of once or twice per day. Thus, the former is rich spatially, whereas the latter is rich temporally. This constraint also means that spatial resolution is determined at the design stage with specific applications in mind; it is not an unconstrained choice made by users. From a user’s perspective this means that sampling choices are, in fact, usually a choice made from the available satellite sensors (of which there are now many), with spatial resolution crucial among the parameters defining the ultimate choice.

One of the key drivers that has opened up the possibility of space–time analysis in geography is the long time series of images now available from several long-term satellite sensor systems, such as Landsat and AVHRR (of the order of 40 years), and MODIS and MERIS (of the order of 12 years) (Wulder et al. 2008). Such data have very recently supported analysis of changes on the surface of the Earth and long-term monitoring. Interestingly, monitoring was the original objective of programs like Landsat, but it was not until a sufficient time series had been built up, and challenges in processing had been addressed, that analysis of change could really begin. Again, spatial resolution is a key parameter that needs to be selected in support of time-series analysis.

In the next section, remote sensing is compared with traditional field measurement and differences drawn out that help to illuminate the meaning of spatial resolution through its context.

The sampling framework

Traditional field measurement in geography and environmental science usually refers to point or pseudo-point measurement – for example, cores in paleoecology and soil science, or quadrats in biogeography and landscape ecology. Such field sampling is characterized by being expensive to acquire and expensive to process in laboratories. Moreover, it is also often difficult to acquire such data in the first place and sometimes impossible due to accessibility constraints, which can lead to biases in estimates.

The focus of sampling in field survey is to design a sampling framework focusing on several parameters (Table 1). Limiting the analysis to the spatial domain initially, the first thing that needs
to be defined is the spatial extent; this has a size, geometry, and orientation. It also needs to be anchored to a specific coordinate system via a spatial position (Table 1).

Once the spatial extent of interest is well defined, it is necessary to design the sampling: this requires definition of the size of sample \( n \) required, definition of a particular sampling scheme (e.g., random, stratified random, systematic square grid, systematic triangular grid – i.e., a specific geometry), and a decision about orientation. It is also necessary to fix the design relative to some coordinate system (Table 1).

Finally, although often neglected, there is a third component of the sampling framework: the support (Journel and Huijbregts 1978; Openshaw 1984; Atkinson and Tate 2000). This refers to the size, shape, and orientation of the space over which individual measurements are obtained. The support is a fundamental concept, just like the concept of spatial resolution, but note that the two are, in fact, different, a point that is returned to later. Once measurement has been made over the support, the measurement process cannot be reversed and there is a loss of information.

In field survey, the goal is often to choose a sample size \( n \) so that it provides sufficient precision (represented here by the standard error, SE) when estimating a mean through, for example,

\[
    n = \left( \frac{\sigma}{SE} \right)^2
\]

where \( \sigma \) is the sample standard deviation. However, this equation applies strictly only to independent data, which invalidates it for application to spatially varying environmental properties. Alternatively, increasingly the goal has been to provide a map through interpolation techniques such as kriging, in which case the goal of sampling design can be centered on achieving some specific function of the locally estimated prediction variance (referred to as the kriging variance). In the latter case, it has been shown that systematic schemes are most efficient, and especially more so than random sampling. The goal then is to select \( n \) such as to ensure a greater than some minimum level of kriging variance everywhere, given a systematic scheme. The use of covariate data to aid in mapping through regression approaches is now common and needs to be incorporated into sampling design.

The above efficiency of design is usually the focus of sampling in the environmental sciences, especially given the associated costs. However, in remote sensing the focus of sampling design, as has been seen already, is the spatial resolution. In remote sensing, then, once the study site extent is defined, the focus of sampling design effort is on the spatial resolution, which defines the entire sampling framework. This switch in thinking arises because the extent and spatial resolution are the only parameters remaining to be defined through the single choice of a particular sensor image, as complete coverage is provided within

a (commonly) square extent on a fixed raster grid scheme, \( n \) is defined by the extent and resolution, and the orientation is predetermined. The rationale for selecting a given image with specific spatial resolution is commonly to ensure that the desired information is captured in the image (i.e., sufficiently resolved).

The next section explores the meanings of support and spatial resolution, and the differences between them.

**Defining spatial resolution**

It is fairly obvious that the concept of spatial resolution in remote sensing overlaps directly with the concept of support in sampling design. However, the support and spatial resolution are not the same. Referring to Table 1, it can be seen that the concept of resolution relates partially to the support but also to what is defined here as the sampling design, including the sample density and sampling scheme, with orientation having relevance only if anisotropy is present in the property of interest. In fact, resolution refers to the smallest object that is resolvable in a dataset, and this arises as a function of both the support and the set of distances between observations which, themselves, are determined by the sampling design. The reason for the confounding of the concepts of support and resolution in remote sensing should now be obvious: complete cover ensures that the support size and spatial resolution are the same in magnitude. There is another reason that the two concepts are often confounded and that is that the cells on the retina of the human eye also provide complete coverage in the form of an image.

It is useful at this point to provide greater definition of the two fundamentally important concepts of support and spatial resolution. The support is important because it is always present, not only in all data but also in everything that we can ever know about the real world through our own senses. The support ensures that measurement is made as an integral of some underlying reality over a positive finite space. This integration is important as several properties are associated with it, including that it is a forward not inverse process and, in general terms, the concepts of the central limit theorem apply. All measurements have a support as it is impossible to measure on a point. Evidently, cores are made over a positive cylindrical volume in 3-D and quadrats lead to an average over a square space in 2-D. These issues are returned to later.

The spatial resolution, on the other hand, is important because it limits the information content of data. All information exists in the relations between data values, not in them. Thus, if presented with a single value, say, 65, it is strictly of zero information content on its own. It means strictly nothing. Of course, your brain will try to interpret the value in relation to values or information that you already hold. So you might try to guess that the value relates to age, for example, or perhaps the age of retirement in some countries. While this may be true, the information content does not lie in the value itself. It lies in the relation between the value and the context provided by your brain. Thus, spatial resolution, as a function of the support and the geographical distances between data, controls the information content of the data, which exists in the relations between them. Importantly, the nature of the relation between environmental data is commonly a function of geographical distance.

While the support can be thought of as an averaging process, stealing all information within the support and replacing it with a noninformative (on its own) single value, the spatial resolution determines the information content between data as a function of the support and the geographical distances between them. Thus, the support and spatial resolution act as a smoothing filter through which low frequency spatial
variation can pass, but through which higher frequency spatial variation does not (it gets averaged out). The information content of the measured data is, thus, a function of the combination of the support and spatial resolution, within the given spatial extent.

To understand the role of the support and spatial resolution it is necessary to consider a third property: spatial variation. While it is assumed that spatial variation exists, in reality this cannot be shown; spatial variation only ever exists in measurements or data. Consider a simple image of say 100 × 100 pixels each of 1 km on a side. The spatial variation (and potential information content) of the image lies in the relations between the data values (i.e., in the set of data values) that, themselves, can be defined as a function of the sampling framework and some underlying external reality. Note that while the former is known the latter is only an assumption (albeit one that all scientists embrace). This relation is general, and is captured by the equations (1) and (2):

\[ I_z = f(z_s(x)) \]  
\[ z_s(x) = f(\theta, R, \varepsilon_s(x)) \]

where, \( I_z \) represents the information content of \( z \), \( z_s(x) \) represents a variable defined at a vector \( x \) of locations in space on support \( s \), \( \theta \) represents the vector of parameters defining the sampling framework (Table 1), \( R \) represents some underlying reality which is not observable without sampling, and \( \varepsilon_s(x) \) is a vector of measurement errors.

To bring home the fundamental concepts, consider zooming in and out. This is, of course, now done readily for Earth viewing using services such as Google Earth. However, the concept is entirely general and applies also to our visual system directly. If we walk away from a particular scene, eventually we are no longer able to see components of it (e.g., ants, then bees, then birds, then mammals, etc.). We are comfortable with this zooming property as it is fundamental and always present. As we zoom out, more of the underlying variation in reality is obscured through the measurement process and the less there is left to provide information to the observer. We do not notice this generally because as the support increases (and resolution decreases) the extent also increases, meaning that we are always afforded a complete “scene”: the information lost within the coarsened support of the old scene is replaced by new information in the added part of the new scene gained through the increased spatial extent.

The most important point is that the spatial resolution (for imagery, also the support size) should be chosen in relation to the spatial variation that needs to be captured in the data. Generally, the spatial resolution needs to be fine enough to capture the important information. This simple message underpins attempts to define an appropriate spatial resolution for remotely sensed imagery (Woodcock and Strahler 1987; Atkinson and Curran 1995). In relation to this, it is worth remembering that the spatial variation that is filtered out by the support is of high (relative to the support) spatial frequency and that which remains between the data is of low spatial frequency; thus, the filtering is specific.

The above concept is general and can equally be applied to temporal variation. Just as humans require the aid of either microscopes or telescopes to “zoom in” to see beyond “human” spatial scales (i.e., spatial resolutions), human comprehension of the dynamics of fast processes such as a fly flapping its wings and slow processes such as a river changing its course on the earth’s surface requires transformation. This transformation is required in order to match the (in this case temporal) resolution to the temporal variation that needs to be captured in the data. In the former case, high frequency (i.e., fine temporal resolution) video allows the capture of wing beats, which when slowed down sufficiently are
SPATIAL RESOLUTION

comprehensible to humans. Likewise, long time series of remotely sensed imagery, as discussed in the introduction, are of sufficient temporal extent that, when speeded up, they allow comprehension of fundamental Earth processes for the first time, particularly through the power of data animation. Interestingly, this comprehension arguably comes because of the specific part of the human visual system that is devoted to movement, as discussed below. Gupta, Atkinson, and Carling (2013) provide an example for the River Ganga in India. Yet more impressive, Google Earth Engine is now bringing this type of animation to a wide audience.

Given the above discussion, it should be clear that the sampling (extent, support, sampling design) imposed by the sensing systems of the human brain fundamentally limits everything that we can know about reality. Interestingly, spatially different parts of the human visual system (which itself is a large part of the human brain) have different functions. Some brain regions are devoted to interpreting color, while some are devoted to interpreting shape, and others are devoted to interpreting movement. It is interesting to consider that such brain functions also fundamentally limit everything that we can know. If our brains are not evolved to sense something we will be forever ignorant of it, even if it exists externally. However, this is beyond the scope of the present discussion, which is focused on the effects of spatial resolution and the support.

It is now time to turn attention to how these basic concepts can be put to good use. The focus of the next section is on changing the support.

Operations

Upscaling and downscaling

The understanding characterized above has been used to develop statistical models that allow scale changes, or scaling, also referred to as “change of support” (Cressie 1996; Atkinson and Tate 2000). This operation falls into two classes: upscaling, which involves increasing the support size, and downscaling, which involves decreasing the support size. It is worth spending some time considering these goals in order to capture what is needed for their solution.

Upscaling is a forward process and, thus, it is tractable. It involves averaging or integration and it is, thus, similar in nature to measurement. Once a scaling function has been defined (which commonly is the simple linear average), upscaling is straightforward given the fine support data if complete coverage is provided. In remote sensing, upscaling is an important process, as it is frequently necessary to compare coarse spatial resolution imagery to sparse (pseudo-) point ground data for calibration and validation purposes. Where the pixel size is large (e.g., >1 km) the link between sparse point data and pixels can be tenuous. In these circumstances, it is common to use imagery of some fine spatial resolution (e.g., airborne imagery) to provide a bridge through which it is possible to scale from points to coarse pixels. The strategy is simple: (i) relate the ground data to their corresponding fine pixels directly through regression; (ii) average the fine spatial resolution image pixels within the coarse pixels; and (iii) relate the averaged fine spatial resolution image pixels to the coarse spatial resolution pixels directly through a second regression.

Downscaling, in contrast, is the opposite to upscaling. It involves attempting to disaggregate a single value into a series of values associated with smaller supports. It is an inverse process and is ill-posed, meaning that there are many possible solutions that will, when upscaled, give the same result. In fact, the condition of coherence, that the fine support solution when upscaled will equal the starting large support value, provides an important constraint on the downscaling
process. Solutions without further constraint are numerous and of little use. For example, taking imagery as an illustrative example, in the continuous case it is possible to imagine a fine spatial resolution image of noisy appearance with values changing haphazardly, constrained only by the coarse resolution image. All these solutions are valid under the coherence constraint. In the categorical case it is possible to imagine the colors of a fine spatial resolution image changing color haphazardly without spatial structure. Neither of these situations is particularly useful.

It turns out that information that can be used to further constrain the solution using optimization type approaches is available. The very fact that the images appear noisy means that they are not plausible solutions. They do not accord with our a priori expectations of what the fine spatial resolution image should look like. This kind of thinking led to two classes of solution to this problem. The first is based on Tobler’s first law of geography, that things near to each other tend to be more similar than things that are far apart, also referred to generally as spatial dependence. Since all phenomena on the earth’s surface are spatially dependent, at least at some scale (if they were not there would be no structure to the world at all, and all noise would be averaged out through the integration of the measurement process – a complete loss of information), it is possible to generate more realistic solutions by maximizing the spatial dependence in the realized fine spatial resolution data (Atkinson 2005).

The second solution is more general and involves characterizing our a priori expectations in some (usually spatial statistical) model. The goal of the downscaling process is then to match the character of geographical variation in the realized fine resolution data to the prior model. Examples of tools used to characterize the variation include the variogram (a two-point statistic that extends the concept of the variance to space by making (semi)variation a function of the vector of separation), the two-point histogram (which captures double the information in the variogram), and multiple-point statistics (which captures the full available information, but is less readily interpreted) (Strebelle 2002; Mariethoz, Renard, and Straubhaar 2010). To bring these ideas to life, imagine that the goal is to downscale an image of a suburban area from a spatial resolution of 30 m to 4 m. Prior expectation about the nature of the size and shape of buildings, as well as the pattern between buildings, will help to greatly constrain the solution.

The above solutions are interesting because the information content implied by the assumption of maximizing spatial dependence and some prior model is tiny compared to the potential information content of the downscaled images. This means that something fundamental has been captured about the nature of both the data and the scaling process.

As an alternative to optimization approaches, geostatistical models and related approaches have been used to downscale imagery and other data directly. Geostatistics is a branch of mathematics that deals with spatial data (Journel and Huijbregts 1978). Kriging involves prediction of unobserved locations as a linear weighted sum of neighboring data. A function known as the variogram is used to determine the weights applied to the neighboring data. This makes intuitive sense because the variogram captures the character of spatial variation and spatial dependence: locations that are near to the prediction are given more weight but, more than this, the exact weights are determined by the magnitude of dependence. However, it also makes statistical sense: by letting the data speak for themselves, the prediction is both optimal and unbiased under the constraint that it is a linear solution.

Kriging has been adapted to allow spatial prediction of continuous values defined on a support
SPATIAL RESOLUTION

that is smaller than that of the original data. This process is termed area-to-point kriging (ATPK) (Kyriakidis 2004; Atkinson, Pardo-Iguzquiza, and Chica-Olmo 2008; Goovaerts 2008). ATPK extends kriging to the downscaling case. It requires the variogram not only between the original data at the large support size but also between the small supports to be predicted along with the cross-variogram between the large and small supports. These can all be predicted as a function of the punctual or point variogram. Unfortunately, the punctual variogram is not measurable directly for the reasons elaborated above as a central message of this entry. Thus, it is necessary to estimate the punctual variogram initially through inverse methods. While this is an ill-posed problem, and many possible solutions will lead to the same observed variogram when convolved or regularized, solutions based on eliciting expert opinion have been proposed.

Scaling the model

Beyond upscaling and downscaling the data, geostatistics also provides a model of the scaling itself. This is conceptually important, as it helps to illuminate the nature of the geographical scaling process itself, and, therefore, it is reviewed briefly here.

In classical statistics, the variance of a group $s^2_G$ is defined as:

$$ s^2_G = \frac{s^2}{n} \tag{3} $$

where $s^2$ is the original sample variance of the original data and $n$ is the number of observations being grouped. Thus, the variance of any new set of data obtained by averaging subsets of the original data can be predicted as a simple function of the original variance and the group size. The potential for application of this equation to the measurement process should be clear: both deal with averaging. However, this equation does not apply to the geographical scaling problem because it assumes statistical independence between the original data, which clearly is not applicable to geographical data, which as already explained tend to be spatially dependent, at least at some scale. Thus, the equation needs to be replaced with an alternative that takes into account the statistical dependence between data that arise as a function of proximity in geographical space.

Using the geostatistical variogram it is possible to predict changes in the variance with change of support directly. First, an equation is introduced that describes the process of coarsening the support of the variogram itself.

$$ \gamma_v(h) = \tilde{\gamma}(\nu, \nu_h) - \tilde{\gamma}(\nu, \nu) \tag{4} $$

In words: the variogram $\gamma_v(h)$ (think variation, or even potential information), which relates the semivariance to lag vector of separation $h$ obtained on a support $\nu$, is defined as a function of the punctual (or point support) variogram $\tilde{\gamma}(\nu, \nu_h)$ integrated over two supports $\nu$ and $\nu_h$ of equal size separated by a given lag vector $h$, minus the double integral of the punctual variogram $\tilde{\gamma}(\nu, \nu)$ over the support $\nu$ overlapping itself without geographical separation (Clark 1977; Journel and Huijbregts 1978). Note that since all data are defined on a support $\nu$ of positive size then so too is any variogram $\gamma_v(h)$ estimated from observations.

Equation (4) means that it is possible to scale the model rather than the data; the variogram constitutes a fundamental parameter set defining a random function, which is central to geostatistical theory and geostatistical operations such as kriging. Thus, equation (4) has captured something fundamental about the measurement process, and the support, which affects all data.

As explained above, the punctual or point variogram can never be measured directly. Thus, it is
necessary to estimate the punctual variogram initially through inverse methods. While this is an ill-posed problem, this does not detract at all from the power of the regularization equation when applied in the forward sense.

Given the punctual variogram it is possible to estimate the dispersion or sample variance $s^2_v$, that would be observed on a support $v$ within a region of interest or extent $R$ using equation (5):

$$s^2_v = \tilde{\gamma}(R, R) - \tilde{\gamma}(v, v)$$

where $\tilde{\gamma}(R, R)$ is the integral of the punctual semivariance over the full domain of interest (the extent) and $\tilde{\gamma}(v, v)$ is the integral of the punctual semivariance over the support $v$, as above. This means that by replacing the classical equation with an alternative based on the variogram it is possible to predict the effect of changes in the support on the sample variance in geographical data. Importantly, if we upscale or “zoom out” we can predict precisely how the sample variance will decrease, where the classical equation fails. Since the variance represents the variation between data values, this means that as we zoom out we are able to capture the measurement process (and the loss of variation, and information, to within the support), and predict the variance (and, thus, potential information), remaining in the data. This scaling process is entirely general and affects everything that can be known about the real world.

Many other interesting tools have been used to explore the concepts of change of support. These include plots that capture the effect of scaling on data such as the scale variance, local variance, and dispersion or sample variance plotted against support size (or spatial resolution in remote sensing). Fractal concepts and wavelet analysis are also central concepts in discussions about scaling, but there is not space here to cover them. Readers are referred to Deidda (2000) for an example involving fractals in space–time.

Discussion

Having considered the change of support problem, attention is now returned to spatial resolution. As explained above, for images and the human visual system, the support and the spatial resolution change in tandem. This means that a discussion of change of support reveals simultaneously the effect of (i) the support (averaging out higher frequency spatial variation within the support) and (ii) spatial resolution (determining the variation and, therefore, potential information content of the data after averaging). However, this is not always the case. Sometimes, the support is very small in relation to the set of distances between the data (Table 1), for example, in field survey. In this case, the information content in the data is determined only partially by the support and more so by the set of vectors between data locations, relative to the underlying spatial variation.

At this point it is worth introducing the possibility of varying the spatial resolution (specifically, the set of distances between the data points) spatially. Since such “nonstationary” sampling schemes can be expensive it might be wondered why anyone would consider it. The answer relates to the simple goal of ensuring that the spatial resolution is sufficiently fine to reveal the variation of interest (in the observations). Spatial variation, or more precisely the character of spatial variation, is not generally uniform across space. A simple example is given by elevation, which commonly manifests as smooth, planar floodplain, rolling foothills, and rugged mountainous terrain; the variation in elevation varies locally. The spatial resolution required to capture such local variation must adapt to each local situation. This is exactly what happens when a digital elevation model is created using the triangular irregular network (TIN).
Future work is likely to focus on extending the change of support problem to the temporal dimension, as suggested by the opening paragraphs on the nature of geography. In particular, the emphasis of downscaling research is beginning to turn to the problem of downscaling in space and time simultaneously. This problem is both challenging and of real potential value in remote sensing (Zurita-Milla et al. 2009). For example, many satellite sensors can be combined with different spatial resolutions. However, the images with coarse spatial resolution, as suggested above, commonly have a fine revisit frequency, whereas the fine spatial resolution images tend to have a low revisit frequency. Thus, a natural space–time downscaling goal is to integrate these two sources of information such as to produce fine spatial resolution imagery with fine revisit frequency. The new Sentinel series of satellites is a case in point, providing data at different spatial resolutions and revisit frequencies simultaneously.

An interesting reflection can be made in relation to the tradeoff between resolution and revisit frequency as discussed previously. It is not feasible to monitor the whole world at very fine spatial resolution (e.g., submeter) and fine temporal frequency (e.g., minutes) because (i) the data volume would be enormous, (ii) the computational burden would be prohibitive, (iii) an individual human brain would not be capable of even looking at all the data, let alone analyzing it, and (iv) depending on the goal, most places are not changing at such high frequency anyway. Thus, it is interesting to consider the design of a system that would allow coarse spatial resolution monitoring combined with fine spatial resolution investigation where necessary, for example, using pointable sensors.

The human brain provides a guide in this case. A part of the human visual system is devoted to movement, and this is connected to the whole field of vision, which has a surprisingly coarse spatial resolution. (Try holding an unidentified playing card at arm’s length and slowly bring your arm around to in front of your eyes. See how long it takes you to identify the card without moving your eyes; you should recognize the card at about 2° from your direction of sight.) However, within this general field of view the human brain is excellent at spotting movement. Once movement is spotted the eyes quickly move to it and settle on it, thus bringing the very fine spatial resolution associated with our central vision to bear on the movement (the bit that allowed you to identify the playing card).

A similar system could be envisaged for monitoring changes on the surface of the Earth. While the association between our visual system and monitoring the Earth may not be obvious, it is worth noting that our visual system developed in this way over evolutionary time as a means of responding to potential threats. The earth’s natural environment has no such mechanism and yet, as a species, we depend utterly on it as a life support system. Thus, ever more sophisticated systems are likely to emerge to monitor our interactions with the environment in the present and recent times and the solution proposed above is potentially highly efficient.

Whatever the solution to monitoring our rapidly changing earth’s surface, understanding the nature of the data (what has been captured in the relations between the data and, more importantly, what has been lost through measurement), and specifically understanding the measurement and scaling processes implicitly present in such data, will be central in both designing appropriate surveillance systems and in interpreting correctly the results.

Samples are selected from populations – such as 100 of 100,000 persons, 20 soil samples from a park, 50 questionnaires at a school – because inspecting the entire population is either impossible, too time-consuming, or too expensive. To obtain meaningful conclusions, sample units should usually be random selections. Non-randomly selected samples may lead to biased estimation, although a biased sample may be remedied by some statistics.

In contrast with an exhaustive survey, a sampling survey is quick, inexpensive, and accurate if the sampling is well designed to represent the target population or if a small, high-quality dataset is used rather than a big dataset with uncertainty. Sampling techniques are thus widely used across a broad range and at various levels of environmental disciplines, such as agriculture, geology, soil science, ecology, oceanography, forestry, and meteorology, as well as socioeconomic disciplines, such as human geography, spatial econometrics, epidemiology, and spatial planning.

Spatial sampling draws a sample from a population with geographical or locational references. The sample is then run through an estimator to infer the parameters of the target population, for example the map, mean, or total values, or the coefficients of population regression. A good spatial sampling method chooses a small sample to infer parameters of population with high accuracy. The size of the sample and the accuracy of the sample estimation are dependent on the properties of the target population, the methods of sampling, and the methods of estimation. These three determinants form the spatial sampling trinity (Wang et al. 2012).

The target population refers to exhaustive observations of an entire study area. For example, a survey that enumerates birth defects in all villages in a country gives the target population of birth defects for the country. Sometimes, the process that generates the target population is of interest, and the observed target population is regarded as just one realization of the underlying process, called a superpopulation. For example, data about birth defects over many years contain almost all information relating to the risk of the disease in the study area, and can thus be regarded as a superpopulation. Sometimes a superpopulation is assumed and modeled rather than observed. Conventional sampling techniques usually ignore features in the target population or subpopulation (Cochran 1977). However, spatial autocorrelation (Tobler 1970; Haining 2003) and stratified heterogeneity (Goodchild and Haining 2004; Wang, Haining, and Cao 2010; Wang et al. 2016) are ubiquitous in geographically distributed target populations. Properly accounting for these properties can improve sampling efficiency (Griffith 2005).

The sample may be drawn randomly, systematically, or by stratifying the study area, as illustrated in Figure 1. These approaches may also be combined. For example, for a stratified systematic sample, the study area is first divided into strata according to the spatial heterogeneity of the target population, and the sample units are then drawn systematically from each of the strata. Another commonly used approach is
two-stage sampling: large units are selected in the first stage, and in the second stage a number of units are randomly selected in each large unit. Random sampling guarantees an unbiased estimation of the population, systematic sampling is more easily implemented in practice, and stratified sampling reduces the variance of estimation. A sample that is geographically random may not be random for a target population, such as prevalence of disease, because the latter is usually not randomly distributed geographically. The difference between the sampled population and the target population causes a biased estimate, which needs to be remedied.

The population or superpopulation can be estimated by both design- and model-based approaches (Wang et al. 2012). Design-based approaches handle data (Cochran 1977), that is, values at sampling sites are fixed while they may vary in different sites; a sample estimate varies with different samples. Model-based approaches handle random variables, that is, value at a sampling site is a variable, which is assumed to follow some probability distribution function (Matheron 1963). Table 1 presents a simple example to illustrate the relationship between the population, the superpopulation, design-based estimation, and model-based estimation.

Spatial sampling (S) and statistical inference (I) are usually connected, and in short written as spatial sampling, which consists of three steps:

\[ I - S - I \]

Step 1 (I₁) Homework before fieldwork. Decide a sample size \( n \) for a prior given a specific accuracy of estimation (or variance \( v \)), or estimate the accuracy (or variance \( v \)) of sample estimation for a prior given a specific sample size \( n \) (related to survey budget). See Table 1 for an example of the relationship between \( v \) and \( n \). The coefficients of dispersion variance \( \sigma^2 \), spatial autocorrelation \( r \) or \( C \), and strata in \( (v, n) \) may come from previous survey data, secondary data related to the target population, or pre-sampling.

Step 2 (S) Fieldwork. Distribute the sample over the target population in the field randomly, systematically, or in a stratified way (see Figure 1). If some secondary information related to and covering the target population is available, the sampling sites can be optimized by simulating different locations of the samples and choosing the one that minimizes the variance of an estimator (Hu and Wang 2011).

Step 3 (I₂) Homework again. Make a statistical inference of the population using the sample collected. The variance of an estimate may be reduced by taking into account

Notations: \( n \) and \( N \) denote the sizes of a sample and a population, respectively; subscripts \( \text{pop} \) and \( \text{superpop} \) stand for population and superpopulation, respectively; subscript \( \text{rand} \) denotes random; \( w \) denotes weight, which is estimated by the minimization of variance of an estimation, subject to some restrictions; \( \lambda \) is Lagrange constant to be estimated; \( E \) and \( v \) denote mathematical expectation and variance, respectively; \( r \) is Pearson correlation; \( \sigma^2 \) is dispersion variance; \( C \) denotes covariance; s.t. stands for subject to.

Note. When populations are i.i.d., spatial autocorrelation in the kriging family is null, so block kriging reduces to a simple random mean.

spatial autocorrelation and spatial stratified heterogeneity.

Sampling an independent and identically distributed population

A target population is independent and identically distributed (i.i.d.) if there are no major determinants, or if there are too many determinants with none dominating across the target population. In this case, a random sampling or a systematic sampling (see Figure 1), followed by a simple average of the sample, is an appropriate estimate of the population mean (Cochran 1977), and no better estimates can be made. Interpolation is not applicable if the population is i.i.d. and there are no explanatory variables, because there is no relationship between any two sites.

Spatial sampling an autocorrelated population

Spatial autocorrelation can be tested by Moran’s I statistic (Moran 1950), which allows a single...
Spatial sampling a stratified heterogeneous population

A stratum is an area where the population is relatively homogeneous and so can be represented by a small sample (Li et al. 2008). The spatial stratified nonhomogeneity can be diagnosed by a geographical detector (Wang et al. 2010, 2016). If a population is spatially stratified heterogeneity, a stratified sampling should be used (Cochran 1977), while mapping can be done by sandwich interpolation (Wang et al. 2013a), which “borrows samples from the same class” and maps both the area values and their variances.

Spatial sampling a target with both autocorrelation and stratified nonhomogeneity

1 If a sample is large enough that each stratum has at least two sample units, then the MSN (mean of surface with nonhomogeneity) can provide a BLUE estimate of the population mean (Wang, Christakos, and Hu 2009) by a summation of weighted sample values. The weights are calibrated to minimize the variance of the MSN estimation, subject to the sample mean being unbiased to the population mean. For mapping, sandwich-kriging is used: first, by removing the stratified means from the sample data to obtain residuals; second, by applying the sandwich mapping to the stratified data, and apply the kriging mapping to the residual data, respectively; and finally, by combining the sandwich map and the kriging map and adding the variances of the two maps together. In this way, the map and the variance of a target are obtained with both autocorrelation and stratification.

2 If the sample size is small and biased, B-shade (biased sentinel hospital area disease estimation) (Wang et al. 2011) can remedy the bias to achieve a BLUE estimate of the population using secondary information. The method does not assume second-order stationarity as with kriging; instead the ratio between sample mean and population mean of the secondary variable is used to remedy the sample bias.

3 If only a single-point sample is available over the stratified population, its observations are obviously biased to that of the stratified population. SPA (single-point area estimation) (Wang et al. 2013b) can remedy the bias of the single-point sample for the entire area giving a BLUE result, if there is secondary information related to the primary variable and covering the area. In SPA, the value at a single point is weighted as a function of the correlation of the values of the primary variable between the single point and the population, with the correlation of the values between the stations virtually distributed over the study area as the second variable. The parameters related to the primary population are estimated by those of the secondary attribute. The estimation error caused by the approximation is largely absorbed by regression to empirical data.
Spatial sampling of a spatiotemporal, multivariate, or spatiotemporal multivariate population

A copula-based model offers a solution if a joint probability density function is available (Marchant et al. 2013). Another solution is to weight the multiple populations into a single population, although this approach suffers from subjective weighting. A third solution is to sample randomly or systematically in space, because any sampling that is optimized to one time or to one variable may conflict with another time or variable. In the inference stage, various inference methods can be implemented flexibly at each time and to each variable when sample data are available.

Spatial social networks

Ming-Hsiang Tsou
Jiue-An Yang
San Diego State University, USA

Spatial social networks, an emerging topic across geographical information science (GIScience), computational social science, and social network analysis, visualize social networks by using real-world or abstract map coordinates. From a geographer’s perspective, spatial social networks represent the linkages between people’s communications (such as e-mails, telephones, social network services) and real-world events (elections, protests, parties, music concerts). This entry gives a brief introduction to social networks and spatial social networks, and highlights the key characteristics of spatial social networks with a real-world scenario (the 2012 US presidential election) in the Twitter platform.

Social networks

We live in a connected world. People interact with each other via various types of social networks. A social network is a communication structure of social connections, personal relationships, or group interactions within a local or global community. It is an important interdisciplinary research domain in social science, communication theory, computer science, and mathematics (Wasserman 1994). The study of social networks can be traced back to the famous epidemiological study by Dr John Snow (1855), who used the locations of cholera death records to examine the spatial pattern of disease and its connection to contaminated water sources in London during the 1800s. The spatialization of social networks can provide valuable information and knowledge discovery for understanding human activities, disease outbreaks, and public opinions.

Traditional social network analysis is a popular method in epidemiology, sociology, psychology, and social work that is implemented using surveys and personal interviews. The recent development of the Internet and wireless communications (such as short message services (SMS) and social network services (SNS) in smartphones) links millions of networks and billions of people together. These services and communication tools provide basic infrastructure for computer–supported social networks (CSSNs) (Wellman et al. 1996). Scientists now can trace, monitor, and analyze the dynamic change of social networks and social communications related to protests, political campaigns, and public opinions via social media and weblogs (Lazer et al. 2009). These research efforts can help us understand the diffusion of innovations (Hägerstrand 1967) and facilitate the discovery of knowledge in cyberspace and social media (Tsou and Leitner 2013).

Social media services (such as Twitter and Facebook) are one type of powerful communication platform and CSSN for idea exchange, personal networking (Lerman and Ghosh 2010), political opinions (An et al. 2011), and collective actions (Earl 2010). By using social media services, people can communicate and coordinate their activities geospatially and, to a significant degree, accomplish these social communication functions in near–real time. The impacts of
SPATIAL SOCIAL NETWORKS

these tools were vividly demonstrated in recent antigovernment protests, including the Arab Spring, Occupy Wall Street, and the Umbrella Revolution in Hong Kong.

Spatial social networks

Spatial social networks transform social networks into visual maps and information landscapes using real-world coordinate systems (latitudes and longitudes) or abstract coordinate systems. After such transformations, geographers can conduct space–time analysis, understand the diffusion of information, and identify spatial cluster patterns of network hubs and elements. One early pioneer in studying spatial social networks was Dr Torsten Hägerstrand. In his famous book (his doctoral dissertation), Innovation Diffusion as a Spatial Process (1967), Hägerstrand used computational methods (Monte Carlo simulation) to simulate the diffusion of technologies across social networks with an empirical analysis of cattle tuberculosis controls (inoculations) by using farm soil mapping, population density, and other map layers in Sweden. Hägerstrand created several simulation models to illustrate which geographic factors (such as population density, locations, and road networks) are influential during the innovation diffusion process by using probability models and statistical methods.

The diffusion of innovations became an important theory and concept in many research disciplines, including business marketing, health promotion, geography, and communication. Along with the popularity of weblogs and social media services, researchers have begun to study the processes of meme diffusion over social networks. A meme is a cultural idea or concept that can be transferred, replicated, and modified (mutated) in a way that suggests genetic processes as they operate in biological evolution. There have been extensive studies on how information (memes) diffuses and spreads in a social communication network, such as the follower network in Twitter and the friendship network in Facebook. In early studies, researchers used and refined the disease-propagation susceptible, infected, and recovered (SIR) model in epidemiology (Bailey 1975) to simulate and understand the information spreading process. Many recent studies considered the spread of a meme through a social network as an innovation diffusion process, where two fundamental models, the linear threshold (LT) model (Granovetter 1987) and the independent cascade (IC) model (Goldenberg, Libai, and Muller 2001), are frequently used.

Using Twitter to analyze spatial social networks: a case study involving the 2012 US presidential election

Established in 2006, Twitter has become one of the most popular online social networking services. Twitter users can post and broadcast short messages (restricted to 140 characters) along with pictures, URLs, or video clips to their “followers.” These short messages are called “tweets,” which are searchable by keywords, authors, and hashtags. Many social media platforms (Twitter, Instagram, Facebook, YouTube, and Flickr) provide application programming interfaces (APIs) to enable automatic data fetching/downloading processes by using Python or other programming languages. Twitter is the most popular platform for studying social network analysis due to the large numbers of users and tweets, the openness of its APIs, and the rich metadata associated with tweets and user profiles.

Developers can define different types of criteria (keywords or predefined regions) via the APIs and conduct spatial searches in social media. The
two major APIs for Twitter data retrieval are the Search API and the Streaming API. Programmers can use the Twitter Search API to conduct a spatial search for specific keywords within a circle by defining the center of the circle (the latitude and longitude) and its radius (typically miles or kilometers). The Search APIs will retrieve those tweets that are posted from the search area from 6–9 days before. This retrospective search function is very useful for monitoring unexpected events, such as earthquakes. On the other hand, the Twitter Streaming APIs can provide a live stream of new tweets (no historical tweets) by defining keywords or a region (defined by a bounding box). When the bounding box is used with the Streaming APIs, search results will only include geotagged tweets. There is a significant limitation in the (free) Twitter Streaming APIs because users can only download up to 1% of total tweets within the selected regions.

There are three types of location information directly associated with social media messages: geotagged locations provided by GPS-enabled devices, self-reported locations specified in user profiles, and place names mentioned in tweets. Geotagged locations are latitude and longitude pairs created by mobile devices with built-in GPS receivers, place names (gazetteers), or by Internet Protocol (IP) geolocation features. The self-reported location is specified by social media users and it can be changed by users at any time. The self-reported location can be a city name, a state name, or any text string that may be unrelated to a typical place name. Based on some previous research findings, between 0.7 and 6% of tweets are geotagged depending on different topics (Tsou et al. 2013).

Downloaded social media data are usually in unstructured data format and stored in No-SQL databases, such as MongoDB. No-SQL databases have better performance and flexibility for storing social media messages compared to traditional relational databases. Many programming tools, such as Python, R, and JavaScript, have useful libraries to help us analyze the contents of social media or to create search tools. Figure 1 is an example of Twitter GeoSearch Tools developed by the Center for Human Dynamics in the Mobile Age (HDMA) at San Diego State University. Each social media message is collected with detailed attributes including a user ID, creation time, text content, media content, and spatial locations, which includes geotagged coordinates or self-reported locations. Since each city (circle) may have a different population, 2010 census tracts were used to calculate the estimated population for each circle (Figure 1, right). The total number of tweets

![Image](image.png)

**Figure 1** The Twitter GeoSearch Tool using Search APIs to collect tweets from multiple US cities.
Figure 2 Social network analysis example: comparing the Twitter followers of Mitt Romney and Barack Obama in Ohio (combining the cities of Cleveland and Columbus) during the 2012 US presidential election.

collected from each city is normalized by this estimated population to reflect the tweeting rates in each area.

Figure 2 illustrates a social network analysis conducted during the 2012 US presidential election using the Twitter GeoSearch and network graph tools. Tweets were searched for using candidates’ full names (“Barack OR Obama” and “Mitt OR Romney”) to capture results that mention the two candidates in full name or first/last name only. Their followers in the cities of Cleveland and Columbus were then analyzed. The right side of the figure illustrates the social network among these Twitter accounts and their following structure. Romney supporters and their following paths were symbolized using red lines and the Obama supporters with blue lines.

In the graphs, it was found that many Romney supporters in Ohio were also following Obama, but only one Obama supporter in Ohio was following Romney (Figure 2, left).

In addition to social networks composed of social media users and followers, the interactions between users can also form other types of networks. The first is formed by the use of mentions in tweets. Mentions (@) are mostly used in Twitter when an author wishes to direct a tweet message to specific users. Retweet activity also forms another type of social network. A retweet is an echo to a tweet posted by another user. The action of user X retweeting a tweet authored by user Y can be conceptualized as a signal being diffused from user Y (the tweeter) and received by user X (the retweeter). However, whether
the retweeter adopts the idea expressed by the tweeter is unclear and requires further study. A list of tweeter–retweeter pairs and a list of author–direct tweet receiver pairs were created to visualize a social network from tweet messages. Figure 3 shows a mention network for New Hampshire and Wisconsin. The network visualization shows that Twitter users in New Hampshire appear to have fewer common mentions that form a sparse mention graph with many small clusters. The Wisconsin mention network has several large clusters and this may suggest that some users in the state received high attention during conversations about the two candidates.

Figure 4 demonstrates the retweet network of New Hampshire, Wisconsin, and Ohio. The smaller number of total tweets from New Hampshire can be seen in the graph when compared to the graph of Wisconsin or Ohio. Wisconsin has relatively fewer clusters than New Hampshire, which can indicate that there are fewer opinion leaders in the network. Based on the retweet network, most Twitter users in New Hampshire tend to have preferred information sources that are highly connected with each other. Ohio has the most connected retweet network, which can result in faster information diffusion in the network when compared to the other two states.

Figure 5 shows another interesting finding from the 2012 US presidential election (Tsou et al. 2013). The tweets collected in the 30 largest US cities are represented using pie chart maps to compare changes in tweet attention levels.
Figure 5  The comparison of tweet attention levels between “Romney” and “Obama” (a) before (October 24, 2012) and (b) after (November 1, 2012) Hurricane Sandy. Red: “Romney” related tweets; blue: “Obama” related tweets. Source: Tsou et al. 2013, 345. Reprinted with permission of Taylor & Francis Ltd.
before and after Hurricane Sandy. Hurricane Sandy caused severe damage to many cities along the US East Coast in October 2012, a few days before the 2012 election. This disaster event created a significant change of tweet attention levels between the two candidates. The size of the circle indicates the total numbers of tweets standardized by city population, with larger circles representing more tweets in the city. Comparing Figure 5a and 5b, the circles of East Coast cities (Washington DC, New York, and Boston) increased significantly after Hurricane Sandy. The attention levels between “Obama” (blue color) and “Romney” (red color) also changed. In New York City, the tweet percentage of Romney decreased from 56% (October 24, 2012) to 34% (November 1, 2012). Overall, 9 of the 30 cities changed from a majority Romney tweeting percentage to a majority Obama tweeting percentage, and many others increased the Obama percentage compared to the Romney percentage (Tsou et al. 2013).

Future developments and research challenges of spatial social network analysis

By tracking and analyzing the contents of social media across different social network services, researchers can reveal important social processes related to specific events (such as presidential elections or protests) and gain insight into the temporal and spatial relationships among messages and human behaviors. The digitization of social networks will provide valuable big data resources for studying human dynamics and is facilitating the emergence of a data-driven computational social science (Lazer et al. 2009). In the domain of GIScience, knowledge obtained from spatial social network analytics can not only help geographers verify existing social behavioral theories but can also contribute to problem-solving across a range of areas. For example, searching social media at municipal or regional levels can help detect disease outbreaks (flu or whooping cough), track natural disaster impacts, or predict political election outcomes. Geographers now can build a new research framework using spatial social media and networks to study human geography topics, such as population, transportation, urbanization, and social theories.

Many research challenges remain in spatial social network analysis. First, social media data samples do not represent everyone in the population. Social media is generally associated with younger generations; older adults have much lower usage. The 2013 Pew Research Center Survey (www.pewinternet.org/) suggests that over 90% of young Internet users (age 18–29) use social networking sites. For example, older teens and young adults are the heaviest Twitter users: approximately 74% of Twitter users are in the age range of 15–25 years (www.beevolve.com). Second, the percentage of geotagged social media data is small when compared to non-geotagged data: only 1–4% of tweets have GPS coordinates. Although 80% of tweets have city-level location info (user profiles), current geographic information system (GIS) software cannot effectively use this type of spatial information. Many geographers only use geotagged data in their spatiotemporal analysis. Third, protecting user privacy and locational privacy in social media is very important, but comprehensive privacy protection measures are difficult to implement. The privacy concerns and spatial information disclosure risks in social media are significant and relevant to users and their social connections. The vulnerability of spatial information disclosure increases significantly when social media users have large social networks (Tsou and Leitner 2013). Finally, different social media platforms require different types of data,...
SPATIAL SOCIAL NETWORKS

analysis methods. For example, Twitter is more open and allows users to access most of the contents in Twitter. Facebook focuses more on personal social networks that provide stricter ways to access the content only when users are already in the network or make their network public. In general, Twitter is more suitable for real-time monitoring (e.g., wildfires) while Facebook can be a great source for studying personal social networks.

Spatial tessellations

Atsuyuki Okabe
Aoyama Gakuin University, Japan
University of Tokyo, Japan

Given a space (e.g., an area on a plane), a spatial tessellation is defined as a set of subspaces (subareas) that are collectively exhaustive for the space (area) and mutually exclusive except for boundaries. In the real world, many kinds of spatial tessellations are observed, such as administrative districts of a country, postal zones covering a country, public school districts in a region, and so forth. To study geometrical characteristics of these real spatial tessellations, various conceptual spatial tessellations have been proposed in the related literature; in particular, geography, geology, ecology, meteorology, and geographic information science. Among these, two of the most frequently used spatial tessellations are Voronoi diagrams and Delaunay triangulations. In this entry, these two types of spatial tessellation are described in depth, together with some of the other types of spatial tessellation.

Ordinary Voronoi diagrams

Voronoi diagrams are named after a Ukrainian mathematician, Georgy Fedoseevich Voronoy (Georges Voronoï) (1868–1908), who specialized in number theory involving quadratic forms and tessellations. The same concept was developed by several other scholars almost at the same time; for example, a German mathematician, Peter Gustav Lejeune Dirichlet (1805–1859), who contributed to number theory as well as Fourier series, and an American meteorologist, Alfred H. Thiessen (1872–1956), who used a Voronoi diagram to compute accurate estimates of regional rainfall averages (Thiessen 1911). Voronoi diagrams are sometimes called Delichlet domains (Delaunay 1929a, 1929b) or Thiessen polygons (Whitney 1929). The history of the concept of Voronoi diagrams and its developers is described in detail in Okabe et al. (2000, Section 1.2).

To provide an intuitive definition of a Voronoi diagram, consider a set of cell phone antennas in a region, and assume that a cell phone at a given location communicates through the nearest antenna. Then each antenna has its own communicative service area, and the set of the resulting service areas forms a spatial tessellation, called a Voronoi diagram. To depict this, suppose that a set of points is placed on the Euclidean plane (the black circles in Figure 1), and assume that the number of the points in the set is more than one but finite and that no points in the point set coincide. Given this set, every location in the plane is assigned to the closest member (i.e., point) in the point set with respect to the Euclidean distances. If a location happens to be equally close to two or more members (points) in the point set (points on the line segments in Figure 1), the location is assigned to those members (points). As a result, the set of locations assigned to every member (point) in the point set forms its own region, referred to as a Voronoi region (a polygon in Figure 1). Because every location is assigned to at least one member (point) in the point set, the resulting Voronoi regions are collectively exhaustive in the plane. Furthermore, because two adjacent Voronoi regions overlap only on
their boundaries, the Voronoi regions in a set are mutually exclusive except for boundaries. The set of Voronoi regions associated with points in the point set is termed the Voronoi diagram generated by the point set (Voronoi, 1908).

To formalize this verbal definition mathematically, let \( P = \{ p_1, \ldots, p_n \} \) be a set of points on the 2-D Euclidean space \( \mathbb{R}^2 \), where \( p_i \neq p_j \) for \( i \neq j \). A point \( p_i \) is referred to as a generator (point), and \( P = \{ p_1, \ldots, p_n \} \) is referred to as a generator (point) set. Let \( d(p, p_i) \) be the Euclidean distance between an arbitrary point \( p \) and a generator point \( p_i \) on \( \mathbb{R}^2 \), and let \( V(p_i) \) be a set of points defined by equation 1

\[
V(p_i) = \{ p | d(p, p_i) \leq d(p, p_j), \quad j \neq i, \quad j = 1, \ldots, n \} \tag{1}
\]

and \( V(P) = \{ V(p_1), \ldots, V(p_n) \} \). The set \( V(p_i) \) is termed the Voronoi polygon associated with (or of) \( p_i \), and \( V(P) \) is termed the Voronoi diagram, or more specifically, the ordinary planar Voronoi diagram, generated by \( P \). This diagram is easily extended to an ordinary \( m \)-dimensional Voronoi diagram by replacing \( \mathbb{R}^2 \) with the \( m \)-dimensional Euclidean space \( \mathbb{R}^m \).

The ordinary Voronoi diagram is generalized with respect to a distance, a generator set, and a space (note that the ordinary Voronoi diagram is defined with Euclidean distance, a set of points, and Euclidean space). This implies that the possible number of generalizations is [the number of different kinds of distances] \( \times \) [that of generator sets] \( \times \) [that of spaces], which amounts to a great number (a variety of generalizations is introduced in Okabe et al. (2000)). To avoid too many generalizations, it is first supposed that a generator set and a space are fixed as a set of points and Euclidean space, respectively.

**Weighted Voronoi diagrams**

Consider a distance, \( d_{MW}(p, p_i) = \alpha_i d(p, p_i) \), where \( d(p, p_i) \) is the Euclidean distance between an arbitrary point \( p \) and a generator point \( p_i \) (\( \alpha_i > 0 \)), which is referred to as a multiplicatively weighed distance. Let \( V_{MW}(p_i) \) be a set of points defined by equation 2.

\[
V_{MW}(p_i) = \{ p | \alpha_i d(p, p_i) \leq \alpha_j d(p, p_j), \quad j \neq i, \quad j = 1, \ldots, n \} \tag{2}
\]

The resulting set \( V_{MW}(P) = \{ V_{MW}(p_1), \ldots, V_{MW}(p_n) \} \) is termed a multiplicatively weighted Voronoi diagram (Aurenhammer and Edelsbrunner, 1984). An example is shown in Figure 2.

Next, consider a distance, \( d_{AW}(p, p_i) = d(p, p_i) + \beta_i \), which is referred to as an additively weighed distance. Let \( V_{AW}(P) = \{ V_{AW}(p_1), \ldots, V_{AW}(p_n) \} \), where \( V_{AW}(p_i) \) is given by equation 3.

\[
V_{AW}(p_i) = \{ p | d(p, p_i) + \beta_i \leq d(p, p_j) + \beta_j, \quad j \neq i, \quad j = 1, \ldots, n \} \tag{3}
\]
The resulting diagram $V_{AW}(P)$ is termed an additively weighted Voronoi diagram (Aurenhammer 1988). Figure 3 depicts an example. An extension along this line entails a mixed distance, $d_{CW}(p, p_i) = \alpha_i d(p, p_i) + \beta_i$, called a compoundly weighted distance. The resulting Voronoi diagram is referred to as a compoundly weighted Voronoi diagram. A diagram closely related to an additively weighted Voronoi diagram is an (additively weighted) power diagram $V_{PW}(P)$ = \{ $V_{PW}(p_1)$, ..., $V_{PW}(p_n)$ \}, where $V_{PW}(p_i)$ is given by equation 4.

$$V_{AW}(p_i) = \left\{ p | d(p, p_i)^2 + \beta_i \leq d(p, p_j)^2 + \beta_j, \quad j \neq i, \quad j = 1, \ldots, n \right\} \quad (4)$$

$k$-th nearest-point Voronoi diagrams

In the ordinary Voronoi diagram, points are assigned to their “first nearest” generator points. In turn, the first nearest may be extended to the “second nearest”, “third nearest”, ..., and “$k$-th nearest”. Let $V_K(p_i)$ be the set of points $p$ whose $k$-th nearest generator point among $n$ generator points $P = \{ p_1, \ldots, p_n \}$ is $p_i$. The resulting set $V_K(P) = \{ V_K(p_1), \ldots, V_K(p_n) \}$ is termed the $k$-th nearest-point Voronoi diagram generated by $P$ (Dehne 1982). A second nearest-point Voronoi diagram is depicted in Figure 4. By definition, the first nearest-point Voronoi diagram is the ordinary Voronoi diagram.

A specific case of the $k$-th nearest-point Voronoi diagram is $k = n$, which is alternatively called the farthest-point Voronoi diagram generated by $P$, $V_F(P) = \{ V_F(p_1), \ldots, V_F(p_n) \}$, where $V_F(p_i)$ is given by equation 5.

$$V_F(p_i) = \left\{ p | d(p, p_i) \geq d(p, p_j), \quad j \neq i, \quad j = 1, \ldots, n \right\} \quad (5)$$

An example is shown in Figure 5.
Figure 4  A second nearest-point Voronoi diagram (note that the configuration of the generator points is the same as that of the ordinary Voronoi diagram in Figure 1; the color of each generator point corresponds to that of its second nearest-point Voronoi polygon) (provided by W. Morioka).

Voronoi diagrams for lines

In the above Voronoi diagrams, a generator set is a set of points. A generator set can be extended to a set of line segments, \( L = \{L_1, \ldots, L_n\} \), which may be straight line segments, curved line segments (including circles), or chains of connected line segments. To define Voronoi diagrams for such lines, let \( d_L(p, L_i) \) be the minimum distance between a point \( p \) on a plane \( \mathbb{R}^2 \) and a point on \( L_i \), and let \( V_L(P) = \{V_L(L_1), \ldots, V_L(L_n)\} \), where \( V_L(L_i) \) is given by equation 6.

\[
V_L(p_i) = \{p \mid d(p, L_i) \leq d(p, L_j), \quad j \neq i, \quad j = 1, \ldots, n\} \tag{6}
\]

The resulting diagram is called the line Voronoi diagram generated by \( L \) (Drysdale and Lee 1978). An example is depicted in Figure 6.

Figure 5  A farthest-point Voronoi diagram (note that the configuration of the generator points is the same as that of the ordinary Voronoi diagram in Figure 1; the color of each generator point corresponds to that of its farthest-point Voronoi polygon) (provided by W. Morioka).

Voronoi diagrams for areas

Noting that a closed chain forms an area, a generator set of lines may be extended to a set of areas. To be explicit, let \( A \) be a set of areas, \( A = \{A_1, \ldots, A_n\} \); let \( d_A(p, A_i) \) be the minimum distance between a point \( p \) on a plane \( \mathbb{R}^2 \) and a point on \( A_i \); and let \( V_A(A) = \{V_A(A_1), \ldots, V_A(A_n)\} \), where \( V_A(A_i) \) is given by equation 7.

\[
V_A(A_i) = \{p \mid d(p, A_i) \leq d(p, A_j), \quad j \neq i, \quad j = 1, \ldots, n\} \tag{7}
\]

The resulting diagram is called the area Voronoi diagram generated by \( A \) (Roos, 1989). Figure 7 illustrates an example of an area Voronoi diagram. Rappaport (1992) discusses in depth a special case in which an area is given by a disk.
So far, distances for defining Voronoi diagrams have been Euclidean distances or those defined in terms of Euclidean distances. Voronoi diagrams may also be defined with distances other than Euclidean distances. An extension of the Euclidean distance is given by:

\[
d_{L^p}(p, p_i) = \left[ \sum_{j=1}^{m} |x_j - x_{ij}|^p \right]^{\frac{1}{p}}
\]

where \((x_1, \ldots, x_m)\) and \((x_{i1}, \ldots, x_{im})\) are the Cartesian coordinates of points \(p\) and \(p_i\), respectively. The distance \(d_{L^2}(p, p_i)\) is termed the Minkowski distance. In a specific case where \(p = 2\), the distance is the Euclidean distance. When \(p = 1\) and \(m = 2\), the distance is written as \(d_{L^1}(p, p_i) = |x_1 - x_{i1}| + |x_2 - x_{i2}|\), called the Manhattan distance. The diagram \(V_{L^1}(P) = \{ V_{L^1}(p_1), \ldots, V_{L^1}(p_n) \}\), where \(V_{L^1}(p_i)\) is given by equation 8,

\[
V_{L^1}(p_i) = \{ p \left| |x_1 - x_{i1}| + |x_2 - x_{i2}| \leq |x_1 - x_{j1}| + |x_2 - x_{j2}|, \ j \neq i, \ j = 1, \ldots, n \} \quad (8)
\]

is termed the Manhattan Voronoi diagram generated by \(P\) (Carter, Chaiken, and Ignall 1972). An example is shown in Figure 8.

Besides the Minkowski distance, Voronoi diagrams can be defined in terms of many other distances. Examples are Voronoi diagrams defined with convex distance, elliptic distance, Karlsruhe distance, Hausdorff distance, boat-in-a-river distance, and so forth. For details, see Okabe et al. (2000, Section 3.7).

### Voronoi diagrams on spaces other than Euclidean space

The Voronoi diagrams above all assume Euclidean space, but they may be defined in other spaces. First, for instance, consider a network space, \(N\), such as a street network, on which points \(p_1, \ldots, p_n\) are placed, and let \(d_S(p, p_i)\) be the shortest-path distance between an arbitrary point \(p\) and a generator point \(p_i\) on \(N\).
Then the set \( V_N(P) = \{ V_N(p_1), \ldots, V_N(p_n) \} \), where \( V_N(p_i) \) is given by equation 9,

\[
V_N(p_i) = \{ p | d_S(p, p_j) \leq d_S(p, p_i), \quad j \neq i, \quad j = 1, \ldots, n \} \quad (9)
\]

forms a tessellation of \( N \), which is termed the (ordinary) network Voronoi diagram generated by \( P = \{ p_1, \ldots, p_n \} \) (Okabe and Kitamura 1996). An example is shown in Figure 9. This diagram can be extended to the weighted Voronoi diagram, the \( k \)-th nearest-point Voronoi diagram and the line Voronoi diagram defined on a network as the extensions of those defined earlier on a plane (for details, see Okabe and Sugihara (2012, Chapter 4)).

Other spaces that are fairly tractable for constructing Voronoi diagrams are cylinder surfaces, cone surfaces, and polyhedral surfaces, because those surfaces in \( \mathbb{R}^3 \) are developed into rectangles (e.g., the left-hand side figure in Figure 10), fan-shaped regions, and polygonal regions in \( \mathbb{R}^2 \), respectively (for details, see Okabe et al. (2000, Sections 3.7.7–3.7.9)). An example of a cylindrical Voronoi diagram is shown in Figure 10.

Spherical surfaces are often used for analyzing global phenomena, but the above development approach is not applicable because a sphere surface in \( \mathbb{R}^3 \) cannot be developed into \( \mathbb{R}^2 \). To define a Voronoi diagram on a sphere surface \( S \), consider a sphere with the unit radius centered at the origin and where generator points \( p_1, \ldots, p_n \) are placed on \( S \). In this case, the distance between points \( p = (x_1, x_2) \) and \( p_i = (x_{i1}, x_{i2}) \) on \( S \) is measured by the great circle distance \( d_{GC}(p, p_i) \); that is, the length of the lesser arc on the great circle (i.e., the circle centered at the center of \( S \)). Mathematically, the set \( V_{GC}(P) = \{ V_{GC}(p_1), \ldots, V_{GC}(p_n) \} \), where \( V_{GC}(p_i) \) is given by equation 10,

\[
V_{GC}(p_i) = \{ p | \arccos(x_{i1}x_{j1} + x_{i2}x_{j2}) \leq \arccos(x_{i1}x_{j1} + x_{i2}x_{j2}) \leq \pi, \quad j \neq i, \quad j = 1, \ldots, n \} \quad (10)
\]
forms a tessellation of $S$. The resulting tessellation is referred to as the spherical Voronoi diagram generated by $P$. An example is shown in Figure 11.

**Delaunay triangulations**

A tessellation closely related to the Voronoi diagram is the so-called Delaunay triangulation.

The triangulation is named after Boris Delaunay (1890–1980), a Russian mathematician. For a given ordinary Voronoi diagram where the number of generator points is three or more that are not on the same line, join all pairs of generator points whose Voronoi polygons share the common Voronoi edge by line segments. The resulting line segments form a tessellation, called a Delaunay triangulation. The Delaunay triangulation obtained from the Voronoi diagram in Figure 1 is illustrated in Figure 12. To state this definition mathematically, let $V(P) = \{ V(p_1), \ldots, V(p_n) \}$ be an ordinary Voronoi diagram generated by $P = \{ p_1, \ldots, p_n \}$, $3 \leq n < \infty$ such that the points in $P$ are not on the same line; let $q_1, \ldots, q_{n_v}$ be the set of Voronoi vertices of the Voronoi polygons in $V(P)$; and let $(x_{ij1}, x_{ij2})$, $j = 1, \ldots, k_i$ be the coordinates of the generator points whose Voronoi polygons share a vertex $q_i$, ($k_i$ is the number of such generator points). Let $D(q_i)$ be the set of points $(x_1, x_2)$ satisfying equation 11.
Spatial Tessellations

\[ D(q_i) = \left\{ (x_1, x_2) \mid (x_1, x_2) = \sum_{j=1}^{k_i} \lambda_j (x_{ij1}, x_{ij2}), \right\} \]

where \( \sum_{j=1}^{k_i} \lambda_j = 1, \lambda_j \geq 0, j = 1, \ldots, k_i \) (11)

and \( D(P) = \{ D(q_1), \ldots, D(q_{n_P}) \} \). The resulting set of triangles is termed the Delaunay triangulation spanning \( P \), which is a tessellation of the convex hull of \( P \) (i.e., the minimum polygon including all points in \( P \)) (Delaunay 1934). The Delaunay triangulation in \( \mathbb{R}^2 \) can be extended to that in a higher dimension \( \mathbb{R}^m \), \( m \geq 3 \), which is referred to as a Delaunay tetrahedrization in \( \mathbb{R}^3 \) and a Delaunay tessellation in \( \mathbb{R}^m \), \( m \geq 4 \).

Random line mosaics

In ecology, the Voronoi diagram generated by random generator points (the Poisson Voronoi diagram) is sometimes referred to as the random-sets mosaic (or just \( S \)-mosaic) (Pielou 1977). Contrasted to this mosaic is the so-called random-line mosaic. To be explicit, a line \( l \) on a plane \( \mathbb{R}^2 \) is written as \( x_1 \cos \theta + x_2 \sin \theta = h \), where \( (x_1, x_2) \) are the Cartesian coordinates, \( h \) is the length from the origin to the foot of the perpendicular line to \( l \), and \( \theta \) is the angle between the \( x_1 \) axis and the perpendicular line in counterclockwise. A random line in the circle with radius \( R \) centered at the origin is obtained from generating a random point \( (\theta, h) \) in the region \( 0 \leq \theta \leq 2\pi \) and \( 0 \leq h \leq R \). A set of independent random lines forms a tessellation, termed the random-line mosaic (or just \( L \)-mosaic). An example of a random-line mosaic is shown in Figure 13. The statistical properties of the \( L \)-mosaic and those of the \( S \)-mosaic are discussed in Pielou (1977, Chapter 12) and in Okabe et al. (2000, Chapter 5), respectively.

Tilings

A tiling, \( T = \{ T_1, \ldots, T_{n_T} \} \), is a tessellation where the number \( n_T \) is usually countable infinite. The origin of tilings is very old and dates back to at least Roman times. In statistical contexts, random tessellations, such as Poisson Voronoi diagrams and \( L \) mosaics, are basic tessellations. In contrast, a major concern of tilings is “regular” tessellations. When all the tiles \( T_i \) in \( T \) are the same size and shape, the tiling \( T \) is termed a monohedral tiling. In a specific case where \( T_i \) is a regular polygon, the monohedral tiling \( T \) is referred to as a regular tiling. There exist only three kinds of regular tilings: regular triangle tilings, square tilings, and regular hexagon tilings. These kinds of tilings are obtained from Voronoi diagrams where the generator points
are placed on regular hexagon lattices, square lattices and regular triangle lattices, respectively. When the tiles in $T$ consist of two types of tile, $T$ is called a dihedral tiling (Figure 14). In a similar manner, trihedral, quadhedral, ..., $n$-hedral tilings can be defined. In addition to these tilings, many other kinds of tilings have been proposed. For details, see Grünbaum and Shephard (1987).

### Computational methods for constructing tessellations

Because constructing tessellations usually requires heavy computation, efficient computational methods are important. Two major methods for efficiently constructing the ordinary planar Voronoi diagram are the incremental method and the divide-and-conquer method. In the former, given $n$ generator points, Step 1 is to construct the Voronoi diagram for two generator points. Step 2 is to construct the Voronoi diagram for three generator points using the Voronoi diagram resulting from Step 1. Step 3 is ... Step $n-1$ is to construct the Voronoi diagram for $n$ generator points using the Voronoi diagram for $n-1$ generator points resulting from Step $n-1$. Figure 15 illustrates that when using the Voronoi diagram for six generator points, the Voronoi diagram for seven generator points is constructed as in Figure 1.

In the divide-and-conquer method, $n$ generator points are indexed as $P = (p_1, \ldots, p_n)$ according to the increasing order of the $x$ coordinates.

#### Algorithm: divide-and-conquer (D&C) method (Okabe et al. 2000)

Step 1. If $n \leq 3$, construct the Voronoi diagram directly and go to Step 3.

Step 2. Otherwise, do the following.

2.1 Let $t$ be the integer part of $n/2$, and divide $P = (p_1, \ldots, p_n)$ into $P_L = (p_1, \ldots, p_t)$ and $P_R = (p_{t+1}, \ldots, p_n)$. 

Figure 14: A dihedral tiling (provided by W. Morioka).

Figure 15: The incremental method for constructing the Voronoi diagram for seven generator points (Figure 1) using the Voronoi diagram for six generator points (provided by W. Morioka).
2.2 Construct the Voronoi diagram $V_L$ for $P_L = (p_1, \ldots, p_t)$ by Algorithm D&C.

2.3 Construct the Voronoi diagram $V_R$ for $P_R = (p_{t+1}, \ldots, p_n)$ by Algorithm D&C.

2.4 Merge $V_L$ and $V_R$ into the Voronoi diagram $V$ for $P = (p_1, \ldots, p_n)$.

Figure 16 illustrates the final step where $V_L$ and $V_R$ are to be merged into $V$ shown in Figure 1. Concerning the implementation of the above two computational methods and that of other types of Voronoi diagram, see Okabe et al. (2000, Chapter 4), Okabe and Sugihara (2012) (Voronoi diagrams along networks), and Aurenhammer, Klein, and Lee (2013). Computation of the Delaunay triangulation may be achieved through the corresponding Voronoi diagram by joining generator points whose Voronoi polygons share the common Voronoi edge or through a “swapping procedure” (Okabe et al. 2000, Section 2.4; Aurenhammer, Klein, and Lee 2013). The $L$-mosaic consisting of $n$ lines on a disk centered at the origin with radius $R$ is computed by generating $n$ points $(\theta_i, h_i)$ independently according to the uniform distribution on the rectangle $0 \leq \theta_i \leq 2\pi$ and $0 \leq h_i \leq R$, $i = 1, \ldots, n$. Preparata and Shamos (1985) show basic computational techniques used in the above computations.

Further reading

Spatial thinking is fundamental to learning geography at all educational levels and it underpins the practice of geography in many problem contexts, from applied to academic. Its value is not unique to geography, playing comparably significant roles in the learning and problem-solving practices of disciplines ranging from the sciences (e.g., astronomy, geology, and physics) to applied domains (e.g., architecture, design, and engineering).

Spatial thinking underpins many activities in the contemporary workplace, ranging from the decision-making by taxi cab dispatchers and air traffic controllers to the use of geographic information system (GIS) software in infrastructure management and urban planning. Spatial thinking also plays a significant role in everyday life, in situations such as a child being taught how to tie a shoelace, a parent following the text and graphic instructions for assembling a child’s bicycle, and parent and child together finding their way to a new friend’s house in the neighborhood.

Spatial thinking is a distinctive, universal, and powerful form of thinking on a par with, although perhaps not yet as well recognized and formalized as, mathematical or verbal thinking (Committee on Support for Thinking Spatially 2006). Although everyone can and does think spatially, there are significant individual differences in capacities and performances in relation to age, gender, training, experience, and context. Spatial thinking can be learned and should be taught at all levels in the formal education system because life in our spatial world is inconceivable without the aid of spatial thinking.

Spatial thinking defined and exemplified

The process of spatial thinking links particular forms of knowledge with cognitive operations that can manipulate this knowledge. It is a constructive amalgam of three things: an understanding of concepts of space, an understanding of the forms and uses of tools of representation, and the use of processes of reasoning (Committee on Support for Thinking Spatially 2006). Taken separately, the concepts of space, representation, and reasoning have long intellectual histories beyond the discipline of geography or any other single discipline. As in chemistry, however, an amalgam is a distinct entity resulting from the synergistic combination of elements.

The idea of spatial thinking as an amalgam is exemplified by one of the well-known classics of epidemiology and geography: Dr John Snow’s discovery in 1848 of the water-borne cause of the diffusion of cholera. Snow studied cholera at two spatial scales: in a neighborhood and city-wide. By mapping the incidence of cholera deaths in a small area of London, Snow saw a possible connection between the spatial pattern of deaths and the location of a particular water pump at the corner of Broad Street. This recognition led to a decision to remove the pump handle and to the subsequent decline in the incidence of cholera in the area around the now handleless water pump. In a second
city-wide analysis, Snow mapped the relation between spatial patterns of cholera deaths and water distribution. There were two companies providing water to London; one company drew its water from relatively uncontaminated inland subsurface wells and the other piped water directly from the heavily polluted and contaminated River Thames. Snow demonstrated the significant difference in the incidence of cholera deaths between areas served by these two water sources. Thus, Snow first connected cholera with water and then with polluted water.

Snow’s work exemplifies the synergies involved in spatial thinking, its role in seeing, believing, understanding, and communicating. By representing multiple datasets in map form, Snow reasoned from the spatial co-occurrence of two phenomena (water sources and cholera deaths) to the likelihood of a correlation between the two phenomena, and subsequently to an argument for a possible direction of a causal relation. Space, representation, and reasoning are inseparably integrated in spatial thinking.

Thinking in general

All three elements are critical for an understanding of spatial thinking. The concepts of space and representation traditionally have been central to the teaching and practice of geography. Although equally fundamental to the practice of geography, the process of reasoning has been relatively less well-articulated (Ishikawa 2013).

As is clear from the name of the concept, understanding space is fundamental to spatial thinking. Space provides the essential conceptual and analytic frameworks within which data about the properties of phenomena can be structured and related. The frameworks allow geographers to employ spatial concepts such as location, density, distribution, pattern, symmetry, isomorphism, continuity, orientation, reflection, rotation, translation, distance, scale, dimensionality, and autocorrelation to define the properties of phenomena and the relations between phenomena.

The key to the process of spatial thinking is spatialization, using the properties of space to represent data about the properties of phenomena that are spatial and, importantly, also those that are not inherently spatial in and of themselves. Phenomena that are nonspatial in nature can be assigned spatial locations based on their properties and the phenomena plotted or mapped in various spatial configurations. Degrees of proximity in the resulting space reflect the degrees of similarity between the phenomena. Patterns in the space reflect structural relations among the phenomena. The patterns can be described as random, as systematic (e.g., linear, grid-like, hierarchical), and as clustered. Pattern descriptions in turn can lead to inferences about the underlying processes generating the patterns (e.g., distance-decay effects, random walks, contagious versus hierarchical diffusion, autocorrelation, increasing or decreasing entropy, achieving stable equilibrium, etc.).

The representations resulting from the spatialization of data can be either internal and cognitive or external and physical in character, and they can be expressed in linguistic, mathematical, graphical, or concrete forms. These forms allow the spatialized data about phenomena to be stored and analyzed. Representations allow us to describe, explain, and communicate about the structure, operation, and function of the phenomena and their relations.

Reasoning processes provide the means by which the spatialized data can be manipulated, interpreted, and explained. The processes can involve making inferences on the basis of if-then analyses (hypothetical or counterfactual),
interpolation, extrapolation, analogies, and up- or down-scaling. Alternatively, by making assumptions about phenomena, relations, and processes, the operation and functioning of phenomena can be deduced.

Spatial thinking in geography

The general concepts of spatial thinking are tailored to the specific phenomena of study in a particular domain of knowledge. In the case of geography, spatial thinking is shaped by a focus on spatial patterns and processes on Earth’s surface, by a sensitivity to scalar relationships, and by an appreciation of contextual relations among people, places, and environments.

For geography, the space is that of Earth’s surface and areas immediately above and below that surface. The physical space of Earth is typically thought of in terms of dimensionality (two or three dimensions); as being described by geometrical primitives such as points, lines, areas, and volumes; as continuous or discontinuous; as bounded or infinite; as homo- or heterogeneous; as being viewed at scales ranging from local to the global, with discrete scalar steps (micro, meso, and macro) or continuous scale changes (zooming in or out); as being scaled by measures such as metric units (kilometers, hectares, etc.) or standard units (miles, acres, etc.); and as being indexed by coordinate systems (e.g., latitude and longitude).

Geographers study the links among people, places, and environments, and therefore they think of spaces beyond the physical space of Earth: there are social spaces (e.g., urban neighborhoods), economic spaces (e.g., the North American Free Trade Area (NAFTA)), political spaces (e.g., the European Union), emotional spaces (e.g., home and the area in which one grows up), and intellectual spaces (e.g., the English-speaking world). In all spaces, geographers identify places, discrete points and areas that can be characterized in multiple ways: as towns, forests, counties, and so on. Spaces are nested in scale; political spaces can range in scale from wards to counties to states to countries to global organizations such as the United Nations. Spaces are interdependent; for example, countries are defined by interlocking relationships among political, economic, social, and emotional spaces. Places take on characteristics of the spaces in which they exist; a town has a political status, a local economy, demographic characteristics, and an identity in the minds of its residents.

Representations of Earth space have been dominated by the visual sense through the medium of hard-copy cartographic maps, remotely sensed images, photographs, diagrams, and graphs, although electronic representations have become increasingly important if not yet dominant. Representations can appear in multiple ways: as small multiples, in static or dynamic forms, in stereo form, in black-and-white or color, and organized into atlases. The range of forms of representation has broadened significantly with the development of the field of geovisualization. One of the advantages of onscreen visualizations is the capacity for users to manipulate the properties and appearance of images online in real time.

Reasoning processes applied to Earth space can be deductive or inductive; they can involve interpolation or extrapolation; they can be based on statistical description or inference; and they can lead to descriptive or normative statements. These lists are by no means exhaustive but they illustrate the ways in which spatial thinking underpins and pervades the thinking processes of geographers.

However, even this description of the three concepts taken separately is insufficient to characterize the idea of spatial thinking in geography
in practice. Thinking is a complex, multi-stage process. Spatial thinking in geography involves understanding when, how, and why to transform a variable into, for example, a logarithmic form. It involves understanding the problems resulting from attempting to downscale the projections from a global climate model to a regional level. It involves knowing how to choose the appropriate map projection to express areal data versus travel distances on a world map. It involves using maps and graphs to plot the residuals from the statistical analysis of spatially distributed data. It involves understanding the effect of the modifiable areal unit problem (MAUP) on the aggregation of demographic data. Spatial thinking is inextricably interwoven into the intricacies of the everyday practice of thinking in geography. It is not a separate step to be applied. It is an integral part of doing geography.

The history of spatial thinking in geographical practice

Google’s Ngram Viewer graphs the frequency of use of words in an extensive corpus of digitized books. “Spatial thinking” has a very low frequency of use, reaching a high value of 0.000003215% in 2008 (the most recent data available). While the value was zero in 1944, there has been a significant increase in use since 2000. Despite this recent focus on spatial thinking, there is no reason to believe that it is a recent addition to the human cognitive repertoire. The “discovery” of spatial thinking is no more remarkable than the discovery made by Molière’s character Monsieur Jourdain, who remarked: “For more than forty years I have been speaking prose without knowing it.” On logical and evolutionary grounds, it is impossible to imagine humans functioning successfully without the capacity to think about the spaces they inhabit. Geography studies the interactions among the people, places, and environments that comprise Earth’s surface and thus of necessity it has always engaged in spatial thinking.

As a consequence, there is a long history of intellectual achievement in geography and the geological sciences based on spatial thinking: Eratosthenes’ remarkably accurate calculation of the circumference of Earth, William Playfair’s ingenious development of statistical graphic diagrams, Alfred Wegener’s provocative description of continental drift, Marie Tharp and Bruce Heezen’s meticulous mapping of the ocean floor that provided critical support for the idea of plate tectonics, Walter Christaller’s creative formulation of central place theory, the imaginative reconstruction by Henry Darby and colleagues of the geography of England based on entries about places in the Domesday book, and Richard Edes Harrison’s brilliant perspectival maps of Earth. To these outstanding achievements, one could add the current efforts to understand the past and, especially, the projected future impacts of climate change at spatial scales ranging from the global to the local and for timescales ranging from decades to centuries.

There have been equally significant practical cartographical achievements based on spatial thinking: John Speed’s seventeenth-century comprehensive set of maps of counties and plans of towns in England, the eighteenth-century Cassini family’s National Survey of France, the late eighteenth-century geological map of England and Wales produced by William Smith, and the nineteenth-century Survey of India’s Great Trigonometric Survey of the South Asian subcontinent.

The explorations of Earth’s surface are a testament to human resourcefulness and persistence and to the power of spatial thinking: the early nineteenth-century Corps of Discovery Expedition through the western United States
led by Meriwether Lewis and William Clark, the multiple expeditions to find the source of great rivers such as the Nile and the Amazon, the now-successful but earlier fruitless effort to find the Northwest Passage between the Atlantic and Pacific Oceans, and the remarkable tradition of South Pacific ocean sailing undertaken by the Puluwatan islanders in Micronesia (Gladwin 1970).

The history of spatial thinking in geographical theory

Within geography, although the term “spatial thinking” may have been either absent or rarely mentioned, there are many antecedents that relate directly to the current understanding of the concept. Intellectual autobiographies, such as The Geographer’s Art by Peter Haggett (1990), make clear the many roles that spatial thinking plays in the process of geographic discovery. Map reading and interpretation have long been valued and instructed skills in all branches of geography. Armin Lobeck’s (1956) Things Maps Don’t Tell Us exemplified the power of the informed geographic eye in going beyond the information given in simple maps and graphs. Fieldwork has always been central to geography, and geographers such as Charles Hunt and Peirce Lewis were incisive readers of the intricate relationships between pattern and process in physical and human landscapes, respectively. W.G.V. Balchin and Alice Coleman (1966) introduced the term “graphicacy” to complement the three skills of articulacy, literacy, and numeracy in specifying what should be taught in schools. To emphasize its importance, they referred to graphicacy as the fourth ace in the pack of fundamental skills. More recently, GIScience has become strongly linked to spatial thinking, with many of the geospatial tools providing support for the process of spatial thinking (Committee on Support for Thinking Spatially 2006).

The history of spatial thinking in psychological theory

In psychology, there are multiple concepts with similar etymological roots that overlap with spatial thinking: spatial ability, spatial skill, spatial intelligence, spatial literacy, spatial perception, and spatial cognition. Although the modifier “spatial” applies to these concepts, there is an important difference carried by the noun “thinking.”

Several of these overlapping concepts derive from the psychometric tradition which measures people’s traits or the ability to do various things: think, solve problems, understand others, perform various activities, and so on. The psychometric tradition has generated tests, especially of intelligence, and a long-standing debate as to whether intelligence is general or multifaceted. Both approaches to intelligence measurement include items based on an understanding of space. In the United States, the Scholastic Aptitude Test (SAT) and the Graduate Record Exam (GRE) contain items that involve an understanding of space. Gardner (1983) defined eight forms of intelligence of which one, visual-spatial, is clearly related to spatial thinking.

However, the psychometric approach to intelligence and concepts such as spatial ability and spatial skill are more restricted than spatial thinking. The noun, thinking, places a premium on the problem-solving process. Spatial thinking is less a property characterizing a person and more a characterization of the actions that a person performs in solving problems. It is the interaction among spatializing, representing, and reasoning that gives spatial thinking its power,
versatility, and applicability (Committee on Support for Thinking Spatially 2006).

**Approaches to spatial thinking in psychological research**

Within psychology, there are three approaches to spatial thinking. The first studies the nature, function, and operation of underlying cognitive processes. The second focuses on the development of spatial thinking over the life span. The third explores the nature, origins, and consequences of individual differences in spatial thinking. The differences among these approaches are ones of emphasis, not kind. Work on cognitive processes leads to questions about the origins of those skills and the extent to which they can be performed by all people of all ages. From the educational perspective, the approaches are valuable because they address the pedagogical question: What should be taught, why, when, and how?

A classic task in developmental psychology, the water-level task, illustrates the psychological approaches and the links to spatial thinking, especially from the perspective of geography. Developed by Jean Piaget and Barbel Inhelder (1967), the water-level task focuses on understanding the experiential links between a person and Earth space: the two universal invariant relations, horizontality and verticality, which result from gravitational forces.

In the task, people are presented with drawings of empty glasses tipped at various angles and asked to draw the level of the water if the glass were half full. The key is recognizing that the water level is invariant with respect to the horizontal, no matter at what angle the glass is tipped. The task is very challenging for young children, and children perform better with increasing age, although significant numbers of college students and adults do not understand the invariance. Results are similar if people are asked to select from drawings rather than drawing a line, suggesting that the mode of representation is not a major factor in understanding. Instructions about what happens to water in tilted glasses, physical demonstrations with water in glasses, and explicit instructions to remember key ideas all increase performance. Even with guidance, however, some people still do not demonstrate an understanding of invariant horizontality. Not only is there a significant age difference but there is also a sex difference, with men performing better, on average, than women (Liben 1991).

These results are typical outcomes from psychological research about spatial thinking. First, psychologists are ingenious in developing ecologically valid tests. For example, experiences with containers and liquids are part of everyday life. Second, hypothetical questions (“What would it look like if …?”) require reasoning about patterns, movements, and relations among objects in space. Third, understanding of space, representation, and reasoning increases with age in complex ways. An understanding of static relations, for example, develops earlier than an understanding of dynamics. Fourth, there are significant differences based on gender, experience, training, and context for many spatial reasoning challenges. Finally, space, representation, and reasoning are intellectually challenging concepts in science and everyday life. Escher’s and Penrose’s representations of impossible shapes and spatial relations are reminders that the eye and mind of a spatial thinker can be deceived, baffled, and amused simultaneously.

One of the key questions for teaching and learning spatial thinking is highlighted by attempts to explain the invariant horizontality of water. Statements about invariance and demonstrations of water’s invariance did improve the performance and, presumably, understanding.
of some people. In some instances, however, statements and demonstrations did not lead to improved performance. This raises the question of to what extent spatial thinking can be taught and to what extent teaching on a particular topic in one subject transfers to an understanding of similar topics in another subject.

Approaches to spatial thinking in education

As is sadly true for geography as a discipline, spatial thinking is not systematically taught in schools. The important qualifier is “systematically.” In school subjects such as mathematics, chemistry, earth science, and geography, spatial thinking is necessary and to some extent taught and practiced. However, its appearance in the curriculum is incidental to and contingent on other purposes. For example, in chemistry, understanding the implications of the periodic table of elements is in part an exercise in spatial thinking. Understanding conic sections in mathematics, understanding the relation between cross-sections and the processes of folding and faulting in earth science, and understanding the properties of different map projections in geography all require significant levels of spatial thinking. However, these exercises are neither sequenced in time nor coordinated across school subjects. Current instruction of spatial thinking is a hit-or-miss proposition.

At present, spatial thinking is not a stand-alone subject as is chemistry or mathematics; instead it permeates most if not all content-based disciplines. Therefore, spatial thinking does not have an obvious stand-alone presence in the curriculum. Although its role is minimal at present, spatial thinking could potentially be the functional equivalent of the concept of reading across the curriculum. Texts are introduced into as many school subjects as possible to foster an understanding of reading as an integral part of learning and thinking. In the United States, given the time constraints posed on the curriculum by the No Child Left Behind legislation (NCLB), finding room for spatial thinking in any subject will be a significant challenge, as will be the need for coordination across subjects. However, to the extent that mathematics and science are two key subjects of concern under NCLB, there is an opportunity to teach spatial thinking as part of mathematics and science instruction.

The explicit addition of spatial thinking was one of the major changes to the US National Geography Standards between the 1994 edition and the 2012 edition. As is the case with curricular statements for other school subjects, spatial thinking was implicit in many statements in the 1994 edition. In the 2012 edition (Heffron and Downs 2012), spatial thinking was explicitly and extensively used throughout many of the 18 content standards. Sinton et al. (2013) show how spatial thinking is aligned with seven of the content standards and suggest that it may underlie all 18 standards.

The goal of systematic instruction in spatial thinking is to foster a generation of students that is spatially literate. First, students must have the habit of mind to think spatially, knowing where, when, why, and how to do so. Second, they must practice spatial thinking in an informed manner. Being informed means having an across-the-board understanding of space, representations, and reasoning, and also a deep understanding of the integration of those concepts within one or more school subjects. Third, they can apply a critical stance to thinking spatially. This entails critical metacognitive awareness of the strengths and weaknesses of the approach and the ability to be articulate and convincing in using it (Committee on Support for Thinking Spatially 2006).
The future of spatial thinking in education

Spatial thinking is one of many interrelated forms of thinking: verbal, mathematical, metaphorical, statistical, and so on. Spatial thinking, for example, uses verbal, mathematical, and statistical approaches. In turn, mathematical thinking draws on notions of space and statistics, and can be represented verbally and graphically. Spatial thinking is important and distinctive but it is not unique. Human thought is multifaceted and flexible.

Spatial thinking is, however, likely to increase in practical importance. Given the increasing availability of “big datasets,” spatial thinking will be important in helping to make data relations visible, comprehensible, and communicable. Spatial thinking is inseparable from the pursuit of geographical understanding. Geography is changing as a function of new approaches, especially GIScience, and new technologies, especially GIS and geovisualization, and therefore spatial thinking is an essential skill to be fostered. Tools, especially geovisualization tools, will support spatial thinking. Those tools will be increasingly important in the workplace and in everyday life as geospatial technologies become commonplace in all forms of processing devices, from geovisualization in computers to global positioning systems (GPS) and GIS in smartphones (Downs 2014).

In the United States, the teaching of spatial thinking may become more significant at all educational levels but especially in the K–12 context. The first reason is concern about the inadequate performance of American students in the area of science, technology, engineering, and mathematics (STEM). In absolute terms, student performances are insufficient for meeting the workforce challenges of the twenty-first century, and in relative terms, the performance of US students lags significantly behind those of students in many other countries. Spatial thinking is an essential underpinning in STEM education (Newcombe 2013). The second reason is the increasing importance of critical thinking across the curriculum (Goodchild and Janelle 2010). The emphasis on critical thinking is based on the ability to reason well and the disposition to do so. Spatial thinking facilitates reasoning across the curriculum, and tools developed to support spatial thinking enable students to translate a disposition into action. The third reason is the increasing recognition of the importance of lifelong learning. Given the role of spatial thinking in STEM activities and the proliferation of rapidly evolving geospatial technologies in many careers, a baseline understanding of spatial thinking is critical for enabling people to engage in lifelong learning. In 2013, for the 25–29-year-old cohort, 90% had a high school diploma, 34% a bachelor’s degree or higher, and 7% a master’s degree or higher. Those numbers will increase and so too will the number of people already in the workforce who take online, distance education courses.

There are also reasons to believe that the teaching of spatial thinking must overcome constraints before it can become significant in education at all levels. First, there is a problem of transfer. This concerns the question of to what extent skills learned in one domain context transfer either to other parts of the same domain or to other domains. At present, there is insufficient evidence to be confident that transfer is possible to near (i.e., similar) contexts, or to far (i.e., different) contexts, and if transfer does occur, under what conditions. Second, there is a problem of developing a generation of trained teachers equipped with the materials and technologies with which to teach spatial thinking.

Within geography, there are signs that there is support for spatial thinking in multiple forms,
Spatial thinking is and has always been an integral and essential part of the fabric of geography. The same could be said for many other disciplines. At issue is the degree to which spatial thinking can be explicitly incorporated into the curricula for individual disciplines versus the extent to which it can play the equivalent role to that of reading as a skill that is essential across the curriculum. The discipline-based approach requires finding room for spatial thinking in each separate discipline, thus teaching it multiple times in an already crowded curriculum. Disciplines have some experience in teaching spatial thinking within a subject domain, but the question of transfer across disciplines remains unanswered. The across-the-curriculum teaching approach would be more efficient in terms of requirements for time, resources, and teacher training. It would be more likely to generate spatially literate generations of students. However, there are no models for a stand-alone spatial thinking curriculum and the transfer questions remain unanswered. Whatever the model adopted, spatial thinking will join the three Rs of the curriculum. That linkage, however, will depend upon research on the particular nature of spatial thinking processes in geography itself and on research on the process of near transfer within geography and far transfer to other subjects.

Spatial weights

Daniel A. Griffith
University of Texas at Dallas, USA

With the advent of spatial autocorrelation analysis in the late 1960s, quantitative spatial scientists began conceptualizing geographic relationships in a variety of ways, one of which is described by Tobler’s first law of geography: “Everything is related to everything else, but near things are more related than distant things.” This statement alludes to the 2-D, two-directional nature of geographic relationships arising from the relative location of things. In doing so, it requires a conceptualization that captures this complicated relational structure. In addition, the locations in question almost always are not systematically distributed across a geographic landscape, although by being evenly spaced remotely sensed images are an important exception. Accordingly, the conceptualization needs to accommodate irregular spacing of points, and varying sizes and shapes of polygons constituting areal units. The statistics literature offers guidance for formulating this type of conceptualization with its entries concerning the use of weight functions to quantify the differential importance of observations in a calculation, perhaps to align the relative frequencies of observation types between a sample and its parent population, or to adjust for non-constant variance associated with observations. These weights are observation specific, with the default case being all observations having the same weight value. In a geographic context, these weights are specific to individual pairs of locations and, as such, are spatial weights (SW) that quantify the relative possibility or strength of a relationship between two given locations. Classical analysis assumes that these weights are zero, implying that geographic locations are independent. Contemporary spatial analysis assumes that they are non-negative, employing model specifications in which locations are correlated. The fundamental idea here is that phenomena present at a given location are related to the same category of phenomena present at its nearby surrounding locations. This geographic relationship can arise from either direct interaction among (e.g., air pollution spilling over into nearby locations), or common factors underlying (e.g., climate, soil fertility), geographically distributed phenomena. SW provide one way to represent the geographic structure giving rise to such geographic relationships.

SW specifications vary according to how geographic relationships are conceptualized. Popular criteria used for this purpose include: contiguity (e.g., common boundaries of polygons, urban system central place linkages), continuous distance (e.g., inverse, power inverse, negative exponential), nearest neighbor distances (e.g., the six closest), fixed distance band (e.g., all locations within a given proximity range), and spatial interaction (e.g., the number of migrating households). Figure 1 illustrates each of these conceptualizations. Because relative location relationships cast a geographic landscape as a set of \( n \) interrelated locations, its set of SW is organized and operated with as an \( n \times n \) matrix, where the row and column labels identify the locations, with common practice being that both matrix axes use the same ordering of the locations. In other words, each location has one row and one column in this matrix. The diagonal
Figure 1  Conceptual bases for operationalizing SW. (a) Rook’s adjacency for a regular square tessellation (black pixels are neighbors to the gray pixel). (b) Black lines denote rook’s adjacency for an irregular surface partitioning (part of Florida). (c) Inverse distance proportional to line weights connecting county centroids (Chicago metropolitan statistical area). (d) Queen’s adjacency for a regular square tessellation (black pixels are neighbors to the gray pixel). (e) Additional zero-length boundary queen’s adjacency for an irregular surface partitioning (part of Florida) denoted by a gray line. (f) Journey-to-work flows proportional to line weights connecting county centroids (Chicago metropolitan statistical area).

entries of this matrix (i.e., the cell for which a location’s row and column intersect) are zero; everything perfectly correlates with itself, which is uninformative and has nothing special to do with location. The off-diagonal cells contain the SW for their corresponding row and column locations. Concatenating the values of some geographic distribution by location into an $n \times 1$ vector permits it to be premultiplied by a spatial weights matrix (SWM). This multiplication yields an $n \times 1$ vector of the sum of surrounding values. The zeros in the diagonal eliminate the values themselves from their corresponding sums (i.e., 0 times any number is 0). A scatterplot of these pairs of values and their surrounding value sums furnishes the information necessary to study a global relationship across, or local relationships within, a geographic landscape. The former is the trend line in the scatterplot; the latter are geographically clustered deviations from the trend line.

SW are used extensively in spatial autocorrelation calculations, spatial autoregressive model
specifications, geostatistical semivariogram construction and kriging, and Moran eigenvector spatial filter construction.

**Principal types of spatial weight**

In the tradition of time series analysis, the initial SW were binary 0–1 values based upon contiguity: if two polygons are contiguous, then they are considered neighbors and are related, and hence their SW is one; otherwise, their SW is zero. Exploiting analogies with rook and queen pieces moving across a chess board, this contiguity may be defined in two different ways. The rook’s definition assigns an SW the value of one if two polygons share a nonzero length (i.e., line) common boundary; otherwise, the SW is zero; the rook moves from square to square in a straight line either horizontally or vertically. Implicitly, this is the definition used in the original Moran Coefficient and Geary Ratio calculations. The queen’s definition assigns an SW the value of one if two polygons share either a nonzero or a zero-length (i.e., point) common boundary; the queen moves from square to square in a straight line either horizontally, vertically, or diagonally. This is the default option in GeoBUGS, the Bayesian mapping module in WinBUGS. In most irregular surface partitioning situations (e.g., counties forming a state), frequently the queen’s definition increases the number of connections by no more than roughly 10%; but for remotely sensed images and other regular square lattice partitioning, this increase can approach 100%. The associated scatterplots describe values at locations as being a function of the sum of values at surrounding locations. Many researchers find this relational description unappealing, preferring to describe values at locations as being a function of the arithmetic average of surrounding values. To achieve this result, the SWM is row standardized: each one in a row is divided by its corresponding row sum. This is the most popular specification for spatial autoregressive models. However, GeoBUGS employs the 0–1 binary version for its autoregressive model specification. The 0–1 and row-standardized versions are limiting cases for a family of possible SW. If $n_i$ denotes the sum of the ones in row $i$ of an SWM, then the family members are given by $n_i^c$, $0 \leq c \leq 1$. If $c = 0$, then the SWM is based upon binary 0–1 values, commonly being denoted by $C$. If $c = 1$, then the SWM is row standardized, commonly being denoted by $W$. The exponent $c$ can be some intermediate value, tending to optimally control for topology induced heterogeneity at 0.5, and as such is referred to as the S-coding scheme (where S signifies stabilizing variance).

Not all georeference data are tagged to polygons. And not all neighborhoods are conceptualized in terms of contiguity. Because irregular surface partitionings often have a large range in polygon size, sometimes neighborhoods are defined in terms of polygon centroids (e.g., geometric center, spatial mean of population, principal administrative city); geometric center coordinates can be calculated easily in most geographic information systems (GISs), although multiple-part and concave polygons may require extra effort. As an aside, geographically distributed points can be converted to polygons by constructing their corresponding Thiessen polygon surface partitioning. SW can be constructed based upon polygon centroids. Binary, S-coding scheme or row-standardized SW can be defined for nearest neighbor centroids. Including a sufficient number of nearest neighbors avoids having the accompanying SWM represent a disjoint set of subregions. Most often, SWMs are specified so that a path can be traced from any given location to any other location in a geographic landscape by at least one sequence of nonzero SW; this is a desirable property of these matrices. Binary,
S-coding scheme or row-standardized SW can also be defined for centroids within a fixed distance band. This conceptualization is the basis for the queen’s definition of contiguity, which involves nonzero as well as zero length (i.e., point) boundary connections. The distance band should be large enough to avoid disjoint subsets, but small enough to avoid corrupting the localness of spatial relationships. Sometimes the (effective) range indicated by a semivariogram is used to determine the size of this distance band. One drawback of this specification is that interlocational relationships are not necessarily formulated to decline in strength with increasing distance.

Row-standardized SW can be created with continuous distance, too. One common specification is based upon inverse distance, \(1/d_{ij}\), for locations \(i\) and \(j\) and their intervening distance \(d_{ij}\). This weighting scheme discounts pairs of points with larger intervening distances. Rather than zeroes being assigned as SW, zeroes are approached asymptotically as distance increases to infinity. Now the diagonal entries of the SWM must be coded zero by construction. Once all of the inverse distances are calculated for the entries of an SWM, each entry is row standardized. This weighting scheme can be generalized (i.e., powered inverse distance) by attaching a positive exponent to \(d_{ij}\), resulting in \(1/d_{ij}^c\) for \(c > 0\). The exponent \(c\) cannot equal zero, or everything is depicted as being related to everything else, regardless of location; \(c = 1\) for the inverse distance specification. As \(c\) increases beyond one, the SW increasingly approximate those for the row-standardized binary SW specification; \(c\) may need to be as large as 6–7 to achieve this outcome. The negative exponential distance decay specification furnishes a third alternative. Here the SW are based upon \(e^{-c d_{ij}}\), where \(e\) is the base of the natural logarithms. As for the generalized inverse distance case, a value is needed for \(c\). The coefficient \(c\) may need to be as large as nearly three for these SW to approximate those for the row-standardized binary SW specification.

The magnitude of spatial interaction flows furnishes an additional basis for specifying SW. The number of goods, services, money, telephone calls, or people (e.g., journeys-to-work, to-shop, and to-recreation), say, flowing among locations can be inserted into an SWM. Next, the diagonal cell entries are coded with zero. Then the matrix is row standardized. This SW specification captures both a contiguity type of spatial relationships, and more distant spatial relationships attributable to geographic hierarchical effects. This latter component is missing from the preceding SWMs. If the locations are cities, then central place theory offers a hierarchical articulation of places that transcends mere contiguity. An alternative approach would be to specify two SWMs with the preceding specifications, one for contiguity and the other for hierarchy.

The conceptualization of SW has changed over time, primarily moving from the binary 0–1 version to the row-standardized version. Few examples appear in the literature involving the use of the S-coding scheme, generalized inverse distance, negative exponential distance decay, or multiple SWMs for a single geographic landscape. GISs often offer the option of employing rook/queen contiguity, fixed distance bands, or inverse distance/squared distance, or a user-defined set of weights (which could be any one of the other specifications). These packages also might furnish a metric other than Euclidean. A few more recent studies employ flows-based SW, a specification that replaces the nominal measurement scale binary row-standardized specification with a ratio scale measure of spatial linkage, although it is not without drawbacks (e.g., it can replace an exogenous with an endogenous SW specification).
Selected salient spatial weights controversies

Current emphases in SW research include the data analytic nature of, and somewhat arbitrariness associated with, SW specifications. The preceding section illustrates this perspective: SW can be specified in a number of different ways, some of which define a particular weight as zero while others define it as nonzero. Various critics argue that endogeneities of SW, arising from their definition in terms of specific phenomena or the choice of locations, are problematic. For example, if a response variable is a function of spatial interaction, and these flows are used to define the SW, correlation may well occur between the error terms associated with the SW and the disturbance terms in spatial autoregressive models. Or, changing geographic scale or resolution almost always results in changes in at least some of the SW.

Frequently, defining SW in terms of geographic distance for a functional geographic landscape avoids serious endogeneity complications. Rather than using phenomena to refine the specification of SW, percentage of common boundary lengths can be employed, as can hybrid versions combining such refinements with intercentroid distances, or changing the metric (e.g., Euclidean to network shortest paths). Meanwhile, because demarcating functional geographic landscapes can be impractical or nearly impossible, corrections for edge effects can be employed to ameliorate SW changes attributable to varying the size of a geographic landscape for a given resolution.

Sensitivity of spatial analysis results to the specification of SW may well be a myth (LeSage and Pace 2011). Incorporating some SW scheme achieves the biggest improvements in data analysis results, whether it is over- (i.e., has too many nonzero values) or under- (i.e., has too few nonzero values) specified. Identifying the correct set of nonzero SW makes little difference if most are correct, if no neighbor set is distorted in such a way that it contains most, if not all, of the other locations (Griffith and Lagona 1998). This feature is desirable because otherwise the SWM would be an unreasonable tool for analyzing relationships involving spatially correlated data. It also helps counter criticisms about the arbitrariness and ad hoc construction of SWMs. If spatial analysis results are robust in terms of an SWM specification, then they are not conditional on subjective decisions about its definition; accordingly, estimates and inferences are insensitive to small changes in SW specifications. However, to preserve mathematical statistical properties of estimators, modest underspecification seems preferable to overspecification, and using SW appears to increase the small sample size threshold from the conventional 30–100 to 60–200 for moderate positive spatial autocorrelation cases. As an aside, the automated procedure AMOEBA (a multidirectional optimum ecotope-based algorithm) has been developed to create SWMs in a more objective way by exploiting local spatial autocorrelation statistics.

Future directions in spatial weights research

Future SW research needs to address three prominent issues: SWM comparisons, integrating multiple spatial structures, and space–time specifications. The first issue concerns informative comparisons of SWMs. These comparisons are needed for a number of different definitions of the same set of SW, as well as for the addition and/or subtraction of various nonzero SW for a given definition. Because a set of SW can be organized as a matrix, mathematical properties of matrices furnish one criterion for comparison.
SPATIAL WEIGHTS

Any matrix can be characterized by mathematical quantities known as eigenfunctions, which relate to a number of its features (e.g., trace, determinant). An \( n \times n \) matrix has \( n \) such functions, each of which is a scalar paired with an \( n \times 1 \) vector. All of these functions are real for a symmetric matrix with real entries. Eigenfunctions are encountered in regression and multivariate statistical theory also. Eigenvalues of SWMs quantify distinct patterns of correlated subsets of locations. If no correlation exists amongst locations, then the eigenvalues equal the diagonal entries of the matrix; for SWMs, each would equal zero. For a row-standardized matrix, the largest eigenvalue in absolute value is one. If all SW are equal (i.e., all locations are related, and to the same degree), then the largest eigenvalue is one and the \( (n - 1) \) remaining eigenvalues are \(-1/(n - 1)\). If a zero spatial weight becomes nonzero, or vice versa, some of the eigenvalues change. Therefore, the rank ordered sets of eigenvalues furnish a means for determining the degree to which different SWMs differ. To maintain a standard measurement scale, an SWM whose largest eigenvalue is greater than one can have all of its eigenvalues divided by its largest eigenvalue. The important research question to be addressed here asks by how much sets of eigenvalues can differ without the SWMs rendering different statistical estimates and inferences.

A second issue is the use of multiple matrices. Defining SW in terms of flows in space may suffer from endogeneity complications. But such definitions capture both geographic contiguity and geographic hierarchical relationships. The two components are necessary for properly analyzing, for example, spatial diffusion phenomena. Spatial relationships channeling leaps across space can play an important role in understanding and properly analyzing the geographic distribution of a phenomenon. Much of the existing SW literature addresses contiguity relationships. Adding a second SWM for an underlying hierarchical structure complicates autoregressive estimation, although its specification is a straightforward extension of existing SW specifications. The mathematical statistics algebra for estimation and inference remains tractable. But calculations become considerably more numerically intensive. Moran eigenvector spatial filtering may furnish an efficient and effective way to handle this complication. This relatively new spatial statistical methodology employs the eigenvectors of the SWM to account for spatial autocorrelation latent in georeferenced data. The important research question to be addressed here asks how these two-SWM spatial statistical models can be implemented. Space–time research offers some hints about this.

A third issue, which relates to the preceding one because it involves multiple matrices, concerns space–time data, which are becoming more readily available. Two popular conceptualizations for such data are instantaneous and spatially lagged space–time correlation. Both cast an attribute value at a given location during time \( t \) as a function of that attribute’s value at that location during time \( t - 1 \). The former also casts an attribute value at a given location during time \( t \) as a function of its neighboring attribute values at time \( t \), whereas the latter casts this attribute value as a function of its neighboring attribute values at time \( t - 1 \). Geographic and temporal distances have different metrics, complicating specification of the overall correlation structure. But the SWM and the temporal weights matrix can be combined, and in efficient ways when space and time correlation components are separable. The important research questions to be addressed here ask how to test for space–time separability, and how space–time conceptualizations can incorporate nonseparable space–time correlation structures. Both Moran eigenvector
space–time filtering and space–time geostatistics already involve research focusing on this topic.

Spatiality

Audrey Kobayashi

Queen’s University, Canada

The conceptual transit from space to spatiality is one of the most significant developments in recent geographical thought. Both space and spatiality are historical concepts that refer to the relationship between people and things, including other people, on the Earth’s surface. While spatiality is relatively recent, space is a historical concept. Like all human inventions, it has been subject to many interpretations. Space is one of the most – if not the most – important concepts in the discipline of geography. It is also the most difficult to define and possibly the most contested. For students of the subject it is a bewildering term, sometimes depicted as an absolute product of nature with a predetermined structure, sometimes as a metaphor that is as changeable as the imagination, sometimes as an abstract concept that defies either specificity or logic. Often it is used uncritically by geographers – as “space and place” – based on unquestioned assumptions that its use will be understood by readers. Such assumptions make understanding space even more difficult.

The major issue is ontological. Just what is this thing geographers call “space”? Is it, after all, a thing? Is it an assemblage or collection of things? Is it a conceptual principle for organizing things? Is it notional, relational, or rational? Does it exist and, if so, where and how? What does space look like? How does it work?

Geographers generally acknowledge that space is “no longer viewed as a fixed and absolute container within which the world proceeds. Rather, space is seen as a co-production of those proceedings, as a process in process” (Thrift 2008, 86). Space then is relational; it is fungible and never static; it is contradictory – both unstable and capable of irrepressible stabilization; it is a product of conflict; it is inherently political and powerful on the one hand, and capable of myriad redefinitions and reimaginings on the other. Many geographers would assert that it is the task of the discipline to understand how space has changed and is changing, treating space as an emergent condition of the world.

Doreen Massey (2005), in one of the major works on the topic of space, challenges geographers to let go of and to reimagine the conceptual categories of space and place. She sees the problem as one in which the inherent spatiality of the world has allowed humans to reify these notions. To contest such reification and the sociopolitical issues it creates, geographers need to refuse to think of space as a singular phenomenon, such as the Earth’s surface, on which the objects that fill the world are placed; to refuse to convene space into time; and to challenge the tendency to acknowledge notions of space or place in ways that convey power relations on earthly territories. Massey’s work has been incredibly influential, and has influenced a generation of geographers to think differently, as well as to meet the conceptual challenge posed by thinkers in other disciplines for whom space has in recent years become something of a fetish.

In the end, however, Massey still titles her book For Space. Spatiality, a condition of relationship between people and things, is somehow returned to space, and the reason for such nominalization is never made quite clear. The
book ends on a somewhat mysterious note (and maybe that is just what she intended) that recasts the taken-for-granted assumptions about space that the book has challenged so successfully. This entry on spatiality challenges the reader to give up on space – especially its conceptual mysticism – altogether, to cast off the comfort blanket of the term, to think instead of spatiality.

**Space: a linguistic paradox**

The term or concept of space varies drastically in different languages, and in many languages there is no usable translation. In English, the term “space” originated with the Latin word *spatium*, translated variously as “room,” “area,” “distance,” “extent,” or “duration.” The Old French term *espace* carries a similar meaning, conveying a sense of distance or interval, which has been taken up by numerous French philosophers in the twentieth century and has influenced recent poststructural thinking. The English term is especially fascinating because its connotations and everyday usages have changed over time with changing philosophies and technologies. During the fourteenth century, it was used in connection with marking territory or boundary, a common part of the discourse of colonial expansion. From the fifteenth century, it was incorporated into musical theory, and by the sixteenth century into typography (still used today, as the “space” between words). By the seventeenth century, it had become more abstract with the development of geometric theory, as that which comes between points and lines, a notion that extends into theories of mathematics and physics of the twentieth century as a metaphor, even more abstract, for that which does not exist except to differentiate points, which also do not exist as such. Also in the twentieth century, the term took on many aspects of modernity, as the void outside of Earth, which became the obsession of both science fiction and astronomy (“space” travel), as a psychological state (from “personal space” to “head space” to “spaced out”), to most recently “cyberspace,” a realm that is both familiar and ineffable to most of the world today.

In most of these popular understandings, space is either full or empty, that is, it is either something or nothing, either a physical thing that has dimensions, is measurable, and provides the substance of the world, or an abstract concept that allows us to think about the relationships between actual things, whatever they are. Space has monetary value (think of its usage in real estate sales), or political value (as a fundamental commodity in colonialism, for example). The myriad uses of the term in ordinary language reflect multiple meanings, conflicting ideologies, diverse cultural practices, and changing technologies. Space is thus a paradox, not only for intellectuals, but also for politicians, capitalists, and ordinary people, a contested “thing” that can only be understood in relation to other things. But its ontological status remains unclear. Geographers have even debated whether an ontology of space is needed, whether more than one ontology can exist simultaneously, and whether we should even think about the issue when there seems to be some sort of linguistic consensus about what we are talking about. How important is it for geographers to worry about the theoretical basis of this thing called space that is both abstract and concrete at the same time? Should they settle for conceptual pluralism?

**Geographical concepts of space as a thing**

For most of its history, the discipline of geography has been a sparring ground for debates over
the thingness of space. Until the mid-twentieth century, much of the discipline assumed, often uncritically, Newton’s "container" theory of space as something independent of the things that fill it. Leibnitz, in contrast, was a relativist, who wrote:

These Gentlemen maintain therefore, that Space is a real absolute Being. But this involves them in great difficulties. For such a Being must need be Eternal and Infinite. Hence some have believed it be God himself or one of his Attributes, his Immensity. But since Space consists of Parts, it is not a thing which can belong to God … I hold Space to be something merely relative, as Time is, that I hold to be an Order of Coexistences, as Time is an Order of Successions. For Space denotes, in Terms of Possibility, an Order of Things which exist at the same time, considered as existing together, without enquiring into their Manner of Existing. And when many Things are seen together, one perceives That Order of Things among themselves. … I have many Demonstrations to confute the Fancy of Those who take Space to be a Substance. (Leibnitz, in Clarke 1717; emphasis original)

This quotation provides the gist of a metaphysical argument that went on for centuries (and in some respects is still going on, although it has been long surpassed in the discipline of physics, where theories of relativity have been firmly established since Einstein’s work in the early twentieth century).

Perhaps none of the Enlightenment thinkers was more influential on the discipline than Immanuel Kant, who attempted to move past the absolute–relativist debate by depicting space as a sensory capacity. Well aware of the debate between Newton and Leibnitz, Kant first wavered between thinking of space as absolute and as relative, before settling on the original and revolutionary idea that space, like time, is a pregiven cognitive category that allows humans to perceive an outer reality in spatial terms. Both external reality and internal perception operated for Kant according to laws that consciousness could not itself violate. The project of the "Enlightenment" was to use human reason to discover and apply those laws to increase knowledge. Kant’s dualism between inner consciousness and the outer material world has been maintained in geographic understandings of space as both outer materiality and inner, or mental, perception.

Kant influenced the modern discipline of geography by positing the spatial as chorological, that is, as the organizing principle for things that occur in proximity, just as time is the organizing principle for events that occur in sequence. Chorological thinking dominated human geography during the first half of the twentieth century. Geographers often referred to things “in space,” and it was largely assumed that areal or regional differences are spatial. Geographers debated the nature and existence of regions; however, discussions of Space itself, or its ontological status, were of little expressed interest for most geographers until the mid-twentieth century.

With the spatial turn from the 1950s onward, interest focused explicitly on spatial theory. Studies of spatial pattern proliferated, and the term “the science of space” became common in geographical writing, so much so that some geographers have labeled thinking during this time as a “spatial fetish.” That fetish, nonetheless, departed from the container or absolute view of space to a relative understanding of the externally driven processes that create spatial patterns and relationships. David Harvey (1969, 209), among others, contended that “Space may well be the central concept on which geography as a discipline relies for its coherence.”

The “space” of the spatial turn was construed relatively, according to Leibnitz, not Newton, and in line with the thinking of relativity theory.
Jones (2009) claims that the four-dimensional concept that resulted depended on two assumptions: (i) that spatial order can be determined only through relations between things in space; and (ii) that spatial relationships are not fixed – they change over time. Regional science, then, depends by and large on a concept of space–time. It is also ironic, however, that, while much was written about discovering the laws of space, very few engaged in a discussion of its ontology. At issue was the status of spatial laws, not space itself, laws that could be observed empirically in predictable, measurable, mappable, and repeatable patterns on the Earth’s surface. At this time, the practice of urban planning expanded, and many of its practices responded to a burgeoning global population, a rapidly expanding network of roads and airways, and massive, unprecedented increases in the movement of people and things, not to mention the proliferation of weapons as technologies that could quickly and dramatically disrupt spatial patterns. To respond to changing spatial conditions and possibilities, practices of regulation and control were developed and strengthened in nearly every aspect of human governance. Geographers who could map such changes were in their disciplinary element.

**Overcoming dualism**

Controversy over space and place erupted in the 1970s as a correlate to controversies over the role of spatial science. Some Marxist geographers, including David Harvey, challenged the spatial turn on the grounds that the aim was to understand not spatial processes but the process of capitalism. For them capital produced space, rather than the other way around. Some humanists, particularly phenomenologists, rejected the concept of space altogether as abstract, and focused instead on place, as that which is filled by human experience. Yi-Fu Tuan (1977) attempted to get past the place/space dichotomy by depicting space as that which exists prior to place; in other words spaces become places as a result of human actions. In this interpretation, space is an abstract concept, since empty space could not exist as such. Many geographers began to write of “space and place,” although much of the work that uses this term, even up to the present, is extremely vague about why geographers study both, and about just what is meant by these two nouns or how they are distinguished from one another.

Marwyn Samuels (1978) penned one of the first in-depth discussions of human spatiality in the discipline of geography, creating not an ontology of space but a spatial ontology of human being. Samuels refuses to reify space and acknowledges that human beings have produced different kinds of spatiality, among which spatial science is but one. Using theologian Martin Buber’s existential notion of human relationship as setting the other at a distance in order to enter into relationship, he explores the complex and ironic situation of human alienation on the one hand, and yearning for relationship on the other, as the result of both the fundamental human condition of spatiality, and the many factors through which relationships (which include everything from direct human contact to the roads by which we overcome distance) are founded. He sees irony in the fact that, as human beings overcome distance technologically, they create new kinds of alienation.

As the tenets of poststructuralism began to infiltrate the discipline, a consensus had developed that there are various kinds, or modes, of space, and that human agency determines the qualities of space. Henry Lefebvre’s (1991/1974) monumental work *The Production of Space* was justified on the grounds that, notwithstanding volumes of work, theorists had failed to
establish a viable science of space, and that spatial scholarship consisted of “bits and pieces” of largely descriptive research without much analytical rigor. Lefebvre set out to address the dualism between mental or psychological space and space as it is experienced in the everyday. He posits that all spaces – abstract, absolute, or social – are historically constructed. They become, are organized, represented, and given meaning, by collective human action. He seeks to analyze “not things in space, but space itself, with a view to uncovering the social relationships embedded in it” (Lefebvre 1991/1974, 89). Space is therefore the totality, the every thing, of a delineated portion of the Earth. It can be a room, a street, a city, even a nation, whose qualities are determined by human habitation. Dialectically, it is both the product of human capacity and constituent of human experience. Lefebvre’s space is thus distinguished from that of the chorologist because he obviates the dichotomy of space and things. For him space is a project – in fact, it is the human project – and thus represents the projection of humanity on the world.

Lefebvre depicts three modes of spatiality: spatial practice, the material process of creating the world around us; representations of space, as the power-laden practice of regulating or structuring human behavior spatially, and finally spaces of representation, in which the human imagination works in various ways to create experiences that are not always open to objective capture. Human geographers have capitalized extensively on this triad in order to organize conceptually the seemingly endless ways of understanding spatial being. The most sophisticated expansion of the triad is by Edward Soja (1996), who deems Lefebvre’s modes first, second, and third space, and then projects the concept of third space into a complex journey across the heterotopic landscape of Los Angeles, an “Exopolis” across which the conditions of postmodernity are spread through imagination, metaphor, irony, paradox, and virtuality. In addition to providing a compelling account of an actualized landscape, Soja provides a healthy geographer’s critique of some of the excesses of spatial thinking in the work of continental poststructuralists.

The recent contributions of poststructuralist feminists in geography have particularly emphasized the complex and often conflict-laden nature of sociospatial experience, and the utilization of “paradoxical space” (Rose 1993) to capture the ways in which especially the spatially excluded imagine and act on the conditions of power and control through which the world has been structured, governed, and disciplined, and in the process made uneven and oppressive. Sue Ruddick (2009, 224) views “Society–Space” as an “immanent field upon which geographers have the potential to unbound, destabilize, re-assemble, and transform the concept of space not only as a geographical theory but as a way of being.” In her view, “space is not strictly a techne, nor a juridicopolitical boundary, but the manifestation of process itself, a kind of becoming … in a process whereby subjects’ capacities are invested through particular roles that they carry regardless of their location” (Ruddick, 2009, 224). In other words, we have reached a point of conceptual no return where we no longer study space itself.

Spatiality

Geographers have bashed away at the concept of space itself to the point where, as itself, it no longer carries much analytical utility, not simply because its meanings have become so diverse as to be almost meaningless (although perhaps they have), but because the discipline is more and more aware that it is precisely the spatial–social,
the becoming of humanity, rather than the fictional quality that encloses or regulates humanity, that is our major concern. Boyle and Kobayashi (2011) turn to Jean-Paul Sartre, whose work has been virtually ignored by geographers (at least in print). They take up Sartre’s refusal of colonialism, and his acknowledgment of the metropolitan anxieties created in a world in which colonial distance is being transformed, as a basis for understanding human existence as collective spatiality, a dialectic that Sartre refers to as spatializing–spatialized:

both a product of and modality through which particular formations of the colonial become possible, through particular forms of human relationship (spatializing–spatialized) and in particular landscapes ... We refer to these historicized phenomenologies as: spatiality as tyranny, spatiality as liberation and spatiality as incarceration. (Boyle and Kobayashi 2011, 420)

Spatiality is the condition, the form, the becoming of human, concretized through and as human relationship. In other words, the shift is from relative space to relational spatiality.

The social theorist Gilles Deleuze once remarked that it was the Sartrean dialectic that made poststructuralism in the twentieth century possible. This dialectic informed subsequent thinking in which knowledge, or discourse, is always and only dialectical reason/praxis, “always partial, necessarily contingent, purposive ... unbounded, and never separate from its concrete, material, historical, circumstances ... Praxis imposes on knowledge the synthetic engagement with the world (existence), as well as the possibility/necessity to transcend existence (becoming) through distantiation,” and therefore is never outside the dialectic either as an ideal (pure thought) or as an external structure (Kobayashi 1989, 170). For geographers, then, to understand spatiality, or distantiation, is fundamental to understanding the possibility of existence. The possibility of “history” becomes the possibility of geography: spatializing–spatialized.

Perhaps spatiality is thus, to use Ruddick’s (2009) term, human geography’s immanent field. To claim that the concept of space itself is therefore redundant is not, however, to substitute one abstraction for another. It is rather to recognize that the sociospatial – the only – world is the complex, interpretive and interpolating, interconnected, often paradoxical and contradictory, stuff of (human) relationship, in all its forms and modes. Spatiality is a condition of being, not a thing in itself. It is no longer possible – if it ever was – to isolate space from its sticky context, nor is it possible to isolate spatiality as a particular mode of being or historical moment, a particular place, landscape, or setting. Rather, geographers increasingly recognize and understand spatiality, and its possibilities, as a dialectical process.

Spatialization

Sara Irina Fabrikant
University of Zurich, Switzerland

Information access and dissemination

Efficient and effective access to and knowledge construction from massively growing spatial and nonspatial databases available online have become major bottlenecks for the rapidly evolving information society at large. The rise of the Internet since the 1990s, especially the rapid expansion of the World Wide Web, and the current growth of social-networking platforms brought about the construction of massive, multivariate and multimedia online databases (e.g., Wikipedia, OpenStreetMap, Flickr, etc.). These (increasingly user-generated) databases can include vast amounts of non-numerical, semistructured data (e.g., Wikipedia entries, blog posts, etc.) or nonstructured data (e.g., online books), and these data very often also contain geographically relevant content. Most geographic information systems, however, typically rely on numerical, tabular georeferenced information for space–time data analysis; the kind of numeric data that fit into a table, neatly organized in rows and columns. Analyzing large and complex alphanumeric datasets with traditional spatial analysis methods can become inadequate, as the data may be bound by a priori assumptions (e.g., dependent on a particular data distribution, or a sampling method, and moderate sample sizes, etc.). Due to their inherent complex, multidimensional nature, vast unstructured and semistructured datasets need to be transformed into meaningful chunks of information, and adapted to the limited information-processing and sense-making capacity of humans. With these information science-related developments mostly happening outside of geography, it became apparent to geographic information scientists that methods and approaches that geographers have been using for hundreds of years to model and visualize geographic phenomena could also be applied to the representation of any data record, object, phenomenon, or process exhibiting spatial characteristics (Fabrikant and Buttenfield 2001).

Many different types of spaces and spatial reference frames exist beyond geographical space that could be reorganized, analyzed, and explored with spatiotemporal methods, and mapped using well-established cartographic practices. For example, chemical structures that build up to the human genome, medical records that refer to human body space, or neuronal connections in the human brain are good examples of non-geographic spaces that lend themselves for spatial analysis and mapping. For example, Atkins (1995, 34) depicts the periodic table as a stepped undulating terrain of chemical properties. The higher the hills in this landscape of the chemical elements, the larger the atom diameters of the depicted chemical elements.

Spatialization offers the field of geography, which investigates space and spatial relations, opportunities to apply its rich spatial knowledge to noneographic, and even nonspatial, data domains (Couclelis 1998). One can also imagine abstract information worlds presented in map-like displays for visuospatial analysis that are not spatial at all. For example, real-time digital
SPATIALIZATION

stock transactions create a space of money flows, and digital interactions of people through online networking platforms form social networks in cyberspace, which could both be mapped in the form of transportation network maps. Songs played on online music sharing websites create a landscape of musical tastes that can in turn be depicted as a relief or terrain map in which musical tastes shared by many people pile up metaphorically to create mountains of popular music styles. Figure 1 depicts a two-dimensional (2-D) space of musical tastes and listening experiences sampled from members of the popular online music sharing website Last.fm. Listeners of this social music media website are invited to share personal information about the music they upload or listen to by tagging songs with additional text information. Based on users’ listening patterns, this information is then used by the system to suggest additional musical pieces that users might enjoy listening to.

The music spatialization in Figure 1 renders a meaningful spatial pattern of musical styles, where rock music pieces cluster in the western parts of this Last.fm landscape (Skupin, Biberstine, and Börner 2013), clearly separated from world music, classical music, and jazz, concentrated in the eastern parts of this relational world of musical tastes. Interestingly, funk music, located in the southeast of the space, seems to be seen as a musical transition zone between jazz and classical music.

Spatial metaphors

Spatialization takes advantage of people’s familiarity with space in everyday life to produce information spaces that are intuitive and internally coherent. Everyday experience of the real world involves visuospatial perception and memory, spatial reasoning, and communication about features and objects in the environment, their spatiotemporal and thematic attributes, and the relationships between these objects. For example, instead of presenting users with large abstract tables or long lists of queried items from an online archive in text format, information spatializations allow users to visually explore graphic displays of information by means of spatial metaphors, as if they were exploring a real landscape or a cartographic map of a real environment, allowing them to see and experience the “layout” of the information in a single view (Skupin and Fabrikant 2003).

Successful interface metaphors create explanatory theories for users interacting with a system (Kuhn 1996). That is, users can map the processes and relations of a real-world source domain (e.g., geographic space) onto the processes and relations of the target domain (e.g., an information space), allowing them to use their knowledge of familiar source domain operation to predict the unfamiliar, often abstract target domain operation. What is common to geographic and nongeographic spaces (e.g., body space) are fundamental spatial concepts such as location, distance, arrangement, hierarchy, scale, and so on. A fundamental assumption is that spatialized displays work because users can understand them intuitively (Wise et al. 1995). If this assumption is generally true, understanding the fundamentals of geographic space (the metaphor’s source domain) as understood by display users will help to construct cognitively adequate information displays based on meaningful spatial metaphors (target domains). Location and distance (i.e., arrangement) on the Earth’s surface are among the most fundamental geographic primitives, and both are reflected in the distance–similarity metaphor, that is, more similar items should be placed closer to one another in a spatialized display because closer items will be seen
by people as more similar than distant items. Montello et al. (2003) have called this principle the first law of cognitive geography, as a consistent result of a series of empirical studies with various types of spatialized displays. This research provides empirically validated evidence to support Gatrell’s (1983) proposal for using a broader conceptualization of space in geography, and thus to employ a variety of distance metrics beyond Euclidean geometry to analyze and visualize a multitude of spaces of interest to geographers. The current popularity of ordination methods utilized to reorganize and mine vast amounts of spatial and nonspatial data, for example, by using nonmetric multidimensional scaling, principal component analyses, and self-organizing map techniques in various subfields of geography (i.e., physical geography, remote sensing, and behavioral geography), is another good example
SPATIALIZATION

of the analytical power of the distance–similarity metaphor.

Metaphors are also successfully employed in everyday communication, because they encapsulate so-called image schemas that have been hypothesized to be at the core of human cognition. Image schemas are fundamental cognitive structures shaped by bodily interactions with the real world that allow basic human reasoning and understanding (Lakoff and Johnson 1980). For example, the spatial image schema MORE IS UP is the basis for understanding any type of linguistic, auditory, or graphical metaphor to communicate the magnitude or quantity of an item of interest. Examples of this image schema are in everyday language: “Her appreciation for beautiful maps keeps rising every day.” When one is pushing up a lever on a vintage analog stereo system this typically increases the volume of the played sound source. Also, in any statistical charting software, when creating a graph of analysis results, the higher the bar, the higher a point or a line in a graph, and the larger the slice of pie in a pie chart, by default, the greater the magnitude of the depicted data. The use of metaphors in user interfaces is also inspired by Gibson’s (1979) ecological theory of visual perception, which postulates that a human observer can intuitively grasp affordances in a perceived environment, resulting in appropriate human action and behavior in that environment. Hence, a perceived sound lever on the analog stereo system, or a depiction of a sound lever in a graphical user interface to play digital music, affords a user to push it up or down to change the sound volume. To be cognitively inspired, and thus intuitively understood, the appropriate mapping of more or less sound to yield the predicted result should in turn be based on the MORE IS UP image schema, with a higher/lower sound lever (source domain) for more/less sound (target domain), respectively. Similarly, on a mobile device, the spreading of two fingers, that is, the increase of distance between the thumb and the index finger, typically increases the size of objects perceived on the graphical user interface and the distances between them in the display, and also the level of graphic detail shown in the interface.

The graphical “desk in an office” interface to run a personal computer is another everyday example of the integrated application of spatial metaphors based on (spatial) image schemas and affordances that spatialize an abstract multidimensional digital data environment. This graphical user interface, initially developed by Xerox’s Palo Alto Research Center in the 1970s, and later popularized in the 1980s by Apple Inc. for its Macintosh computer, is still the dominant interface metaphor and user interface spatialization to this day. The 2-D view of a computer operating system as an office desk covered with writing tools, documents, and folders, in an office equipped with filing cabinets and a trash can (a table-top source domain), enables a user to visually create, process, store, and delete data in a digital filing system (target domain). Using spatial properties such as proximity (i.e., NEAR–FAR image schema), users typically regroup related files or applications, by putting them into a common folder (CONTAINER image schema). Consequently, hierarchies of folders can be created to simplify navigation through “data space” (VERTICAL ORIENTATION image schema). Deeper into the hierarchy, more detailed information about the data is revealed, thus relating to scale dependence in the real world (PART–WHOLE image schema). Moreover, by surmounting distance with the “drag and drop” option (SOURCE–PATH–DESTINATION image schema), we are able to perform actions within the computing environment, such as copying or deleting files. Files that have to be deleted are carried to a specific place on the
desktop, to be put into a trash can. Typically
the trash resides somewhere at the edges of
the desk, neither obstructing our working
environment, nor being too close to important
files (CENTER–PERIPHERY image schema).

Applying the distance–similarity metaphor
(i.e., NEAR–FAR image schema) to a spa-
tialized digital online library, one can couple
document locations with distance, and thus two
documents may be cross-referenced by a linear
connecting transect (i.e., SOURCE–PATH–
DESTINATION image schema). Items falling
along this transect may be characterized as being
more similar to one item (endpoint) or the other.
Documents within a given (radial) distance of a
central thematic location form clusters of related
information (i.e., CENTER–PERIPHERY).
Clusters may be nested hierarchically and build
up document ontologies. Introducing the con-
cept of scale, clusters can be explored at different
levels of detail. One level of detail provides an
overview of the entire information space. Other,
more detailed levels “zoom in” on a specific
theme or a specific document, and so on.

The power of metaphors in spatialization is
its strength, but can also be one of its greatest
weaknesses. It is important to realize that a
metaphor is only like the real thing, not the thing
itself. This means that a metaphor may include
some but not all characteristics of the mapped
source domain, and may in fact have additional
(magical) or counterintuitive properties in the
target domain. Consider a digital folder to store
files as mentioned above. The digital folder
(target domain) exhibits similar properties to
an analog manila folder (source domain) in that
“files” can be stored in it. However, the digital
folder cannot be bent, and files never fall out if
it gets too full. The digital folder also exhibits
“magical” powers in that it can hold many
hierarchically stacked folders, and potentially
store an infinite number of files (provided an
infinite amount of digital storage space is avail-
able). In fact, the manila folder might not even
be recognized as such outside of the United
States, because in many parts of the world the
cream-colored folder with tabs to write on is
not known or used at all.

Empirical research suggests that a continuous
landscape metaphor to represent document
collections is not as self-evident as information
designers seem to believe. Like visualization
designers, lay users reveal a similar naive under-
standing of geomorphological structures and
processes used as source domains, and thus have
difficulty interpreting and fully grasping the very
popular continuous terrain metaphor to depict a
news article collection (Wise et al. 1995). On the
one hand, the spatial metaphor might be taken
literally; viewers interpret depicted features as
islands, mountains, and so on, because of their
graphic appearance, even after they have been
specifically told that the display is an abstract
information space of new stories. On the other
hand, once the abstract news concept is applied
by users, it is mixed with naive conceptions
about landscape forms, because spatialization
users are not familiar with the true nature of
geomorphic processes (e.g., more information
is accumulated in the valley) and do not share
commonsense/naïve ideas about topography
suggested by spatialization designers (e.g., higher
mountain means more information) (Fabrikant,
Montello, and Mark 2010).

Spatialized views

Spatialization is related to geographic visu-
alization and geovisual analytics in the sense
that powerful interactive map–like displays and
interfaces are used to gain insights into massive
databases that are spatialized. These spatialized
SPATIALIZATION

views are typically the result of applying sophisticated data mining and exploratory multivariate data analysis approaches, including dimensionality reduction techniques (i.e., factor analysis, multidimensional scaling, principal component analysis, etc.) to large multivariate databases of interest. Such advanced multivariate statistical methods themselves are based on spatialization, that is, they reorganize and visualize massive and complex high-dimensional databases based on the distance–similarity metaphor (e.g., any type of mathematical ordination method), with the goal to uncover interesting patterns and gain an overview of latent relationships buried in the data, which in turn can be further analyzed statistically in more detail.

A spatialized view differs from ordinary data visualization and geographic visualization in that it may be treated as if it depicted geographic information. Armed with the arsenal of long-established cartographic visualization techniques, information spaces can be visualized in various ways, for example, as simple point maps, network maps, or continuous terrains. The more cognitively supportive the employed spatial metaphor, and the more perceptually salient its depiction, the more intuitive the spatialized view, and eventually the more effective the use of spatial analysis techniques for data exploration and knowledge construction. While technical developments and analytical innovations in spatialization research have continuously and rapidly advanced, theory development, empirical evaluations, and validations of design principles for spatialized views have received much less attention. Early empirical findings suggest that spatialized views should be based on sound spatial theory and principles, and adhere to cartographic design guidelines to be cognitively inspired, usable, and useful (Fabrikant and Skupin 2005). For example, empirical evidence shows that 2-D point and surface spatializations are equally effective as their 3-D equivalents. This is probably due to the fact humans rarely experience 3-D space directly (e.g., flying or diving), and thus human perception and cognition are closer to 2D than to 3D (Gibson 1979). The strength of a similarity relationship between spatialized items is most effectively depicted by connecting lines between items, and by varying line width, akin to showing the magnitudes of flows on quantitative flow maps. This is because the visual variable size is based on the MORE IS UP image schema, and the links between nodes on network maps encapsulate the SOURCE-PATH-DESTINATION image schema (Fabrikant et al. 2004). Groups of related items are shown either in clusters on point-display spatializations (Montello et al. 2003), similar to a dot density map (i.e., NEAR–FAR image schema), or as distinctly colored regions in region display spatializations (i.e., CONTAINER image schema), akin to area class or choropleth maps (Fabrikant, Montello, and Mark 2006).

Ongoing spatialization research focuses on how to effectively and efficiently depict multivariate, increasingly non-numeric, and nonspatial data stored in massive online databases, so as to provide aesthetically pleasing, perceptually salient, and cognitively supportive displays for effective and efficient sense-making and knowledge construction.

Spatiotemporal analysis

Li An
Stephen Crook
San Diego State University, USA

Despite being central to the study of many disciplines, spatiotemporal analysis has not been defined in a unified way. This encyclopedia entry aims to bring together the different uses of, and methodologies for, conducting spatiotemporal analysis in order to provide a more centralized understanding of the topic. To achieve this, we define spatiotemporal analysis as “the depiction, representation, visualization and tracking of changing location in space and time of a certain phenomenon or event of interest, which are often (yet not necessarily) connected to seeking understanding about the mechanisms behind such data of spatial locations and temporal stamps” (An et al. 2015). Spatiotemporal analysis is also referred to as spatio-temporal analysis, space time (sometimes space–time) analysis, spatial temporal (sometimes spatial-temporal) analysis, and the like. Following an introduction of its historical, intellectual context, this entry investigates the range of disciplines that contribute to spatiotemporal analysis and the specific methods employed for conducting it. To conclude the entry, the future directions of spatiotemporal analysis are presented.

Intellectual context

From early civilizations to modern times, space and time have been the two fundamental domains under which people have characterized events and phenomena of interest around them. Space and time, both abstract and often invisible, are conceptualized in a variety of ways. Space can be understood as “absolute space,” which can be characterized with a number of specific properties (Hinckfuss 1974). Under this view, space and time exist in their own right, which represents an object-independent framework. Space, along with time, is considered as a container within which all things or events of interest take place. Newton’s analysis of space and time followed this line of conceptualization. To describe the laws of motion in regard to the trajectories of moving objects in space and time, he used the languages of mathematics (e.g., geometry and calculus). In his absolute framework, the objects move and change their properties in space and time, but the framework or the container itself remains unchanged (see Peuquet 2002).

In an alternative conceptualization of the so-called relative space proposed by Leibniz, space is created differently (Cresswell 2013). In contrast to a pre-existing container in the absolute space concept, relative space is conceptualized to represent relative locations among objects. Along this line, Minkowski extended the traditional three-dimension \((x, y, z)\) geometry to include time as a fourth dimension, which forms the basis of the united, relativistic space–time concept. The relative view of space continued in its development and culminated in Einstein’s work on the theory of relativity. Research in physics and mathematics, in particular, has enriched the conceptualizations of space–time at very large and very small scales, such as those in electronics, mechanics, and cosmology. At the human and landscape scale,
conceptualizations of space–time analysis have been fertilized by the study of biology, ecology, hydrology, epidemiology, and geography (especially the subdisciplines of geographic information systems (GIS) and remote sensing).

Springing from the ideas of Kant and his fellow philosophers, earlier scholars largely held a dichotomous view of space and time, that is, that they are two separate key categories within which all activity occurs. Early geographers, such as Darwin, von Humboldt, and Ritter, focused their academic effort on depicting and understanding places, including their physical and human differences (Cresswell 2013). Under this view, space and time are not considered in tandem. For instance, regional geographer Hartshorne regarded that history aims to address changes in time, while geography addresses differences in space (Cresswell 2013). Early geographic models took a stance of either ignoring time or viewing it as a function of spatial variables such as distance or transportation costs (e.g., Von Thünen, Christaller; Cresswell 2013). Movement and transportation, which are concerned with time as much as space, can be “effectively studied in spatial terms” (Cresswell 2013). This means that movement is dictated by economics: supply and demand, least net effort, and travel costs (Cresswell 2013). Geographers, especially regional geographers, continued with this tradition until the so-called quantitative revolution in geography in the mid-twentieth century. The quantitative revolution has also witnessed the rise of spatial science within geography and the entry of geographers into the field of quantitative modeling. Since then spatiotemporal analysis has boomed in both quantity and quality (An et al. 2015), largely due to the advent of computers and advances in computing and analytical power.

Spatiotemporal analysis, as defined earlier, seeks to answer questions of both “when” and “where” (and, to some extent, “why” at the time or location) things occur. However, people use the words “when” and “where” in a variety of different ways (Couclelis 1999). The word “when” can be used in a relative sense (e.g., one event happens between two storms), or in an absolute sense that refers to time span (e.g., time duration of a storm) or clock time (e.g., at which time point a storm occurs). Similarly, space can be defined and used in varying ways. These ambiguities have led to a rich literature on the nature of space and time in physics and philosophy. In addition to the absolute/relative classification, Yuan, Nara, and Bothwell (2014) bring in another dichotomous classification of realism versus idealism, which refers to whether space–time, objects, or events are mind-independent (realism) or mind-dependent (idealism). The unifying principle underlying these conceptualizations and classifications is that space–time representation lays a foundation for subsequent spatiotemporal analysis methods as well as the corresponding results (see Yuan, Nara, and Bothwell 2014 for examples of this principle). Spatiotemporal analysis must recognize the intimate link between space and time, implying that changes of a phenomenon or object over either space or time would often inherently include a change in the other. This endorses the importance of putting space and time together to perform spatiotemporal (in contrast to spatial or temporal) analysis, and helps explain the exponential increase in the number of publications related to spatiotemporal analysis since the late 1940s (An et al. 2015).

Spatiotemporal analysis in geography

The absolute or relative conceptions of space–time structure can be found in spatiotemporal models in geography (Massey 1999). In an
SPATIOTEMPORAL ANALYSIS

absolute representation, researchers use fixed coordinate systems to represent the study site and events of interest, mark the changes in the associated variables, and explain or predict the pattern of change over time. Traditional geographic models represent the physical environment of interest in a two-dimensional space of grid or vector, without specific representation of time as a key dimension of concern. Largely ignoring time, such models are essentially spatial models. As time has moved on, the possibility of a space–time conceptualization has been explored by geographers. Early spatiotemporal analysis in geographic models often resorts to a GIS. Traditional GIS have elegantly represented space, but not so time (Peuquet and Duan 1995). The mainstream space–time representation in traditional GIS is through the snapshot model, where a spatiotemporally continuous world is shown at limited snapshots in time (Peuquet and Duan 1995). To address some difficulties faced by the snapshot model, the event-based spatiotemporal data model (ESTDM) by Peuquet and Duan (1995) allows organization of space–time data by time. Other data models, including the space–time composites model, the spatiotemporal object model, and the three-domain model, offer different tradeoffs between representing both space and time (An and Brown 2008).

On the other hand, a relatively new, object-oriented approach is arising in the geographic modeling and analysis arena. This approach leans more toward the relative representation of space and time. Under this approach, features on the Earth’s surface (e.g., land parcels, people, households) are conceptualized and represented as objects that are relatively independent entities, which may change their locational and nonlocational attributes over time – some of them may even have a certain level of intelligence and autonomy, make decisions, and/or adapt to the changing environment or the changes made by other entities (see the section for agent-based models below).

Spatiotemporal analysis techniques

This section sets out to give an overview of spatiotemporal analysis methods that have been used in geography, environmental sciences, and related disciplines. Each method will have a brief discussion of how it represents time and space, what type of data is required, what type of output it may yield, and whether it is primarily focused on prediction or explanation. These methods have been selected because they share several important features: they allow representation, visualization, or quantification of a system over space and through time in a dynamic way; they help in identifying mechanisms for observed changes in spatial patterns over time; and/or they can predict changes in temporal patterns by analyzing spatial data over time steps.

Time geography

Unlike early spatial science with its focus on place-based aggregations and generalizations, time geography has arisen attempting to integrate individual trajectories of human movements in both space and time (Hägerstrånd 1970). As a pioneer, Hägerstrånd (1970) emphasized the need “to have not only space coordinates but also time coordinates” because people exist both in a specific space and at a particular point in time. In his seminal work on space–time life paths, a horizontal plane represents position in space and a perpendicular axis represents time. Space–time prisms, often derived from space–time life paths, are a powerful tool to show movement patterns within an individual’s world, which are subject to physical and physiological constraints and also
SPATIOTEMPORAL ANALYSIS

conform to public and personal decision-making (Hägerstrand 1970).

Recent years have witnessed rapid improvement in geospatial information technology, paving the way for quickly collecting individual, georeferenced human activity data in large amounts or over large spatial extents (Kwan 2004). In parallel with this increasing data availability, a number of models and techniques are being developed to capture, represent, and analyze such data, including the ones focusing on the exploration, visualization, and generalization of large space–time trajectory datasets in the GIS software environment (Kwan 2004). Such models and rich datasets have also opened new perspectives and opportunities in geocomputation; for example, real-world accessibility measures can be developed and obtained by calculating the maximum travel distance of individuals subject to multiple constraints (Kwan 2004; Lenntorp 1976). Among these models and techniques, statistical methods have played an essential role in time geography, allowing quantitative analysis and comparison of the space–time trajectories of different individuals or groups. The statistical methods allow calculation of a number of different measures, including the Hausdorff distance, Fréchet distance, dynamic time warping algorithm, and longest common sequence algorithm. Also worthy of mention in time geography is space–time path clustering analysis, which classifies individuals sharing similar space–time paths into groups.

There is no doubt that the time geographic approach is particularly important in space–time analysis, because for individuals under investigation, both spatial coordinates and temporal coordinates are tracked down continuously and given equal weights in later data analysis. Nonetheless, it is a big challenge for time geographic researchers to address patterns and processes at multiple spatial and temporal scales. Currently, most activities captured in time geography research operate either at a small spatial scale or over short time periods, or both. Seldom have movements over larger distances and larger time scales, without sacrificing spatial or temporal resolution of data collection and analysis, been included and characterized well in this type of continuous tracking (Meentemeyer 1989).

Analysis of time-series spatial data

One category of spatiotemporal analysis methodologies consists of analysis of time-series spatial data using a number of spatial statistical and analytical techniques. Broadly, this category includes time-based descriptive statistics, statistics for clustering and dispersion, and establishment of correlations or causal relationships through regression analysis. Change through time is assessed either qualitatively or quantitatively, through the comparison of maps and graphs at different time steps, and by graphical output of statistical change over time. Below, several increasingly recognized methods are introduced, which are powerful at analyzing time-series spatial data and potentially unveil the mechanism behind such data – for nearly all these methods, spatiotemporal patterns are represented by the so-called snapshot data model, where space at one time is represented in a certain GIS layer (often raster unless otherwise specified) and time is represented at (and constrained by) the associated data collection frequency.

Exploratory space–time data analysis

This category of spatiotemporal analysis attempts to develop novel measures (including graphs) to show trends in both space and time. A number of space–time statistical techniques in this general category are included in commercial GIS. For
instance, ArcGIS has enabled the visualization of events in three dimensions, with the time dimension being displayed vertically, which is conceptually similar to the space–time paths in time geography. The Crimestat software has tests for spatiotemporal clustering, diffusion, and interaction (Levine 2004). The Space–Time Analysis of Regional Systems (STARS) package is designed to perform exploratory analysis of spatial data with numerous time points (Rey and Janikas 2006). STARS offers several important functions, including qualitatively displaying spatial data patterns over time, and calculating descriptive statistics such as global and local Moran’s I, and the Gini coefficient (Rey and Janikas 2006). Though spatial analytical and statistical software tools are not elaborated here, it is worth mentioning that software development is one of the rapidly improving areas for spatiotemporal analysis.

Identifying spatiotemporal clusters, for example epidemiologists identifying clusters of disease outbreaks, stands out as a very important type of applications. Many useful indices and/or tests have thus been developed for different purposes: (i) the Barton and David test, which aims to find if spatial patterns of events vary by temporal cluster; (ii) the Knox test, which focuses on finding whether events in one time–space window would differ from the expected amount in the same window given the total number and time range of all events; (iii) the Mantel Index, which helps find correlation between distance and time interval (Levine 2004); and (iv) many other indices, including frequency, duration, intensity of events, spatiotemporal covariance structures, and space–time hotspot indices (local indicators of spatial autocorrelation or LISA, bivariate LISA, Getis-Ord Gi*), which continue to be developed to assess the spatiotemporal patterns of the phenomenon or event of interest.

In addition to finding clusters, assessing changes in an individual feature’s locations in a GIS environment is another application domain of spatiotemporal analysis. Worthy of mention is the Spatio-temporal Moving Average and Correlated Walk Analysis by Levine (2004), which facilitates tracking of the mean location of a moving event/feature and thus helps prediction of its location in the future. All these methods conceptualize a spatially continuous world at limited snapshots in time (Peuquet and Duan 1995), and the snapshot GIS data model (often raster layers over multiple time points) underlies the corresponding data collection and analysis.

Spatial panel data analysis

Spatial panel data refer to time-series observations of a number of spatial units over time (Elhorst 2010), and often raster layers over multiple time points are data input. Spatial panel data analysis consists of two types of models. The first type includes dynamical models that predict the dependent variable at a given time by its value at the prior time and a set of independent variables using the so-called difference equation models. Though conceptually such models are ideal for spatiotemporal analysis, they are considered less compelling and more complex and thus not commonly employed in literature. The second type is related to two kinds of multilevel models (MLMs), that is, fixed effects and random effects models, where the multi-time observations for each individual unit (e.g., land parcels) are lower-level (level-1) data, and the individual units are higher-level (level-2) data. This data structure is the same as that in MLMs (see the section for MLMs below). The model for this type of panel data analysis is similar to an ordinary least squares (OLS) regression model in many aspects (Elhorst 2001; Petersen 2009).
SPATIOTEMPORAL ANALYSIS

What distinguishes the above spatial panel data analysis from regular OLS regression models is a spatial effect term that deals with the impact of neighboring spatial units on the unit of interest. Depending on how the space–time autocorrelation in data is to be addressed, researchers may use spatial lag models (when the dependent variable of interest is autocorrelated) or spatial error models (when residuals from OLS models are autocorrelated; Anselin, Le Gallo, and Jayet 2008; Elhorst 2010). Then essentially spatial panel data analysis has to extend the fixed (or random) effects models with a spatially lagged dependent variable or with a spatial error term. Therefore the challenges related to MLMs, for example the need for large and balanced samples and the inability to incorporate endogenous predictor variables, are also extant (see the section for MLMs below). Also, model estimation may be biased by the spatial dependence among observations, and this complication may need special attention, according to Anselin, Le Gallo, and Jayet (2008).

Markov chain modeling

This type of model aims to represent changing temporal dynamics and spatial patterns of spatial units (e.g., individual cells/pixels). With input being often raster layers over multiple (at least two) time points, Markov models often focus on predicting or projecting future spatiotemporal patterns (e.g., in terms of raster maps). All units have spatial coordinates, and their attributes can change over time. In a Markov process, the landscape type at a given location and certain time depends only on its previous type and a transition probability. Transition probabilities, often presented in a matrix form, are obtained through assessing historic conversions between transition types.

Markov chain models are logically simple and useful for exploring patterns of spatiotemporal changes within a relatively short time span. Nonetheless, they have a number of drawbacks that deserve the attention of spatiotemporal modelers (An and Brown 2008). Primarily, the assumptions of spatial independence and stationarity (in time and space) may not hold true in many applications (NRC 2014). In addition, Markov models focus explicitly on prediction, and provide little insight into causality or low-level processes that generate the observed spatiotemporal patterns (NRC 2014). In many studies, Markov chain models are made more useful when they are integrated with other modeling or analysis techniques (see the section for cellular automaton).

Bayesian spatiotemporal models

Bayesian statistical models have been adapted for use in spatiotemporal analysis. With input being often raster layers over multiple time points, Bayesian models often focus on predicting future spatiotemporal patterns (e.g., in terms of raster maps) or explaining observed patterns. In this type of model, a spatial dependent variable (with both spatial and temporal stamps) is described as a function of both time and a number of parameters (that are related to the specific site). According to prior knowledge (e.g., physical laws) about the phenomena or events of interest, a priori statistical distributions are used in order to impose constraints on a model that may have too many parameters, for example through a conditional autoregressive function. This results in a relatively small number of site-independent hyperparameters. Posterior distributions of site-specific parameters are used to update the parameters based on empirical spatiotemporal data, specifically by maximizing the probability of observing the empirical data.
through modifying parameter values. In determining these probabilities, researchers could use techniques such as the Markov Chain Monte Carlo method to generate samples for these posterior distributions. Weaknesses related to Bayesian spatiotemporal models include the fact that subjectivity might come into play when choosing either the posterior distribution or the a priori distribution, and also that modelers may have to assume some untested parametric distributions between space, time, the dependent variable, and the independent variables.

Survival analysis

Survival analysis is a methodology that successfully integrates both time and space in order to understand the contribution of different mechanisms to observed spatiotemporal patterns. While related to, and comparable to, more traditional static spatial analysis techniques such as logistic regression, it represents a more dynamic, integrated method for spatiotemporal analysis (An and Brown 2008; Wang et al. 2013). With input being raster or vector layers over multiple time points, survival analysis models are very useful for either prediction (e.g., in terms of raster maps) or explanation purposes. The technique has been adapted to land-change studies from a diverse range of earlier uses, including public health and demography (An and Brown 2008). While the name of the methodology is derived from investigations into mortality, it can easily describe the survival of a particular land unit, that is, not being changed to an unintended land use or land cover. Indeed, in recent years, a multitude of studies have used survival analysis to find drivers of land change (An and Brown 2008; Wang et al. 2013).

The hazard function is central to survival analysis. Based on theoretical assumptions or empirical event frequency and timing, the hazard function can be calculated as a measure of the risk that a change will occur at a given space and time point. Related to survival probabilities, the hazard function differs in its ability to either increase or decrease depending on the influence of explanatory variables over time. Survival analysis uses information at all of the time steps to calculate the hazards for each individual pixel over time. The hazard function is regressed against a set of predictor variables, including those time-dependent ones. Because it accounts for the dynamic values of these variables at different time steps, a key strength of survival analysis is that it allows varying contributions of each time-dependent predictor variable to the hazard over time. Survival analysis is also suited to accounting for censored data: if an event happens outside of or in between time steps in a set of time-series data, it can still be included in analysis and contribute to estimating the related model parameters.

Despite its strengths in incorporating time into statistical studies of change, survival analysis has a number of drawbacks. First, it is weak in handling continuous changes in a certain dependent variable because essentially it deals with events or qualitative changes that happen at specific time points. Second, and related to the first drawback, it depends on the use of subjective thresholds to specify whether change has occurred if the dependent variable is continuous. Percent of a land cover cannot be included in the corresponding dependent variable, which must be declared as one type or the other based on a cutoff value. Third, the hazards of different spatial units sometimes may require certain untestable assumptions to be made; for example, the hazards are constant within each period in the piecewise exponential model.
Multilevel models and latent trajectory models

Multilevel models (MLMs) and latent trajectory models (LTMs) are two types of relatively new models that contribute to spatiotemporal analysis. MLMs use data at multiple hierarchical levels, including individuals who are members of a group or neighborhood, in order to account for the clustering effect that may exist within individuals of the same higher-level grouping (Browne and Rasbash 2004). These clustering effects violate the assumption of independence in standard OLS regression, meaning that conclusions of statistical significance may be drawn incorrectly at the individual level. In various demonstrated case studies in health and education, outcomes at the individual level were found to no longer be significant when clustering due to higher-level group membership, such as classrooms or hospitals, was accounted for. Functionally, MLM differs from OLS regression by allowing variability in both the intercept and the coefficients of the model. For each intercept or coefficient, there is one random term that is allowed to change from entity to entity, and/or a fixed term that describes the influence of the higher-level grouping on each individual within the same group.

MLMs are used in spatiotemporal analysis because of their ability to investigate time-series spatial data by nesting multiple time measurements within each individual unit. In this case, time measurements would be the level-1 units, individual observations (which could be pixels) would be level-2 units, the neighborhood or other higher-level group would be level-3 units, and so on (Subramanian 2010). By structuring spatiotemporal analysis in this way, causal mechanisms that are operating at different levels over time can be revealed. Challenges in using the technique include the need for sufficiently large populations of higher-level groups in order to draw a sample of adequate size, as well as the related need for significant computing power to conduct analysis of such large datasets. In addition, MLM models do not allow endogeneity within the model, that is, they do not allow parameters of the model to function as predictors for other variables (Preacher et al. 2008).

LTMs are related to MLMs, and in some cases result in equivalent models for spatiotemporal analysis. This technique, however, is more explicitly aimed at analyzing longitudinal data in order to find the impact of time and a number of independent variables on a dependent variable (Guo and Hipp 2004). The input data of both LTMs and MLMs could be either vector or raster maps at multiple times, and both can be used to predict or explain spatiotemporal patterns. Using patterns of change (such as quadratic or linear, but not necessarily monotonous increase or decrease) in the response variable \( y \) as latent variables, LTMs are able to model change patterns in \( y \) as latent variables, and estimates complex causal relationships or plausible pathways among these change patterns and a set of independent variables (Preacher et al. 2008). Weaknesses of LTMs include the assumption that the dependent variable follows a mathematical function in time, when the reality may be more complex, and also the assumption that LTMs are limited in integrating hierarchical data in the way that MLMs do. By combining LTMs and MLMs into hybrid multilevel latent trajectory models, the strengths of both can be accentuated and the weaknesses minimized.

Spatiotemporal simulation techniques

The previous sections focus on statistical models that establish empirical relationships between drivers and outcomes in order to derive understanding about processes from observed patterns
Another category of spatiotemporal models is that of simulation-based ones that focus more explicitly on the processes through which changes develop. These rule-based models, including cellular automaton (CA) and agent-based modeling (ABM), concentrate on how systems function, and how lower-level processes result in emerging higher-level patterns.

**Cellular automaton**

CA models portray the spatial variable of interest in a contiguous array of cells (or pixels), and the cells can change between a certain number of predetermined states (e.g., land-use and land-cover types) as time passes (Parker et al. 2003). CA rules and parameters are set on a time step basis such that each snapshot outcome represents the system's status at a certain step. CA models can be used for either prediction or explanation purposes. In these models, change is dictated by transition rules, under which the change of state of a certain cell of interest is often dependent on the state of neighboring cells. For instance, one rule might state that an undeveloped cell that has four developed cells in its neighborhood may remain in its undeveloped state due to "crowding." Due to these simple rules, the states of all cells may change over each successive time step, resulting in a progression of new patterns. In empirical studies, change rules can become more complex. For example, one study assessing patterns of urban growth over time in the Bay Area of California formulated transition rules based on slope, roads, and amount of nearby development (Clarke, Hoppen, and Gaydos 1997).

CA models are often combined with other techniques such as Markov models, overviewed earlier. Markov analysis alone projects future change based on transition probabilities calculated from time-series data. Integrating CA with Markov models allows neighborhood interactions to be integrated so that the amount of change between any two types is derived from a Markov process, while change locations are prioritized based on CA rules. Together, they better address spatial dependence while predicting changes over time. Despite their utility in projecting change and investigating emergence, CA models have a number of drawbacks. Specifically, they are weak in making links between real-world, human decision-making and conversion rules, and they have a poor ability to project over long time periods (due partly to an inability to include feedbacks that operate across spatial, temporal, or organizational scales; NRC 2014).

**Agent-based models**

Agent-based models (ABMs), also called multi-agent systems and individual-based models, focus on lower-level processes that generate larger-scale patterns (Parker et al. 2003). Unlike a CA model that only deals with fixed pixels, ABMs use agents that are allowed to move in time and space. Its input often includes (i) at least one layer of raster data, ArcGIS shapefile, or ASCII file (increasingly vector data as well) that contains spatial information; (ii) data for agent attributes (e.g., an ASCII or Excel spreadsheet for agent information); and (iii) rules and parameters that make the actions or processes play out. ABM models can be used for either prediction or explanation purposes. The output of ABMs can be different graphs (e.g., population dynamics over time), maps (e.g., shapefiles, ASCII files), or numbers (e.g., An et al. 2005). Each agent contains a number of the attributes that characterize it, and behaviors that can cause changes to the agent itself, to other agents, and
Spatiotemporal Analysis

to the environment as time passes. As in a CA model, ABMs function based on a set of decision rules. As these decision rules play out over time steps and agents interact with other agents and the environment, they update the attributes of themselves, other agents, and the environment. Consequently, the system represented by the ABM will evolve over time.

When applied to human-environment systems, urban systems, or other geographical systems, agents can include individuals, households, neighborhoods, or other hierarchical groupings. The spatial domain in which the agents operate is often made up of GIS data layers that can include pixel-based or sometimes vector-based representations of the landscape. The representation of time is via time steps, or ticks. At each tick, which coincides with a real-world time interval such as a month or year, agents make decisions regarding themselves, other agents, and the environment. In a human-environment ABM, for example, these decisions can relate to things such as marriage, childbirth, the decision to collect fuelwood in a forest, or the decision to create a new household where there had previously been forest (An et al. 2005).

ABMs are especially suited for modeling complex systems, allowing the investigation of emergent properties, due to the fact that each agent has autonomy, intelligence, the ability to communicate and interact with other agents and the environment, and the ability to make informed decisions regarding the environment (Parker et al. 2003). These features allow ABMs to characterize further features of complexity such as feedbacks, nonlinearity, thresholds, time lags, and resilience. In doing this, they demonstrate strengths in integrating heterogeneous, multiscale data, including a diverse array of agent types at different hierarchical scales. Despite these strengths, challenges in ABM implementation include steep learning curves for new modelers, high data requirements, challenging verification methodologies due to path dependence, equifinality, and multifinality (Brown et al. 2005; NRC 2014).

Verification, validation, and other aspects in spatiotemporal analysis

All of the spatiotemporal methods above purport to have utility in understanding, describing, and/or predicting spatiotemporal patterns of interest. In order to show this utility, the degree to which models demonstrate agreement among their theoretical frameworks, model predictions, and real-world observations needs to be established. Verification refers to the task of making sure that the construction of the model (usually in computer code) reflects the design intentions of the modeler, and is achieved partly through debugging (NRC 2014) and a set of other techniques (An et al. 2005). Validation can jointly refer to “structural validation,” or demonstrating that model processes largely reflect or approximate real-world processes, and “outcome validation,” in which model outputs are compared to real-world data of the same outcome through, for example, map comparison if the outcomes are maps (NRC 2014). One of the most-used methods is to compile an error matrix and calculate a Kappa statistic based on a sample of points, tabulating cases of agreement and disagreement between types. However, other methods for outcome validation have arisen that allow more sophisticated comparison. These include fuzzy set approaches, multiple resolution map comparison, and the variant–invariant method (Brown et al. 2005; Pontius, Peethambaram, and Castella 2011). These methods are crucial in examining outcomes of spatiotemporal analysis.
Conclusion

The aforementioned models represent some, though not all, of the methodologies used in spatiotemporal analysis in geography, environmental studies, and related disciplines. Other techniques, including some geovisualization and land-change models, contain overlap with these spatiotemporal analysis techniques but are less explicitly focused on looking at changes over both space and time. Despite the strengths of the demonstrated methods in appropriately dealing with spatiotemporal systems, there are a number of future research directions and challenges that the discipline faces.

In traditional spatiotemporal analysis, there has always been a dominant focus on space. Most analysis techniques are built around GIS software packages that give a good representation of space, at the expense of offering an adequate representation of time. Indeed, in many applications of spatiotemporal analysis in geography, the decision regarding the number and resolution of time steps to include is based on convenience or data availability. While space can be represented in a continuous way, time steps are broken up and included without much thought as to what the most appropriate time span and/or temporal resolution might be (An and Brown 2008; Wang et al. 2013), which might cause important patterns and processes to be overlooked and thereby generate biased or even misleading conclusions.

Spatiotemporal analysis, with limited capability to handle temporal variability, has a bunch of other implications. First, changes in state are often limited to low temporal accuracy, as it can only be said that a change happens before or after a time step, or between two time steps. Survival analysis models offer one potential solution to this problem by appropriately dealing with censored data. Second, the common methods of storing data based on consecutive time steps may be inefficient in data processing and data storage when compared to time-based storage techniques that are organized by the times an event happens (Peuquet and Duan 1995). Finally, it has been noted that spatiotemporal models are generally conceptualized using an absolute conception of space and time. Relative conceptions of space and time, focusing on where and when events happen in relation to other events rather than in relation to fixed space time stamps (latitude/longitude, clock time), should be further developed. Fuzzy land-change methods are one methodology moving in a direction toward relative space–time conception and deserve more attention in the future (An et al. 2015).

The techniques discussed in this entry offer an introduction to the many methods used for spatiotemporal analysis in geography, environmental studies, and related disciplines. An important note is that many of these models can be combined to create hybrid models (NRC 2014). Some, such as CA/Markov models, or the use of statistical methods in parameterizing an ABM, have been demonstrated here, though other hybrid combinations exist. When undertaking spatiotemporal analysis, the selection of a proper model is key to characterizing the desired pattern or processes. Understanding the models listed above, each with their advantages and drawbacks, provides a starting point for conducting spatiotemporal analysis.

SPATIOTEMPORAL ANALYSIS

Peuquet, Donna J., and Niu Duan. 1995. “An Event-Based Spatiotemporal Data Model (ESTDM) for

Spiritual geographies

Avril Maddrell
University of the West of England, UK

Spirituality concerns beliefs and associated practices that pertain to being in relation to self, others, the material world and, crucially, what is believed to be beyond that material world, whether that be a deity, a number of deities, angels, fairies, spirits, natural energies, or the occult. The “spiritual” has been defined as part of the non- or more-than-representational and posthuman arena: “that part of the virtual in which faith forms a significant part of the move beyond rationality and of the possibility of other-worldly dispositions” (Dewsbury and Cloke 2009, 696). The spiritual is part of the virtual or more-than-human, which informs lived epistemologies and ontologies, addressing what is beyond human limits. Spiritualities play an important role in the conceptual understanding of many individual and community relations to identity, embodiment, consumption, community, politics, material, and visual culture.

Common preconceptions represent spirituality as the opposite of religion, that is, religion is an institutionalized approach to regulated beliefs and practices, whereas spirituality relates to the beliefs and practices held by those outside the confines of a religious regimen, leading to descriptors such as “spirituality without religion,” “do-it-yourself,” or New Age spirituality (MacKian 2012). This dichotomy is an over-simplification. Rather, spirituality can coincide with, but can also operate independently of, religion. Like love, the spiritual is an umbrella concept, encompassing the inner prayer life of a devout Buddhist or Roman Catholic nun, a therapeutic reiki massage, or energy-seeking at Sedona or Stonehenge.

How then does this wide-ranging but significant set of phenomena relate to geography? On a global scale, spirituality is often represented as an essentialist Oriental/Occidental dichotomy of “natural” Eastern spirituality, versus spiritual paucity in the West. While the effects of the Enlightenment, decline in institutionalized religious practice in Western societies and other social changes have marginalized spirituality, spiritual beliefs and practices persist. Spiritual beliefs and associated practices have contributed to shaping historical and contemporary designations of sacred places, nodes, and routes in palimpsest landscapes across the globe. For example, India is etched with an ancient spiritual geography of Hindu shrines linked by pilgrimage paths, sacred rivers and crossing points (tirtha), which are deemed to be spiritual resources. Likewise, some perceive Europe – and indeed the world – as a mesh of leylines. Such sacred sites are frequently multivalent and can fluctuate in meaning and status; they are also performative, reflecting spiritual beliefs and practices which may be woven into everyday life and/or mark extraordinary moments in life and experience, such as birth, marriage, and death.

Hence spirituality can be practiced, marked, or can leave traces on a wide range of geographical landscapes and arenas: the body, the home, at places of religious practice, or sites associated with the life cycle. Recent themes emerging within geographical work on spiritualities have drawn particularly on the agenda and methods of cultural and, to a lesser extent,
SPIRITUAL GEOGRAPHIES

social geographies, and have built on work on historical geographies of belief, geographies of religion, and studies of sacred spaces to consider wider contemporary spiritual beliefs and practices marked and performed within urban and rural landscapes, therapeutic environments, and domestic arenas. This can be seen in studies of postsecular cities and suburbia, young people’s spiritualities, and spaces of wellbeing and retreat. Feminist and queer geographies have prompted engagement with the intersection of embodiment, gender, sexuality, and spiritualities; and the non- or more-than-representational turn within cultural geographies has underscored attention to performative spiritual practices such as meditation at domestic shrines, rituals at pagan sites and memorials as well as through yoga and the spiritual mobilities of many forms of pilgrimage. There is enormous scope for further geographical engagement with the spiritual, which will enrich understanding of particular places, practices, and people’s relation to space and the environment, such as migrants’ and older people’s spiritualities, spiritualities and art, and spirituality-informed consumption.

Qualitative methodologies appear best suited to studying experiential and embodied spiritual geographies but emerging work suggests that quantitative techniques, such as geographic information systems (GIS), effectively capture complex spiritual networks and are potentially powerful analytical tools for examining geographies associated with particular forms and practices of spirituality and their complex interrelation with other factors such as gender, ethnicity, socioeconomic class, politics, migration, and so on.

Anne Buttimer (1993, 3) has argued that “For each facet of humanness – rationality or irrationality, faith, emotion, artistic genius, or political prowess – there is a geography. For each geographical interpretation of the Earth, there are implicit assumptions about the meaning of humanness.” Spiritual geographies represent a specialist field in their own right, but attentiveness to the significance of the spiritual in the lives of many would enrich many wider geographical studies beyond the subdiscipline.

Sports

Paul Gilchrist
Kath Browne
University of Brighton, UK

Sports geographies deal with the social and spatial dynamics and impacts of sport. Research and scholarship have engaged with many established areas of geographical investigation – landscape, place, environment, nature, colonialism and imperialism, nationalism, globalization – and have intersected with and catalyzed the study of sport in other fields. Academic interest in sport is of course not confined to geography. In addition, the significance of space and place in understanding sport is recognized by other disciplines across the social sciences and the humanities, though many scholars working on sport in these areas and from within mainstream geography have attested to a concern over the marginality of the subject, where there is a tendency to dismiss or overlook sport as trivial or not central to the core concerns of a parent discipline. As a result, analyses of the spatialities of sport are to be found predominantly in the more developed multidisciplinary field of “sport studies.” There are few in geography departments who define themselves as “sports geographers.”

Histories of sports geographies

The origins of sports geographies reside in regional cartographic analysis of geographical variations in American sport undertaken by North American scholars in the 1960s and 1970s. There has been a long-standing interest in the geographic diffusion of sport based on factors such as distance, population density, transport infrastructure, the presence of cultural brokers, and forms of social capital at work in the development of sporting systems. Historians and political scientists have addressed spatial themes, for instance, the suppression of street football and other premodern games in industrializing towns and cities and the emergence of sporting venues and facilities through commercial entrepreneurship and working-class self-organization. Colonial and imperial histories of sport have added a wider scope for understanding the spatial trajectories of modern sport during a phase of internationalization throughout the nineteenth and twentieth centuries, directing scholars to investigate the coercive and collaborative forms of power at work between center and periphery in the transmission of and encounter with dominant cultural forms.

A major geographical theme has been to trace the diffusion of modern sport from its origins in folk games to nationally organized leagues and competitions toward its US-influenced globalized form and to sport mega-events played out in super-stadia to television audiences numbering in the billions. Soccer is viewed as the world’s most popular sport, a form of popular culture that transcends provincial boundaries. This claim may hold true for the rest of the world, but not for the United States where its exceptionalism to the spread of the global game has been noted by many authors.

Mapping of common or divergent features of sporting forms and practices across time and space has been organized around the concepts of “diffusion” and “adaptation.” Tomlinson and
Young (2011) note a narrative orthodoxy across sport studies that credits England as the cradle of modern sport able to successfully export sports such as football, rugby (both codes), and cricket through the military, trading, and ecclesiastical arms of the British Empire. Globalization is seen as crucial to understanding contemporary sporting landscapes, including sports stadia (see below). Although sports are rarely globalized in the sense of being in every country in the world in equal measure, the hegemony and prestige of particular sporting events, such as the Olympics and the soccer World Cup, create and are created through globalizing factors. These include transnational migrations, the movement of capital, and, perhaps most importantly for vast sporting audiences, globalized media. The media provide a key way in which sport travels internationally and sporting fixtures can be globally consumed. The global media–sports–culture complex (Rowe 1999) operates to globalize sporting practices, open new markets for sport and consumption, as well as often to reiterate core–periphery relations through the scouting for sport talent in areas where sport participation and achievement are not as lucrative. In other words, the globalization of sport can reiterate and reproduce global inequalities.

A homogenizing globalized view of sport is increasingly challenged by sports geographers and historians who have highlighted the importance of local conditions to processes of transmission, reception, and adoption, pinpointing more complex cultural flows to the sharing of new sporting practices and technical innovations. In this way globalized trends are seen to be created locally and their manifestations related to local contexts, what is termed glocalization. Diffusion narratives can also work for particular sports, in specific contexts, but do not account for sports that challenge the move from Global North to Global South, colonized to colonizer, for example, the popularity of Eastern martial arts in Europe and North America.

**Sportscapes and cities**

British sports geographer John Bale is a pioneer in the field. Bale’s work has been core to sports geographies, and he remains a key figure in a field that has few who would define themselves as “sports geographers.” He has coined the concept of “sportscapes” to identify the material and bounded nature of modern sport. Drawing upon Arjun Appadurai’s notion of “-scapes” to show the nature of global cultural flows, Bale delineates the spatial ordering and reproduction of sites of sport. Unlike its premodern forms where participation takes place in unconfined and unmarked spaces in an existing landscape – the traditional spaces for folk games and contests at fairs, feast days, and holidays – modern sport is “refined and ordered in both time and space.” “Sportscapes” are, Bale argues, increasingly “monocultural,” focused solely on sports rather than “multi-functional landscapes” (Bale 2003, 131). While “sportscapes” do not account for the whole of potential sites of sport the concept has alerted geographers to key and enduring trends which emanated in the nineteenth century toward the construction of sites of sport according to the modes of a scientific-rational orientation essential to the production of the controlled conditions necessary for “achievement sport.”

Sport is key to understanding historical and contemporary built environments. The concept of “sportscapes” is useful in helping to explain built environments. Evidence for sports practice can be seen in places far and wide across many cultures and civilizations, from the gladiatorial contests staged in arenas throughout the Roman Empire to the ballgames played in specially constructed courts across Mesoamerica to the
shooting galleries of Edo-period Japan as Samurai warriors showed off their skill with the bow. Archaeologists and historians have recorded the changing spatial parameters of sports and the variation of practices, forms, and institutions.

The study of new sporting practices, particularly sports classed as “extreme,” “action,” or “lifestyle” sports (Wheaton 2013) has contributed to a deeper consideration of urban dynamics and an understanding of domination and contestation. Skateboarding and parkour are two well-studied sports for understanding spatial appropriation and redefinition, with many studies heavily indebted to the spatial theories of Henri Lefebvre in terms of understanding the spatial tactics mobilized by participants in opposition to the normative regulation of the built environment and the omnipresence of capitalist relations. Parkour has been conceptualized as a critical spatial practice and urban intervention that ascribes new meanings to places as parkour practitioners – traceurs – extend mobilities in the city through viewing everyday material objects – benches, railing, fences, lampposts – as ripe for tactile engagements that generate new place-meanings. The poststructuralist writings of Gilles Deleuze and Félix Guattari have been employed to theorize the juxtaposition between the fluid movement of the traceur and the negotiation of “striated” urban space. While the conceptualization of parkour as a form of subversive urban politics can be overstressed, sport sociologists have claimed that in their hyper-awareness of the environment and urban landscape, participants exercise “post-sport” subjectivities defined by morally oriented, community-centered, green and anarchic physical cultural practices which can generate an aesthetic-spiritual realization of the self. The valorization of play/playful within a redefinition of sport as a physical cultural practice opens up possibilities for the study of other practices and forms (e.g., urban exploration) which contain aspects of the sporting in their standards of challenge, need for physical competency, and embrace of personal risk.

Stadia

The use of sport facilities for urban regeneration emerged as a specific public policy in North America in the 1970s and continues to feature in location decisions of stadia linked to sport franchising business models. The hosting of sport mega-events such as the Olympic Games and FIFA World Cup has led to the construction of new stadia and arenas for domestic spectators and international visitors keen to observe sporting action. Human geographers have documented the relationship between sport-led regeneration and urban and regional planning, which have provided empirically rich accounts of the rationales for the construction of stadia linked to strategies for local economic development, gentrifications, city image creation, and inward investment, and their subsequent legacies and impacts, including negative externalities. Bale (1995) explained that stadia were as much economic entities, appearing on business pages, as they were sporting venues. They are seen as boosting cities, markers of successful urbanities as well as “urban machismo and vibrancy.” Moreover, stadia attract inward investment and development because they are understood as providing “a much-wanted – or, at least, much perceived – multifunctional leisure facility” (Bale 1995, 13).

The human experience and meanings that accrue to stadia have been widely researched, drawing on Yi-Fu Tuan’s (1974) concept of “topophilia” to articulate the “sense of place” and affective qualities of place-attachment. Such work has challenged the attribution of the modern sport stadia as “placeless” entities.
The argument of placelessness suggested that sporting spaces are globalized to such an extent that they are no longer locally specific, and that sporting stadia have become homogenous in form and structure. However, Tuan’s concept of “topophilia” has been used to question stadia as placeless, drawing attention to the ways in which they are the site of multisensory experiences and collective imaginaries shared by consumers and spectators, rendering the space of the stadium meaningful. The importance of fan communities in constructing a “sense of place” through cultural expression and festive celebration and following stadium relocation has widened the appreciation of personal and community investment in a sporting space and the forms of agency involved in collectively producing a sense of belonging.

Everyday spaces of sports

Cultural geographers, sociologists, and political scientists have extensively illustrated how sports foster senses of collective belonging in terms of civic pride and regional and national identities. The predictability of the sporting calendar produces the recipe for expressions of what Billig (1995) terms “banal nationalism” as the identification with a sport team spills over into the everyday spaces of the home, street, shopping center, café, and bar. Sport then can be key to the performance of contemporary national identities and uniting diverse people and places in expressions of nationalistic pride. This unity creates imagined communities of people who may never meet, but share national identities and expressions through how they “support” “their” team.

Sportive nationalism is thus a mechanism for geographical, class, and ethnic identification as well as serving assimilationist policies successfully in places like the United States through baseball and Canada where Quebecois nationalism finds an expression in ice hockey. Sport has high symbolic capital in the campaigns for separatist nationalist movements (e.g., Barcelona/Catalonia), and entering a sports team to the Olympic Games as representative of the nation sends a strong symbolic message about the territorial legitimacy of the nation-state.

Bodies, difference, and emotions

Despite assertions of the recent inclusion of bodies into social theory, sporting bodies have long been explored as core to thinking through sporting places/spaces. The German sociologist and historian Henning Eichberg has been influential to sport geographers in tracing the evolution of the sporting landscape. Eichberg (1998) proposed a trialectic model of “body culture” to identify the spatial parameters of sport. Within this model sport is practiced under welfare-oriented guises concerned with health, fitness, and the recreation of the body, typically practiced in purpose-built halls and leisure centers as facilities for mass sport. A playful body culture accounts for a spatially less defined encounter with nature where the spontaneous and the sensual are not so strictly constrained. “Achievement sport”, the third in the model, covers the time/space constraints of rule-bound and record-oriented elite sport, with super-stadia the pinnacle for the display of sporting excellence. Eichberg’s (1986) thesis of an indoor–outdoor impulse in the spatial configuration of modern sport has influenced subsequent considerations of the changing forms of outdoor recreation and the withdrawal of some sports – climbing, surfing, snowboarding – from natural environments to purpose-built, commercialized, and confined indoor facilities.

Sport geographies have engaged with phenomenology, feminism, and poststructural theory to examine the (re)production of the
sporting body by material, performative, and discursive practices that occur spatially, and which emanate through human and nonhuman encounters. At a microscale, the sporting body which runs, jumps, swims, surfs, and climbs has been reported upon, detailing the cognitive and corporeal forms of knowing which are produced through the exercise of visceral skill and talent in a sporting space. The felt intensities of bodily movement, where environment is sensed through sporting performance and is inscribed upon the sporting body through tactile and kinaesthetic engagement, are pronounced in considerations of the socio–nature relationships underpinning outdoor sport. The emotional state of the sport participant in extreme sport cultures and spaces – where the demands of fear, anger, relief, freedom and ecstasy are confronted – has further complicated the analysis of gendered embodiment and subjectivities.

The broader cultural and ideological contexts of sporting bodies account for another strand of scholarly interest. Bodies have also been examined in terms of constraint, power relations, and regulation. Seeing sportscapes as a disciplinary space, scholars have been interested in the control of bodies through the banning and control over movement. Access and maintenance of exclusivity of landscapes for sporting and recreational purposes create a specific form of exclusion, not only from the physical spaces but also from the symbolic meanings of these spaces. Scholars have been encouraged to attend to the social construction of bodies by hegemonic power relations so as to cultivate more nuanced inquiries into the spatialities and materialities of gender, sexuality, and race. A well-developed literature has considered the body as a spatial scale within patriarchal sporting cultures, revealing the maintenance of corporeal ideals by consumerist social forces and forms of exclusion and oppression faced by divergent, transgressive, and less able “Others.” Queer geographers have highlighted the presence of the erotic and sensual as part of sports places, contested homophobia in sporting places, including stadia, and sought to critically interrogate heteronormative sporting spaces. Racial differences are also a key social difference through which sporting spaces are created. The racializations of bodies through sports include the ways in which white ethnicities in certain sports pass unnoticed while Black successes require explanation, often through genetics.

Access to both sporting cultures and sporting spaces is also classed in historically specific as well as spatial ways. Legal factors relating to property rights and patterns of land ownership can shape the ability to use space for sporting purposes. Various outdoor sports in the United Kingdom – canoeing and kayaking, climbing, mountain biking, surfing – continue to confront access issues linked to the defense of land rights, and conflicts over multi-uses of limited natural resources have been persistent aspects of the sporting experience as participants seek to exercise a right to enjoy the countryside for recreational purposes. Land ownership conflicts are also a feature of sport tourism development in Canada as the rights of First Nations come into conflict with economic development priorities over new ski resorts, while a global antigolf movement has been prominent in Mexico and elsewhere, showing the limits to the imposition of “sportscapes” on indigenous populations with differing development priorities.

Future directions

There are numerous productive avenues of investigation for sports geographies. These include: critical spatial theories which can address recent developments around affect/nonrepresentational theory where affect and materialities become
key in investigations of sporting places and experiences and to account further for the actants/agentive capacities of sporting landscapes in the production of the sporting experience; political ecology of sports tourism/sport-for-development, and the links to global social justice campaigns and movements; sport and virtual geographies, to account more deeply for the importance of new media technologies in extending sportscapes into private and virtual settings; and the greater employment of Geographic Information Systems to map sportscapes, sites, and places and to provide the researcher with greater evidence on the complex networks existing among players, coaches, fans, and consumers, accounting for the forms of transnational exchange and cultural encounter that can occur in and through sport and the various spaces it is practiced.

References

States differ in terms of their population and the size of the region upon which they seek to exercise their authority over social forces and events. The significance and power of states in world politics and world economy differ fundamentally. In scholarly literature, states may be categorized as “weak” or “strong” with regard to the legitimacy they enjoy among their population as well as with regard to their capacity to exercise territorial sovereignty. Histories, development trajectories, and institutional structures of states also vary significantly.

In everyday language the state is often understood as a subject or as a thing. But as a scholarly concept the state is hideously slippery and tends to escape all attempts at consistent definition. The modern state nonetheless marks a development from medieval to modern space: the homogenization of territorial authority, particular linearization of state borders, as well as more or less successful elimination of alternative and often non-territorial forms of political organization. The state affects the everyday lives of people across the globe and is constantly reinforced through ideas such as democracy and nation. Forecasts of the demise of the state have proven premature.

Theorizing the state

With very few exceptions, the land surface of the Earth is divided up into territories over which states claim authority. Again with very few exceptions, all human beings inhabiting the Earth hold a citizenship that makes them citizens of one state or another (or, in case of multiple citizenship, of several states). In traditional ways of thinking about the modern state, the state is defined by three central components: territory, population, and authority. Specifying the relationship between these components, the German sociologist Max Weber coined the formulation that the state “is a human community that (successfully) claims the monopoly of the legitimate use of physical force within a given territory” (1994/1919, 310–311; emphasis in original). For a variety of authors from a range of academic disciplines, this definition and its components have become the point of reference for theorizing the concept of the state and its multiple and changing forms.

Following Weber, the British sociologist Anthony Giddens (1985, 120) calls the (modern) state a “bordered power container” and describes it as a political organization whose rule is territorially organized and which is capable of using the means of physical violence to sustain that territorial rule. Accordingly, the state is the container of modernity and the power of the state is exercised almost uniformly throughout an exclusive territory. In this tradition, it has become common to understand the state as a social organization that is composed of a relatively coherent
matrix of institutions of executive and political control (regulative authority) and core personnel (elites) through which it exercises power over a particular population within its well-defined geographical space.

Taking issue with the Weberian tradition, some scholars have questioned whether the monopoly of legitimate violence can ever be actually achieved, whether other spatial forms such as networks and spatial scales are not at least as important for the state as is territory, and in what sense the people of a state actually form a “community.” Through such controversies, the theory of the state has both progressed and differentiated into rather specialized debates. Another important controversy revolves around the question whether the state is primarily defined by internal relationships, such as the capitalist economy, gender relations, nation building and nationalism, and the national legal systems or by its external relationships, mainly by the fact that states need to be recognized by other states in order to actually become a state.

While more traditional positions focus on the state as a subject or a thing possessing these components as properties, most authors today will agree that it is much more fruitful to understand the state as a process, that is, as a flexible entity defined by territory, population, power, and a relationship to other states which develops over time. In this regard, more materialist traditions emphasize the way in which the state, as a social relation, is the result of practices that obtains a certain fixity which in turn structures practices. More poststructuralist positions on the other hand emphasize the way in which the state is mainly the effect of practices, especially of mundane and discursive ones, and therefore not so much structuring but itself structured. Believing that both traditions need to be taken seriously and should be combined, a brief sketch follows before focusing on selected aspects of the state which are deemed to be of particular importance within geography.

The state as social relation

The Greek theoretician of the state, Nicos Poulantzas, coined the formulation that the state is “the specific material condensation of a relationship of forces among classes and class fractions” (1978, 129; emphasis in original). By this he means that in capitalist societies, social processes – the capitalist economy in particular – result in different groups (especially classes and class fractions) with different and partly antagonistic interests. To prevent these antagonisms from turning into upheaval, the state organizes social classes in a way that includes the interests of all relevant classes into the regulation of society without touching class society as such. Social relations are “condensed” in state apparatuses such as ministries and administrations in a way that grants influence to all relevant groups to pursue their interests. For example, in many Western countries the labor unions have a strong influence in the ministry of social affairs and in welfare administrations, whereas financial capital has strong influence in the ministry of finance, and environmentalist groups in the ministry of environment. For this arrangement to be possible, scholars in the materialist tradition emphasize the relative autonomy of the state vis-à-vis civil society. This line of argument goes back to the Soviet legal scholar Evgeny Pashukanis, who asked as early as 1924: “Why is the apparatus of state coercion created not as a private apparatus of the ruling class, but distinct from the latter in the form of an impersonal apparatus of public power distinct from society?” (1980/1924). The answers that Pashukanis, Poulantzas, the West German state derivation debate, and others in this tradition give is that this is the most efficient structure for capitalism to function and the
unintended result of struggles between classes and inherited forms of domination from the pre-capitalist period. The separation of the state from society is thus explained both structurally and historically, that is, as the result of practices and as a structuring feature of practices.

Building on this tradition, the British sociologist Bob Jessop has developed his strategic-relational approach to state power (e.g., Jessop 1990). In his conceptual frame, the state is first the site of strategies of groups, classes, and class factions, and as such more accessible to some social forces than others at a particular conjuncture according to the strategies they adopt to gain state power. Second, the state generates strategies. It is an institutional platform through which societal forces are able to mobilize strategies for accumulation and related projects. Third, the state is a product of strategies, a particular sum of currently existing organizational structures and modes of intervention which are conditioned by inherited strategies.

The state as effect

Following an examination of some arguments by Poulantzas, the British historical sociologist Philip Abrams argued that the processes and relations that make up the “palpable nexus of practice and institutional structure centred in government” (1988/1977, 82) do not result in the object “the state,” which is “an essentially imaginative construction” (pp. 75–76), but only in the pervasive idea of the state which legitimizes domination. Accordingly, the state is not considered as a thing but rather as a powerful spatial imaginary and a mystifying idea, an abstract-formal object. The state is thus an abstract phenomenon that comes into being as a structuration within political practice. In a similar vein, the French philosopher Michel Foucault (2007, 144) doubts that the state has a “unity, individuality, and rigorous functionality [or] importance. After all, maybe the state is only a composite reality and a mythicized abstraction whose importance is much less than we think. Maybe.” What these and other discussions of the state have in common is that they acknowledge the concrete institutions and practices of state institutions and discourses about “the state” but refuse to accept the actual existence of an entity or object called “the state.”

Along these lines, the British geographer Joe Painter (2006) discusses the “everyday prosaics of stateness,” that is, the mundane practices in which “statization” takes place. In such a view, the state does not exist independently of the everyday practices which make up the state. The state, in short, is a reification of social practices. Painter uses the concept of statization of social life as opposed to a separate sphere called “the state” in order to overcome the binary between the state and civil society as well as to describe “the intensification of the symbolic presence of the state across all kinds of social practices and relations” (Painter 2006, 758; emphasis in original). Accordingly, the statization of social life (and space) proceeds through and thus also depends on quotidian practices undertaken by thousands of citizens and state officials on a daily basis.

Geography and the state

The development of geographical thinking in Europe has always been closely associated with the state. The institutionalization of geography as a university discipline from the nineteenth century onwards took place concomitantly with and often in the service of the “nation-state.” Geographic knowledge was regarded as important for more practical questions such as the mapping of the nation-state’s territory and the drawing of external and internal boundaries or the gathering of useful information about
international commerce, colonialism, and war, as well as for more ideological ones such as the production of discourses that tied together the imagined community of the nation within its territory and state, especially for schools. While the actual importance of the contribution of geography and geographers toward these goals is disputed, the theoretical foundation of academic geography in the nineteenth century as well as major works of central figures of the discipline of that time is evidence of the close relationship between the discipline and the state.

Historians of the discipline regard the German tradition as an especially important, clear-cut, and problematic example of the close relationship between the discipline and the state. Carl Ritter (1779–1859), the first chair of geography in Germany (1820) and one of the founders of the academic discipline of geography based on environmental determinism, and others who further developed this tradition, such as Friedrich Ratzel (1844–1904) and Alfred Hettner (1859–1941), argued that states were “not only earth-bound, but also earth-determined” (Schultz 2013, 21). In this tradition of thought, people of nations with distinct cultures develop by dealing with distinct natural environments whose borders should, ideally, also form the borders of the state (Schultz 2013). In the twentieth century, this line of thought became one of the foundations of Geopolitik or Geopolitics, which is often associated with Adolf Hitler’s thinking and politics.

After World War II, the focus on the relationship between geography and the state changed. Within the national welfare states that were constructed between the 1940s and the 1980s in advanced capitalist states, academic geographers in Europe and beyond have explicitly contributed to the constitution of state spatiality. Consider, for instance, the influence the discipline provided in many European state contexts to the birth of spatial planning (sometimes termed as town and country, or regional, planning) as a “scientific” approach to organizing the space of the nation-state and to the emergence of regional planner as a profession.

The state has long been equated with the territory or society, which has conditioned research questions, and thereby results, in geographical scholarship by being the taken-for-granted object of research (“methodological nationalism”). It has formed a powerful and often taken-for-granted structural frame for disseminating knowledge in lecture halls and geography textbooks. Coupled with descriptiveness, this embedded statism, as Peter Taylor would have it, was the defining characteristic of most of the geography of the state prior to the 1970s (for an overview of theories of the state in geography prior to the 1980s, see Clark and Dear 1984).

**Geographies of the state**

The relationships between population, territory, authority, and state institutions are continuously changing and are underpinned by shifting power structures. Their relations have been widely discussed in geographical literature during the past twenty years. Geographers’ and other spatially oriented social scientists’ contribution to the state-related literature has been made through conceptual work on the interconnections between state power and state spaces. The key contention has been that the (capitalist) world is constituted spatially within societal processes and practices and that the state remains one of the key components of this spatiality. State spatiality is not only a passive outcome of societal process, but rather its constitutive dimension.

The rise of social theorizing in human geography in the 1970s resulted in challenging the taken-for-granted spatiality of the state in geography. Structural (for early contributions see Clark and Dear 1984) and poststructural
positions in particular have been central in this endeavor. The re-assessment of the geography of the state stems from the debate on capitalist globalization. This debate deals with whether the state is being “hollowed out,” “filled in,” or is under transformation in the age of growing “marketization.” The transformationalist argument to this debate is that though the state remains a key constituent of the world political map, the ways in which state power has been exercised have fluctuated over the past decades (Peck 2004). There is also geographical variation in this process: state transformation has taken place differently, say, in Western Europe and in North America, in the former Eastern Europe, and in the “developmental states” of East Asia.

The materialist (spatial) research on state transformation has from the 1990s been structured around a few concepts such as the competition state, the workfare state, the rescaling of the state, and the neoliberalization of the state. These literatures are predicated upon an idea that the state has not been hollowed out but rather has been under qualitative change in recent decades. Today, state power is exercised differently compared with the so-called Keynesian welfare state that was characterized by nationally scaled systems of redistribution, planning, reproduction, and so on.

One influential way to describe this transformation in state theory is Jessop’s (2002) distinction between the “Keynesian welfare national state” and the “Schumpeterian workfare post-national regime.” These terms are used to elucidate the state transformation that has occurred in the advanced capitalist economies over the past decades. The Keynesian welfare national state refers to the economic policies that clustered around the issue of fighting unemployment in a relatively closed economy. Here state intervention was intended to compensate for market failure. Moreover, it was a regime that sought to use the state to construct demand and create norms of mass consumption throughout state territory. The national was in this regime the primary scale in policymaking.

The “Schumpeterian regime,” which emerged in the 1980s, in turn, highlights innovation policies and policies of competitiveness as central public policies for coping with the purported “open economy.” Social policies become increasingly subordinated to economic imperatives and governance is invented to compensate for market failures. Scale-wise, this regime marks a relativization of scale. The Schumpeterian competition regime does not result in the evaporation of the national but rather it de-stabilizes its supremacy in policymaking (Jessop 2002).

Neoliberalization of the state

Neoliberalism, as a theory or ideology of market fundamentalism built on privatization, liberalization, deregulation, and neoliberalizations, as processes enforcing changes following these principles, were central to the way in which societies and states have been transformed in the last decades. In a broad sense, neoliberalization is a process of state restructuring under contemporary capitalism (Ward and England 2007). Scholars of neoliberal state transformation are concerned with the ways in which financialization, trade liberalization, boosting of internationalization, individualization, and the associated politics of entrepreneurialism, privatization, and increasing labor market flexibility have been articulated and enacted in policymaking. Here state power is understood as the primary catalyst of neoliberal globalization. The Italian political scientist Giandomenico Majone (1994) coined the concept of the regulatory state to highlight the fact that political re-regulation has been essential to the neoliberalization of the state. Neoliberal restructuring of the state has been possible only through projects in which
states engineer their own reform and in so doing rework their internal spaces and institutional matrix.

Not only is neoliberalism a multifaceted phenomenon that has been subject to mutation over time but there are also spatially variegated forms of neoliberalization. Given that the process is both historically and geographically contingent, it is critical to investigate the multiple and sometimes unexpected ways in which neoliberalism is domesticated in different contexts, through different sites and in particular conjunctures as well as how it coexists with other political rationalities. This is crucial for an understanding of how capitalism becomes sociospatially differentiated in different state contexts as inherited state structures and transnational policy processes get entangled.

Rescaling the state

Scholars interested in rescaling usually depart from the idea that state spatiality needs to be viewed as a complex expression of ongoing practices and associated processes of sociospatial regulation at various scales. Drawing from strategic-relational state theory, the American urban theorist Neil Brenner (2004) has made important contributions to the debate on the rescaling of the state. His synthesis on the “new state spaces” that emerged in the 1980s as a response to the crisis of Keynesian state strategies and associated North Atlantic Fordism is a careful empirical and theoretical work on the processes of state restructuring that have taken place in Western Europe during the past four decades. Following German theoretician of the state Joachim Hirsch, he contends that Western European states, through all sorts of policymaking and associated regulatory experiments, were increasingly becoming “competitive states” that foremost aim at restructuring society in the service of the competitiveness of national capital. In this process, one strategy has been the rising importance of subnational scales, that is, the local, metropolitan, and regional scale. Sociospatial transformation must thus be seen as a response to the crises of previous forms of regulation. Whereas some of the recent scaling activities of the state, which Brenner conceptualizes as rescaled competition state regimes, may facilitate economic growth, these attempts are also characterized by potential failures, uneven development, and sociospatial polarization.

Even though one who is writing from another welfare state context may question the argument that post-Keynesian states have abandoned the ideology of uniform territorial development altogether, and moved toward fostering the competitiveness of selected nodes in state space, Brenner’s approach (2004) is very insightful. The territorial state is understood here as an essential “geographical arena” and “agent” of the process often dubbed globalization rather than as a passive victim of it. One of the strengths of the rescaling approach is that it provides a vocabulary to analyze developments which take place today in, say, metropolitan governance as expressions of broader state rescaling processes which often aim at promoting territorial competitiveness rather than generating inter-territorial equalization. One may thus focus on the urban governance and urban policies to understand the state restructuring in the Organisation for Economic Co-operation and Development (OECD) sphere and beyond.

Spatial selectivity of the state

The rescaling of the state, which is motivated by neoliberal political rationality and associated regulatory experimentation and which marks the resurgence of the local and regional as sites of governance, indicates a growing “spatial selectivity.” Spatial selectivity refers to
the processes of spatial privileging and articulation in state strategies and related projects through which public policies become differentiated in state territory in order to target particular conceived scales such as the “European” or “global” (see Jones 1997). To illustrate, governments are investing lots of money to make new spaces, ranging from certain local transport infrastructures to various high tech areas, special economic zones, and convention centers in order to “go global.” Although these scaling attempts may be done for a variety of purported aims, they nonetheless accentuate the claims that local developments can be understood as components of global processes and that the “national” is actually one of the key sites for the “global.” The national features of state space can become de-nationalized through different kinds of spatial arrangements.

The spatial selectivity which manifests itself in different globalizing investments has often been motivated by policies of competiveness and other economic priorities. Spatial selectivity can be understood as resulting in “neoliberal exceptions,” that is, often highly economized spatial exceptions (such as “special economic zones”), which treat different segments of population differently in terms of rights and privileges (Ong 2006). The spatial selectivity of the state underscores the fact that state spatiality is never fixed. Rather, the spatiality of the state can be understood as a process of constant becoming which is underpinned by changing political rationalities and conditioned by political contestation, shifting power relations, and inherited spatial structures.

The everyday spaces of the state and nation: prosaics and embodiments

The state should not be understood as a “thing” which occupies a clearly separable sphere of the social whole. The state, conceived of as a coherent entity separate from society, has proved a remarkably elusive object of analysis. Geographers have sought to overcome the persistent state/civil society binary through inquiry into the everyday spaces of stateness/statehood. These everyday geographies point not only to the inescapably uncertain and potentially unexpected spatial outcomes of state-related actions but also to the potential spatial unevenness of state-effects (Painter 2006).

The everydayness of the state also alludes to the entanglement of “nation” and the “state.” For example, media, religion, education, and military are often examined in the context of national identity construction, indicating that the statization of people takes place through these “national” institutions and related practices. Accordingly, the nation is constantly connected to the state as an imagined collective actor in mundane symbolic practices such as festivities, commemorations, sporting events, food, shopping, and so on. The very foundation and functioning of conceived nation-states is dependent on these and many other mundane routines.

Over the past two decades, scholars drawing from different strands of feminism have significantly contributed to the spatial study of the state. They “embody” the nation-state, and demonstrate how the state is embodied in all sorts of social practices. The feminist scholarship is often in line with the previous arguments which challenge the conventional position of viewing the state as a coherent entity that exists independent of practices and configurations of the everyday.

Feminist scholars approach the state as a set of gendered and raced institutions and associated social relations and practices (Mitchell, Marston, and Katz 2003). They examine how gender and patriarchal relations make a difference to the state. The state is viewed as a form of potential
STATE, THE
domination – a complex mixture of social practices that are potentially spatially discriminating and marginalizing (Mountz 2004). The focus can be, for instance, on how particular gender identities are privileged in state strategies and how the structures of the state tend to reinforce gender biases.

Rather than treating the state and civil society as two distinct spheres, feminist scholars seek to make visible the fact that embedded power relations position individuals and groups of people in different hierarchical relations, with the state as an imagined collective actor. Some identities may become privileged and some others silenced or marginalized in the sphere of decision-making, planning, and political agenda setting. This is particularly the case in some policy sectors such as security policies. Feminist scholars thus destabilize the conceived coherence of the state by inquiring into the silenced voices and discussing, for instance, mundane aspects of security of the private (home) and the everyday spaces of the local. It is equally important to study “human security” related to issues like immigration or labor mobility rather than militarized and bounded versions of state security (Sharp 2007). The feminist approach thus challenges the militarization of states and attempts to develop a politics of security at the scale of the body.

The state/violence nexus

The modern state attempts to institutionalize and to stabilize a certain societal order in line with established class, gender, and race relations, thereby producing and continuously reproducing these very relations. In modern states one central method for effectuating this order is criminalization, that is, the defining of rules of allowed conduct in criminal law and their enforcement through the police, criminal courts, and the penal system – all in the name of security. As all these institutions, together often referred to as the criminal justice system, are state institutions, it is here that the state’s claim of the “monopoly of the legitimate use of physical force within a given territory” (Weber 1994/1919, 310–311, emphasis in original) or state power becomes most tangible.

On all stages of the process of criminalization a constant struggle occurs between social forces that aim at de-/criminalizing certain conduct. Think of the struggle to decriminalize homosexuality, or the status of the sans papiers (undocumented immigrants), feminist campaigns to decriminalize abortion and to criminalize domestic violence, or the struggle over what counts as legitimate social protest in public spaces. Also, a tension between fixed rules and regulations on the one hand and the flexibility of the discretion of individuals, for example, police officers or judges, can be observed.

Processes of criminalization also have a geography. The extent to which panhandling or demonstrations are tolerated or prohibited differs not only between states, but also within a territory depending on, for example, condensed relations of force within a city tending more toward “law and order” or more toward “social justice.” Whether a person is perceived as “out of place” and possibly dangerous based on her or his appearance is fundamentally geographical as well – and so is the police’s mental geography of possible dangers (Herbert 1997). While this mental geography and the discriminatory results of geographically uneven policing (“racial profiling”) were regarded as a problem during Fordism, with the neoliberalization of societal relations we can observe policing and police institutions increasingly turning to spatialized ideologies, technologies, strategies, and measures. Keeping the impoverished victims of neoliberalizations out of certain parts of the
city that are reserved for affluent residents, consumption, or higher education, for example, can be accomplished by criminalizing panhandling, loitering, or gathering. In such instances, state power is used in the service of particular interests and legitimized with security.

Investigating territorial and relational state spaces

The state can be understood in a number of ways. It is abstract yet concrete, a thing and a process, structuring practices and structured by practices, material and imagined, theorized and experienced. In recent human geography, these seemingly mutually exclusive characteristics have often been discussed under the rubric of “the relational” versus “the territorial,” with the relational being associated with poststructuralist, feminist, and network approaches, and the territorial with materialist and structural interpretations. Far too often, this has been presented as an ontological questions about how the world really is or how it should be (for some scholars, the issue of territoriality and relationality is a pressing political concern). This framing sometimes prompts superficial “articulations of change”: for instance, that the contemporary world is increasingly made up of networks rather than bounded state territories.

In contrast, the mutual exclusivity often constructed between these two perspectives needs to be overcome. Scholars have argued that social processes are more often than not relational and territorial at the same time, that the difference between the two is not ontological but practical, and that to understand the qualities of a phenomenon is a matter of ex post and empirical rather than a priori and theoretical engagement with it. Thus, network-related practices create state territory, but similarly territory-related practices create “state networks.” “Territory” and “network” are not separate or contradictory attributes of space.

An illustrative argument could be, for instance, that in spatial planning the concurrent presence of both territory and network is something unforeseen. Rather than taking the novelty of the coming together of territorial and relational as given, there is a need to engage in spatially and temporally sensitive scholarship that is interested in the intertwining of the relational and the territorial processes in different historical conjunctures (of modernity) and in different state contexts.

The challenge for geographical studies of the state is to examine the coming-together of the territorial and the relational in a variety of state-related social practices such as the metrics and indicators that measure competitiveness or creativity of places and states, education, policing, planning manuals, and so on. To meet this challenge requires empirical research on the coming-together of the interface of yet another binary, that of politics and economy, meaning that the distinction between the territorial and relational state spaces gets easily reinforced if economy is understood as inescapably relational (movement, networks, openness, inclusion, soft spaces, porous borders) and politics is conceived strictly as a matter of bounded territory (exclusion, spatial closure, hard spaces, fixity, borders, sovereignty).

Second, one of the possibilities for actually examining this coming together is to pay attention to the political rationalities that are in operation in state transformation and in the related process of policy formation. Such political rationalities can be investigated empirically, for instance, by examining various critiques of the territorial state. During the past two decades, such critiques have been aired by very different actors such as neoliberal globalization boosters, consultants promoting “sustained growth,” and
all kinds of urbanists and environmentalists. For instance, (global) city-centered arguments that governance based on territorial states should be replaced by city-network based governance and democracy (the so-called let the mayors rule the world thesis) have become increasingly salient, at least on both sides of the Atlantic.

Some have indeed been ready to suggest that intercity networks are rapidly taking over the interstate networks in global governance. In such a view, the territorial state is dysfunctional in contemporary world politics which is less based on command of territory than on capabilities to associate the state with “global networks.” This form of reasoning is often predicated on all sorts of “flow arguments” that highlight the economic and political significance of the so-called global cities as both critical circulatory infrastructures for growth and political command centers. In sum, the numerous critiques of the territorial state highlight the changing city/state relations as a nodal research topic for the geography of the state.

A third issue merits scholarly attention. The way in which state power is exercised through different kinds of assemblages/ensembles/apparatuses is an important topic for the geography of the state. Consider, for instance, the knowledge-based society ensemble as a form of government that seeks to govern life and spaces within states according to the conceived rules of the purported ubiquitous and borderless “knowledge-based economy,” which has been the dominant narrative of state transformation in the OECD sphere and beyond during the past two decades. In addition, an investigation of the different spatial imaginaries through which different kinds of assemblages/ensembles/apparatuses exercise power over life and spaces is an important topic that may provide insights on the progressive and regressive dimensions of the coming together of the territorial and relational spaces in contemporary state transformation.

Fourth and finally, examining the territorial-relational aspects of state transformation may open up new perspectives to understand the economization of the political and the associated processes of de-politicization. Again, there are many possibilities to study de-politicization. One may, for instance, study strategic (spatial) planning through an examination of the representations of space – such as maps. These representations may “sell” particular planning ideas as politically neutral devices and de-politicize neoliberal development within the state. In such a view, representations of space regulate thought and action by concealing motives, interests, and societal tensions. Another example of the study of de-politicization would be an inquiry into the role of different forms of management knowledge and the transfer and mutation of such knowledge in policymaking and in state spatial transformation more generally.

State-owned enterprise

F.Z.Y. Hu
Hong Kong Institute of Education, China

State-owned enterprises (SOEs), as defined in law and economics, refer to enterprises in which the right to use, to benefit from, and to transfer the assets within a firm’s organizational boundary accrue to the state in an abstract sense, albeit in reality this right is exercised by an ensemble of bureaucratic entities or government jurisdictions. The phenomenal rise of SOEs through large-scale nationalization programs during the decades following World War II was inseparable from disillusion with market fetishism, but the move to state ownership has taken on distinct forms and functions in different world regions (Toninelli 2000). In the developed world, SOEs were driven by the perceived need to correct market failure; in developing countries, SOEs more often served the purpose of post-independence governments seeking to achieve developmental goals. The significance of SOEs is particularly pronounced in former socialist economies, where they were the extension of the state redistributive regime to steer production, extract surplus, and organize society.

Since the 1980s, SOEs have become the subject of aggressive privatization (Megginson and Netter 2001). Neoliberal discourse ascribes the privatization of SOEs to potential efficiency gains resulting from a clearer definition of private ownership. Political-economy perspectives focus on the incentive structure of state bureaucrats and other related stakeholders in affecting the pace, form, and effect of ownership transformation in the state sector. While ownership matters for the growth and performance of SOEs, it is increasingly accepted that their functionality depends on prevailing political, social, and geographical conditions.

The conventional wisdom about SOEs, of a public versus private dichotomy, is challenged by the presence of variegated organizational forms taken by SOEs. Scholarly debate exists over the nature and implications of such hybrid or recombinant property forms. Some underscore the transitional nature of such intermediate property forms, positing their inevitable convergence on the conventional private ownership of liberal capitalism. Others, following a path-dependent treatment of SOEs, advocate the search for a theory of state capitalism as an alternative to the hegemonic project of neoliberalism.

The growth trajectory of China’s SOEs has presented itself as a rare and valuable way to interrogate the received wisdom on the necessity of getting the institution right in order to foster development (Whyte 2009). Whereas the recent rise of China’s SOEs on both the domestic and the global economic stage is interpreted by neoliberal proponents as hindering the growth of private entrepreneurship and long-term sustainable development, others acclaim state ownership of firms in the Chinese economy as the core feature of a successful alternative development model to the Washington Consensus, one with normative implications for the world’s developing countries.

States

There are a variety of definitions of what constitutes a “state” and also many theories about their purpose and nature. For Strange (1996) states are institutions to mediate and resolve conflicts. However, this arguably neglects how states initially, and the interstate system more generally, came into being, often through war. For Jessop (2002, 6), however, states are social relations. For him the state is “an ensemble of socially embedded, socially regularized and strategically selective institutions, organizations, social forces and activities organized around (or at least selectively involved in) making collectively binding decisions for an imagined political community.” The extent to which this applies to “weak” or “failed” states in parts of the Global South can, however, be debated.

States serve, or are often meant to serve, a variety of functions including the provision of security and public goods, management of the economy, and the reduction of inequalities generated by and through markets. However, different states have different emphases even if most states around the world are now capitalist, in the sense that they generally serve to promote economic growth and capital accumulation for reasons of legitimation, collective good, and sometimes the self-interest of officeholders.

Development

For mainstream analysts development is synonymous with economic growth, industrialization, and modernization. However, as noted previously, the term “development” is also highly contested, with some arguing that this ideology is in effect a Trojan horse for a neocolonial or imperial project. For others, development can be both a project and a process.

The “age of development” is sometimes traced to US president Harry Truman’s speech in 1949 when he argued that “We must embark on a bold new program for making the benefits of our scientific advances and industrial progress available for the improvement and growth of underdeveloped areas.” Despite the contested nature of the term, “development” has arguably become the central mission, rationale, and justification for the existence of states in the Global South. Indeed there has been a substantial amount written in recent decades on a purportedly new genus of states – developmental ones (Wade 2004; Amsden 1989).

The role of the state in development

For some scholars the nature and role of the state are the central issue in international development. For example, Acemoglu and Robinson (2012) argue that where colonial institutions have been more fully implanted the result has been more successful development. This perspective feeds into the debate in economics about whether institutions or geography matter more for developmental outcomes. However, this neglects the fact that institutions are
States and Development

geographical, in the sense that they are both associated with geographical territories and interscalar relations and help to constitute them. More recently, others have argued that it is policies, rather than institutions or physical geography, that matter most for economic development outcomes. However, this perspective might be questioned for its methodological nationalism and geographical theorization. Relations between places shape policies, as do the particular socioeconomic and physical geographies of nation-states. Nonetheless, the state remains a central ensemble of institutions and practices or an “actor” in the (under)development process.

In the immediate postcolonial period for Africa and much of Asia there was extensive optimism about the role that the state could play in development. This was, in part, based on the successes of postwar rebuilding in Europe under the auspices of Keynesian welfare states. Some of the most influential theories about the role of the state in development included those of Rosenstein-Rodan (1943), Hirschman (1978/1958), and Myrdal (1968). These different theories emphasized the importance of the state’s promotion of development through planning and the expansion of manufacturing, in particular, which was seen to be more technologically dynamic, to create higher value-added, and to have greater employment potential. Rosenstein-Rodan’s “big push” theory argued that both capital and consumer goods industries should be developed simultaneously to allow for complementarities, market creation, and economies of scale. Somewhat later, Thomas (1974) argued that there were “basic industries,” such as intermediate goods ones, which had the greatest potential for value addition and economic transformation.

The Latin American structuralist school of economics argued that the imperative for economic development was to engage in import substitution of manufactured imports from the United States and Western Europe in order to diversify and develop economies. While the raising of tariffs and import quotas and bans did protect domestic markets, it raised costs and was often import-intensive in terms of capital goods, contributing to debt accumulation. The raising of costs and the limitations of small domestic markets also meant that economies of scale were also often not realized, further reducing efficiency, unless complemented by measures to promote exports, as was the case in the successful newly industrializing countries of Asia. In some of the most successful newly industrialized countries of Asia, stepwise policies of primary import substitution were followed by primary export promotion and then secondary import substitution of more technologically advanced and capital intensive industries.

While the World Bank was willing to selectively support policies of import substitution until the early 1980s, under Robert McNamara that institution promoted state-led development strategies in the 1970s focusing on “basic needs,” such as water provision and integrated rural development. These twin foci were later to reappear in different guises in the emphasis on health and education in the World Bank and International Monetary Fund (IMF) Poverty Reduction Strategy Papers from the late 1990s and the Millennium Villages Project supported by the United Nations Development Program. The World Bank sometimes engaged in historical amnesia, with its staff critiquing projects such as the Morogoro shoe factory in Tanzania, which never operated at more than 5% of capacity and was meant to export shoes to Italy, even though the Bank itself had funded this project.

Both modernization theory and heterodox structuralist approaches placed a heavy emphasis
on the role of the state in development. Both shared an underlying assumption that states would be rational, Weberian actors which would promote development. However, with sometimes poor performance and the economic crises of the 1970s and 1980s, this optimistic view of the role of the state generally gave way to more sanguine, pessimistic, or restricted views of the role that these institutions could or should play in promoting development.

Rethinking the state’s role in development: “overdeveloped” and “neoliberal” views

After the initial postindependence optimism about the role which the state could play in guiding and promoting economic and social development, some social scientists began to question earlier, positive managerialist (Weberian) conceptions of the state. Neo-Marxian theories were developed which posited an alliance between domestic capitalist classes, bureaucratic elites, and international capital and great powers which perpetuated economic underdevelopment, or in the case of Brazil “dependent development.” For Hamza Alavi (1972) the underdevelopment of the domestic bourgeoisie in postcolonial societies resulted in an “overdeveloped” state which was relatively autonomous in relation to its own society but heavily influenced by the needs of, and responsive to, international capital. In relation to Africa, the “Kenyan debate” was about whether the state was primarily responsive to the domestic or international fraction of capital. Later work emphasized the importance of the domestically based, but “nonindigenous” bourgeoisie of Asian extraction.

While cynicism about the role of the state in the economy is often traced to the Reagan and Thatcher “revolutions” in the United States and United Kingdom respectively, and the intellectual currents associated with these and their precursors, there was also, as noted earlier, substantial left-wing criticism of actually existing states in the Global South. These concerns, from both left- and right-wing perspectives, were to come to a head with the Latin American debt crisis of the early 1980s.

The global economic turbulence of the 1970s and the abandonment of the Bretton Woods system of fixed exchange rates, the second oil crisis, and the Mexican debt default created conditions whereby many developing countries experienced economic crises and severe difficulty in accessing private international capital markets. Many countries were consequently forced to turn to the World Bank and IMF for balance-of-payments support. In exchange these international financial institutions demanded wide-ranging programs of economic liberalization be implemented. Fundamentally these, at least in the initial stages, were about reducing the role of the state in the economy, so that it would function as a “nightwatchman” over the market, which it was felt would drive development.

According to the World Bank, officials at the IMF and also a number of academics took the view that the economic crisis in much of the developing world in the 1980s was an outcome of inappropriate economic policies, which protected inefficient domestic industries and were biased against rural development and exports. It was argued that these policies were designed and perpetuated, not because of their inherent public merit, but because of the “rent-seeking” opportunities they afforded state elites and their cronies. In order to discipline the state and force “economic efficiency,” it was argued that privatization, trade liberalization, monetary tightening, and other policy reforms should be instituted. This neoliberalization was paradoxical
in that it was a process of the global deregulation of capital through the international regulation of states, and indirectly driven by the world’s most powerful states, such as the United States, through their voting weight and influence in the international financial institutions.

The impacts of programs of economic liberalization varied depending on the specific geographical political economies undertaking them. They were generally more “successful,” in their own terms, in countries in Southeast Asia for example, where there was a regional product cycle at work. However, where this was not operative, they often resulted in competitive displacement of manufacturing production and social immiseration, particularly in much of Latin America and Africa during the “lost decade(s)” of the 1980s and part of the 1990s.

State failure, violence, and underdevelopment

The programs of economic liberalization sponsored by the World Bank and IMF were known as “structural adjustment programs” (SAPs). While the reasons for their general failure in the developing world have been explored extensively in the literature, the effect on states varied depending on the economic context and the balance of social forces. In cases of previous state collapse, a “trough factor,” where in effect the only choices were continued disorder or state reconstruction, was sometimes observed. In some cases “strong states” emerged, as in Ghana and Ethiopia for example, which were able to take advantage of inflows of hard currency associated with structural adjustment to relieve foreign-exchange constraints on economic growth. In other cases however, the cutbacks in government expenditure associated with fiscal rectitude under SAPs resulted in the dissolution of the “patrimonial glue” which held some extant regimes together, fomenting disorder. In some instances these dynamics fed into the creation of transborder crisis complexes, for example in West and Central Africa.

From a rational choice perspective Bates (2008) argues that state rulers are “specialists in violence” who may choose to deploy it either to prey on wealth or to protect its creation. Despite conditions of often intense poverty and the incentives it creates for conflict, such as the lowering of opportunity costs for youth to engage in violence, African rulers tend to remain in power longer than those in other world regions. In part this is because of the way in which they are able to leverage external resources, such as aid or inflows of foreign currency from natural resources, into internal authority. In many developing countries, regime maintenance rather than economic and social development is the primary goal of state regimes, despite public pronouncements to the contrary. This often results in unstable social formations, however, as state hegemony is not secure.

Developmental and catalytic states

The general failure of structural adjustment to achieve economic transformation in the developing world led to increased academic interest in a variety of other state models, particularly those of the newly industrialized countries of East Asia (Amsden 1989; Wade 2004). It was argued that these states had succeeded by deliberately creating economic incentives which deviated from those of the “free” market – “getting prices wrong” (Amsden 1989), channeling finance to fast-growing industrial sectors, and adopting a variety of other policy interventions to deliberately steer industrialization. According to Amsden and
Wade, developmental states are characterized by insulated, meritocratic, yet embedded bureaucracies. Others characterize the social relations of developmental states as “embedded autonomy,” where the bureaucracy is embedded in and responsive to, but largely autonomous from, rather than captured by, societal interest groups (Evans 1995). According to Woo–Cumings (1999, 27), “such economic and political relationships often imply a corporatist framework, involving large economic groupings (like the keiretsu, corporate conglomerates in Japan, or the chaebol, their equivalent in South Korea) with which the state can coordinate and negotiate investment decisions.”

In an evolution of this literature Linda Weiss (1998) argued that states in Europe, East Asia, and elsewhere continue to play a vital role in the promotion of economic development. She coined a new category of states – catalytic ones – which facilitate and guide private sector development rather than being highly directive as in the developmental state model. In light of the revisionist thesis promoted by authors such as Amsden and Wade, and partly at the instigation of the Japanese government, the World Bank also began to revise its conception of the appropriate role of the state in the economy in the 1990s, arguing that states should match “capabilities” with “roles.” However, this ignored the possibility of how to build state capacities; one of the most important questions in international development. In practice, however, it has supported the work of, among others, the African Capacity Building Foundation, which works to develop national statistical or financial management capabilities, for example.

One of the key, and often neglected, factors in the emergence of developmental states is either an internal or external security threat which incentivizes state elites to develop the economy as a source of legitimation and funding stream for the military. In Africa the developmental states of Rwanda and Ethiopia are dominated by minority ethnic groups who have experienced genocide, for example. However, this state strength may be implicated in the perpetuation and deepening of state weakness in other countries. For example, the Rwandan government has repeatedly invaded the neighboring Democratic Republic of Congo and has been implicated in support for rebel groups in the east of the country. This is another important reason to avoid the “territorial trap” of methodological nationalism when considering state forms in the developing world.

There are also a variety of models in development not captured by the state/market dichotomy. For example, some scholars have also written about the role which civil society can play in the coproduction of (public) goods and services (Tendler 1997). For Tendler the key to effective, development-oriented governance may be “synergy” between different social forces and actors. Brazil has also been marked by state innovation at a national level through programs such as Zero Hunger. The Brazilian state can be characterized as a hybrid neoliberal–developmental or neostructuralist one, where macroeconomic policy follows economic orthodoxy but microeconomic and social policy is more interventionist.

Globalization: the rise or retreat of the state in development

The nature and role of the state in development is fundamentally related to globalization. However, globalization is not a static process but a dynamic one involving rapid evolution in the forms of sociospatial relations. The rise of China in the international political economy has reconfigured the nature of globalization, given the still strong
role of the state in the economy there and the prominent role which state-owned enterprises have played in that country’s “Go Out” policy to promote investment by its companies overseas.

There has been a debate about the nature of the Chinese state. It has been variously characterized as developmental, neoliberal, neo-Stalinist, market socialist, or fragmented authoritarian. Even as it has liberalized its economy domestically, the Chinese government has expanded its spatial reach overseas through its state-owned corporations, respatializing rather than reducing the power of the state. This new model of globalization, which is state-promoted, not only calls into question the ontological distinction between “states” and “corporations” as separate social forces, but also the posited opposition between the power of states and “globalization.” Most of the 89 Chinese corporations in the Global Fortune 500 are state-owned. One of the most influential works which questioned the separation or distinction between state and society is Migdal (2001).

While many analysts now agree that states have a vital role to play in promoting economic and social development, the extent to which they can do this depends on their particular configuration. A central axis of debate is the nature of the state: whether it is hard (has the ability to enforce its will) or soft (ineffective and reluctant to challenge powerful social forces) (Myrdal 1968). Other axes of debate center on whether or not states or societies are “strong” or “weak” in relation to each other. This approach also suffers from methodological nationalism, by not interrogating which social forces are designated by such terms. For example, authoritarian states may be “strong” in relation to their domestic societies but weak relative to international capital.

Actor-network theory provides a more nuanced characterization of states as assemblages of institutions, practices, actors, and artifacts. Under conditions of globalization such a perspective allows us to examine the constitution of particular states and how they may be differentially and selectively internationalized (made responsive to international forces), for example. Geographers have also recently theorized the spatiality of state networks and sovereignty using assemblage theory, arguing that, under conditions of globalization, with a shift from “government” to “governance,” a primary characteristic of states is that they possess “reach,” not “height” (Allen and Cochrane 2010). In this theory states are not “national” but operate through multisite power relations and assemblages, and consequently development outcomes depend on the nature of these interactions and the power capabilities of other actors.

Different world regions have given rise to different theorizations of the state. For example, in relation to Africa much has been written about neopatrimonial or rhizome states, which have patronage networks through society in a root-like fashion but fail to achieve state hegemony because of their inherently exclusionary nature. Other influential theories related to the African context include those of the “suspended” and “bifurcated” state. In the East Asian region the central theory in recent decades has been the developmental state. However, with the advent of network trade, where components for manufactured products are often sourced in multiple different countries and then assembled in a low-wage economy before being exported for consumption, some have questioned whether this model still applies in the original newly industrialized countries. Others have also questioned the opposition between patrimonialism and developmentalism, arguing that some states in Africa are characterized by developmental patrimonialism.
Despite widespread neoliberalization across much of the developing world, the role of the state in promoting economic diversification and improved living standards and the ways in which it may hamper or prevent these outcomes are still some of the most debated topics in the international development literature. The “rise” of China and the South, more generally, is creating a new macro-political region – a “South space” – which has greater policy latitude and autonomy from the international financial institutions of the World Bank and the IMF. This greater policy autonomy which countries across the Global South are experiencing may not fundamentally challenge neoliberalism, but it could lead to its renegotiation through resource nationalism, whereby resource-rich states capture greater shares of resource rents and revenues. Some refer to this conjunction of events as providing scope for neodevelopmentalism.

As noted at the beginning of the entry the terms “state” and “development” are highly contested. Globalization and the widespread shift from government to governance as a modality of authority and rule have troubled the notion of the state as an ontologically distinct actor (if it ever was). What constitutes development has also been debated and redefined, and looming climate disruption and ecological constraints raise the issue of the sustainability of carbon-intensive global industrialization. What constitutes development is arguably partly about values and what different people may consider to be worthwhile. New metrics, such as Gross National Happiness or the Happy Planet Index, suggest that less attention should be paid to traditional indicators of “development” such as increases in economic output and more to ecological and social sustainability.

Strategic essentialism

Raksha Pande
Newcastle University, UK

“Strategic essentialism” is a term coined by Gayatri Chakravorty Spivak, a postcolonial feminist philosopher and literary theorist who is currently University Professor at Columbia University. She is an eminent thinker in the fields of postcolonialism and subaltern studies. Strategic essentialism can be understood as a deconstructive strategy of representation that involves taking the risk of adopting an essentialist position with respect to identity categories, or as Spivak (1993, 3) calls them, “masterwords” (such as woman, worker, nation, or the subaltern), in order to mobilize a collective consciousness for achieving a set of chosen political ends. The genesis of the term follows her central academic pursuit of exploring the role of representation in subject constitution. Along with the notion of the subaltern, strategic essentialism has been hailed as one of the most significant theoretical contributions of subaltern studies. It has been adopted as a slogan for identity-based politics and remains an important and contested theme within feminism.

Strategic essentialism: epistemological origins

Spivak first uses the term in her analysis of the works of the Subaltern Studies Group, a Marxist history collective of Indian scholars engaged in reclaiming Indian history from its elite imperialist versions and moving towards a historiography that gives due credence to the previously unheard voices of the subaltern – the so-called underclass of Indian society, including the peasants, Dalits, and women. In reading the work of the group “against the grain” (Spivak 1988a, 10), she interrogates the representational tactics employed in the writing of history from below. She argues that in their attempt to restore the subaltern as the subject of their history, the Subaltern Studies Group can, at first glance, be seen as embracing an essentialist position, one that assumes a stable, foundational essence as characterizing the nature of the subaltern subject. Spivak uses deconstruction as her approach to critical analysis, and posits that there is no such thing as a stable subject but only “subject-effects” brought into existence through complex networks of politics, ideology, economics, history, sexuality, and language (1988a, 13). Consequently, the subject-effect of the subaltern is brought into being through the writing of their history by the well-meaning historian, and essentialism guides the epistemology through which this subject position is restored; however, she explains that this is not substantive/positivist essentialism, which homogenizes the subject as its essence (the subaltern studies collective is well versed in the nonfoundational poststructuralist philosophies), but a strategic one, which encourages “a strategic use of positivist essentialism in a scrupulously visible political interest” (Spivak 1988a, 13). For example, in representing the history of the peasant uprising
in pre-independence India, the historians can be seen as establishing a subject position, namely that of a collective subaltern or peasant consciousness, as the focus of their inquiry. In so doing, they strategically presume the stability of that subject position (akin to an essentialist approach) in the political interest of retrieving the hitherto unheard stories of the subaltern role in the Indian independence struggle and also in critiquing the elite histories that omit them from any account of the Indian past. This essentialism is strategic because it is self-conscious and is always attuned to its “constitutive paradox,” which evokes that the object of historiography is not reducible to the essence of subaltern (1988a, 13), but at the same time it also involves taking the risk of essentialism in order to have collective political purchase. Strategic essentialism also involves the methodological presupposition that the strategically essentialized subject position is marked by “a negative consciousness – the consciousness not of the being of the subaltern but of the oppressor.” Moreover, the strategic restoration of a unified or essentialized subaltern consciousness is done with the knowledge that in the task of representation the subaltern consciousness “is subject to the cathexis of the elite” and it is never fully recoverable beyond its discursive origins, since “the subaltern cannot appear without the thoughts of the elite” (Spivak 1988a, 11); or, in other words, the subaltern cannot speak (Spivak 1988b).

Strategic essentialism can be seen as the hallmark of a “negotiated postcolonial positionality” (Spivak 1990, 72), which involves strategically intervening in the constitutive discourses (for example essentialism, colonialism) of the identity positions inhabited as a colonial or marginalized subject. Homi Bhabha (1994, 6) has called this positionality an “in between” or “hybrid space,” which allows a more complex ontological basis for understanding the material and discursive aftermaths of colonialism and Western domination. The notion of hybrid space has been highly influential in postcolonial human geographical approaches calling for alternative geographical imaginaries that recognize the complex web of relations that characterize the interconnections between the Global North and Global South (Raghuram, Madge, and Noxolo 2009). This strategy also reveals the limits of Western poststructuralist critiques of the essentialized subject, where the author is either engaged in granting the “very expressive subjectivity” to the oppressed, which she or he critiques as being discursive, or failing that, arguing for a “total unrepresentability of the marginalized subject” (Spivak 1988a, 17). According to Spivak, neither approach leaves much room for political agency and change. Instead, strategically adhering to the essentialist notion of identity categories provides a “transactional” reading of the subject (1988a, 15) where a stable, unified essence for identity categories (contextual to practical exigencies) is accepted in exchange for collective political mobilization. In other words, Spivak (1990, 45) acknowledges the impossibility of escaping an essentialist understanding of the productions of our beings and consequently advocates that we recognize and strategically “carve out a representative essentialist position” in order to “do politics according to the old rules” while staying attuned to the dangers of universalism that arise from adopting such a position.

For Spivak, all historiography, and by extension all acts of representation, can be better conceptualized as strategy (Spivak 1988a, 15) – one that determines to what extent the author chooses to embrace the notion of a stable and unified subject, and to what political end. On a wider scale, she offers the strategic essentialism of the subaltern studies groups as a representational
strategic essentialism in human geography

Within human geography, strategic essentialism can be read in the works of feminist geographers. Whether it was the initial calls for gender equality in the academy or the demands for establishing gender relations, sexuality, family, home, and the so-called irrational subjective notions of the body and emotions as legitimate topics of geographical scholarship, feminist geographers have strategically employed their subjectivity as women to expose and critique the hegemony of masculinism in the discipline (Rose 1993). The works of the Women in Geography Study Group (WGSG), for instance, can be seen as a very successful example of strategic essentialism in practice where, through their insistence on telling women’s stories (and provisionally accepting the stability of the identity category “women”) in geography, they have helped to dismantle the elite masculinist traditions of academic geography.

Gillian Rose’s arguments in the path-breaking book *Feminism and Geography: The Limits of Geographic Knowledge* can be seen as the most cogent example of strategic essentialism in practice within geography. Although she does not use the term herself, her manifesto for an emancipatory geography, which empowers women in favor of the extant masculinist epistemology of the discipline, has all the hallmarks of a strategic approach to essentialism. In interrogating the nature–culture dualism, which has fed the masculinism of academic geography, her vocabulary is redolent of strategic essentialism, with references (1993, 78–85, 159) to “strategies of critique,” “other tactics,” and “master subjects” in suggesting what an alternative geographical imagination that allows for thinking space beyond dualisms may look like. Her proposal for a feminist politics based on the strategy
of “paradoxical space” – which “straddles the spaces of representation and unrepresentability” (Rose 1993, 154) – shares the central paradox of strategic essentialism, which posits that although essence as identity (woman) is being mobilized for political ends, the subject is heterogeneous and never reducible to her essence. Her “paradoxical geography” thus allows for understanding the subject of feminism as “that of both prisoner and exile” (Rose 1993, 155) – prisoner of the essentialist category “woman” but also exiled from that essentialism in insisting on the possibility of resistance, which in its emancipatory intent will lead to the dismantling of the stability and unity of that category. This “strategy of oscillation,” or strategic essentialism (Rose 1993, 152), between the categories of self and other, inside and outside, center and margins, allows for a more politically flexible and vigilant feminism and geography.

The “hybrid spaces” (Bhabha 1994, 6) that characterize the oscillation and blurring of sharp distinctions between the center and margins have also been the focus of postcolonial human geographical approaches to development. For example, in their critique of the neoliberal discourses of development, Raghuram, Madge, and Noxolo (2009, 5) offer “care” and “responsibility” as an alternative vocabulary to developmentalism. Their focus on discourses of care and responsibility, instead of the ethnocentric vocabulary of development and aid, is aimed at revealing the power relations underlying neoliberal approaches to development where the Global South is imagined as the developing margins with the developed Global North as the center. They call for transcending the margin–center distinction by recognizing the “postcolonial intimacies” and interdependencies that characterize the relationship between the Global North and Global South. This approach involves inhabiting a “negotiated postcolonial positionality” (Spivak 1990, 72), which involves inhabiting one’s location always in relation to the other – as a relationality that posits that “all of us are already implicated in each other’s ‘presents’ in complicated ways” (Raghuram, Madge, and Noxolo 2009, 9).

A paradoxical positioning with respect to identity categories such as “race” is also evident in the work of geographers examining the viscosity of the categorization of racial identities (powered by biological essentialism) while also accepting the nonfoundational and socially constructed nature of such identities (Tolia-Kelly and Crang 2010).

When she first “began to write as a feminist,” Spivak (1993, 17) supported thinking strategically in feminist practice by choosing essentialist discourses of the category “third world woman,” for example, in order to articulate a voice and representational tactic for those on the margins of Western bourgeois feminism. Such politics of location within feminism has been expressed in the works of feminist postcolonial geographers such as Richa Nagar (2002), who have attempted to clear “a representative space” (Spivak 1990, 46) for the “third world woman” by simultaneously deconstructing this subject position and showing how it is symptomatic of the cathexis of Western feminists, while in the same vein also using the identity category and location as a third world feminist to argue for a feminist politics of difference. Here, a critical awareness driven by strategic essentialism finds a way of using essentialism as a discourse for achieving the political ends of representation and voice without making an overall commitment to these concepts.

In spite of the fact that the term “strategic essentialism” has been enthusiastically embraced as a slogan for progressive identity politics both in the academy and in the world beyond it, its critical edge has been dulled over the years, so much so that Spivak (1993, 17) now rejects the term,
saying that for her “like most strategies … it has served its purpose” and her “feminism now takes a distance from that debate.” In its wide-ranging adoption, strategic essentialism has lost its deconstructive strain and at its best has become a reference for coming to terms with the inevitability of essentialism in feminist and postcolonial discourses. At its worst, essentialized understandings of cultural difference have now replaced essentialized understandings of gender, where strategic essentialism is used to signal the feminism of the other woman. This approach has also had the unwitting effect of fragmenting the feminist movement. The notion that “the personal is political,” Spivak argues, has been understood, at least in the US academy, as something like “only the personal is political” (Spivak 1993, 4, original emphasis), where strategic essentialism is understood as only being able to speak from one’s own ground, rather than strategically moving between the personal and the collective, depending on what the particular situation at hand demands.

The notion of strategy from which the term derives much of its transactional import has been forgotten while the term is adopted and adapted as another postcolonial theory of difference. For Spivak, strategic essentialism is a strategy, not a theory, most effectively employed as a provisional enterprise in conducting a deconstructive critique of the theoretical, the ultimate goal of which is: “Not to arrive at a point where one no longer says I, but at the point where it’s no longer of any importance whether one says I or not” (Spivak 1988a, 18).

STRATEGIC ESSENTIALISM

Ozone is a gas naturally present in the Earth’s atmosphere. Its molecule consists of three oxygen atoms (O$_3$). Ozone concentration is largest in the stratosphere, a region in the atmosphere at approximately 10–50 km, depending on latitude and season. The so-called ozone layer in the stratosphere contains about 90% of atmospheric ozone. Even in this region, ozone’s abundance is very small, not exceeding 8 to 10 molecules per million of air molecules. Yet, ozone is one of the key species in the atmosphere, since it protects life on Earth by filtering out damaging ultraviolet (UV) radiation from the sun. Ozone is the main atmospheric constituent that absorbs solar radiation in the UV-B band (280–320 nm), protecting living organisms from direct DNA (deoxyribonucleic acid) damage. Before the appearance of ozone in the Earth's atmosphere, living organisms could only survive in marine environments, and it was only after the ozone layer was formed about two billion years ago that life could expand at the surface.

While ozone in the high atmosphere is beneficial to life, it is also a powerful oxidant. Its oxidizing properties make it a potent respiratory hazard and pollutant. At ground level, it can be formed by chemical reactions between air pollutants emitted by vehicle exhaust and human activities. High concentrations of ozone (e.g., larger than 90 molecules per billion of air molecules) are toxic to people, animals, and plants. Ozone can thus be considered as good or bad for life on Earth, depending on its location in the atmosphere. The vertical distribution of ozone in the atmosphere is displayed in Figure 1.
At the end of the twentieth century, the discovery that man-made chemicals, referred to as ozone-depleting substances (ODSs), could destroy stratospheric ozone stirred international concerns about the possible impact of human activities on the Earth’s atmosphere at a global scale. Such a decrease of stratospheric ozone abundance would induce an increase in UV radiation at ground level, dangerous for human health. ODSs include various gases produced by the chemical industry, such as chlorofluorocarbons (CFCs) and halons (organic compounds containing bromine atoms). They were used as refrigerants, solvents, blowing agents for plastic foam manufacture, fire extinguishers, or aerosol propellants.

ODSs are very stable and, once released into the air, degrade very slowly. They can remain intact for many years until they ultimately reach the stratosphere through atmospheric transport processes. In the stratosphere, they are broken down by the more intense UV radiation at this altitude range, and release reactive chlorine and bromine molecules that are involved in the ozone destruction catalytic cycles. Ozone chemical loss is thus increased, which induces a thinning of the ozone layer.

The discovery of the so-called ozone hole in the mid-1980s (Farman, Gardiner, and Shanklin 1985) heightened the general concerns about the fate of the ozone layer. This phenomenon, which is still observed today, corresponds to an important decrease (larger than 40%) of ozone total column during the springtime over Antarctica. Satellite measurements show that the ozone hole covers an area larger than the Antarctic continent. At the time of discovery, this decrease was far larger than the natural year-to-year variation in monthly averaged total ozone. In situ measurements of ozone by balloon soundings also show a near complete disappearance of ozone molecules in the lower stratosphere, between 16 and 20 km, at an altitude range where ozone concentration is at its maximum, over Antarctica.

The elucidation of the specific mechanisms that lead to the rapid disappearance of ozone in the Antarctic lower stratosphere during the springtime took a few years after the discovery of the ozone hole. Aircraft and ground-based observation campaigns were carried out, which allowed the scientific community to identify the main culprits. It was shown that the destruction of polar ozone during austral spring required (i) increased concentrations of chlorine and bromine species in the stratosphere, (ii) very low temperatures in the polar stratosphere in winter, and (iii) the return of sunlight above Antarctica at the end of the winter.

The existence of very low temperatures in the austral stratosphere in winter is due to the formation of the polar vortex, a persistent and large-scale cyclone hovering over the pole. Strong westerly winds isolate the polar air masses, which then cool to temperatures lower than $-80^\circ$C. In this extreme environment, polar
Stratospheric and tropospheric ozone

Stratospheric clouds are formed and chemical reactions at the surface of cloud particles liberate active chlorine species, in much larger quantities than in any other stratospheric regions. When solar radiation reappears above the pole at the end of winter, it initiates rapid catalytic chemical cycles that destroy ozone at a rate of a few percent per day. By the end of September, total ozone content has decreased by more than 50–60% within the polar vortex. The polar stratosphere then warms gradually, stopping the ozone destruction processes, and the breakup of the polar vortex at the end of spring dilutes the poor ozone air masses into the whole Southern Hemisphere. Since the early 1980s, the ozone hole over Antarctica has become a recurrent seasonal feature of the austral climate. As an example, the average ozone hole in September 2014 is displayed in Figure 2. After a regular increase up to the end of the 1990s, the size of the ozone hole area has stabilized at around 20–25 million km².

In the Arctic, similar processes occur but seasonal ozone losses are much smaller, due to the higher temperature conditions in the arctic stratosphere in winter. The arctic polar vortex is less stable than its Antarctic counterpart, due to the different configuration of continents in both hemispheres, and is generally warmer. The largest arctic ozone depletion to date was observed in the winter 2010/2011. Exceptionally cold meteorological conditions throughout the whole winter led to a record total ozone loss of about 40% (Manney et al. 2011). At a global scale, evidence was also found of a thinning of the stratospheric ozone layer due to elevated ODS abundance. Ozone decrease was observed up to the end of the 1990s in the lower and higher stratosphere. According to the last scientific assessment of the ozone layer, current average ozone levels are about 3.5% lower than those measured before 1980 over the 60°S to 60°N latitude range. The decrease is largest in the Southern Hemisphere mid-latitudes with a reduction of 6%, compared to 3% in the Northern Hemisphere. Ozone reduction in the tropics is very small (WMO 2014).

In order to regulate the emission of ODSs, the Montreal Protocol on Substances that Deplete the Ozone Layer (MP) was signed on September 16, 1987, in Montreal, Canada. It entered into force in 1989 and was amended several times up to 2007. The MP is the first environmental treaty to reach global ratification (UNEP 2015). Due to its widespread implementation, it has been hailed as an example of exceptional international cooperation. The protocol and its successive amendments have led to the near complete phase out of the production and consumption of ODSs in developed countries. The main regulated compounds

Stratospheric and Tropospheric Ozone

are chlorofluorocarbons CFC-11 (CCl\textsubscript{3}F) and CFC-12 (CCl\textsubscript{2}F\textsubscript{2}), carbon tetrachloride (CCl\textsubscript{4}), halon 1211 (CF\textsubscript{2}BrCl), halon 1301 (CF\textsubscript{3}Br) and methylchloride (CH\textsubscript{3}Br). These products have been replaced by hydrochlorofluorocarbons (HCFCs), which are much less toxic for the ozone layer. HCFC molecules contain a hydrogen atom and are thus mostly dissociated in the troposphere. The hydrofluorocarbons (HFCs), substances that are harmless for the ozone layer, now replace HCFCs: unlike CFCs and HCFCs, HFCs do not contain chlorine that depletes the ozone layer. Thanks to the MP and its amendments, the abundance of ODSs in the atmosphere is now decreasing after a peak reached in the mid- to late 1990s, depending on latitude. Yet, due to their long lifetime in the atmosphere (e.g., 100 years in the case of CFC-12), the return to levels below the abundance observed in 1980 will not occur before 2040. The recovery of the ozone layer will thus follow this path, and ozone levels are projected to increase slowly in the course of the twenty-first century.

Stratospheric ozone depletion and climate change

Climate change and ozone depletion are separate yet intrinsically linked issues: climate change influences ozone recovery while ozone depletion has influenced climate change in the troposphere, mainly in the Southern Hemisphere. Increased greenhouse gas abundances induce a cooling of the stratosphere. This cooling is caused both by less infrared terrestrial radiation reaching the stratosphere as it is absorbed in the lower atmosphere and larger infrared emission to space by carbon dioxide in stratospheric thermal conditions, which cools the local environment. Ozone depletion itself has induced a cooling of the stratosphere, since the formation of ozone heats that region. In the polar stratosphere, the cooling enhances the formation of polar stratospheric clouds, thus reinforcing ozone destruction processes. In the higher stratosphere, the cooling slows down ozone destruction reactions and acts as a self-healing effect, which accelerates ozone recovery. Climate change can also affect the meridional circulation that naturally transports ozone from the tropics, where it is formed, to the higher latitude regions. Current climate model simulations indicate that climate change will accelerate this meridional circulation inducing a super-recovery of ozone at high latitude and a decrease of ozone in the tropics. On the other hand, ozone depletion has altered the surface climate, particularly in the Southern Hemisphere. The most notable effect is a southward shift of the jet stream in summer. In addition, winds above the austral ocean have intensified and contrasted temperature trends have been observed on the Antarctic continent in summer, with a warming across the peninsula and a cooling on the plateau (WMO 2014).

Tropospheric ozone

As in the stratosphere, tropospheric ozone is formed from the recombination of an oxygen atom with an oxygen molecule. But in the troposphere, the main source of oxygen atoms is the photolysis of nitrogen dioxide (NO\textsubscript{2}) by visible solar radiation (wavelength \(< 400\, \text{nm}\) since energetic UV radiation likely to dissociate oxygen molecules does not reach the troposphere. In the absence of nitrogen oxide, ozone is rapidly destroyed by deposition to the ground or via reactions involving water vapor or by UV radiation with wavelength larger than 320 nm.

The abundance of ozone throughout the troposphere is generally much lower than in the stratosphere, for example less than 100 molecules
per billion of air molecules (100 ppb). In the free troposphere (3–10 km altitude), large temporal variability of ozone is also observed but on the scale of a few days. This variability is due to dynamical processes that transport ozone from rich air regions such as the stratosphere or the polluted continental boundary layer. Long-range transport between continents also plays a role since tropospheric ozone has a lifetime of several days and can thus be transported away from its source regions.

Although ozone protects human health by filtering out the harmful solar radiation, it is also a strong oxidant, which causes problems with breathing. Ozone has been linked to tissue decay and cell damage by oxidation. Inhalation of ozone can exacerbate lung diseases such as emphysema, chronic bronchitis, and asthma. Ozone also affects vegetation through oxidative stress. It can cause damage in trees and decreases in agricultural yields. At ground level, ozone is produced by reactions involving nitrous oxides (created by combustion in industry and vehicles), sunlight, and volatile organic compounds (VOCs). VOCs are carbon-containing compounds that evaporate readily. They are emitted by a variety of sources that include gasoline vapors, chemical solvents, emissions from vegetation, and household cleaning products. Large concentrations of ozone can build up in summer during so-called photochemical smog episodes that are characterized by conditions of low wind and high levels of sunlight. Ozone is then considered “bad ozone,” in contrast to the “good ozone” in the higher atmosphere that protects life from UV radiation. In the presence of large ozone concentrations at ground level (e.g., 90 ppb), pollution alerts are issued reducing urban traffic or urging people with respiratory problems to remain indoors. Various environmental agencies have set programs for the reduction of nitrogen oxides and VOC emissions from vehicles and industry in order to improve air quality in urban areas.

During the twentieth century, tropospheric ozone levels increased substantially, particularly in the continental atmospheric boundary layer in the Northern Hemisphere (Parrish et al. 2012). This positive trend is attributed to increased emissions of nitrogen oxides and hydrocarbons by human activities. Present estimates from chemical transport models indicate that 60–80% of the tropospheric ozone burden results from chemical production in the troposphere while the remaining part is linked to air mass transport from the stratosphere. Uncertainty remains regarding the magnitude of increase from the preindustrial era since very few routine ozone measurements were made before the late 1970s. Early measurements showed values around 10–20 ppb prior to the 1950s over Europe compared to 40–50 ppb in the 1990s (Marenco et al. 1994). For the most recent decades the global picture from surface station observations is not uniform. Increases are largest from the 1970s to the mid-1980s and tend to slow down afterwards. Anthropogenic emissions of ozone precursors are mainly located in Europe, North America, and more recently East Asia. Certain regions have implemented emissions controls since the 1980s, leading to decreases in ozone precursor emissions. As a consequence, tropospheric ozone levels have stabilized and show signs of decrease at some sites in some seasons, particularly in summer.

Atmospheric ozone and climate

Changes in ozone can have a significant impact on climate because ozone absorbs both solar and terrestrial radiation, and plays a major role in determining the energy balance of the troposphere and the stratosphere. Ozone acts as
a greenhouse gas by absorbing longwave terrestrial radiation. The global average radiative forcing due to increases in tropospheric ozone since preindustrial times is estimated to have enhanced the anthropogenic greenhouse gas forcing by about 0.4 Wm$^{-2}$ compared to a total of 2.29 Wm$^{-2}$ (IPCC 2013). The effect of increased ozone levels is largest near the tropopause (the region between the troposphere and the stratosphere) due to the thermal conditions in this region. In contrast, stratospheric ozone depletion has induced a negative radiative forcing, resulting in a cooling of the surface. But this negative forcing is very small compared to the net positive radiative forcing caused by the emissions of ODSs, which are strong greenhouse gases. It was indeed shown that reductions in atmospheric ODS concentrations have benefited the global climate (Velders et al. 2007).

Stream ecosystems are organized within a catchment network that is characterized by unidirectional flows of water from source to mouth. Stream networks form spatially nested hierarchies, from catchment, stream segment, reach, pool/riffle to microhabitat. Each level of the hierarchy represents the environment for the habitat contained at the lower level, and maintains dynamism of habitat structure and ecological processes over particular spatiotemporal scales, from microhabitats that may reorganize over days to years, to whole-system changes that may take many thousands of years (Frissell et al. 1986).

Flows vary according to water inputs, which change temporally. Streams will typically follow broad annual flow regimes within particular climatic regions, but finer levels of flow variation are also important. Flow variation creates longitudinal (upstream–downstream), lateral (channel–floodplain) and hyporheic (channel–streambed) connectivity that is crucial for the ecological processes that structure stream ecosystems and their communities (Ward et al. 2001). A typical stream structure is given in Figure 1. Such connectivity between stream structural components increases exchanges and flows of biota (e.g., organisms) and abiot (e.g., sediment), and helps to disturb and reorganize physical habitat, increase habitat heterogeneity, disperse species, cycle nutrients, and oxygenate backwaters, among other processes. Less frequent increases in flow that greatly facilitate connectivity are often referred to as “flood pulses,” while more frequent (e.g., daily) minor fluctuations are termed “flow pulses.” Streams may be persistent (with continual, year-round flows), intermittent (with seasonal flows or dry periods), or ephemeral (with flows occurring only after temporary inputs such as rainfall in semiarid areas). “Streams” and “rivers” are governed by the same processes. The two terms are often used interchangeably, though “stream” may (though not universally) indicate a relatively small channel or system.

Streams are among the most biologically diverse ecosystems within a given region. Stream communities have evolved specialisms of physiology and life cycle to live in flowing water (lotic) conditions, which are characterized by hydrogeomorphological variability and dynamism. Each structural component of the river (Figure 1) has particular species and communities that have adapted to the typical conditions associated with the component, though there is much variability within communities. Benthic organisms live on or close to the streambed and may utilize the shelter provided by bed sediments and debris to avoid fast flows. Many organisms are free-floating in the water column, sometimes seeking sheltered areas for particular purposes such as spawning. Some organisms, particularly macroinvertebrates, may be found mainly on the surface of the water column. Organisms in the riparian zone or floodplain may be tolerant of temporary high-water conditions and may display a gradient of tolerance to fluvial disturbance, from primarily aquatic species adjacent to the channel to those that are largely terrestrial, with increasing distance or elevation from the...
STREAM ECOSYSTEMS

channel. Hydraulic conditions are important for structuring communities, with plants, for example, being found mainly in areas where flows are lower and disturbances reduced. Backwaters and other areas where hydraulic stress is reduced may display different communities to within the main channel.

The most abundant and diverse organisms in stream ecosystems are microbes, meiofauna, and macroinvertebrates, with plants and vertebrates being less common but often important in structuring communities and food webs (particularly fish). Communities change with longitudinal position along the river, reflecting change in flow conditions and the physical environment. This is termed the river continuum concept (RCC), and suggests that headwater (upper catchment) areas are dominated by “shredder” species that break down the large amount of coarse plant material that enters the channel from outside the stream (allochthonous). Middle reaches have an increase in internally produced (autochthonous) fine organic material, and communities are dominated by collector and grazer species, while downstream reaches have a high abundance of collectors. The RCC has been regarded as an oversimplification of longitudinal trends, with other highly variable factors such as channel hydraulics being particularly important in structuring the distribution of species.

Historically it was assumed that biota were primarily governed by the physical processes found within streams, and simply responded to the hydrological and geomorphological conditions present. More recently it has been recognized that a more reciprocal relationship between

Figure 1  Simplified cross-section of a stream, highlighting broad habitat types.
STREAM ECOSYSTEMS

organisms (particularly plants) and physical processes exists, with (for example) vegetation reinforcing banks and bar formations by trapping sediment and preventing erosion, and thereby influencing stream morphology. Some organisms may have particularly dramatic impacts on stream ecosystems, such as beavers (Castor spp.) being responsible for the creation of wood dams and areas of wetland habitat that have increased depths and reduced flows, which would not exist without their presence. Such organisms are termed “ecosystem engineers.” Streams have therefore been fundamental in highlighting biogeomorphological processes occurring within ecosystems.

Streams supply important ecosystem services, such as provision of food, water, energy, transportation, species habitat, nutrient cycling, recreation and spiritual wellbeing. Despite (or because of) this, they are among the most degraded ecosystems in the world (Dudgeon et al. 2006). Particularly significant impacts include regulation for hydropower, navigation, or irrigation; urbanization; industrial pollution; and colonization by alien invasive species. These impacts are especially problematic when they interrupt the connectivity of stream networks and compromise essential processes. As a result of extensive global degradation of stream ecosystems, there are significant efforts in many parts of the world to improve or restore their condition.

Streams, gaining and losing

Woonsup Choi  
*University of Wisconsin–Milwaukee, USA*

Water moves both horizontally and vertically across the Earth, between the atmosphere, lithosphere, hydrosphere, and biosphere. Vertical moves include precipitation, evapotranspiration, infiltration, and percolation. Surface and subsurface flows can be viewed as horizontal moves. Surface flows occur according to the elevation gradient, and stream channels are conduits for water on the land surface. Naturally, with a cross-sectional view, a stream channel has lower elevation than its surroundings (Figure 1).

Water in stream channels is supplied from different sources, such as atmosphere (in the form of precipitation), snowpack (in the form of snowmelt), and subsurface storage (in the form of groundwater flow), depending on the season and geographic location.

Underneath the land surface, water is stored in unsaturated and saturated zones (Figure 1). Water in the saturated zone is often called groundwater, and an underground geologic layer saturated with groundwater is called an aquifer. A saturated zone that is not overlaid with an impermeable layer and thus interacts with the unsaturated zone (like in Figure 1) is called an unconfined aquifer. The unsaturated zone (also called the vadose zone) is located above the saturated zone, right underneath the land surface, and the boundary between the saturated and unsaturated zones is called the water table. The water table is an undulating surface; it fluctuates in response to recharge and discharge of water to and from the saturated zone. For example, it rises with rainfall, and falls with an extended period of no rainfall.

Water in the saturated zone flows in the direction of maximum hydraulic gradient. In other words, it flows in the direction where the water table falls most per unit distance. In general, the water table will slope toward lower elevations of the land surface, such as streams or lakes.

If the water table is coincident with the surface of the stream and the groundwater flows toward the stream (Figure 2), the stream is supplied with water from the saturated zone, and is called a gaining stream. It is also called an effluent stream when the saturated zone is used as a reference point. In other words, water “flows out” from the saturated zone to the stream. Gaining streams generally have increasing discharge as water flows downstream.

If the water table is not coincident with the surface of the stream or is coincident but lower than the stream surface, the stream loses water to the saturated zone, and is called a losing stream (Figure 3). In this case water “flows in” to the saturated zone from the stream and is also called an influent stream. Because water is lost to the saturated zone, stream discharge tends to decrease as water flows downstream in a losing stream.

The interaction between stream water and groundwater takes place in the hyporheic zone in which saturated sediments lie beneath the streambed and stream banks. Stream water flows through these short segments of its streambed and banks. The hyporheic zones have varying depths depending on the composition and size of the streambed, from several centimeters to more than one meter. This is where exchanges of water and material take place between stream...
STREAMS, GAINING AND LOSING

Figure 3  A: Cross section of a losing stream. B: Water table contour and groundwater flow off around a losing stream (Winter et al. 1998). Reproduced from US Geological Survey. © Department of the Interior/USGS.

Water flowing above and groundwater sitting below, and is receiving increasing recognition for its importance for aquatic organisms, such as fish during their spawning.

The definitions of gaining and losing streams have somewhat different nuances between references. In Dingman’s book (2002), a losing stream “is one in which discharge decreases downstream” (p. 344). Dingman’s book says the reason why the stream loses water downstream is because the water table is lower than the stream surface. The definition is sometimes considered as sinking streams in karst topography, which disappear underground as losing streams. On the
other hand, other sources define a losing stream as one that loses to the saturated zone (e.g., Cech 2010). The difference is whether the focus is given to stream discharge changing downstream or interaction between surface and groundwater, even though they are intertwined.

Gaining streams have water flowing year-round or for extended periods such as wet seasons. Losing streams tend to have flow only in response to water-input events like rainfall and otherwise have no flow because water is lost. Streams with year-round flow are called perennial streams, and streams with flow only during wet seasons are called intermittent streams. Streams that flow only in response to precipitation are called ephemeral streams.

Gaining and losing streams can occur in different reaches of the same river. Correspondingly, gaining and losing reaches can be distinctly defined. A stream encounters a variety of geologic characteristics, land covers, human activities, and even climates as it flows from headwater to outlet, thus gaining and losing reaches can appear alternatingly. For example, if a well is drilled near a stream, the water table will be lowered and the stream reach can become a losing reach. In some cases, streams switch between gaining and losing by season or during floods. Covino and McGlynn (2007) suggest that streams do not simply lose or gain over a particular reach, but the gain/loss is spatially and temporally dynamic. The switch between gaining and losing conditions is particularly variable in headwater areas where the location of start of streamflow can move up- or downstream, depending on snowmelt or rainfall events and groundwater recharge (Winter et al. 1998).

Because the flow between the streambed and the saturated zone occurs in opposite directions between gaining and losing streams, the pore size and content of fine particles in streambeds, thus hydraulic conductivities thereof, have different characteristics. Downward movement of water in a losing stream pulls fine particles to the bed, resulting in clogging, whereas upward movement of water in a gaining stream lifts fine particles and expands the pore space. Therefore, it is likely that the streambed hydraulic conductivity of a losing stream is smallest at the top layer of the streambed and increases with depth. On the other hand, that of a gaining stream is likely to be greatest at the top layer and to decrease with depth (Chen et al. 2013). These hydraulic conductivities were demonstrated in a field study (Chen et al. 2013) of the Platte River Valley in Nebraska.

The importance of the hyporheic zone lies not only in water exchange but also in material exchange. Contaminants released into a losing stream will result in contamination of both the stream and the underlying aquifer (Field 2006). Nutrient exchange also occurs in the hyporheic zone with opposite characteristics between gaining and losing reaches. Harner and Stanford (2003) found faster growth of cottonwood trees (Populus trichocarpa) in a gaining reach than in a losing reach in a floodplain as a result of water availability and nutrient (nitrogen and phosphorus) delivery from regional upwellings of hyporheic water. Because the saturated zone interacting with streams can underlie the land surface, the biochemical conditions in a given reach reflect interactions between water in the hyporheic zone and groundwater from distant sources (Winter et al. 1998).

Good examples of gaining streams include the Mississippi and Columbia Rivers in North America and the Amazon in South America, and many other rivers in humid climates. Losing streams are far less common than gaining streams and mostly found in arid climates (Strickler 2012). Losing streams are also common in regions of karst topography, along with sinking streams (Field 2006).
The Colorado River in North America is a good example of a losing stream. It begins in the Rocky Mountains, flows generally southwest, and drains to the Gulf of California in Mexico. It used to have abundant flow, discharging approximately 18500 million m³ each year into the Gulf of California (Flessa et al. 2013). However, it no longer regularly reaches the Gulf due to a range of reasons, such as dam building, overuse of water, and droughts (Zielinski 2010), and the flow crossing the border into Mexico today is only about 1850 million m³ each year (Flessa et al. 2013).

Structuration theory was arguably the most influential of theoretical imports into human geography during the 1980s. Its influence and allure came as a direct result of a capacity ascribed to structuration theory to transcend the binary polarity between “structure” and “agency,” which at the time dominated theoretical discussions in social theory and in human geography. At the same time, it also marked a considerable incorporation and adaptation of geographic discourses and practices by non-geographers. The result was a two-way street of theoretical traffic between geographical discourses and associated practices on the one hand and social theory broadly construed on the other. The ensuing circulation of concepts helps explain the lasting appeal of structuration theory within geographical discourses as well as the continuing interest of social theorists in space and spatially-resonating concepts. As such, structuration theory was thus very much part of the “spatial turn” taking roots across the social and human sciences during the 1970s, the legacy of which is still very much present today.

In both the social sciences and human geography, structuration theory addressed a key issue that had vexed the work of both theory and practice, namely the question of how to relate the working of structural elements (state, companies, institutions) with those of individual or collective agents in a coherent manner without prioritizing one over the other. In social theory and philosophy, the problem was not unknown and had motivated the writings of many authors from Marx to Weber and beyond; however, it was the work of Anthony Giddens from the late 1970s onwards that provided a genuinely novel answer in not starting to theorize from either “agency” or “structure” and work towards a synthesis but by seeing both “agency” and “structure” as always already the product of a wider dialectical process that predates whatever concrete empirical shape either of these would take (Giddens 1984). It was at this pre-existing junction between “agency” and “structure” that the eponymous “structuration” took place: a formatting process that theorizes the mutual constitution of individual and society through institutionalized (and thus routinized) practices. Giddens characterized this process with reference to a quote from Marx’s *Eighteenth Brumaire of Louis Bonaparte*: “Men […] make history, but not in circumstances of their own choosing” (Giddens 1984, xxi). Mention of Marx furthermore allows us to state that, in a broader sense, structuration theory can be read as an extension of older epistemological questions that have been central to social theory at least since the nineteenth century. Marx’s elaborations on and crucial differentiation between what he called “formal” and “real” subsumption, itself related to Hegel’s dialectical philosophy, are perhaps the most obvious antecedents. Here as there, social transformation is theorized in a nuanced and locally resonating manner, shifting the analysis from one focused on abstract structures to their emergence and sustainability within concrete local settings and practices. In contemporary social theory, a close relative to the notion of “structuration” can thus be found in Pierre Bourdieu’s concept of “habitus.”
STRUCTURATION THEORY

It should hence come as no surprise that many geographers began to embrace structuration theory from the early 1980s onwards. Following a decade that was typified by theoretical responses to a perceived hegemony of “quantitative” forms of geography (which had developed in the aftermath of World War II), responses that by-and-large emerged from the two distinct philosophical traditions of Marxism and phenomenology, geographers, too, were eager to embrace nondualist modes of explanation (Gould and Strohmayer 2004). This willingness to part company with at the time established modes of explanation was motivated less by shortcomings identified within these existing theories (most commonly labelled “determinism” and “voluntarism”) (Thrift 1983, 25) but by a Zeitgeist best characterized by the cultural and “spatial” (or “linguistic”) turns then prevailing in the human sciences. Disaggregating these “turns” allows us to conceptualize the latter or “spatial” turn as directly motivating less hegemonic, “functionalist” or determinist theoretical narratives while the former or “cultural” turn implicated arguably more nuanced approaches to questions addressing issues of social relevance. Both were united, however, in their theoretically motivated rejection of stable, aspatial structures, most particularly of the dualist kind, of which the artificial but long-established separation between “structure” and “agency” was perhaps but the most obvious of expressions. In geography, the inability of the spatial science tradition conceptually to embrace nondeterminist approaches supplied a further easy target to unite towards (Gregory 1994, 119).

But the appeal issued by a decidedly nondualist approach only partly explains the popularity of structuration theory throughout the 1980s; equally important was the fact that structuration theory incorporated concepts and methods known to geographers into its explanatory frame. Chief among these must count the interest accorded to “time geography,” as developed by Torsten Hägerstrand in the 1960s, especially by Anthony Giddens. The visualization of “constraints” and “abilities” as combined in the form of time-geographic “life-paths” provided a welcome means to articulate the ever-present (and thus original) structuration of social action; for geographers, who were just then learning to appreciate the fact that other social and human sciences had discovered space, the nod to the work of Hägerstrand and others provided further incentive to engage with structuration theory. At any rate, the result was a more thoroughly aligned surface of theoretical possibilities where geographers conversed effortlessly with other social scientists.

Beyond academia and given its overall thrust, it is not surprising that the political corollary of structuration theory came in the form of a reformulated social democratic program in the 1990s and early 2000s: heralded initially as a “post-Marxist,” “third way” and supported by Anthony Giddens and the creation of Polity Press as a sympathetic publishing outlet, structuration theory proved to be amenable to reformulated progressive politics precisely because it was eminently flexible, adaptable even (Hannah and Strohmayer 1991). Of course, this involvement (or political use-value) can also be used to critique structuration theory as a rather “toothless” form of social theory – or, more pertinently, as asking as many questions as it could answer within its own stated epistemological frame.

Since the height of its visibility within human geography in the mid-to-late 1980s, structuration theory has lost considerable sheen: its explicit invocation, even by those who regularly trumpeted its virtues, has significantly diminished since the turn of the last millennium. In a less openly discernible manner, however, all geographers inhabit a world profoundly shaped
by structuration theory, a world characterized by an absence of attempts to explain significant social, cultural, or economic developments or events through recourse to theoretical explanations based singularly on either “agency” or “structure.” Virtually all key terminology that has since dominated (or more modestly sought to contribute to) theoretical discourses in the social sciences and in geography implicitly accepts the mandate bequeathed by structuration theory: to conceptualize its work and workings in an explicitly nondualist manner. Furthermore, the proliferation of “site-specific” material, performed and explicitly “scaled” forms of geographical knowledge since the 1980s similarly owes more than a passing nod to structuration theory given its insistence on the importance of “local” anchorage for processes of structuration. If larger social and historical processes only acquire momentum by being embedded within specific local configurations, research on the latter becomes of paramount importance not because it uncovers something specific about such sites themselves but because it contributes knowledge that is essential to any understanding of social processes at large while accepting that those social processes remain no less essentially different in dissimilar places or regions.

“Subaltern” is an emotive, elastic, and elusive term and critical concept pertaining to issues of domination and subordination, voice and agency, and the domineering way in which Western discourses relate to other cultures and ways of knowing. Geographers have characterized “subaltern space” (Clayton 2011) and “subaltern geographies” (Jazeel 2014) as the media and outcome of relations of power and identity formation that split the world and its inhabitants into elite (or superordinate) and subaltern (or subordinate) sectors and locations, and that give the condition these processes fashion – subalternity – both general and specific qualities.

The term has two meanings: first, a person, group, or entity of subordinate status; and, second, a junior army officer (introduced into nineteenth-century European armies to convey the orders of military leaders to troops). The formative theorist of the subaltern, the Italian communist Antonio Gramsci, deployed the term in both ways. He used it to signal a concern with the most oppressed, disadvantaged, and voiceless sectors of society (he had in mind a largely peasant southern Italy), who, in his remarks on subaltern history in his *Prison Notebooks*, are the group that take the orders and “are always subject to the activity of ruling groups, even when they rebel and rise up” (Gramsci 1971, 55). He also used “subaltern” as a surrogate term (in part, to get his writing past prison censors) that flipped the military idea of the subaltern as a medium of communication and re-envisioned this subject as pivotal to a broader “war” over social power in fascist Italy. That war was over how charismatic leadership and dominant control in society were effected, and how, for Gramsci, this was achieved by consent as well as coercion (creating what he termed “hegemony”), with intellectuals playing a vital link between the elite and subaltern masses akin to the link role that a subaltern army officer plays in a military chain of command. In other words, Gramsci’s subaltern was a code word for resistance and the difficulties of realizing it.

Partly because of the unfinished quality of Gramsci’s treatment of the subaltern, he bequeathed the term a prolific and pliable afterlife. The subaltern has variously been conceived as an object of study, a form of agency and resistance, and a mode of consciousness and critique. It has been approached differently through modalities of gender, sexuality, race, culture, and socioeconomic differentiation (class and caste), and has different connections to debates about modernity, colonialism, historicism, nationalism, Eurocentrism, and now globalization (and related problematics of governance, aid, humanitarianism, cosmopolitanism, minority status, and risk and conflict). Questions of subalternity have been studied at different scales (with the subnational scale long privileged, but with local–global articulations, and a language of “networks” and “assemblages” currently in vogue), and taken on different inflections in different fields of theory and study (history, anthropology, geography, literary history, Marxism, feminism, postcolonial studies) and different parts of the world (especially South Asia and Latin America).
Since Gramsci, the term has been conferred on a wide range of groups – peasants, workers, the poor, women, indigenous peoples, the colonized, slaves, refugees, asylum-seekers, and religious and ethnic minorities – and is often used loosely (to the point of losing its critical efficacy) as a generic expression for oppression and disenfranchisement on the one hand, and for emergent and insurgent knowledges and practices on the other. The term is often equated with the project of rereading “history from below” and with politico-intellectual anxiety over who has the right and authority to speak for “the other”: however, it is usually reserved for non-Western, colonial, and developing-world configurations of domination and subordination, and has played an important role in radical global history and politics, naming the pursuit of a non-Western and nonindustrial revolutionary subject (other than “the proletariat”), and thus serving as a means of questioning the primacy of class struggle in Marx’s theory of history, and becoming linked to a family of terms that stem from anticolonial and communist-internationalist thought and praxis (“the people,” “the masses,” “the popular,” “the multitude”).

During the 1980s and 1990s Gramsci’s idea was popularized and reconfigured in relation to Indian history by Ranajit Guha and the “subaltern studies” group and book series he spearheaded. The founding aim of this group (of mainly Indian and British historians) was to challenge the elitist biases in the colonial, nationalist, and Marxist historiography of India – its failure to speak for India’s peasant masses. Guha used the terms “the people” and “subaltern classes” interchangeably, and argued that Indian nationalism (both pre- and post-Independence) was not simply the product of elite initiative. He contended that, while subaltern resistance to the British was not strong enough to generate a nationwide struggle for liberation, peasant consciousness and resistance were not backward or immature in the way that European Marxist historians had described preindustrial peasant rebellion in Europe. The subaltern studies group questioned the class determinism and evolutionism in Western Marxist historiography and found in Gramsci’s work a complex figure of subordination and resistance with no easy route to historical recognition or political representation. The peasant insurgent in colonial India had been written out of history (captured and denigrated by elite discourse, including that of the Communist Party of India). Guha invested the subaltern classes of India with political agency, and in a structuralist vein claimed that the (minority) elite and (mass) subaltern sectors of society ran “on parallel tracks over the same stretches of history, as mutually implied but opposed aspects of a pair of antagonistic consciousnesses” (Guha 1983, 11). Reading hundreds of cases of peasant resistance to the British between 1783 and 1947, the subaltern studies group identified a subaltern will and logic to resistance that could be excavated from colonial texts, recovered from Indian sources, and used to show that the peasant insurgent was not an ineffectual relic in a modern (industrial, colonial) world.

Moving now from how the subaltern is configured as a subject/class to how it serves as a category/epistemological figure, theorists underscore the relational qualities of the category. The term enjoins us to specify how subordinate groups are connected to power and “hegemony” in specific times and places. But, from Gramsci onward, the subaltern has usually been conceived as a bifurcated (and, as shall be seen, paradoxical) category that has been politicized both negatively, in terms of what it is not, and in positive and prospective terms, as an oppositional figure of creative resistance. The subaltern is a figure of both constraint and release – of what power and knowledge can and
cannot grasp and control, what power clasps in its
own image and making, and what it excludes and
casts to one side. The subaltern has been located
both outside (exterior to) and at the margins
of (but still inside) fields of power, and as both
separate from, and an effect of, power. Geogra-
phers are not the only scholars to examine how
this bifurcated configuration of the subaltern is
shaped in and through space – through politically
charged sociospatial processes of partitioning,
segregation, classification, surveillance, targeting,
exclusion, expulsion, and hierarchization oper-
ating at a range of scales (for instance, at border
patrols; in ethnic enclaves, refugee camps, slum
districts, war zones, migration flows, and national
and international citizenship strictures; and in
terms of unequal access to wealth and welfare).

There is a core tension in conceptual work
on the subaltern between what might be called
“interiorizing” and “exteriorizing” visions of
how the subaltern generates a politics of knowl-
dge that is geared to the question of how
hitherto ignored and disqualified knowledges and
ways of life might be approached and analyzed.

This exterior–interior split in the subaltern’s
location frames the question of whether the aim
of subaltern critique and resistance is to identify
and protect the subaltern’s exteriority, or to dis-
solve the subaltern’s interior marginality. Some
subaltern projects are underpinned by the desire
for autonomy, critical-intellectual investment
in seeing the subaltern as untouchable, and the
search for a subaltern history, space, and politics
that can be deemed a record and indicator of
these drives. Others are framed by the idea that
the subaltern is a marginal, incomplete figure
that can only ever be spoken for, and that cannot
simply be plucked from the past or present as a
full-blooded subject and used to turn the tables
on domination.

Conceptualizing subalternity in locational
terms – that is, as meaning different things in
different times, places, and projects – generates
the worry that the subaltern can be broken into
so many diverse and localized pieces that it loses
conceptual coherence, comparative utility, and
critical bite. Subaltern worlds and agendas can
become closed in on themselves – scattered,
disconnected, and incommensurable. The whole
idea of the subaltern is also disheartening in
that it names an abject space of domination and
a closed space of difference. Yet the subaltern
also names an anticipatory space of opposition
from which, it is hoped, subordination can be
assuaged, if not overturned. It is common to find
the subaltern invoked in this double sense: as a
space of denial and denigration, in which the
subaltern is assigned a place in society by elite
power and its norms, and granted an identity
that marks her or him as subordinate and adrift;
but also as an alternative and counterhegemonic
space in which the desire and ability to challenge
power are imagined and enacted. Geographers
view the subaltern in this twofold way, as both
a figure of oppression and a liminal space of
becoming and critical position “on the mar-
gins.” They thus enact the “classic fissure,” as
Timothy Brennan (2001, 164) sees it, in the sub-
altern literature, “between opposition as action
and opposition as a demand for recognition.”

Two examples to fill in this picture will need
to suffice. First, the image of the subaltern as
an essence (a constant and compensatory oppo-
sitional presence in history) cultivated by the
subaltern studies group has solicited extensive
debate. In being “understood as the essential
resistance of the voiceless,” Brennan (2001,
163–167) remarks, the subaltern is “shielded
from an imposed and always arrogant rational-
ism”: he is kept on the outside; but by the same
token, it is “a life privileged only insofar as it
remains subaltern.” Consequently, the subaltern
“would seem to represent a sacred refuge, a
dark space of revelation … [and an] occult
subalternity is conceived as theory’s deepest and most irreducible value.”

Second, Gayatri Chakravorty Spivak is perhaps the best-known theorist of the subaltern today, and the doubleness glossed over in the previous paragraph is captured in her characterization of subaltern space as “differential space” – on the one hand, naming a “position without identity” (albeit for her a profoundly gendered figure) and without a basis for action, naming a group “whose identity is its difference,” that is “cut off” from society and history, with no access to the structures of the state and citizenship; but, on the other hand, declaring a critical intent “to clear a space” in which dominant groups and privileged figures and institutions (including, of course, academics and universities) can learn how to listen to and work with subordinated people and groups (Spivak 2005, 476–479; also 1999, 272–308). Her 1988 essay “Can the Subaltern Speak?” is one of the most cited papers in the critical humanities of the past 50 years, and has had an important impact on geographers. Her core concern with what she terms “epistemic violence” (1999, 272–308) – the predilection of language and knowledge not only to “decipher” but also to “intervene,” “cage,” and “dominate” – fuels a staple concern that attempts to “speak for the subaltern” can be self-defeating. It is through this problem that geography students generally encounter the subaltern in textbooks (e.g., Sharp 2009, 110–120).

But subaltern themes cast a longer shadow over the discipline of geography, and have been broached in eclectic ways. They can be found in critical histories of geography that alight on the Eurocentric blinkers and conceits that imbue the discipline’s modern development and contemporary (chiefly Western) hegemonic forms. Geographers here use the subaltern as a code word for the need to decenter geography’s imperial maps of meaning and challenge derogatory images of otherness in both popular and academic geographical writing and representation. There are also subaltern threads to research on postcolonial and development geographies that endeavor to “learn from other regions” (to use David Slater’s expression), which work on spaces and networks of conflict, terror, risk, and security; and in radical (oppositional, activist, and participatory) geographies that are concerned with social movements and antisystemic projects. Finally, in a more vexed way, the image of the subaltern as space on the margin shadows geographers’ incessant search for novelty and variety: their cultivation of ever new “margins of study” and quest for unencumbered spaces in which new freedoms (at least of inquiry) might be found (albeit often through a surreptitious romancing of resistance).

Geographers have paid considerable attention to the historical and containment and constraint dimensions of the subaltern concept, although there is also a range of geographic research on subaltern dynamics today that is yielding an inventive geographical vocabulary, of “convergence spaces,” “translocal assemblages,” “subaltern networks,” and “subaltern cosmopolitanism,” and that advocates a subaltern politics of place and space, yet without lapsing into romanticized and reactionary shibboleths of nativism, and its geographical corollary, place-bound identity (see Jazeel 2014).

Cultural and historical geographers have a strong interest in the processes of subalternization at work in different imperial and colonial projects, discourses, practices, spaces, and networks – in plantations, native reserves, missionary activity, projects of mapping, naming, and scientific classification, and colonial practices of settlement and native dispossession. Subaltern themes also influence a wider range of work on modernity’s historical geographies. Modernity
generated new distances – between worker and product, producer and consumer, city and country, knowledge and the conditions of its making, viewer and object, self and other, and representation and reality – and its self-image as an ideology of “the new” involved the creation of specific locales and spatial markers that tied ideas of progress to those of distance and absence. Ulf Strohmayer (2003, 523) and other geographers have noted that the epistemological question of how European knowledges about “there” and “them” are produced “virtually disappears behind their claim to validity” – as detached and disinterested, rational and scientific, and civilizational, and so on, and in binary opposition to non-European knowledges, which are represented as backward and superstitious. Geographers have opened up how European “objectivity” hinged on the denial of coevalness (two-way encounters and flows of ideas and influences between metropole and colony), the promulgation of sweeping imaginative geographies (with their stereotypes about ignorance and savagery), and distinct spaces (such as the ship, laboratory, map, museum, learned society, and exhibition) where European authority was shaped and secured. The same interior–exterior tension regarding the subaltern applies to this Eurocentric imperial worldview. The West justifies colonization on the grounds that the beneficent colonizer seeks to civilize the benighted subaltern (“native” and “subaltern” are sometimes used interchangeably) by bringing “gifts” of science, civilization, and material and social progress (in some discourses it is the native subaltern who beseeches them). But, at the same time, if colonialism is to endure and remain legitimate in Western eyes it can never admit that it has completed its job; there is a constant need for a subaltern to be worked on by European reason and its colonial scripts. As a large body of postcolonial theory contends, the colonial subaltern becomes a conscript of civilization but is ultimately always denied access to modernity’s full liberating potential and told to follow orders in this Gramscian subaltern way.

Finally, and as much of the preceding discussion suggests, subaltern space may be construed as a paradoxical space. An elementary paradox is of inside and outside: the idea of the subaltern as separate, and immune from, yet only discernible in terms of, an organizing center of meaning, representation, and power. A potent criticism of much subaltern theory and scholarship is that the desire for a separate subaltern history and identity can only be expedited via those processes of connection and division that have brought putatively autonomous histories, identities (and geographies) into the elite–subaltern relationships that are now a source of consternation and contestation. This core paradox leads to a related one, of language and progress, acutely apparent today in subaltern struggles over land, cultural recognition, citizenship, and ecological and political security. The ability of subaltern groups to articulate their grievances is seen as a sign that they are no longer subaltern, for such grievances are recognized only if they are articulated using the language of hegemony. In other words, do subalterns have to abandon or devalue their languages and lifeworlds in order to undo their subalternity? This question has a pivotal bearing on debates about the remit and responsibilities of a postcolonial (and post-development) geography. A third paradox, of situated knowledge, has a wider bearing on how geographers approach issues of othering and subordination. How, in rendering the subaltern as profoundly “situational,” will the geographer account for the locational qualities of her or his own work, particularly as their discipline has shaped and rationalized Western dominance and fueled exoticism over the centuries? A final paradox, of impossibility, frames subaltern theory
more generally. If, by definition, subalternity connotes a lesser, or outside, position that cannot be unraveled either in theory or with hindsight, why should we want the term? Is the subaltern condemned to always be a subject and category of failure and despair? An awkward, stubborn question remains: Can the subaltern be placed in an unreachable realm of exteriority to power and yet be rendered inside a space of domination enough to provide a recognizable ground for action and politics?

Subculture of poverty

David Wilson
University of Illinois at Urbana–Champaign, USA

The controversial theory of a subculture of poverty was first offered by University of Illinois anthropologist Oscar Lewis in his attempt to understand the persistence of poverty in rural and urban settings (particularly in Mexico, Puerto Rico, and New York City). His 1959 book, *Five Families: Mexican Case Studies in the Culture of Poverty*, was his initial foray into this intellectual project. The subculture of poverty theory asserts that the poor adapt to conditions of poverty and marginality by creating a culture or subculture adapted to those conditions that ensure some degree of normalcy and happiness. This culture sustains poverty by normalizing its supporting value orientations: helplessness, the search for immediate gratification, dependency, marginality, and powerlessness. This culture, to Lewis, becomes akin to a prison without walls: for those who bear these powerful feelings and lack the education to see beyond them, a kind of social entrapment follows. Structural forces, then, come to cage and isolate the poor, as these are ultimately self-created forces that bind and permeate a population.

The subculture of poverty theory has remained a widely accepted way to explain the persistence of poverty in the United States and beyond. It has been a dominant influence on US public policy, forming the basis for programs on how to redistribute wealth and resources to the poor since the 1960s. Its shift to the political center was fueled especially by Senator Daniel Patrick Moynihan’s (1965) report, *The Negro Family: The Case for National Action*. Moynihan stated that a pervasive “tangle of pathology” was responsible for the plight of America’s urban poor and that a particular group, the black poor, were most dramatically affected. The fundamental dynamic was the breakdown of the black family which was purportedly afflicted by the decline of the traditional male head of household. To Moynihan, the loss of a key parental influence, the eclipse of an important role model, and the evaporation of discipline transmitted across generations were most crucial. Moynihan argued that the origins of this deviant family structure lay in slavery, where the destruction of the “traditional” family “broke the will of the Negro people,” particularly black males. This sense of powerlessness led to, in effect, a culture of dependency.

Criticisms of the notion of the subculture of poverty have been widespread and virulent. A dominant criticism focuses on its very reading of poverty communities and people: the poor are cast as unduly passive and uncreative in their everyday lives. They seem unable to reflexively and creatively make decent lives for themselves, to accurately read how society operates, or to organize to make their lives and their communities better. Yet, it can also be posited that the poor are frequently adroit readers of their predicament and the broader society and that they only superficially appear as caught in a powerless vice of marginality. Beneath the surface are active beings who seek to remake the forces that engulf them. Following this reasoning, the subculture of poverty theory shifts the blame for poverty from social and economic conditions to the poor themselves. According to this view,
the poor, seemingly, need to be smarter, more responsible for shaping their everyday lives, and more actively involved in civic duties.

A second major and related criticism has focused on a reliance on the assumption that the behavior of the poor derives solely from preferred cultural values. That is, everyday realities, particularly underemployment, unemployment, criminal behavior, dropping out of school, and drug use are the result of behavior freely chosen by individuals. According to this view, these are the choices that people have made and are an accurate reflection of their preferences. Yet, to critics, such behavior may reflect something else, for example patterns of compensatory survival. Thus, people may act in ways that push legality to the limits, for example engage in shadow economies or participate in youth gangs, less because they desire to do so or are following cultural norms, but because there is little choice given their limited education and the job opportunities available to them. Therefore, “ghetto dwellers” may see themselves as having few real options about what they can do to survive materially and psychologically. In the final analysis, so-called ghetto behaviors are adaptive, not normative, and, given sufficient opportunities, individuals within the ghetto would welcome alternative options.

The subculture of poverty thesis continues to be used as a way of explaining the persistence of poverty, particularly its resiliency in urban environments. Among geographers, political scientists, sociologists, and policy analysts, the debate continues as to the core sources of poverty. While the popularity of this notion ebbs and flows over time, its remarkable durability speaks to the concept’s visceral appeal of pointing to the culpability of individuals for their own choices.

Subjectivity

Patricia Noxolo
University of Birmingham, UK

The term subjectivity has been used in geographical research in two closely interrelated ways: as the antithesis of objectivity in research, and as a way of locating the individual in their social and political context. The unifying factor might be understood most broadly as perspective: subjectivity describes the situated perspective of the individual in society and, more specifically, of the researcher and of the researched in the research encounter. The specific role of geography in theorizing subjectivity, then, is in thinking through the locatedness or the situatedness of the subject: what is the place from which the subject’s perspective comes?

This might seem a rather tortuous question, containing its own answer: subjectivity is the perspective of the subject. If the subject is understood as the Cartesian subject, the rational individual who can say with certainty, “I think therefore I am,” then subjectivity is a product of that rationality. Each human being looks out at the world from the fixed center of the thinking individual. In relation to research, by disciplined application of that rationality, combined with reliable and valid research methods, each individual can come to understand objective truths about the world surrounding them, objective truths that all other rational subjects can also come to understand. Subjectivity, then, is the perspective of thinking subjects who are located in a world of objects that their individual rationality, combined with their collective tools of enquiry, allows them to comprehend. Researchers are, in this limited sense, individually and collectively, masters and mistresses of all they survey.

Even within this Cartesian concept of the rational subject, however, there has always been an understanding that human beings are not simply rational brains. Human beings have emotions and sensory experiences that may radically change the way we see the world, making the perspectives of one subject sometimes very different to the perspectives of other subjects who may have different experiences. Taking this into account, subjectivity can be seen as much more individual than collective. The purpose of rigorous methodological techniques can be to minimize the effects of the subjective bias of individual researchers, often attempting to screen out opportunities for the researcher to interpret the data through experience or emotion. However, this screening out can rarely, if ever, be complete. Indeed, phenomenological approaches to research argue that the outcomes of research are ultimately entirely constrained by subjectivity: that is, that human subjects can only ever know that which we can perceive through the senses available to us. Subjectivity appears always as somewhat in tension with objectivity.

So it becomes clear that the place of the subject is not so easy to locate as it would seem. Even the rational, centered Cartesian subject is located within a body that has sensory and emotional experiences that are not completely governable by the subject. One might say that Cartesian subjectivity is bounded by the body and mind of the individual, but that these boundaries have always been recognized as porous and open to influences that the subject cannot control. Perhaps
as much in response to this internal pressure as in response to historical and academic change, theories of the subject and their subjectivity became much more complicated over the course of the twentieth and early twenty-first centuries, and subjectivity has become much more difficult to locate. Subjectivity has gradually become recognized as more diverse, more fragmented, and more relational, and all three of these qualities make it more open to spatial theory.

The global history of the twentieth century has been marked by an increasing recognition of diversity, for example, in terms of gender, ethnicity, and sexuality. The quest for equality for a range of worldviews and in a range of professional spheres has included recognition of diversity in academic research, both between researchers and between the researcher and the researched. Subjectivity has therefore begun to be understood as diverse – it is not located in a universal capacity for rationality, but is mediated by a range of political and social contexts. Although this insight leads to shorthand formulations of this diversity, such as “black female subjectivities,” this does not mean that individuals’ perspectives are necessarily or essentially determined by particular identity positions; however, it does mean that uniformity across all subjectivities should not and cannot be assumed.

The category of “experience” has often been deployed in understanding subjectivities as diverse. Experience, particularly as routed through feminist geographies, highlights that subjectivities are diverse because people are diversely located: people experience the world in different places and in different bodies. Among the many effects of being in different places is that “interpretive communities” give rise to particular assumptions and interpretations of how the world works (Livingstone 2005, 395) – that is to say, place matters in shaping subjectivities. Similarly, the different meanings inscribed on different bodies – their gendering, racialization, and so forth – make for lived experiences of the world that are both spatially and historically contingent. Bodies change their social and political meanings over time and over space, mediating our experiences, and these mediations make for different subjectivities. So, although this is not a question of essential difference (the same body can be interpreted and experienced differently at different times and in different places), it can be a question of radical difference in that the subjective experiences and perspectives of differently embodied people can be (but are not necessarily) radically different.

As researchers, this possibility of radical difference in subjectivity can push us well out of the comfortable zone of objectivity (in which “error” and bias can be eliminated through methodological rigor) into a more uncomfortable translation zone between different subjectivities, most notably those of the researcher and the researched. Questions of how the subjectivity of the researcher relates to the subjectivities of those being researched become particularly sharp in field-based research. Where development geographers, for example, relocate from well-heeled universities in richer countries in order to study communities in poorer countries elsewhere, the question of power becomes crucial: whose subjectivity is prioritized in research design, data collection, and interpretation? Some argue that it is always preferable to research within one’s own interpretive community for this reason, because the researcher and the researched will only really understand each other within a shared subjectivity (Tuhiwai Smith 1999). Others argue for the possibility of intersubjectivity through participatory approaches, in this way becoming a dialogic process across acknowledged difference demanding from the researcher an ongoing reflexive alertness to power differentials.
Combining these last two points conveys us to the second way in which subjectivity has changed over time: that is, the ways in which subjectivity is increasingly understood as fragmented. Those who argue that subjectivity needs to be shared in the research encounter also routinely acknowledge that there is always some difference within, as well as between, interpretive communities – broadly speaking, for example, women are differently raced and classed, black women have different incomes and sexualities, black lesbians are located in a range of countries with a range of juridical and political regimes, and so on. Intersectionality (Brah 1996) has been a useful tool in pushing understandings of diversity in subjectivity beyond the image of a range of separate interpretive communities to an understanding of subjectivities as internally diverse. In an analogy with recent understandings of places as meeting points or intersections, rather than as bounded parcels of space, individual subjectivity becomes the unstable meeting point of a range of aspects of identity that do not simply juxtapose or appear as a list (black, female, Global North, high-income, etc.), but that interact with and shape each other as experiences and perspectives. Each individual is engaged in an unpredictable dialogue between different aspects of their own subjectivity. At the same time their dialogue with the subjectivities of others is an engagement with both shared and contrasting aspects of others’ identities – understood as unbounded in this way, individual subjectivity is an intersection, with multiple connecting lines with other subjectivities, as well as multiple aspects of difference.

One implication of this fragmentation for the research encounter is that, while there may be radical differences in subjectivity that make it difficult to establish a dialogue between researcher and researched, there may equally be a range of unpredictable meeting points between the subjectivities of researcher and researched. These can shape the research encounter as a fragile, but nonetheless real, moment of intersubjective meaning-making, albeit with no guarantees for prolonged or replicable connection. For example, some have found that shared embodied experiences between some (though of course not all) women, such as pregnancy and childbirth, can form connecting lines that allow for shared understanding in some areas of research, but others have argued that even these apparently unmediated experiences can have so little purchase in the research design and execution, or can be so radically differentiated by diverse experiences of medical and community care or of maternal and political rights, that potential lines of identification are effectively erased (Noxolo 2009).

A second implication of the fragmentation of subjectivity is that the perspectival center of the subject has become radically unstable. There is no central characteristic of the multiple aspects of the researcher’s intersectional identity that necessarily adjudicates truth for the researcher; there is no necessarily universal rationality that steps in to define what is and what is not the right interpretation of the data. In this sense, from the so-called god-trick (Haraway 1988, 587) of comprehending everything everywhere (or at least wherever the right methodological tools were applied rigorously), the perspectival center of the researcher-subject now appears to be nowhere. Even where there is a concerted attempt to carry out the so-called goddess-trick (Rose 1997, 311) of reflexive vigilance toward the circulation of power in the situated research encounter in order to ensure intersubjective meaning-making, there is no centered researcher subjectivity to do this monitoring in an incontestable and coherent way – how much of the power relations in which they are themselves implicated will this researcher really be able to see in their vigilance, how will...
they interpret what they see, and, given their partiality, how will they ensure that this knowledge is deployed in ways that are valuable for both researcher and researched in all their multiplicity?

Partly as a response to subjectivity becoming more diverse and more fragmented, the third way in which understandings of subjectivity have changed is a shift in focus, which can be understood spatially as a shift away from locating the center of the subject toward understanding the spaces between subjectivities, or the spaces of relationality. The metaphor of intersection or meeting place conjures up images of lines of connection, but is less able to assist us in understanding the qualities of different kinds of relationship, or indeed the absence of connection. Work by a range of geographers on aspects of materiality and technological change has led to analogies for relationality that are more intimate and more textured than lines, analogies that allow researchers to reinterpret the research encounter as intersubjective relationality. For example, concepts such as the “economies of touch” (Ahmed 2000, 50) allow researchers to conceive relationality as fine-grained, with multiple subtle but powerful distinctions in quality, as are found in the different ways in which bodies relate one to another. These insights have a particular force for face-to-face or immediately embodied methods, such as interviews or participant observation, in which subtle nonverbal performances (e.g., gestures, handshakes, or the arrangement of the research space) can have profound intersubjective effects. Concepts such as the cyborg or the “technological unconscious” (Thrift 2004) allow researchers to conceive of relationality as dynamic and diverse multidirectional interactions and interpenetrations, as are found between human beings and the technologies with which many human beings increasingly share their lives. Such insights can allow a reappraisal of notions like “interviewer bias” (where the interviewee adapts their responses to meet the supposed desires of the interviewer) to allow greater openness to the mutuality of effects of and on the research encounter between researcher and researched. Finally, concepts such as networks and translations allow researchers to conceive of relationality as subtle but ongoing mutual transferences of matter and meaning, as are found between human and nonhuman actors or “actants” (Latour 1997). Again, such insights can allow the researcher to interpret the roles of both human and nonhuman contributors to the research space, recognizing the roles of physical environments (from landscapes to furniture) in the construction of the intersubjective encounter.

What comes out of the focus on the relationality between subjectivities, in the context of recognizing the diversity and fragmentation of subjectivities, is a reappraisal of the research encounter as a performance that needs to be interpreted with multiple actors playing roles that all need to be interpreted, including that of the researcher. Of course, there are no guarantees in this interpretation either, and multiple interpretations may be possible. This notion of the intersubjective research encounter as a performance to be interpreted is very different to that of the incontestably powerful researcher-subject who sits at the center of the research encounter and uses methodology to engineer the research objects in order to optimize the flow of unbiased data and its rational interpretation. This said, changing understandings of subjectivity do not of course remove researchers’ responsibility to carry out research in a methodologically careful and critical way. What they do call for is an equally careful and critical attention to the demands of intersubjectivity in the research design and in the production of the knowledge that comes from it.

Suburbanization

Paul Watt
Birkbeck, University of London, UK

Suburbanization is a prominent feature of global urban development, even if there is considerable variation in what “suburbs” look like in architectural terms (Clapson and Hutchison 2010). The geographical, demographic, and sociological significance of suburbanization is especially marked in the United States, which in many ways can be described as a “suburban nation” (Jackson 1985). Suburbanization has massively expanded during the latter half of the twentieth century, with over 50% of the US population living in the suburbs of metropolitan areas by 2000 compared with only 23% in 1950 (Hanlon, Short, and Vicino 2010).

The suburbs and suburbia can be conceptualized in several ways, cultural as well as spatial. The focus here is geographical and revolves around the notion that suburbs are peripheral locations that lie beyond a city’s boundaries, but have strong economic and social connections to the city. Connections between the city and the suburb include employment and transport whereby many suburban residents commute into the central business district (CBD) on a daily basis for work, a prominent feature of Anglo-American suburbia. The suburbs are spatially in between the city and the countryside, and they are also intermediate in terms of population densities, having lower densities than cities but higher than rural areas. Within this overarching geographical framework, suburbanization is the concomitant sociospatial process whereby cities expand outwards beyond their original central areas. This suburban expansion involves the building of new homes for sale or rent, combined with residential mobility in which people leave the city in order to live in suburban homes and neighborhoods.

Up until the last twenty years, the dominant geographical and sociological picture of the suburbs was one of white, middle-class residential areas consisting of nuclear families living in owner-occupied houses, that is, what is often called the Anglo-American model of nineteenth- and twentieth-century suburbanization in the United States, United Kingdom, Canada, and Australia. In these societies, the spatial movement from the city to the suburbs is often associated with a process of social mobility whereby those moving out also move up the social hierarchy, for example, in terms of class, income, and housing, as seen in the notion that suburbia represents a “bourgeois utopia” (Fishman 1987). This centrifugal movement outwards and upward is a significant aspect of early/mid-twentieth century US and UK suburbanization which involved intertwined processes of middle-class formation and suburban homeownership (Jackson 1985; Clapson 2003). These Anglo-American residential suburbs were based upon – and simultaneously reinforced – a pronounced gender division of labor in which wives undertook domestic labor while husbands commuted to paid jobs in the CBD. Classic examples include the outer London suburbs consisting of rows of 1930s semi-detached houses, and the postwar US Levittowns such as that built on Long Island as a suburb of New York City. Culturally the Anglo-American suburbs involve a “suburban way of life” based on maintaining social order, reinforcing class, status, and gender distinctions,
as well as conforming to middle-class norms of respectability.

During the last two decades, “revisionist” suburban scholars have increasingly challenged this dominant representation of the suburbs. Thus attention is given to the distinctive characteristics of urban peripheries in the Global South, for example, the Brazilian favelas (Clapson and Hutchison 2010). Revisionists have importantly highlighted the socially diverse nature of the Anglo-American suburbs along ethnic, racial, and class lines throughout the twentieth century (Li 1998; Harris and Lewis 2001; Clapson 2003; Wiese 2004). Immigrants to the United States and Canada, for example, have lived and worked in the suburbs, as well as in the more famous urban “ghettos.” In his study of Chinese suburbanites in Los Angeles, Li (1998) introduced the concept of the “ethnoburb” in order to highlight the geographical significance of suburban ethnic enclaves. While African Americans were less suburbanized during the first half of the twentieth century than immigrants (Harris and Lewis 2001), this does not mean to say that there were no black suburbs either, as Wiese (2004) details in his history of US African American suburbanization.

Suburban diversity also encapsulates the existence of “industrial suburbs” which contained factories as well as homes. In class terms, this means that while male, middle-class suburbanites commuted into the CBD for work, blue-collar workers in the United States and Canada lived and worked in working-class suburbs dominated by factories. US and Canadian workers often owned their homes, partly as a result of self-building (Harris and Lewis 2001). In the United Kingdom, working-class suburbanization from the 1920s to the 1970s also resulted from the large-scale provision of suburban public housing estates by local authorities at below-market level rents (Clapson 2003; Watt 2007).

While white, middle-class residential suburbanization came to dominate the early post-war period in the United States (Jackson 1985), suburban diversification has accelerated. Recent demographic and economic trends have prompted Hanlon, Short, and Vicino (2010) to suggest that there is as much diversity between suburban areas in the United States as there is between the city and the suburb. Such suburban diversity also means that the axiomatic association between outwards and upward mobility via suburbanization requires qualification. This is especially the case given the academic and media concern with contemporary suburban poverty, notably in the inner suburbs of the United States, which has given rise to the negative term “slumburbia.”

Before examining explanations for suburbanization, a definitional caution is necessary. When cities had walls, as during the Middle Ages, the suburbs literally lay outside (under) the city walls. Modern European cities have expanded well beyond their medieval boundaries, however, which indicate how areas can change their geographical status over time in that “suburbs” can subsequently become urban. Dyos (1961) notes that Fleet Street, which is now considered to be in central London, was a designated suburb in the Middle Ages, but that the “suburban frontier” gradually moved south over the centuries so that by the mid-nineteenth century Camberwell, a mile and a half south of London Bridge, became a Victorian suburb. In the epilogue to his book, however, Dyos identifies most of early 1960s Camberwell as urban. In 2013, Camberwell is swallowed up in the inner south London borough of Southwark and is simply part of the metropolis. In the United States, Brooklyn was a suburb of Manhattan at the beginning of the nineteenth century but became the fourth largest city in the country by the century’s end, eventually to become incorporated into New
Suburbanization is thus in many ways a moving frontier.

Explaining suburbanization

Explanations for suburbanization encompass a wide range of causal factors. The Chicago School, and especially the work of E.W. Burgess on the concentric ring model of the city, provided an ecological explanatory framework for suburbanization using Chicago as an exemplar city. Suburbanization here is the end product of a supposed inevitable consequence of the middle- and upper-middle classes moving out of cities in search of more space and pristine environments. The Chicago School approach has been extremely influential in relation to understanding how suburbanization occurs, but critics have drawn attention to its US-centric bias, as well as a tendency to naturalize suburbanization as being an inevitable consequence of rising affluence, and hence underplaying processes of class and racial differentiation.

The development of transportation infrastructure that facilitates commuting has been shown to have a key role in suburbanization. Developments such as the railway, the streetcar, and later the suburban highway have all been associated with the creation and expansion of suburban residential settlements, notably around transport hubs. This can be seen in the association between the development of London’s suburbs and its expanding railway network and stations, first overground and later underground. Camberwell in southeast London, for example, became a railway suburb by the 1860s (Dyos 1961). The enlargement of the railway line between Liverpool Street and Ilford in Essex during the 1890s helped to facilitate the latter’s reputation and growth as a commuter suburb into the City of London; Ilford’s population subsequently increased sevenfold from 1891 to 1911 (Heller 2013).

Contra to the one-dimensional account given by the Chicago School, suburbanization has occurred in various different ways (Clapson and Hutchison 2010). In Anglo-American societies, notions of voluntarism and powerful anti-urban ideologies are prominent, even though neither can be regarded as universal. In such societies, two groups in particular have tended to dominate suburbanization. The first group comprises property developers and speculative house builders who produce suburban housing. In the United States this has typically taken the physical form of detached houses located in what are, by international standards, large yards (Jackson 1985). In the case of the United Kingdom, especially England, suburban housing has often taken the form of semidetached as well as detached houses, but with gardens that are much smaller than their US counterparts (Clapson 2003). The second group is middle-class suburban dwellers who consume housing, usually by taking out long-term loans (mortgages) in order to finance homeownership.

A key debate is the relative causal role played by the producers and consumers of suburban housing. Many mainstream scholars have located the roots of suburbanization in the middle classes exercising consumer preferences in the sense that they optimize their utility by living in large houses in low-density areas – in other words, that they prefer to move out of crowded inner-city homes and neighborhoods. Jackson (1985) discusses the prevalence of the US “suburban ideal,” while Clapson (2003) similarly highlights the “suburban aspiration” in the United States and England, including a combination of anti-urbanism with a desire to own a home and garden in a high-quality residential neighborhood.
Marxist geographers have alternatively sought to explain suburbanization with reference to the spatially uneven nature of capital accumulation. For Harvey (1989), the period of massive postwar suburban development in the United States was primarily driven by flows of surplus capital into what he terms the “secondary circuit of capital,” that is, investment in the built environment. This investment in suburban housing and infrastructure in turn fueled a huge demand for consumer goods in order to facilitate the American suburban lifestyle, notably household motorcars and domestic appliances. Harvey even goes as far as suggesting that suburbanization helped save postwar US capitalism. Thus for Harvey, pursuit of the American suburban ideal was as much a product of capitalist property developers, aided and abetted by advertising agencies and realtors who pushed the dream onto acquiescent US consumers.

Harvey has undoubtedly highlighted the vital contribution played by capitalist processes in the production of the suburbs, as Jackson (1985) also notes in his history of US suburbia. At the same time, Jackson gives more credence to the notion that there was a deep and widespread desire on the part of ordinary middle-class Americans to relocate to the suburbs. A similar desire has been identified on the part of African American suburban residents (Wiese 2004). In other words, capitalist developers were pushing at an open door since potential suburbanites all too willingly wanted to buy into the suburban ideal.

Clapson’s (2003) notion of the suburban aspiration appears to be both relatively benign and democratizing – everyone presumably aspires to live in a “better” home in a “quality” neighborhood. In reality such aspiration involved middle-class suburban inmovers putting miles between themselves and what they disparagingly regarded as “slums” and “slum dwellers” in the city. In other words, suburbanization involved processes of sociospatial class differentiation whereby there was a desire on the part of affluent groups to spatially distance themselves from working-class people and places that they looked down upon. Moving out was – and to some extent still is – a cultural signifier of moving up, even if the objective social distance traveled is in many cases negligible.

As Watt (2007) indicates in his research on London suburbanization, the move to a “better” neighborhood can also have racial as well as class connotations, since white out-movers sought to distance themselves from ethnically mixed inner-city areas. While the role played by race and ethnicity in UK suburbanization remains under-acknowledged, early postwar US suburbanization was a largely white phenomenon, and part of the rationale for this was middle-class whites leaving inner-city areas because they had large African American populations – “white flight” – a racist process of residential mobility that enhanced racial residential segregation (Jackson 1985). Middle-class African Americans also came to leave deindustrialized inner-city ghettos in increasing numbers since the 1970s, prompting some scholars to refer to processes of “black flight.”

The impression is sometimes given that Anglo-American suburbanization was and is simply a matter of market forces, an approach that underplays the historical and contemporary role of the state. In the United States, the state has facilitated the growth of the suburbs, for example, via federal funding for highways and providing tax breaks for home ownership (Jackson 1985). In the United Kingdom, the state has more obviously played a crucial role in working-class suburbanization, notably via local authorities building peripheral public housing estates (Watt 2007). The presence of such estates is also a prominent feature of suburban areas in other Western European societies, for example, the French banlieues.
which have increasingly become home to first and second generation North African immigrants from France's ex-colonies. Finally, if early twentieth-century suburbanization involved the formation of industrial suburbs, these were the result of industrial decentralization.

The above discussion has tended to treat the various explanations of suburbanization as if they are more or less discrete causal factors. In reality, however, these factors work together. One example can be seen in the development of the Essex suburb of Ilford near London from 1880 to 1914. As Heller (2013) notes, we must recognize not only the consumers of new suburban, owner-occupied houses – the growing numbers of male city clerical workers – but also four stakeholder groups involved in the production and marketing of Ilford as a respectable, middle-class suburban neighborhood. These groups are, first, the property developers who built and sold the houses, second, the Great Eastern Railway who doubled the commuter railway tracks, third, Ilford Urban District Council (IUDC) who provided public infrastructure and assisted in the provision of credit for homeownership, and last, Ilford's existing local population who facilitated the social integration of the newcomers. Importantly, Heller (2013) demonstrates the multiple interconnections between these stakeholder groups, for example, in relation to IUDC members who were themselves developers and hence profited from the building of new suburban housing estates.

Suburbanization in post-socialist societies

Rapid and extensive suburbanization has been one of the main themes of urban change in post-socialist societies since the 1990s. In comparison to Western capitalist societies, suburbanization is a relatively recent feature of societies in Central and Eastern Europe, one that has accelerated in the period since the collapse of communism.

In the case of Poland, suburbanization is prominent in the major cities of Warsaw, Krakow, Poznan, and Wroclaw. Polish suburbanization is often based around the core of existing old villages, rather than US-style large-scale real estate developments. In her research on the suburbs of Wroclaw, Kajdanek (2014) highlights how suburbanization involves purchasing or self-building new detached houses. The primary motivation is a desire for improved housing – in terms of size and facilities including gardens – after people have lived in blocks of flats, the predominant dwelling form in Polish cities. In Wroclaw, there is little sense of the anti-urban “suburban aspiration” that Clapson (2003) identifies in the United States and England. The Polish suburbs have a more pragmatic, housing-quality based appeal which facilitates a privatized familial lifestyle. Kajdanek (2014) also found little sense of neighborliness and community in the Wroclaw suburbs and indeed considerable tensions exist between the old villagers and the suburban newcomers who tend to keep very much to their own homes and families.

Post-suburbanization

It has been suggested that suburbanization is currently mutating along “post-suburban” lines. According to Phelps and Wu (2011), suburbs have simultaneously changed form (from mainly residential to mixed use) and exploded across city-regions, a process of entropic urban decentralizing and fragmentation which has created a “post-suburban world.” Suburban hinterlands are no longer mere residential dormitories for commuters to the CBD, but are increasingly sites of out-of-town shopping
SUBURBANIZATION

malls, industrial parks, office complexes, warehouse and distribution centers, airports, and other transport infrastructure. This putative post-suburbanization – variously associated with “Edge Cities,” the “In-between City,” “city-regions,” and so on (Phelps and Wu 2011) – has rendered the question of “where does the city end and the suburbs begin?” increasingly difficult to answer.

If post-suburbanization exists anywhere, it is in the United States and especially Los Angeles which represents the de-centered metropolis par excellence, as seen in the work of the Los Angeles School. However, evidence for post-suburbia has also been identified in European, East Asian, and South American city-regions.

Superstate, supranational union

Julian Clark
University of Birmingham, UK

Historical and intellectual context

Superstate defines an organizing political-administrative entity constituted from multiple states, and possessing substantive or total authority over these states. Constituent states may be ethnically and linguistically varied. The notion of superstate has parallels with, but is distinct from, related concepts of superpower, hegemon, and empire. Historical examples of superstates include ancient China, India, and Persia. In the late nineteenth century, there was discussion about reorganizing the British Empire into an imperial federation, which would technically have been a superstate. More recently the Soviet Union, though constitutionally defined as union of republics, was de facto a superstate because of its major cultural, linguistic and ethnic diversity. As superstate has few definitive characteristics, however, the term is often used descriptively (for example, in terms of scale, to contrast with the nation state), or pejoratively (as in an undemocratic, authoritarian form of statehood).

In geography, superstate has a lengthy intellectual history. There is no definitive claim to its first use, though its antecedents lie in Friedrich Ratzel’s organic theory of the state. Existing geographical theories of superstate are poorly defined, with a lack of clarity over what exactly constitutes a superstate, or how they might be created. Early examples include Naumann’s (1915) advocacy of an Oberstaat (superstate) comprising Germany and Austria-Hungary with an associated free-trade area in central Europe; Kjellén’s (1916) assertion that competition between states would lead to the emergence of superstates in Europe, Africa, and Asia; and Mackinder’s (1904) territorial explanation of how a single dominant world power could emerge by seizing control of central and eastern Europe.

All three notions of a single dominant power underpinned Haushofer’s (1931) concept of “pan-regions,” defined in terms of their distinctive resource, political, and cultural attributes and extensive land area, sufficient to create their own autonomous economic space. Haushofer maintained pan-regions would be unified by a “pan-ideen”: a supranational conception or doctrine, creating regional coherence, unity, and distinctiveness. Instantiations of supranational doctrines during the early twentieth century included Pan-Slavism, Pan-Africanism, and Pan-Europeanism. Haushofer identified four potential pan-regions as the United States, Germany (“Eurafrika”), Russia, and Japan (the focus for a “Greater Asia Co-Prosperity Sphere”). Pan-regions would depend upon their constituent states developing economic and political alliances with core states and yielding to sanctions and major cultural designations enacted by these states.

Each of these geopolitical conceptualizations portray the construction of superstates as inherently geographical – through, variously, the control of strategically positioned territory;
the use of particular technologies to maintain flows of trade, commerce, and military control between states; and by the command of space for explicit geopolitical purposes. Thorndike (1942) provides one of the first popular descriptions of superstate derived from these formal geopolitical theories. By contrast, theories of superstate and supranational union in political science are better developed, the most influential of which are neofunctionalism and liberal intergovernmentalism.

By the mid-twentieth century, with the advent of the Cold War, the importance of superstate was largely supplanted by the notion of superpower. In political geography, superstate is now rarely a topic for explicit study. Recent debates about sovereignty and democratic deficit in domestic and international politics, however, particularly in Europe, have seen a modest revival of interest in the concept.

Major contemporary dimensions of superstate/supranational union

In European mass media, superstate is increasingly used to describe one possible outcome of European Union (EU) integration. Euroskeptics argue that the EU is an emergent superstate, with the term “European superstate” used to critique further supranational union and to imply the forced loss of national sovereignty and autonomy among EU member states, and the gradual erosion of their national identity. The term is often used, mistakenly, as a synonym for a “federal Europe” which, however, differs in that national identities are accommodated with partial sovereignty retained by states, with a new tier of authority above state level given exclusive competence in one or more policy areas. A more accurate expression would be “supranational Europe,” where sovereignty of constituent states would be distributed to European institutions such as the European Parliament, European Commission, and European Court of Justice, with member states retaining little or no autonomy.

Nonetheless, from the outset the EU foresaw a supranational rather than an intergovernmental method of political cooperation. Thus the preamble to the founding Treaty of European Union, the Treaty of Rome (1957), pledges “ever closer union” between the peoples of its member states and is often cited by Euroskeptics as indicative of the covert supranational goal of the “European project.” However, this and subsequent European treaties do not clarify what is meant by “ever closer union,” or whether it should be attained through supranational or intergovernmental means, leading to uncertainty among political scientists and political geographers over the EU’s status. In reality the prospects of a European superstate are remote, as the day-to-day processes of European integration are a complex admixture of intergovernmentalism (with growing importance attached to the European Council as decision-taker) and cooperative federalism. Moreover, there is widespread public opposition among European citizens to concentration of powers in a centralized bureaucracy and little attachment to a European identity; while national identity continues to be overwhelmingly the strongest form of collective affiliation.

It should be noted that there exists a more generalized historical notion of Europeanness spanning national borders which is pertinent to notions of a European superstate. Thus during the Renaissance, the concept of “Europe” was often invoked by humanists as the secular counterpart to Catholicism. Later, “Europe” was used by Voltaire to argue for a European federation based on the rule of law. In the early twentieth century, Richard Coudenhove-Kalergi (1923)
argued the need to recognize and engender Pan-Europeanism. Similarly in the late 1960s the French journalist Jean-Jacques Servan-Schreiber set out a case for the then European Economic Community becoming a superstate in the context of growing US power globally.

While some work has been done to describe the incompatibilities between superstate and the apparent multiple social, economic, and political constructions of Europe, very few studies have been conducted by geographers explicitly on the EU as a superstate. Hudson (2000) sets out three “visions” for the EU’s development in the twenty-first century, one as a superstate. Boedeltje and Van Houtum (2008) characterize a European superstate/suprastate as an “abduction” of European identity.

The fact that there is a wealth of work now on the EU but very little that systematically engages with superstate suggests this category, like superpower before it, fits the analytical categories of the Cold War. This assessment is reinforced by the rise of international organizations (such as the United Nations) and global social movements that undermine the rationale for superstates; the presence of nongovernmental organizations (NGOs) campaigning against state authoritarianism and corruption, such as Transparency International; and the extraordinary growth in importance of social media as a means of moderating citizen–state relations. Yet it should be noted seven of the sixteen Arab states still pledge the creation of a superstate (khilafah) in their constitutions. Al-Qaeda also claims an Islamic superstate as its ultimate aim, while the Salafi jihadist group Islamic State announced in June 2014 its intention to create a worldwide caliphate. Some philosophers and political scientists maintain adherence to the superstate concept. Habermas (2006), for example, has argued in favor of a European superstate to counterbalance perceived US hegemony, while Wendt (2003, 491) contends a “world state” is inevitable if global society is to avoid nuclear annihilation.

Fresh perspectives on understanding the state and the possible role of superstates are thus needed. Two possibilities present themselves. One is to build upon work in political geography on neoimperialism and the reemergence of empire and world states as a focus of study in political science to develop greater cross-disciplinary engagement on the superstate concept. Another is for critical geopolitical analysis of the wealth of fictional superstates in literature, often depicted as dystopian, as a means to explore more utopian possibilities that can enhance contemporary state interdependencies and combat growing authoritarianism and increased surveillance of citizens within states.

SUPERSTATE, SUPRANATIONAL UNION

Supervised classification

Xiuping Jia
University of New South Wales at Canberra, Australia

Supervised classification is one of the machine learning approaches. While no training data are used in unsupervised classification, supervised classification relies on an analyst to define the classes that the data are classified into and provide the training data of each defined class. The output of the trained classifier with the training data is an assignment of a class label to each input data point. Several classifiers are widely used, including a minimum distance classifier, maximum likelihood classification, K-nearest neighbors, and support vector machines. When an image dataset is classified, a thematic map is generated from the class label of each pixel. Training data play the key role in the establishment of the discriminant rules among the classes. The quality and quantity of the training samples are critical issues.

While unsupervised classification generates data classes (clusters) itself based on the defined similarity criterion, the first step of supervised classification relies on the analyst to define the classes to classify. They are information classes and often associated with culture names, for example, lake, ocean, urban, and road. These definitions are direct in terms of meeting users’ interest and the requirement of specific applications. However, it often needs a powerful classifier to handle the complex and highly likely nonlinear class structures. The training of the classifier becomes challenging as well. Alternatively, it is better to define a class that is relatively pure in its constitution to minimize within-class data variation, such as clear water, healthy grass, and concrete car park. By doing this, a few advantages can be obtained: it is easier to capture and describe the unique characteristics of a class; the ability to separate classes from each other is higher and a relatively simple classifier is adequate. It is also important, in general, to define all the classes present in the dataset. For example, if an imaged scene consists of deep water, shallow water, four types of vegetation, and two types of soils, all the eight classes must be defined, even if the user is interested in shallow water and one type of vegetation only, or many pixels may be wrongly labeled as the shallow water and the type of vegetation defined. A postprocessing of class merging must then be performed before a final product is generated for the user.

The second step of supervised classification is for the analyst to provide training samples and corresponding data, which are called training data. Take remote sensing image classification as an example: training samples can be identified with local knowledge, by site visits or using photo-interpretation skills based on the understanding of the remote sensing data. Training data play the key role in establishing the discriminant rules among the classes. They are used directly or indirectly via class modeling and class signature extraction (depending on the classifier used) to recognize to which class a new datum belongs to. Therefore, the quality and quantity of the training samples are critical issues to ensure the classifier is appropriately trained. Basically, the training data of each class are expected to represent the characteristics of the complete class, that is, to cover the variations presented within
SUPERVISORY CLASSIFICATION

the defined class. In the case of remote sensing image classification, multiple training areas may be selected for each class to accommodate the spatial variations. To provide a full picture of each class data and ensure the class statistics can be estimated reliably, the more training samples, the better.

The third step is to select an appropriate classifier. There are several supervised classifiers. They are different in terms of whether or not they model each class data and, if modeled, how they model. A few typical ones are briefly explained here.

Parallelepiped (boxed) classifier: this classifier uses the minimum and maximum values of each attribute (also called measure, or feature) as a class signature. The data are labeled depending on which “box” the unknown datum falls in. This method is simple and fast, but can be sensitive to noise. Class overlapping can happen easily.

K-nearest neighbors (K-NN): this classifier uses the training data in the original form without modeling. An unknown datum is basically labeled based on the labels of its surrounding training data (neighbors) in the feature space by majority vote. The neighbors are first identified using a selected distance measure, for example, Euclidean distance. The distribution of the labels of those neighbors is used for unknown data classification. This method is direct in concept, but can be time consuming to implement.

Support vector machines (SVM): this is a binary classifier, which considers two categories (one class versus another class, or one class versus the rest of classes) at a time. The training data are used to generate a hyperplane in the feature space to separate the two categories with the maximum margin. The regions on each side of the hyperplane define the data space of the two categories, respectively. If the data cannot be separated linearly by a hyperplane in the original data coordinates, kernel SVM can be applied by mapping the data to a higher dimensional space. The data on the class boundaries are called support vectors and they are the critical data in determining the separation plane.

Minimum distance classifier: the mean value of each dimension is calculated using the training data of each class. A mean vector with N elements (N is the number of dimension of the data) is formed and used as the class signature. An unknown datum’s distance to each class mean vector is evaluated and the minimum distance indicates the class it belongs to. This method is insensitive to noise and the requirement for the number of training samples is not high, as only mean values are estimated. However, the difference in the data distribution from class to class is not taken into account.

Maximum likelihood classifier: this classifier considers the distribution of each class datum by modeling it as a normal distribution. The normal distribution parameters, mean vector and covariance matrix, are estimated using the training data. Bayes’s rule is then applied to find out the highest probability of the class that an unknown datum belongs to. This classifier works well if the class data can be reasonably assumed as a normal distribution and the parameters can be estimated reliably using the training data. Mathematically, the minimum number of training samples is N + 1, where N is the dimension of data, so that the covariance matrix has full rank and can be inverted. In practice, multiple times of N are required to avoid overtraining. When a classifier is overtrained, the training results are biased and are unable to be generalized to the data other than training data.

Considering the new big data era, N can be a high number. A very large number of training data is required to run supervised classification. Unfortunately, collecting training samples is an expensive procedure as human resources are
heavily involved. A semi-supervised approach (Chapelle, Schölkopf, and Zien 2006) has been developed that incorporates the use of unlabeled samples. In this approach, the initially trained classifier, using the original training dataset, is updated via self-learning using the information provided by the unlabeled data. An active learning approach (Tuia et al. 2011) addresses the problem through optimal experimental design to minimize the effort in training data collection. The classifier is initially trained using a small training set. Then a learning algorithm is applied to ask the analyst to provide the labels for the new most informative samples. In this way, the redundancy in training data collection can be reduced. Alternatively, feature mining can be applied to reduce the dimensionality of the data and, consequently, reduce the size of the training data set required (Jia, Kuo, and Crawford 2013).

The performance of a supervised classifier can be evaluated using another set of labeled data, namely testing data, which is independent from the training data. Similar to training data, testing data can be identified with local knowledge by site visits or using photo-interpretation skills based on the understanding of the remote sensing data. However, they are not used in the class modeling and classifier training. Instead, they are labeled by the classifier and the results are checked against their ground truth. The checking results are often given in tabular form (called a confusion table). Classification performance can be measured by producer accuracy, user accuracy, overall accuracy, and kappa coefficient (Congalton and Green 2008). A reasonable size of testing samples for each class is required to provide meaningful statistics.

Surface water

L. Allan James
University of South Carolina, USA

This brief synthesis of nonsaline, surface water integrates both the physical and human elements of freshwater resources, that is, both hydrologic and water resources perspectives. The hydrology of surface water is concerned with the physical aspects of water, such as the hydrosphere and hydrologic cycle, water budgets, and runoff-generation processes. In a complementary manner, societal aspects of surface water resources management are concerned with interactions between water and humans that involve types of water use, water availability, scarcity, and equity, global sustainability, and demand management and reallocation. This holistic view of water and water resources management can be summed up under the rubric of integrated water resources planning and management. Management requires an appreciation and understanding of the physical resource but goes beyond that to embrace complex issues of water allocation, conveyance, forecasting demand, and planning for future availability. Growing water demands to irrigate food crops in order to provide for rapid population growth exemplify the dire necessity of getting both physical and human planning perspectives right and getting future supply and demand to meet in an equitable manner.

The study of surface water is commonly separated with a strong focus on either societal facets of water resources or physical, chemical, and biological science perspectives. Such a separation is artificial, however, and often leads to specialized treatment of isolated problems rather than an integrated approach to problems that recognizes interactions between systems. Familiarity with both physical and human phenomena provides water managers with an overview of how physical and social systems interact regarding surface water. This integration is highly geographic insofar as it mimics several geographic traditions, such as regional complexes, spatial analysis, and tensions between humans and the environment.

Constraints for brevity of this entry combined with the broad topical approach to surface water taken here mandate a summary synthesis rather than comprehensive coverage. Thus, several key elements of surface water are omitted entirely. For example, broad topics such as water quality, flood and drought risks, and legal constraints on use and protection of water resources are not covered. For treatment of these topics elsewhere in this volume, please consult the “see also” section at the end of this entry. Moreover, concepts of local water management are given less attention than global views, due to emerging issues of global change, climate variability, and the research and policy initiatives aimed at addressing these problems on a global scale. This article begins with a brief discussion of geographic traditions in the study of surface water. This is followed by the physical aspects of surface water and by resources management concepts.

Geographic traditions in studying surface water

Geographers have long been involved in the study of surface water. In the United States this history can be traced to the explorations...
and studies of John Wesley Powell, a founding member of the National Geographic Society, whose explorations of the western North American continent led him to recognize the critical importance of water resources to western settlement (Powell 1878). In the mid-nineteenth century, surface hydrology became a core concern of physical geographers in the United States and Great Britain through an extension of interest in fluvial geomorphology by scholars including Richard Chorley, George Dury, Reds Wolman, and many others. At the same time, the work of Gilbert White and his students spawned an era of research in two areas: water resources in developing nations and water resources hazards.

The increasing importance of spatial analysis, investigations of human interactions with the environment, climatology, and other traditional areas of geographic research led to a growing involvement of geographers in water science and management over the past several decades. The value of remote sensing mapping technologies coupled with spatially distributed hydrologic modeling brought geographers into mainstream scientific research and planning programs. A panoply of diverse hydrologic models emerged during this period for rainfall–runoff relationships, water yields, droughts, water use, and water quality. Geographers also bring a sophisticated recognition of the importance and complexity of human–land interactions from scientific, environmental, and humanistic perspectives. These perspectives are useful for modeling but also are essential to water resources management and planning. Geography was a mainstay of climatology and hydroclimatology throughout the twentieth century. The tight linkages between surface water and both climate and environmental sensitivity to human activities resulted in a rich tradition of hydrologic and water resources research in geography from a variety of viewpoints.

Representing freshwater resources

Water resources management is a 4-D problem that can be accounted for with simple mass balance methods. A complete accounting should consider water transfers in 3-D Euclidean space over time, which involves evaluations from both hydrosphere and hydrologic cycle perspectives with quantitative accounting methods.

Hydrosphere and hydrologic cycle

The location and amount of fresh water at the Earth’s surface relies on inputs and outputs that vary greatly with location and scale. The global water system consists of the hydrosphere, a snapshot of large-scale water budgets, and the hydrologic cycle, large-scale hydrologic processes and water-flows. The hydrosphere includes water stored in oceans, rivers, lakes, glaciers, soils, the atmosphere, the lithosphere, and the biosphere. From this static standpoint, most of the water on Earth is stored in oceans and is too saline for most human uses. Of the 3.5% of water that occurs on land, most is in glaciers or groundwater reservoirs. Nonsaline surface water that is not locked in ice is only a very small percentage of the total hydrosphere (0.01%) and only 0.28% of the nonoceanic water (Table 1).

Although these freshwater storage reservoirs are a critical resource, fluxes of water between them – integrated over time – are what governs these reservoirs and are what environmental and social systems depend on. Water is a renewable resource, so an appreciation of the hydrologic cycle with flow rates to and from the volumes of storage in the hydrosphere is a central concern of planning and management. By analogy, the volume of water stored in a short garden hose may seem negligible in comparison with the volume of water in a rain barrel. Over a period of time, however, flows through the hose may fill

thousands of barrels. So it is that the dynamics of atmospheric fluxes and river flows may deplete or replenish the largest storage reservoirs and persistent withdrawals may disrupt balances in water resources systems. Flow rates and processes of the hydrologic cycle are important for maintaining the storage compartments of the hydrosphere.

The hydrologic cycle emphasizes fluxes and flows of water between the atmosphere, land, and water bodies, including precipitation, evapotranspiration, infiltration, and surface runoff. Water may move across the land surface as runoff and be stored in soils, biomass, rivers, ponds, lakes, reservoirs, and wetlands before returning to the atmosphere or to the sea. The large amounts of latent energy stored by evaporation and released by condensation, coupled with energy transfers due to convection and atmospheric circulation, result in strong links between climate and surface water at all scales.

Water budgets

Given the principle of conservation of mass, a water budget (also known as a water balance) can be used to determine water movements by accounting for all inputs, outputs, and changes in storage. For example, a simple water budget can express the primary pathways that precipitation (P) may take:

\[ P = ET + RO + I_{nf} + I_{nl} \pm dS \quad (1) \]

where \( ET \) is evapotranspiration, \( RO \) is surface runoff, \( I_{nf} \) is infiltration, \( I_{nl} \) is interception by vegetative matter, and \( dS \) is change in water stored in rivers, ponds, lakes, soil, groundwater, and so on. Change in storage may be positive if inputs are greater than losses or negative if less than losses. Budgets such as equation 1 can be used to compute a missing parameter by specifying all of the terms but one. Each of the terms can be expanded or redefined to account for different fluxes such as adding irrigation water to precipitation inputs, adding water withdrawals, or assuming a parameter is negligible. For practical management purposes, surface water is essentially incompressible, so water budgets can be expressed as masses or volumes. Alternatively, they may be expressed in units of depth over a given surface area, that is, as centimeters of precipitation, evapotranspiration, and runoff. Water budgets are often expressed at regular time intervals, such as hourly or monthly,
in order to track water through a system. Water budgets can be created at any scale. For example, a budget can be constructed for the effects of a storm or long-term fluxes on an individual water body such as a lake or a reservoir. The ending volume resulting from an initial volume and net inputs and outputs can be computed from the mass balance:

\[
V_2 = P - ET + I_{sfk} - O_{sfk} + I_{sub} - O_{sub} + V_1
\]

where \( I_{sfk} \) and \( O_{sfk} \) are surface inflows and outflows, \( I_{sub} \) and \( O_{sub} \) are subsurface inflows and outflows, and \( V_1 \) and \( V_2 \) initial and ending lake volumes. Water budgets are needed that are based on accurate assessments of inputs and outputs and changes through time.

At the global scale, climate is the overarching driver of water availability unless external water sources are available, such as an exotic river or independent groundwater sources. Long-term global water budgets are dominated by precipitation and evapotranspiration fluxes (Gleick 1993). Approximately two-thirds of global terrestrial precipitation is lost to evaporation. Global budgets representing average conditions factor out large spatial and temporal variations. Geographic variability is key to accurate assessments of water availability. As a first approximation, freshwater availability can be mapped by subtracting evapotranspiration from precipitation. Several international assessments of past and future global water availability have been made (Shiklomanov 2000; Shiklomanov and Rodda 2003). Ultimately, however, human activities must be added to these estimates in the form of water transfers, consumptive use, land use, and climate changes that alter evapotranspiration, infiltration, runoff, and storage.

### Surface runoff and flood generation processes

Surface water results primarily from precipitation that does not infiltrate into the soil and from groundwater seepage back to the surface. Pathways of water at the atmosphere–land boundary determine the rate and proportion of precipitation that is lost to abstraction and how much will run off as surface water. Human land-use activities have a tremendous effect on these processes, rates, and proportions of surface runoff generated.

### Water pathways at the hillslope scale

As rain falls or ice melts, surface water at the soil–atmosphere interface flows along identifiable pathways such as through the vegetation canopy, into the soil, or downslope. These paths include interception by vegetation, infiltration into and percolation through soils, surface runoff, and storage. Surface runoff may occur rapidly by Hortonian flow when precipitation intensity exceeds infiltration capacity or by typically lower-velocity saturated overland flows when soils are saturated. Much slower delivery may result from shallow subsurface flows within the unsaturated vadose zone of soils. Flow paths determine the timing of water delivery that governs flooding and the magnitude of soil erosion and pollution generation, which govern water quality. Abstraction processes of interception by vegetation and infiltration by soils reduce runoff so less of the precipitated water runs off on the surface. This abstraction tends to reduce flooding, erosion, and generation of pollution. The infiltration capacity of soils, that is, the maximum rate at which water enters the soil, governs abstraction and the generation of surface runoff. Infiltration diverts water from relatively rapid and erosive surface pathways to...
subsurface pathways that are relatively slow and nonerosive. Both interception and infiltration decrease greatly during storms as vegetation and soils become wet, so rates of initial abstraction are much greater than after it has been raining for some time. In fact, little of the initial rainfall runs off. Later phases of rainfall that generate runoff are referred to as the effective rainfall. Infiltration capacities vary with a number of natural factors, including geology, soils, precipitation characteristics, and vegetation, but they are greatly altered by human activities such as soil compaction and land use that changes land cover.

Human impacts and urbanization

Human manipulations of soil, vegetation, and land cover often result in substantial changes in infiltration capacities. These changes may result in dramatic hydrologic responses, including increased surface runoff, erosion, and generation of nonpoint source pollution. A key environmental consequence of urban land-use changes is exacerbated flooding due to a transition from gradual hydrologic response with relatively low flood peaks to amplified flood peaks that rise rapidly. Pavement, rooftops, storm sewers, vegetation clearance, and soil compaction that often accompany urbanization all contribute to magnified and accelerated runoff generation. In fact, dense urbanization causes increases in flood magnitudes to much greater multiples of flows in unaltered basins than are anticipated with even the worst-case climate change scenarios in noncoastal areas.

The percent area of impervious surfaces has become a common metric in urban hydrology that can be used to indicate not only the degree of increased risk of flooding but also the degree to which riparian habitats and ecosystems have been compromised (Schueler 1994; Walsh et al. 2005). Similarly, the degree to which a basin is drained by storm sewers drives hydrologic response. Computations of runoff for urban watersheds where stream-gauge data are not available should adjust estimates upwards for areas with high percentages of impervious surfaces and high drainage densities of storm sewers in order to compensate for greatly increased drainage efficiencies of those systems. To some degree these processes can be mitigated through the use of conventional storm detention or retention structures or the use of more spatially distributed low-impact development (LID) techniques, such as bioretention (rain gardens), tree-box filters, rain barrels, cisterns, permeable pavements, and green roofs.

Characteristics of different water uses

Water is used in a variety of sectors that may be generally classified as municipal, agricultural, industrial, thermoelectric cooling, and hydropower. At the global scale, water-use categories are defined broadly in a simple tripartite classification system of agricultural, municipal, and industrial, because more specific details cannot be distinguished consistently between nations. These classes can be applied to areas with sparse, incomplete data collected by a variety of methods or approximated by indirect methods such as global modeling. A fourth water-use category for reservoir evaporation losses is included in data developed by Shiklomanov (2000). Fundamental differences within and between water-use categories include variations in consumptive use, in-stream versus off-stream use, environmental impacts, cost, and requirements for water quality, including the ability to use saline water. Understanding water-use statistics is a surprisingly complex skill due to these variations in water requirements and outcomes. For example, in developed nations, the largest
SURFACE WATER

water-use sector may be hydropower production, which is an in-stream, nonconsumptive use. Hydropower production may have extensive environmental consequences and may alter water temperatures and the timing of daily releases. However, impacts of hydropower production on water availability tend to be relatively benign compared to agricultural water applications that are an off-stream, highly consumptive use. Municipal water use, which tends to be of the order of 10% of total use, requires high-quality water and generally has the ability to pay a higher price than other sectors. This use is not as consumptive as agricultural use but returned water requires extensive treatment. The dominant water-use sector in a region tends to be related to the level of economic development. Developed nations often use a high proportion of water for hydropower, thermoelectric cooling, and industrial applications, whereas the dominant water use in developing nations is usually irrigation for food production. The inflexible and highly consumptive nature of agricultural water use for feeding vulnerable local populations reduces flexibility in water use and has grave implications for growing water demands.

Global water scarcity and food security

Shortages of water call for quantitative indicators, that is, metrics of water availability. Available water refers to the amount of water normally accessible for human use. A shortage of available water differs from drought conditions that are relatively brief deviations below normal conditions. Low water availability in arid or semiarid regions is a long-term condition and persists during relatively wet years. In humid regions, a relatively large availability prevails even during droughts. Water shortages depend on both available water supplies and on demand.

Two common water shortage metrics that factor in demand are the Falkenmark index (water stress) and relative water demand (RWD). The Falkenmark index measures water availability per capita. A condition of water stress occurs when long-term per capita availability drops below 1700 m³ year⁻¹ (1230 gallons day⁻¹). Water scarcity occurs when per capita availability drops below 1000 m³ year⁻¹ (724 gallons day⁻¹); this condition is associated with severe health, economic development, and human wellbeing issues. Water shortages can also be expressed as the RWD or criticality ratio, defined as the ratio of demand to supply, that is, the ratio of water withdrawals to available water:

\[ RWD = \frac{\text{annual withdrawals}}{\text{available water}} \]  

Specific thresholds of RWD have been defined with moderate RWD setting in at 20% and severe RWD beginning at 40%. RWD can be defined over the long term, seasonally, or by sector. Water availability is strongly dependent on scale; that is, the amount of water available increases as a power function of the area of the basin or grid cell used for computation. Conversely, water scarcity and RWD are scale-independent because they are standardized by population and water availability, respectively (Perveen and James 2011).

Water stress and RWD are strongly interdependent insofar as demand is often related to population. Scatter around the predicted line in a plot of the two metrics for 26 global regions, however, reveals important differences between regions (Figure 1). African regions all plot below the line indicating that water shortage is driven more by population (per capita water availability) than by other demand factors generating withdrawals (RWD). Subsistence agriculture is prevalent in Africa with relatively small withdrawals by industry or thermoelectric cooling. Developed nations with high withdrawals for
industry or cooling water, such as in North America, plot above the line. Of the 26 regions, only northern Africa has critical water scarcity, although southern, central, and western Asia have extremely high RWD values and several regions have moderately high RWD values. The small number of regions with water scarcity in this plot is due in large part to regional averaging that dampens out local extreme shortages. Mapping at subregional scales would reveal many areas with critical water shortage conditions.

Two types of water can be identified (Falkenmark 1995). Green water is stored in soils, is relied upon by rain-fed farming, and is usually available for plant use. Most global food production is currently based on green water. Blue water is water stored in surface and groundwater bodies and can be transported and used for irrigation projects. Water resources management is largely concerned with storage, transport, and allocation of blue water. Global water demand for irrigation water is growing, however, in response to exponential population growth. The need to shift water to irrigation to meet growing food demands stems from the much greater efficiencies of irrigated food production over dry farming. Postel (1993) estimated that irrigated lands comprised only 16% of the farmland areas, yet they produced approximately one-third of the global food supply (Figure 2). Expansion of food production to feed growing populations represents a rapid increase in the demand for blue water for irrigation.

Global expansion of irrigated lands accelerated greatly after World War II, as mechanized farming and the use of chemical fertilizers proliferated and demand for food grew in response to population growth during the baby boom era (Figure 3). Details in the rate of growth of irrigation after 1960 can be inferred from the areal expansion of irrigation land. By far, Asia has the largest area of land under irrigation and irrigated lands in Asia more than doubled from 106 million hectares in 1961 to 229 million hectares in 2012 (Table 2). North America and Europe have the next-greatest areas of irrigated

Figure 2 Irrigated land can produce much more food than dry farmed land. The area of irrigated land is a modest proportion of global farmland (left). Yet, irrigated lands produce approximately one-third of the global food supply (right). Data from Postel (1993).
Global sustainability and water resources

Sustainability refers to rates of resource use that can be maintained for an extended period of time without substantial depletion of the resource or damage to social and environmental systems. This implies time periods that should be measured in centuries or longer. Violations of sustainability principles may lead to both intergenerational inequities and environmental damages, because shortages often generate serious socioeconomic and ecological damage. Global water supply and demand are presently out of balance and projections indicate that this imbalance is growing, which will continue to damage environmental and social systems. In other words, present water-use policies are not sustainable. Solutions to this situation are extremely difficult to find because the fundamental problem is rooted in population growth and the growing need for food production.

At the tenth Stockholm Water Symposium in August, 2000, acute water shortages in dozens of nations were recognized, and water shortages or worse were projected for up to two-thirds of the world’s population by 2020. In the interim, climate change and political unrest have complicated such forecasts, but shortages are coming to bear. Implications of these shortages vary with supply and demand as well as with social resiliency. In impoverished areas with severe water scarcity, extreme hardships may emerge. The traditional approach for meeting demand in times of water shortage has been to increase supplies, but this has shown rapidly decreasing effectiveness as sources of additional water have dwindled. Conservation of water resources,
that is, water demand management, must be an important element of the solution. Conservation will be difficult, however, due to increasing demands for food production, which requires a growing proportion of use for irrigation, a highly consumptive application. One strategy for increasing food production in wealthy countries with limited water supplies is to import food. Market exchange of commodities for food, known as using “virtual water,” is a practice that may be a viable alternative to increasing irrigation for nations that can afford it, but it is not a solution for the poor countries with severe water stress.

**Integrated water resources planning and management**

Complex interactions between environmental and social systems that interact with surface water—require a broad, integrated management perspective. An interdisciplinary approach to water resources management is needed that integrates economic, political, physical, and technical methods to achieve sustainable and ethical ends. Integrated approaches were advocated by Gilbert White (1961) and were still considered relatively new in the 1990s (Getches 1993). The concept of integrated water resources management (IWRM) is now commonplace, but in practice procedural norms are far from integrated. Integration requires coordination of diverse methodologies and disciplines as well as cooperation between regulators, institutions, and stakeholders across a spatially diverse landscape. It requires public and professional interactions that only arise from active attempts to engage diverse viewpoints in dialectic exchanges. Spatial integration of phenomenon is also an important element of IWRM. Locations of features and stakeholders in space are affected by adjacency, proximity, and distance, and these geographic factors should be considered essential.

Integration can greatly reduce redundant efforts between groups studying and managing water resources. It can also reduce errors generated when nonspecialists attempt to solve problems outside their areas of expertise by ensuring a diverse team approach. Efforts to integrate broad scientific, sociopolitical, and environmental perspectives initially encounter challenges due to communication and ideological differences. Once these barriers are overcome, however, integration results in improved efficiencies, as solutions are developed from a variety of perspectives that satisfy multiple objectives.

SURFACE WATER

“Surplus labor” is a concept developed by Karl Marx in the mid-nineteenth century. Unlike classical economists of his day and ours, Marx’s labor theory of value explains economic relations through the lens of the production and distribution of surpluses. Surplus is something extra, something beyond that which is needed. Surplus labor refers to the labor that produces a value over and above what is necessary for the reproduction of an individual worker or workforce. Workers in societies of all kinds perform surplus labor, which is “extra” labor beyond what their immediate subsistence requires. Thus workers in all kinds of societies produce a surplus beyond what they need for their own survival. Those surpluses are distributed in a variety of ways in different contexts. For Marx, how and by whom that surplus is appropriated and distributed is the moment that distinguishes an economic process as capitalist, slave, communal, or feudal to name a few among many possible relations of production.

In order to consider some portion of labor “surplus,” it follows that some other portion of labor is considered “necessary.” Thus, it is helpful to divide the working day into two (see Table 2; see below). For Marx, necessary labor is the portion of the working day that produces the value of the means of subsistence. The value of what is necessary for subsistence is socially defined and continually negotiated. For example, workers in many places have fought to establish and raise minimum wages. We might consider the minimum wage of a given location, the socially recognized value of necessary labor. We could call this variable amount the survival payment or, in the language of Marx, the value of labor power. It is the amount workers need to pay for necessities such as housing, clothing, medical care, food, and transportation to and from work. It is the amount they need in order to show up to work the next day. Consider the example below.

A small business with one employee generates $200 in revenue per day. The employer pays the minimum wage set by law which in this fictitious example is $10 per hour. As depicted in Table 1, after the owner has covered his/her nonlabor inputs of $40 and labor inputs of $80, there is $80 left over. That remaining $80 is called “surplus.”

The $80 per day wage paid by the owner to the worker is the socially negotiated value that covers what the worker needs to show up for work the next day. “Necessary labor” is the labor required to produce the $80 value of the workers’ survival payment, the minimum wage. If the worker produces that value in four hours, they perform four hours of “necessary labor.” Labor performed above and beyond those four necessary hours is considered “surplus labor” which is in this accounting unpaid labor. The value produced during those surplus labor hours is called “surplus value” (“SV” in Table 2).

Scenario “A” in Table 2 depicts a work day in which the value of the survival payment is produced in four hours but the worker continues working an additional four hours. The first four hours of the work day are spent performing necessary labor dedicated to the reproduction of the worker while the second four hours are considered surplus labor. The value that he/she produces during the portion of the day performing surplus labor is called surplus value.

</table>

In scenario “A” the worker produced a surplus value of $80. As the wage rises (incrementally in scenarios B, C, and D), we see a decrease in surplus value (from $60 to $20 respectively).

The boundary between what is considered “necessary” and what is considered “surplus” labor varies between enterprises and geographic location and it is often intensely negotiated among economic agents. As shown in Table 2, an increase in survival payment results in a decrease in surplus labor. If the minimum wage rises or the employer decides to increase the wage to $12.50 per hour or $100 per 8 hour day, as depicted in scenario “B,” surplus labor would decrease by one hour. Thus, when other variables remain constant, an increase in the survival payment is equal to the decrease in surplus value. In scenario “B,” we see a reduction of surplus value in the amount of $20 per worker per day. Instead of increasing the wage (or survival payment), the employer could decide to donate surplus to charity, invest it in the business, keep it for him/herself, or return some of it to workers in the form of profit share or bonuses. From a Marxist perspective, regardless of what the owner decides, the enterprise in this example is considered capitalist because decisions regarding surplus labor reside with the owner of capital.

Surplus labor analysis reveals a fundamental antagonism between workers and owners of capital in a capitalist context because profit originates in the unremunerated labor hours of surplus labor. In productive industries, surplus value is maximized by lengthening the working day and minimizing the wage (again see Table 2). The profit motive thus drives the capitalist business owner to minimize what is deemed “necessary labor” and maximize “surplus labor” by minimizing the wage and expanding the work day. Conversely, workers
fight for shorter days and higher wages, which, as we see in Table 2, decrease surplus labor from which profit is derived. Throughout the history of industrial capitalist development, labor movements have fought for greater wages and limits to the length of the work day.

Due partly to the success of organized labor in the developed regions of the world, some labor-intensive manufacturing production has shifted from places with highly paid union workers and an 8 hour day to places in which the working day is longer, survival payments are smaller, and labor is not unionized. Workers in China, for example, tend not to be unionized and may require $1.50 per 10 hour work day while workers in Canada or the United States might require $80 for an 8 hour day. Given nonlabor costs of production and production output equal to those of the business depicted in Table 2, a worker earning $1.50 per day would produce the value of his/her necessary labor in one and a half minutes. The remaining 9 hours and 58.5 minutes of the work day would be spent performing surplus labor generating surplus value of $198.50.

Surplus labor is performed, and surplus value produced, by workers in a variety of economic arrangements or processes, not just capitalist. For example, a worker cooperative may look very similar to a capitalist enterprise. Worker members perform necessary and surplus labor and produce surplus value just like waged workers in a capitalist enterprise. However, from a Marxist perspective a worker cooperative is considered a noncapitalist communal enterprise because the workers themselves appropriate and distribute the surplus value produced by their own surplus labor. Unlike capitalist businesses in which decisions regarding surplus labor are made by the nonproductive owners of capital, in a worker cooperative, members negotiate decisions with their coworkers about their own surplus labor and the surplus value they produce.

The concept of surplus labor is essential to understanding the origin of profit from a Marxist perspective. It is a key concept in critical geography concerned with labor and capitalism because profit, the sole motivation of conventional business, is derived from surplus labor. Surplus labor accounting can be used to measure the rate of exploitation in the form of unremunerated labor hours in a given enterprise. It also provides an understanding of geographic trends in a profit-driven enterprise as well as economic diversity and possibility. For if a capitalist process is simply one in which surplus value is appropriated by nonproductive owners as profit, the economy appears far from definitively capitalist.

Surplus labor accounting demonstrates that even in industrialized economies people participate in multiple rather than exclusively capitalist modes of production and exchange as workers, owners, producers, appropriators, and distributors of surpluses. Feminist economists and geographers distinguish over half of economic processes worldwide in both rich and poor countries as noncapitalist. Thus understanding surplus labor illuminates capitalism and its exploits as well as the ways through which an economy is constructed through feudal, slave, capitalist, gift, volunteer, and communal among other economic processes.

**Surveillance and geography**

In these times of increasing tension and insecurity, surveillance has become an important topic in many academic fields, including geography. While surveillance studies is a growing and genuinely multidisciplinary field of research, scholars from each discipline have their unique perspectives whereas geographers focus on space. In terms of sustaining order, it matters who is where and when – hence, the combination of space and time is essential. Technologically advanced systems use positioning or define geolocation – practices which also have their foundation in spatial existence. As a matter of fact, most forms of surveillance are spatial in one way or another. Nonetheless, there are two contexts that have caught the attention of academic geographers: border control and the monitoring of public urban space.

This entry proceeds from some historical notes and essential definitions toward metaphors and theories. Metaphors such as “1984” or “the panopticon” have commonly been used for describing the manners of surveillance. Nevertheless, critical examinations of these metaphors have helped in developing academically significant social and spatial theories. Thereafter, the entry goes on to highlight two research lines within geography. The political geography of surveillance focuses on the changing nature and role of borders and border control. Urban geography, on the other hand, examines surveillance practices in public urban space and claims that they produce a risk of spatial segregation. Last, a brief look at counter-surveillance shows what developments are likely to take place in the future.

**Defining surveillance**

The definition of surveillance as a practice is far from easy to elucidate. Generally, surveillance is understood to mean observing people’s behavior, activities, and communications for the purpose of controlling, managing, directing, or protecting them. Surveillance is often perceived as something or someone looking from above. The French origins of the word support this perception: surveillance combines two French words, “sur” – meaning “from above” – and “veiller” – meaning “to watch.” Hence, literally the word would translate “watching over.” However, while surveillance can include visual control, it also includes various other forms of information gathering and management. In terms of location, surveillance can take place “on the site” where something is happening at the moment, but it can as well include monitoring from a distance by detaining electronically transmitted data. Surveillance can be used for intelligence gathering, for preventing and investigating crime, and for protecting citizens and borders.

While the bodies which currently conduct surveillance are on the leading edge of developing technology, the history of surveillance has been
rather “low-tech.” Humans have monitored each other by various methods long before current technologies were established. Postal interception, eavesdropping, and telephone tapping have been among the first surveillance techniques. Furthermore, espionage has long been associated with an institutional effort by governments spying on potential or actual enemies. Mostly this has been for military purposes – identifying enemies coming from “outside” – but there are notorious examples of countries monitoring their own citizens – identifying the enemies “within.” Former communist East-European countries had an intense net of informers who surveilled their fellow citizens. Currently, similar practices take place in many nondemocratic countries around the world and, all the more, significant amount of surveillance technology is developed by military institutions. Surveillance tends to increase “in layers”: the old forms do not disappear when new ones are invented, but stay “underneath” the more sophisticated forms. This has led to a widespread intensification of surveillance.

People persistently perceive surveillance as centralized, as if there would be one database and one monitoring station managed by the authorities such as security guards or law enforcement executives. However, this is quite often not the case. When it comes to video surveillance, cameras operated by the private sector have outnumbered those used by the authorities for a long time. The majority of cameras are operated by corporations or other private parties. Furthermore, the authorities currently have very little control over how and where surveillance is used. Surveillance is increasingly conducted by people other than the police and security guards, for example, by janitors, shopkeepers, bus drivers, nurses, teachers, and so on. Corporate surveillance – both in physical and online environments – is used for consumer profiling and marketing. While corporate surveillance has its own specific purpose, it does not take place in a vacuum but information is often conveyed to government agencies.

With cheaper production techniques, surveillance cameras are simple and inexpensive enough to be used in home security systems and for everyday surveillance. Private individuals have been active in applying new technologies. Home security systems with alarms, cameras, and private policing services have become increasingly common. Also, mobile phones enable instant photographing and tracking. Both the responsibility for evaluating risks and the responsibility of implementing control have increasingly been moved away from different institutions toward individual citizens. David Lyon (2014, 72), accurately states that “[i]t is time to stop thinking of surveillance merely as a top-down phenomenon where ‘they’ monitor ‘us.’ Surveillance has become an everyday social experience, from a serious security issue to an incessant demand for data from numerous organizations to a playful part of mediated relationships.”

There are so many different constantly developing types and forms of surveillance that formulating any solid definition is challenging.
While these practices are overlapping in many ways, a rough categorization of different types increases understanding. Visual surveillance – video surveillance, often also called closed circuit television (CCTV) – is likely to be the form of surveillance people most often face in their everyday lives. Surveillance cameras are so widespread, especially in Western cities, that visual control has become a permanent condition. Video surveillance is also used for traffic control. Cameras can identify and track vehicles as they move around. Future development is likely to increase the amount of facial recognition software and other advanced video analytics which will then identify and track individuals everywhere they go. Visual control does not always need human workforce: rapidly developing algorithmic surveillance is able to identify many kinds of “risky” behavior without human intervention. Pictures and video can be gathered from aerial vehicles such as helicopters or unmanned vehicles called “drones.” Military surveillance is a typical setting for aerial vehicles but there are applications for civil use. In fact, helicopters – and increasingly also drones – are used by the police both for searching criminals and for “crowd control” in demonstrations and other mass gatherings.

Biometric surveillance is a term defining various technologies which measure human biological characteristics for authentication, identification, or screening purposes. These technologies include, for example, documentation of fingerprints, DNA profiling, facial recognition (which identifies people based on the unique configuration of a person’s facial features), and iris recognition (which is based accordingly on the uniqueness of each person’s eye). Identification of people is most crucial when crossing international borders, but some countries have internal ID cards and identification systems. Regular use of identification forms a cumulative electronic data storage, which can then be used for profiling a particular individual.

Dataveillance is the term most often used for surveillance by means of personal data systems. Dataveillance means the systematic and automatic monitoring (of actions or communications) of individuals or groups through information systems that collect personal data. These personal data systems store a “copy” of the individual. They reduce the physical body into binary categories through which a coded counterpart, “data double,” is formed. However, the information that is gathered and coded can always only be fragmented and incomplete and so can the data double. Mistakes are easily made in the data input and these mistakes can be challenging to correct. The data double is not a mere theoretical concept, but in certain events it can “take over” one’s material body. This is the case, for instance, when a person ends up on a blacklist of international travel restrictions without knowing the reason why. Data enables, but also restricts, and surveillance data is very difficult, if not impossible, to correct or erase.

One currently prevalent form of surveillance takes place in the Internet and focuses on the activities of individuals who are online. Cookies track users across Internet sites and collect information about browsing practices. This information can then be used, for instance, in targeting advertisements for that person. Monitoring and restricting Internet use is also a powerful political tool. Internet censorship is widespread, especially in nondemocratic countries, where data traffic on social media sites and other networking tools, such as Facebook, Twitter, and MySpace, are heavily monitored or even banned. In actual fact, this censorship could be conceptualized as a global indicator of democracy and freedom of speech.

Surveillance can also specifically focus in physical space and be based on identifying location and movement. Radio frequency identification
(RFID) commonly called “tagging” is the use of small electronic devices which can be incorporated into artifacts, animals, and so forth, for the purpose of tracking by radio waves. Using RFID tagging on people is a controversial but emerging trend. Global positioning system (GPS) is another way of identifying location and movement. GPS tracking system is a space-based satellite navigation system that provides detailed information on locations. Mobile phones can also be used in order to collect geolocation data. Besides being used for surveillance, people readily use GPS systems themselves. For instance, dating-related mobile phone applications based on GPS data are widely used by people who give out their own location and in return gain information on potential spouses in the vicinity. The types of surveillance mentioned here are only a few, but already one can begin to understand the scope of varying political, societal, and personal implications succeeding these practices.

Metaphors and theories

The “Big Brother” metaphor is often associated with surveillance. This metaphor refers to George Orwell’s novel, *Nineteen Eighty-Four*, that was published in 1948. The novel describes a fictional totalitarian society with a mass surveillance system involving human operatives, lay informants, and “telescreens” in people’s homes. This novel has had a significant influence on the public imagination on surveillance: it is both based on and further nourishing the idea of centralized control.

In academic contexts, surveillance has commonly been compared to the panopticon: a prison house designed by an architect called Jeremy Bentham in the late eighteenth century. The design consists of a round structure with cells on an outer ring surrounding a single guard tower situated in the center: from the cells it is impossible to see whether or not someone is looking from the tower. However, it was not the design itself that made this prison a metaphor for modern disciplinary societies, but the panopticon’s social meanings were pointed out by a French philosopher and social theorist, Michel Foucault, in his book *Discipline and Punish* (1977).

Since Foucault’s interpretations, the panopticon has been described as an ideal architectural figure of modern disciplinary power. Its unique structure creates a consciousness of permanent visibility as a form of power, where no bars, chains, and heavy locks are necessary for domination any more. Constant surveillance makes the
exercise of power almost automatic: people are controlled, categorized, disciplined, and normalized without any clear purpose. Foucault saw this as an accurate technology of power which was designed to solve the problems of surveillance.

It is understandable why panopticon has charmed scholars in surveillance research: the metaphor has often been found to be a useful tool when analyzing the functioning of surveillant power. For instance, video surveillance has a similar feature as panopticon does: it is a technological solution designed to solve the problems of surveillance in urban space. Through surveillance cameras the panoptic technology of power has been electronically extended, almost like cities would become “enormous panopticons” (Koskela 2000).

However, as surveillance practices expand and the theoretical understanding of surveillance increases, the panoptic framing of research starts to become more restrictive than enabling. It seems that even though panopticon, like “Big Brother,” has influenced surveillance research in its early years, present-day surveillance is too complex to be explained simply by these metaphors. The Big Brother metaphor, for instance, is nowadays more often connected to “surveillance entertainment” and performing for the camera than it is understood as the grand ideal of centralized control. Similarly, panopticon fails to take into consideration the complex roles of watchers and watched in decentralized surveillance. Nevertheless, Foucault’s work does show that space has a crucial role in the exercise of power: there is a reciprocal relationship between power and space.

The political geography of surveillance

The terrorist attack on New York’s World Trade Center on 11th September 2001 has continuously been articulated as a derivation of contemporary surveillance culture. In terms of global terrorism, 9/11 was nothing new. Yet, in terms of global surveillance, it made a difference. The United States – with all its political power – has been able to intensify surveillance on a new level. Any local threats there might have been were combined with global threats. The use of the discourses of terrorism has become both politicized and anchored in global and national policies. This has caused tension in international relations and change in Western foreign policies, which now increasingly emphasize national strategies for protecting territory. Further, the global and local definitions of security have become increasingly overlapping, leading to a “rescaling and reterritorialization of security as both a concept and a practice” (Coaffee and Murakami Wood 2006, 504). Surveillance is used to protect the territoriality of the state. The state can use surveillance both to control access to its territory and to resist unwanted political activity inside its boundaries. These practices together form a particular political geography of surveillance with new attention being paid to borders.

Figure 3 Surveillance cameras are typically a part of contemporary urban renovation projects, St Petersburg, Russia. Photo by Hille Koskela.
SURVEILLANCE

Borders are an important topic in surveillance research as they are the focal points of intense surveillance practices. Security issues which previously were defined as being in between the states have now geographically changed: the conceptualizations of local, regional, and global have become fuzzy. The more eagerly people seek to protect their own and gain national security, the tougher becomes the national border control. The contemporary geopolitical forces are forcing the rise of a new authoritarianism, heightened border anxieties, hostility toward refugees, and the legitimization of violence. Hence, many ethnic and minority groups face tight control procedures as well as routine harassment and racial and religious profiling. At worst, minority groups are deemed to pose a threat to national security.

Borders are constantly challenged and redefined. Boundary-producing practices, discourses, and performances both constitute and are constituted by diverging elements of power, such as authority, coercion, domination, seduction, and manipulation (Paasi 2009). Borders no longer exist merely in the far edges of a territory but they are located deep within the territory (in international airports, inland harbors, and equivalent points of entry) or far outside it (in points of origin from where it is possible to travel into that territory).

Overelaboration of the proactive and preemptive border control strategies – such as transnational databases of foreigners, profiling of potentially threatening nationalities, or biometric control on the borders – mean that surveillance has increasing influence on human mobilities. “Intelligent surveillance” includes smart passports with biometric information such as fingerprints, iris, and facial recognition features. This will change our concept of both the dynamics of present global flows and that of belonging.

Being able to move freely and being entitled to a positive sense of place have become privileges.

The urban panopticon

The number of surveillance cameras, and the amount of urban space under video surveillance, have grown vastly in recent decades. Video surveillance is changing the nature of urban space by making it more defended (Koskela 2000). Many contemporary scholars have pointed out that the principle of video surveillance is much the same as the principle of the panopticon: to be seen but never to know when or by whom.

Urban space surveillance has become most common in publicly accessible urban spaces, such as streets and squares, transport terminals, and shopping malls. In these spaces surveillance has emerged as a means of reducing crime and fear of crime. It not only aims to protect property but also tries to reduce violence and to achieve better safety and inviolability for people. One reason for the popularity of video surveillance is its easiness and assumed effectiveness. Compared to patrolling by foot, video surveillance enables the same amount of workers to oversee larger spaces.

Despite all the policing with surveillance cameras, it remains uncertain whether surveillance cameras really reduce crime, and if so, how significantly. Research reveals contradictory results as, in addition to not having any effect at all, CCTV systems have been found to both decrease and increase crimes in separate areas under research. The positive effect of these systems also tends to fade as time goes. Furthermore, there is evidence that surveillance causes “crime displacement”: while in some cases the areas under surveillance might become safer, the adjacent areas not covered by cameras can become more dangerous. In relation to property
crime, which can be compensated, the gains of surveillance are quite obvious. In relation to violent crime, they are less so. Video surveillance operates mainly backward: it helps more in solving crime than preventing it. In the event of, for instance, street violence, surveillance might have no effect in preventing the event. This is a common reason for doubt and mistrust.

Crime prevention, however, is not the only reason for urban space surveillance. Control of urban space – public and private policing, access control, and surveillance – aims to “normalize” it – making the space appealing to “normal people” instead of “suspicious groups.” The more there are “normal” people in urban places, the less space is there believed to be for panhandlers, wanderers, and other unwanted groups. Thus surveillance contributes not only to what but to who is allowed in public space. The contradiction is that it is always a matter of debate about who is considered normal and therefore allowed. While the idealistic aim of urban surveillance is to make public space safer and more available to different groups, surveillance in fact targets various groups differently, and specifically focuses on those groups deemed “suspicious.” This heterogeneous assortment of suspicious groups include, but is not limited to, youths, political activists, people of color, people of different origin or religion, homeless, and sexual minorities. Surveillance creates knowledge based on certain assumptions, categories, and technical abilities. Since urban surveillance is widely used to monitor those perceived as deviant, it entails an element of discrimination by default. Surveillance data is used for social sorting, in which less privileged populations are disproportionately stigmatized, discriminated against, or excluded. Thus, surveillance data is no less political or value-laden than any other information.

Surveillance in urban space is also relational: in addition to considering “what” is normal or “who” is normal, it is a matter of debate “when” is normal. This means that if something is considered to be appropriate behavior in a particular time and place, it might be regarded as “deviant” in another context. The norms change depending on time and place but also according to gender, age, race, color of skin, sexuality, and so forth. People targeted by surveillance have different understandings of their relations to society; some are strong, others are marginalized and threatened. The condition of being under surveillance, accordingly, can make people react in different ways.

Emotionally, there is a big difference between being looked at by someone directly and being looked at through the lens of a surveillance camera. The variety of feelings surveillance evokes is enormous: those being watched may feel guilty for no reason, embarrassed or uneasy, irritated or angry, or fearful; they may also feel secure and safe (Koskela 2000). Clearly the experience of surveillance is also dependent on whether or not the persons know they are watched. If someone discovers that they are exposed to surveillance involuntarily, it “provokes emotional, psychoanalytic and corporeal responses which are sometimes stultifyingly profound” (Ball 2009, 644).

Quite often, however, people’s feelings toward surveillance are ambivalent or even indifferent. What is characteristic of surveillance design is its paradoxicality – while everything (and everyone) under surveillance is becoming more visible, the forces (and potential helpers) behind this surveillance are becoming less so. Ambivalence toward urban space camera surveillance might simply be because there is “no identifiable ‘watcher’ or perceivable ‘control’ being asserted” through the cameras (Ball 2009, 641).

At the societal level, the expansion of urban surveillance and protection has been claimed
to lead to a vicious circle of defense. Although increasing security might make some people feel safer, it can also create increasing fear, racist paranoia, and distrust among people. A city that is designed to look dangerous starts to feel dangerous. Furthermore, this development might lead to a “fortress” city where some parts of the city are heavily guarded and controlled while others are left to their own devices. As a result, the original effort to make public space safer and more used might actually lead to the opposite.

Counter-surveillance and criticism

In much of surveillance research the role of surveillance technology has been perceived either overly optimistically (embracing the prospect that all social improvement is technology driven) or overly pessimistically (believing that all surveillance leads to totalitarianism). Surveillance is often a violation of privacy, and as such is opposed by various civil liberties groups and activists. However, surveillance can also be understood as a “social experience” (Lyon 2014) and as such is a part of the daily lives of many. As there are numerous different and developing types of surveillance, there are at least as many approaches for dealing with that surveillance.

Obviously, the purpose of surveillance is to exercise power: to curb “deviant” behavior, to prevent crime, and to keep a space safe. The Foucauldian way of understanding surveillance treats power as something that is exercised: those who can see and who are in the position to see are considered more powerful than those being monitored. However, this apparent control engenders other forms of power, both intended and unintended. The politics of seeing and being seen are complex: who has the right to look and whom will be looked at? What kinds of power relation and structures shape the space under surveillance, and how?

Furthermore, the politics of seeing is not merely about the right to look, but the possibility to do so. In the 2000s, surveillance equipment has become readily available to an increasing amount of people. Camera phones, portable video cameras, webcams, and other visual recording technologies have become more common, are more often connected online, and can instantly link images to global information flows. Although not all of these technologies are explicitly surveillance devices, people who carry them can easily turn into surveying subjects. People are wary of being passive targets of an ever-increasing surveillance and instead seek to play a more active role in producing, circulating, and consuming visual material. And as more people have access to surveillant devices, the differences between watcher and watched, controlled and controllers fade. People start to take surveillance into their own hands, either aiming to resist the official forms of surveillance or wanting to create their own practices of monitoring.

Resisting surveillance can take many forms. At the societal level, one can implement resistance by challenging the legitimacy of various surveillance measures, making surveillance practices more visible and recognizable and attempting to raise public debate about them. Critical people can also take surveillance equipment into their own use, turning surveillance against the authorities. For instance, video activism as a form of counter-surveillance targets police and other authorities in demonstrations and such in an attempt to prevent possible police brutality and provide evidence in such cases. On a personal level, resistance can be lived out by aiming to avoid surveillance systems in private life – to be anonymous despite surveillance. These societal and personal forms of resistance have been conceptualized as counter-surveillance.
While counter-surveillance always involves some form of criticism toward surveillance or a certain kind of political agenda, people also adopt surveillance equipment into their own use without a specifically critical stance. This can include, for instance, producing or watching visual material for one’s own purposes or simply playing with surveillance equipment. In surveillance research this type of “resistance” has been labeled “hijacking surveillance” (Koskela 2011). More than an organized form of political resistance, hijacked surveillance is about random witnessing (and recording) of incidents.

The transparency fostered by surveillance no longer operates in a single direction as people are involved in various counter-surveillance practices that can reveal official misconduct. Similarly the surveillant power is no longer merely in the hands of the authorities, but anyone, anywhere, can become a surveillant.

Surveying

Andrew J. S. Hunter
University of Calgary, Canada

Surveying is the science of collecting data about the location of geographic features, and drawing those features on a map, plan, or digital model. Geographic features include natural landforms, lakes and rivers, bridges, roads, and other things that have been built by people, and even abstract things such as property boundaries. In this context surveying is all about measurement, the technologies, and methods used to locate a feature in two- or three-dimensional (3-D) space, and to determine its size. Common forms of surveying include land surveying (determining where (property) boundaries are), topographic surveying (collecting 3-D data about the shape of the Earth and the location of features such as rivers, lakes, roads, trees, etc.), and “geodetic” surveying (the measurement of the size and shape of the Earth, and the setting up of triangulation networks that define coordinate systems to which topographic details can be mapped).

Today, wherever there is land development, there is also surveying, whether above or below ground, on or in water. Surveying ensures that new developments fit with the old.

Surveying requires knowledge of mathematics, astronomy, geography, physics, mechanics, metrology, statistics, geophysics, and other scientific disciplines. Practitioners of surveying, surveyors, also require a theoretical and practical understanding of scientific measurement devices. Surveying locates features on the ground by measuring angles and distances with respect to a datum, a geodetic coordinate system, or a map projection. With recent progress in technology, global positioning systems (GPS), for example, time is also critical. To measure accurately, surveyors are most concerned with the effect of the atmosphere, as changes in temperature, pressure, and humidity will affect measurements. Surveyors are also concerned with the geometric configuration of measurements to ensure that the necessary positional accuracy can be achieved through a network of measurements.

The earliest historical records suggest that surveying began in Egypt around 1400 BC. Herodotus, the fifth-century BC Greek historian, recorded that the ancient Egyptian pharaoh Sesostris divided the Nile Valley into equal-sized plots and allocated them to Egyptians. He then raised the revenue he needed by levying a tax on each landholder. Annual flooding of the Nile River would wash away portions of the plots and surveyors would be sent to replace the boundaries and calculate how much land landholders had lost. These early surveyors were known as the dragger of the rope, since they measured distance using a schoinion (a measuring cord) 100 cubits long (150 ft or ca. 45.7 m), with knots every 12½ cubits (18.7 ft or ca. 5.7 m).

The science of geometry and trigonometry formalized by early Greek mathematicians such as Euclid and Archimedes is believed to have arisen, in part, out of the practical demands of surveying. Greek and Roman surveyors worked exclusively in Euclidean geometry using the concept of similar triangles to compute areas and volumes. Hero of Alexandria developed several treatises, including the Dioptra, which discussed field survey methods, survey calculations, and the drawing of plans. Many of the
surveying methods are still recognizable in today’s survey practices. The *Dioptra* also discussed the first survey instrument, a Hellenistic period dioptra, a precursor to today’s theodolites. Julius Africanus, Anonymous Byzantinus, and al-Karaji also wrote similar works. The Romans developed a number of survey instruments, the *libra aquaria* (water leveler or balance) being the most well known, which was used for leveling during the construction of engineering works.

The profession of the ancient surveyor, whether Greek or Roman, consisted of four distinct categories.

1. The land surveyor (in Greek, *geometres* or *geodaiestes*; in Latin *finitor, mensor, agrimensor*, or *gromaticus*) carried out local surveys on the ground. They recorded the shape of existing fields worked by landholders to calculate their area so that taxes could be levied. They might divide land into rectangular plots for allocation to settlers, or they might set out a grid of streets for construction in a town. In a military context they laid out fortifications or *castra*. A land surveyor was concerned solely with horizontal measurement. There was little need for measurement of heights, as all “cadastral” survey work was assumed to be on a plane.

2. The cartographic surveyor (*chorographos, geographos*) made maps, generally of large areas covering potentially many regions. From this work arose inquiry into the shape of the Earth, so that large areas fit together on the map; and the heights of mountains, for orientation and as points of interest on the maps.

3. The military surveyor (*mensor*) provided information to commanders and engineers. They developed indirect measurement techniques because the features they were measuring were typically occupied by hostile groups: the height of a city wall, so that ladders or a siege tower of the right height could be built; or the width of a river, so that a pontoon bridge could be built to the correct length.

4. The engineering surveyor (*mensor* or *liberator*) surveyed the terrain so that roads, aqueducts, irrigation channels, navigable canals, tunnels, mines, harbor works, and so on, could be constructed.

As is the case today, these categories were not exclusive. Surveyors used the same instruments and similar techniques for each type of survey. Astronomers who, particularly after the development of spherical trigonometry, wanted to measure angular distances between stars and planets also shared in the use of many of the instruments and techniques. History records that Eratosthenes estimated the size of the Earth ca. 200 BC. He reasoned that, because of similar geometries, measuring the distance between the two Egyptian cities of Alexandria and Syene (he believed they lay on a similar longitude) and measuring the length of the shadow cast by a pole of known length at Alexandria (he had observed that the sun was directly over Syene at noon on the summer solstice), he could compute the angle subtended at the center of the Earth between the two cities, and thenceforth compute the earth’s circumference.

As land has become scarce its value has increased, as has the demand to establish precise boundaries. The need for public works has also ensured that the value of surveying to society has remained high. The ongoing call for economic growth, and the use and preservation of earth’s resources will continue to drive the demand for surveying.

Surveying and mapping tools have now evolved to the point where the traditional instruments – theodolites, the level, the chain
or steel band – have almost been completely replaced by high-tech instruments, such as robotic total stations that can measure horizontal and vertical angles and distances automatically; and global navigation satellite systems (GNSS) such as the Global Positioning System (GPS), which can provide accurate data for virtually any type of survey. Terrestrial and airborne laser scanning instruments combine automatic distance and angle measurement to compute dense 3-D clouds of points that can quickly be converted to 3-D models. New aerial cameras and remote sensing systems can collect digital images that are then processed to obtain spatial information. Integrated systems that combine GPS, inertial measurement units, digital cameras, and other sensors can map items within tens of meters of a road at highway speeds, and the data collected can be provided to users as georeferenced coordinates overlaid on high-quality imagery. With these changes in technology, the term geomatics has now become synonymous with surveying, and covers all methods of measuring and collecting data about the physical Earth and our environment, and processing the data so that they can be used for planning and management of the land, the sea, and any structures thereon. Surveying and geomatics also includes research into the practices and instrumentation to develop them further.

As noted, surveying has a long history. From the earliest times, it has been necessary to mark boundaries and divide land. Today, surveying remains indispensable because of the need to map the Earth above and below sea level; to prepare navigation charts for use in the air, on land, and at sea; to establish property boundaries of private and public lands; to develop databases of land-use and natural resource information that aid in management of the environment; and to determine facts about the size, shape, gravity, and magnetic fields of the Earth.

Surveying and geomatics continues to play an important role in many branches of engineering. Surveys are required to plan, construct, and maintain highways, railway lines, rapid transit systems, buildings, bridges, tunnels, canals, residential land development, storm water and sewerage systems, pipelines, mines, and so on. Surveying methods are also commonly employed to lay out industrial assembly lines to minimize the wear and tear of moving parts, and to guide the fabrication of large equipment such as planes and ships where separate pieces have been assembled at different locations, and must fit together. Surveying also plays a role in many other industries today where accurate measurement is required – agronomy, archaeology, geophysics, meteorology, and seismology, to name a few.

Sustainability science

Robert W. Kates
Independent scholar

Sustainability science is an emergent field of science whose origins are found both in elite institutional efforts to bring environment and development together and in an outpouring of published studies related to sustainability or sustainable development. Sustainability science is characterized by use-inspired research and as such similar to the agricultural or health sciences. It is defined by the practical problems of sustainability which it addresses and by theories and models of interactions between natural and social systems. It is clearly transdisciplinary in structure integrating research from the natural, biological, social, and engineering sciences. Above all, sustainability science seeks to link knowledge with action on the identified problems of sustainability.

Origins of sustainability science

A series of major reports and international meetings document the first efforts to bring together environment and development beginning with the 1980 International Union for Conservation of Nature (IUCN) World Conservation Strategy, followed by the emergence of sustainable development in the 1987 Bruntland report, Our Common Future, and acted upon at the 1992 first Rio Earth Summit. Sustainable development, while politically successful, had little science content until the preparation of the US National Academy of Sciences 1999 report, Our Common Journey, that called for the development of a sustainability science and followed in 2003 by its journal, Proceedings of the National Academy of Sciences USA (PNAS), creating a sustainability science section now containing hundreds of research articles.

Figure 1 also graphs the individual authors of articles and conference proceedings written in English between 1974 and 2010 with “sustainability” or “sustainable development” in the title, abstract, or keywords. There were over 20,000 papers, published mostly in biology, engineering, and social science journals, with 37,000 distinct authors based in such diverse institutions as corporations, governments, NGOs, and universities (large and small) in 174 countries and 2200 cities. From the 1990s on, the number of authors of articles grew rapidly, doubling about every 8 years, with its worldwide authorship, including many developing countries. By analyzing the author’s interconnections, the field seems to unify around 2000, when the size of interconnected clusters of authors began to grow and the number of disconnected clusters of authors and reflecting disciplines rapidly declined.

Sustainability science as use-inspired research is often illustrated by Donald Stokes’s quadrant model of scientific research contrasting the quest for fundamental understanding with considerations of use by society. The quest for fundamental understanding is called, by some, basic science in contrast with applied science characterized by user needs. But a third option
is use-inspired basic research as exemplified by such researchers as Louis Pasteur and such fields as the agricultural or health sciences. Within this category, sustainability scientists address use-inspired problems of sustainability, perhaps emphasizing interactions between natural and social systems, perhaps emphasizing applied solutions to practical problems, or both.

Sustainability science as interactions between natural and social systems

Basic overviews of interacting natural and social systems have been used for many years labeled variously as nature–society, socio-environment, socio-ecology, or human environment and often presented as box–and–arrow diagrams rather than as operable models. Geographers have played major roles in developing this view of nature–society relationships and related research. This research, which is a study of how interactions between natural and social systems emerged in global change, notes the key roles of eight geographers whose discipline “by training, bridged social and natural sciences and had a strong spatial focus; furthermore, they had a cadre of scientists with strong leadership attributes” (Mooney, Duraiappah, and Larigauderie 2013, 3).

These box–and–arrow diagrams of nature–society interactions usually contain a societal or human subsystem, a natural or environmental subsystem, and other external systems that impact or modify these subsystems. Analysts differ on the important elements of each. Judging from the literature, much of nature–society systems study focuses on the environmental subsystem, especially its production of ecosystem or environmental services (provisioning, cultural, supporting, or regulating). Important elements of social subsystems are population, technology, governance, and economy, but these are seldom interacting and studied primarily as separate elements. If present, they are introduced into models usually as external inputs or scenarios.

As a research field with a theoretical perspective on coupled nature–society systems, sustainability science has evolved a set of seven core questions and research themes. These are as follows.

- What shapes the long term trends and transitions that provide the major directions for this century?
- What determines the adaptability, vulnerability, and resilience of nature–society systems?
- How can theory and models be formulated that better account for the variation in nature–society interactions?
- What are the principal tradeoffs between human well-being and the natural environment?
- Can scientifically meaningful “limits” be defined that would provide effective warning for nature–society systems?
- How can society most effectively guide or manage nature–society systems toward a sustainability transition?
- How can the sustainability of alternative pathways of environment and development be evaluated?
Sustainability science as applied problems of sustainability

The core questions and research themes can also be asked of specific places or sectors of human activity where applied problems of sustainability occur. Six initial sectors were first identified in 1987 by the World Commission on Environment and Development as global challenges for sustainable development: population and human resources, food security, species and ecosystems, energy, industry, and urban. With the addition of water, these have appeared in various guises, the latest being water, energy, health, agriculture, biodiversity, and urban.

Scientists and technologists who wish to help provide knowledge useful in addressing such sustainability problems do so best when these problems are determined collaboratively with potential users and policymakers, who often have their own traditional or practitioner knowledge to contribute. Such coproduction of knowledge enhances the search for solutions and the likelihood that use-directed knowledge will actually be used.

Transdisciplinary sustainability science

There are three kinds of major interactions between traditional disciplines when trying to understand or address a scientific or practical problem. In its simplest form, multidisciplinarity, which is when various disciplines present their separate perspective of the problem and the research on it found within their discipline. A more interactive form is interdisciplinarity, where relevant disciplines are brought together, usually in teams, to conduct joint research on the problem. Much of sustainability science functions in this way. But, increasingly, many sustainability scientists aspire to transdisciplinarity, moving beyond the approaches, training, and skill sets of their disciplines to become problem oriented rather than discipline oriented. In so doing, they seek to master and use the skills and approaches needed to address the problem, from whatever sources these may be derived.

Sustainability science in 2015

Since its unification as a scientific field in early 2000, sustainability science has become rooted in the scientific enterprise with new research, publications, institutions, and educational opportunities. As noted, its research increasingly seeks solutions to problems along with deepening theoretical perspectives in coupled nature–society systems. It has a very large published library of work, much appearing in new dedicated journals. Centers and institutes and a growing number of degree programs dedicated to sustainable development, sustainability, or sustainability science are found in many parts of the world and in their variety reflect the regional differences in how the science is pursued and that no common sets of needed competencies for students have yet emerged.

But sustainability science is a young science and there is much more work to be done. Most important is moving knowledge into action. The practical problems of sustainability are increasingly studied in joint undertakings with practitioners from local communities, industry, government, and civil society, but there is a lag between research and implementable solutions offered or problems solved. (A set of videos of such problem-solving in the state of Maine in the United States is available at www.mpbn.net/Telelevision/LocalTelevisionPrograms/SustainableMaine.aspx.) The next major metric
SUSTAINABILITY SCIENCE

for sustainability scientists should be in practical problems solved.

Sustainable cities

Pierre Filion
University of Waterloo, Canada

Sustainability is about securing the conditions for the long-term existence of an organism or system. In its urban application, it concerns primarily the relation between cities and the environment, although the concept of sustainability can also pertain to social and economic requirements for the durability of urban systems. Different motivations prompt cities to adopt environmental sustainability trajectories. Cities can strive to maintain or improve the quality of their own environment to provide healthy living conditions and thus assure the wellbeing of their residents. Another reason for cities to engage in such initiatives is to preserve resources essential to their long-term survival. Cities can also commit to a lessening of their contribution to global environmental damage – most notably emissions of greenhouse gases. In this instance they assume the role of instruments of global sustainability. The emphasis in this entry is on the environmental, rather than social and economic, dimensions of sustainability, and mostly on sustainability issues confronting cities in developed countries.

Sustainable development and its application to cities

The expression “sustainable development” was coined in the 1987 report of the United Nations World Commission on Environment and Development. The Commission was chaired by Gro Harlem Brundtland, a former prime minister of Norway. The report, entitled Our Common Future, defined sustainable development as “development that meets the needs of the present without compromising the ability of future generations to meet their own needs.” The concept has been a catalyst for environmental consciousness in many parts of the world, and was soon adopted as a standard to strive for in many areas of human activity, including the planning of cities, the construction of urban infrastructure, and the delivery of urban services. It is important to note, however, that sustainable development has remained more an object of discussion than a source of radical policymaking and human behavior transformation.

With over 50% of the world population residing in urban areas, and given the concentration of economic activity in these locales, it is to be expected that cities will be a foremost target of sustainable development strategies, whether deployed on a local, regional, national, or international scale. The impact of cities on the environment is further accentuated by the fact that they are primary sites of consumption, which causes them to draw resources from extensive hinterlands. Relationships between cities and their environment have always been critical of their existence. Jared Diamond (2005) has chronicled how throughout history human-caused deterioration of the environment and an inability to adapt to environmental change have provoked the collapse of civilizations and their cities. The origins of the planning profession and of present regulations guiding urban growth can be traced back to efforts to safeguard public health in
the severely degraded environmental conditions of nineteenth-century industrial cities. People living in these cities were victims of repeated epidemics and overall poor health, in large part due to contaminated water, foul air, and crowded living conditions. Progressively, over more than a century, public policy addressed these perils. These policy responses have culminated in the elaborate urban development control mechanisms found in the cities of rich countries, which can be partly credited for their sanitary conditions (Porter 1999). Still, one must not lose sight of the fact that the cities of poor countries, and especially their informal settlements, experience living conditions comparable, if not worse than, those of early industrial cities.

The lens through which environmental impacts are perceived has widened over time. From a consideration of immediate health effects, the perception of these impacts has broadened to include long-term health consequences, and the regional and then global environmental consequences for cities, along with the repercussions of these consequences on humans. In the 1960s and 1970s, much attention was paid to the health effects, many of them long-term, of the rapidly deteriorating air quality, and of regional impacts of water pollution. In rich countries these problems were partially addressed by relying on technical fixes: fitting catalytic converters to car emission systems, using cleaner heating fuels, and building sewage treatment plants. Sustainable development introduced a longer-term and more comprehensive perspective on the relationship between cities and the environment. It raised concern about environmental consequences of all aspects of urban life and development, and led to environmental proposals ranging from less energy-demanding patterns of development to recycling programs.

Efforts at measuring the environmental load of urban areas in terms of the resources they consume and the space needed to absorb the waste they generate have cast further light on the global environmental repercussions of cities. One method for representing these impacts of cities is the urban ecological footprint, which transposes into spatial units the carrying capacity of the Earth needed to support cities. Studies adopting this approach conclude that humanity consumes resources at a rate that is 1.5 times in excess of the carrying capacity of the Earth, thereby mortgaging coming generations. Worse still, if the entire world achieved the standard of living of rich countries, resource and absorption capacities of several Earths would be needed (Rees 2006).

Since the late 1970s, mounting evidence of global warming and its association with human activity has cast a sobering light on the limited absorption capacity of planet Earth. Here again, cities come out as foremost contributors to this environmental threat.

The sustainable development of cities presents itself differently depending on whether they are in rich or poor parts of the world. McGranahan and Satterthwaite (2002) have formulated an urban environmental transition theory, which links different environmental agendas to distinct economic development stages, and echoes the evolution of environmentalism in countries of the Global North since their industrialization. Environmental attention in poor countries is monopolized by water supply and sanitation. As countries industrialize, they become confronted by the pollution generated by industrial production and consumption, especially automobile use. Finally, in their postindustrial phase, cities are allured by green agendas driven by concern over greenhouse emissions and other side effects of consumerist lifestyles. Perceived in this fashion, the scope of environmental preoccupations becomes ever larger as countries make their way through the different stages of the transition, from a household to a planetary
Sustainable city models

There are different versions of sustainability. Weak versions accommodate adjustments to production and consumption, which do not challenge their fundamental mechanisms. Cities maintain their present form and dynamics, but see their environmental footprint somewhat reduced by recycling programs, improved home insulation, and more energy-efficient automobiles, for example. Strong versions of sustainability are more ambitious. From their perspective, sustainable development should involve the redefinition of all human systems. Many researchers believe that nothing short of such radical transformations can avert the crises on the horizon, such as global warming. This thinking reverberates on urban planning. One manifestation of this is the designing of new cities that profoundly curtail carbon emissions, by lessening dependency on coal, gas, and oil. The environmental footprint of such cities would be considerably smaller than the prevailing urban norm.

Masdar City, a new town in Abu Dhabi in the United Arab Emirates, has been designed by Foster and Partners to host 50,000 residents in a near carbon-free environment. Another example is the proposal for a new Chinese city with a population of 80,000 planned by Adrian Smith and Gordon Gill, which would be fully pedestrian-oriented, allowing all destinations to be reached within 15 minutes on foot. Great City, located close to Chengdu, will produce 60% less carbon dioxide per capita than other Chinese cities do. An early prototype of an environmental community is Arcosanti, the brainchild of Italian architect Paolo Soleri, which has been under construction in the Arizona desert since 1970. The town, to house 5000 people is intended to demonstrate how cities can function in close harmony with nature.

These efforts at rethinking urban development according to its impact on the environment are consistent with the tendency to design new urban forms that address one specific issue. The purpose of the Garden City at the turn of the twentieth century was to provide an alternative to crowded industrial cities. Likewise, the Radiant City, consisting of towers surrounded by green space, purported to address the unhealthy living conditions of the densely built cities of the early to mid-twentieth century (Fishman 1982). The present tendency is to formulate new urban models according to sustainable development principles.

Specific sustainable urban interventions

Given their extreme rarity and small scale, we cannot expect new cities entirely designed around sustainable principles to contribute much, collectively, to an improved global environment. Moreover, their high construction costs are likely to cause them to become environmental havens for the rich only (Hodson and Marvin 2010). More likely to have a positive influence on global environmental conditions are more narrowly focused, but also widely adopted, measures promoting urban sustainability within existing or new urban areas conforming to prevailing land-use standards. These measures concern multiple aspects of the urban phenomenon, including those exemplified in the next paragraphs. The resources the erection of the built environment requires, and the energy to heat or cool them, make buildings a natural target for environmental measures. In addition, the built environment of a city
SUSTAINABLE CITIES

affects consumption choices and, more generally, lifestyles. High density can encourage public transit patronage and walking. Meanwhile, spacious living environments are more conducive to the accumulation of consumer goods than are smaller ones. One way of decreasing the environmental impact of buildings is to rely on infill development, which consists of surgically redeveloping parcels of the urban texture rather than demolishing and rebuilding wide swaths of the city. The replacement of large urban sectors results in the loss of the resources and energy locked in the existing built environment and the channeling of additional resources and energy towards the construction of the subsequent buildings. Least environmentally harmful is the retrofitting of existing, rather than the erection of new, structures.

The LEED (Leadership in Energy and Environmental Design) certification rates buildings according to their respect of the environment. Certification involves an evaluation of over 100 aspects of buildings, including water and energy efficiency, material selection, and innovation in design. Launched in 1998 in the United States, LEED certification has spread to many parts of the world.

An innovative approach to the creation of an urban built environment that consumes less natural resources and energy is to turn to biology to inspire design – a process called “biomimicry.” The outcome of this approach, which is adopted mostly in rich countries, is new types of building that borrow from biological forms and processes: roofs that espouse the shape and structure of leaves, for example.

Transportation represents the other principal source of energy consumption in cities. As expected, urban sustainability efforts aim at abating reliance on automobiles, the form of transportation that is the foremost consumer of energy and contributes most to carbon emissions. Public transit improvement and expansion along with programs encouraging walking and cycling thus fall under the sustainable transportation rubric by virtue of their reduced energy demands relative to the car. Transit Oriented Development and New Urbanism are examples of efforts to combine urban form and transportation systems in an attempt to create public transit- and walking-conducive urban settings (Schiller, Bruun, and Kenworthy 2010).

Urban sustainability efforts also target the production and consumption of energy. The main issues arising from energy generation and use are the destruction and contamination of extraction and generation sites (coal mines, oil fields, hydraulic fracturing, large reservoirs for hydro-electricity, nuclear power plants), air pollution, and above all, contribution to global warming. From an energy production perspective, advocates of sustainability call for a rapid transitioning from methods that carry a heavy environmental burden – those relying on coal, oil, and natural gas, or nuclear power, whose system failure comes with tragic consequences – to processes that are in harmony with nature – for the most part, solar and wind power generation. Solar power lends itself to a microproduction of electricity at the individual building level, marking a shift away from a concentration on generation in large power plants. On the consumption side, attempts are made to reduce demand through higher-efficiency devices. Until now, however, the aggregate effect of these measures on energy consumption has been limited.

Other initiatives striving to enhance urban environmental sustainability include increased reliance on green infrastructures, which depend as much as possible on natural processes. A vivid illustration of this renewed respect of nature is the change in the treatment of streams in urban areas. Until recent decades, the dominant approach
involved burying them in storm sewers, which caused serious deterioration of water quality and, in combination with the impervious surfaces that cover much of cities, heightened flood risks. In North America, the tendency is now to “daylight” streams (by bringing them back to the surface), and naturalize areas abutting them.

There is also rising interest in the quality, availability, and environmental implications of food within urban areas. One major food-related issue is the concentration of food outlets in increasingly large premises, causing the spread of “food deserts,” especially in low-income sectors. At the same time, efforts are made to bring food production close to urban consumers, be it through the 100-mile diet encouraging the purchase of food produced close by to reduce transportation needs and assure freshness, or through a proliferation of urban gardens.

Finally, there are also measures being taken to reduce the waste produced by cities. Many municipal administrations have adopted recycling programs, which contribute to divert waste from landfill sites. There is a great deal of difference in the goals and achievements of these programs. Few cities approach the 80% diversion rate attained in San Francisco. Most ambitious are proposals for zero-waste and zero-emission closed-loop systems whereby at the end of their consumption phase all the components of goods are transformed into new products, which then share the same fate at the end of their own consumption period. Closed-loop production and consumption are an example of biomimicry, as they attempt to reproduce natural cycles which take place without generating waste.

The question that emerges from the consideration of all above-mentioned sustainable urban interventions is whether, in the event of their full implementation, their cumulative effects are sufficient to make cities as environmentally benign as if they were designed from the start around sustainability principles. There is no clear-cut answer to this question. Past and present experience, however, points to the much more likely adoption of incremental narrow-focused approaches to urban sustainability than a radical redesigning of urban areas.

The present state of urban sustainable development

The reality of urban development rarely coincides with the commitment to sustainability expressed in plans. In North America, the resulting discrepancy is currently illustrated in the gap between a near-universal adherence of metropolitan-scale plans to public transit, recentralization (downtown expansion and the creation of networks of dense and multifunctional nodes), and overall compact development on the one hand, and the persistence of automobile-oriented sprawl on the other. Prominent among the obstacles preventing metropolitan plans from achieving their objectives are closely intertwined relationships between land use and transportation. Such interrelations constitute a powerful path dependence, making it difficult to substantially modify either land use or transportation systems because transformative policies must have a simultaneous large-scale effect on both land use and transportation to induce desired changes.

Incidentally, just as North American planners are becoming concerned about the adverse consequences of automobile-dependent urban land uses, this urban pattern is gaining popularity in new middle-class suburbs in different parts of the world. Issues related to car-reliance in large cities are increasingly universal phenomena.

There is also resistance to change from interests deeply vested in current patterns of urban land use. Additionally, global consciousness of the
need for urban sustainability as global warming progresses does not necessarily translate into coordinated responses. In fact, often the opposite happens. Some nations, notably the United States, Canada, and Australia, point to the inaction of other countries to justify scaling back efforts at containing their greenhouse gas emissions.

Over the past decades, sustainable development initiatives have mirrored the sharp discrepancy between the financial capacity of developed and developing countries. For example, public transit strategies of cities in the Global North emphasize expensive rail systems; light rail transit in many instances. Meanwhile, Latin American cities, notably Curitiba, Brazil, and Bogotá, Bolivia, have based their public transport strategy on more affordable bus rapid transit systems (Hidalgo and Graftieaux 2008).

Debates on sustainable cities

Beside the uncertainty about how to transform sustainable urban development principles into actual urban change, there are questions about which are the most effective urban sustainability formulas. One such question concerns the opposition between polar perspectives on optimal urban form from a sustainable perspective. The first proposes compact, high-density settlements to minimize the footprint of cities and lessen energy requirements and emissions, especially by reducing dependence on the automobile. In this vein, David Owen (2009) celebrates Manhattan as a model of sustainability. In his view, despite the wealth it concentrates, the exceptionally dense and public transit-reliant urban form of Manhattan accounts for much lower per capita energy consumption than is registered in other US urban areas. The opposite approach calls for a blending of urban development with natural systems. The outcome is a low-density urban form structured around protected natural features. This view was first articulated in the 1960s by Ian McHarg and is now promoted by the landscape urbanism movement (Waldheim 2006). The problem with this option is an enduring reliance on the automobile, with ensuing high energy needs and environmental repercussions. Perhaps, in a not so distant future, the generalization of electric traction will reduce some environmental downsides of the car.

Recently, sustainability has been criticized for the change of emphasis it brings to the study of urban issues. In this regard, Michael Gunder (2006) has noted an association between the rise of interest in urban sustainability and reduced attention to social equity.

Sustainable development

Rob Krueger
Worcester Polytechnic Institute, USA

Every generation comes around to the question at some point, at least in so-called developed countries: How long will the material conditions exist to support our economic systems and lifestyles? Sustainable development has been one conceptual means of organizing our responses to this question. For a generation, those advancing the idea of sustainable development have sought to render visible previously “unseen” environmental and social costs associated with the development and allocation of resources. Sustainable development represents the first effort by world leaders to explicitly consider the broader environmental consequences of economic development and the geographical distribution of the benefits derived from it. However, students of geography know that this approach is not as simple as the champions of sustainable development had hoped or thought it would be. Sustainable development is a social construct – this means the concept was founded in a certain political-economic context that represents the product of interactions between people and institutions with varying interests and access to power. When its various forms are examined and judged, what should be understood, above all, are the relations of power and the impacts they have on humans and nonhumans, so that they can be viewed with a sharp, critical eye and their dangers, as well as their promise, identified. Indeed, sustainable development is a framework for organizing economies, but it is also a lens through which to view these relationships (see Political economy and regional development). This entry will explore the concept of sustainable development at the macro and local scales, as it emerged as a response to earlier beliefs (also social constructs: see Social constructionism) about societal and economic development, contemporary social relations, and economic imperatives.

Sustainable development and its antecedents

Sustainable development is a modern concept only in name. Humans have attempted to live sustainably for millennia. Hunter-gatherer societies were nomadic because they followed food. Once humans learned agricultural techniques, sustainability took on another meaning: the ability to produce adequate food for the social group year on year. During the Industrial Revolution, the English were concerned about establishing a sustainable energy supply. As European human populations grew, philosophers and economists raised concerns about resource scarcity. How long could nature support agricultural and then industrial endeavors and aspirations? Scholars such as Malthus, Ricardo, Jevons, and the French physiocrats all wondered – and sometimes strongly disagreed – about the capacity of land and other resources to support human communities. In these different examples, and in our own recent history, diverse understandings of sustainable development have been shaped by our different social contexts and institutional systems, technologies, and authority figures. This point can be illustrated with an important historical example.
SUSTAINABLE DEVELOPMENT

Sustaining resource access, and sustaining “Western” values in a Cold War context

With the full onset of the Cold War in the early 1950s, uncertainty about the scarcity of natural resources resulted in tangible effects. Commodity prices rose dramatically during the first year of the Korean War (1950–1953). Western leaders asked themselves whether they had access to enough raw materials to defeat the Soviet Union – not for military use, but to provide industry with the materials needed to meet the rapidly expanding demand for goods and services since the end of World War II. The Paley Commission, named after its chairman William Paley, president of the Columbia Broadcasting System (CBS), was appointed by the US president to examine commodity needs based on population projections to the year 1975. Using commodity price as an indicator, the Commission found that US demand would grow significantly and that supplies of some resources were adequate to support the economy. However, the Commission found other raw materials, as a matter of price, to be increasingly scarce. Thus the report suggested that an adequate supply of these materials could be sustained if it was acquired from other sources, but at an increasing cost. Therefore, according to the report, the government would have to identify and procure new supplies while at the same time searching for substitutes. Two elements of this report informed future discussions about sustainable development. First, the Paley Commission recognized the difference between absolute scarcity and relative scarcity. Relative scarcity arises from the lack of control over existing resources. The second was the doctrine of technological substitution, which means that technologies could change to require fewer or different resources to support the same function. Both of these points would later figure in the version of sustainable development famously proposed in the United Nations report *Our Common Future*, or the Brundtland Report (World Commission on Environment and Development (WCED) 1987).

In response to its insight about relative scarcity, the Commission looked to identify government actions that might secure the resources necessary to sustain Western economies and their militaries. For decades, Western economic powers had been funding explorers to identify and map the locations of key natural resources: oil in the Middle East, copper in Chile, and gold in South Africa, for instance. At the same time (the 1950s to the 1970s) these same nations were undertaking a process of relationship building and policy exports. Key aspects of these policy exports were based on W.W. Rostow’s ideas about stages of economic development, which culminated in “modern” or “industrialized” economic forms. These stages provided Western governments with a framework for creating model regimes through policy interventions, aid packages, and consultations for countries seeking industrialization. As a result, the West nurtured new political regimes in Iran and in Chile, and maintained a convivial relationship with the apartheid regime in South Africa. In these ways, for the sake of securing natural resources in scattered regions across the globe, the US-led Western nations made various alliances that blatantly defied their own explicit principles about democracy and human equality.

The second important insight of the Paley Commission, the doctrine of technological substitution, proved to have even more powerful and long-standing implications. Indeed, the notion that technology will provide solutions to environmental and economic problems remains a core belief for many. Technological substitution was popularized by Paley’s Commission and codified a decade later by the academic economists Harold Barnett and Chandler Morse in their book, *Scarcity and Growth* (see Environment
and resources, political economy of). Barnett and Morse (1963) echoed the Commission’s findings that, under conditions of increasing scarcity, rising raw material prices would trigger innovation and a process of technological substitution. These concerns revived discussions from the previous century by neoclassical economists about the possible decoupling of material scarcity and economic development. Of course, the notion of sustainable development as it is now conceived results from myriad conditions, but the arguments of the Paley Commission and of Barnett and Morse would have had a lasting effect on the political, economic, and discursive underpinnings of the sustainable development discourse. In contrast to the arguments put forth in the Paley report, which characterized economic development as a deliberate effort requiring risky and unethical international policies, the sustainable development concept argued that development is a sociopolitical process that works on its own in some deterministic way.

With this background in place, the entry now turns to this concept and various attempts to define it.

Simply sustainable development

The concept of sustainable development proposed a set of organizing principles for future economic growth. The phrase itself was coined in the 1980s, and shaped by the environmental movement and a recognition that our material relationship to nature was harmful to humans and the earth systems on which they depend. The environmental movement resulted from industrial disasters and risks in the United States and elsewhere, which led to debates about the connections between economic growth and environmental degradation. Debates also took place in academia—most prominently in the Romanian economist-mathematician Nicholas Georgescu-Roegen’s radical ideas linking economic systems to the Second Law of Thermodynamics. The concept of scarcity took a central position in the internationally recognized Club of Rome group (see Environment and development). In 1972 the club published its now famous system dynamics model which, for them, demonstrated the “limits to growth” because of the world’s finite ecological capacities. A few years later Herman Daly, father of ecological economics, published a now well-known work that called for a steady-state economy, one characterized by mildly fluctuating population growth and energy input. These new perspectives were informed not only by environmentalism but also by a systems thinking approach. In contrast to their predecessors, these analysts did not see single resources as being scarce inasmuch as they understood the systemic capacity of the planet’s ecosystems.

The term “sustainable development” entered public discourse in the early 1980s when the International Union for the Conservation of Nature and Natural Resources (IUCN) published its World Conservation Strategy (1980) (see Conservation and capitalism). Like its more widely known counterpart, the Brundtland Report, the IUCN report addressed the escalating, environmentally destructive, and systemically damaging approach to the use of natural resources. The report cited a long list of hazards and disasters, including soil erosion, loss of agricultural lands, industrial pollution, deforestation, ecosystem degradation, species extinction, and more. It also called for a new global ethic grounded in the interrelatedness of global development. Questioning the reasoning of previous approaches, this ethic charged all nations with identifying coordinated global strategies that outline strategic environmental
SUSTAINABLE DEVELOPMENT

conservation measures. Most importantly, the interrelatedness of global development required that development and environmental conservation be considered equally with mutually reinforcing goals.

Environmentalists celebrated the Brundtland Report (WCED 1987) as a large step forward in thinking on economic development, the environment, and the human condition. The report was grounded in concepts of “limits”: economic and technological activities can be improved but we are still limited by the “biosphere to absorb the effects of human activities” (WCED 1987, 8). It distinguished itself from its immediate predecessors by asserting environmental quality and social equity as fundamental goals of development for both impoverished and wealthy nations. Where the IUCN report limited its concern to environmental degradation and identified conservation as the remedy, the Brundtland Report argued that growth must be revived in developing countries because that is where the links between economic growth, the alleviation of poverty, and environmental conditions operate most directly. Yet, developing countries are part of an interdependent world economy; their prospects also depend on the levels and patterns of growth in industrialized nations. (WCED 1987, 51)

Given that its progenitors recognized the interdependence (between developing and industrialized nations, between economic growth, social justice, and environmental stewardship), it is not surprising that the report was explicit about the role of social and economic conditions in shaping sustainable and unsustainable behavior. To quote directly:

Sustainable development is a process of change in which the exploitation of resources, the direction of investment, the orientation of technological development, and institutional change are all in harmony and enhance both current and future potential to meet human needs and aspirations. (WCED 1987, 46)

It may be easy to overlook the dramatic change in environmental discourse exemplified in Brundtland, but it should be noted that in this context, “human needs and aspirations” refer to more than the natural resources needed to meet the demands of consumers. For the first time, the discourse of sustainable development was paying explicit attention to the quality of all human life. The concept of social justice had entered the development conversation in a potentially powerful way.

Brundtland famously defined sustainable development as “development that meets the needs of the present without compromising the ability of future generations to meet their own needs” (WCED 1987, 46). The report set a new standard by which the success of any development program should be measured. To support this broad goal, the Brundtland Commission suggested a system of governance that extended from the global to the local scale. A key feature of the proposal was an ecology-first approach to governance. In other words, policymakers would develop regulations and policy to set the stage for economic activity that was first and foremost ecologically appropriate. Brundtland also called for a system of regulations to be developed to address existing problems of environmental protection and resource management. These were to be defined by a rigorous risk assessment using sophisticated indicators and other methods of assessment. Finally, these actions would be based on the participation of stakeholder groups and marshaled evidence so that deliberations would be inclusive and actions appropriate.

In some ways, the Brundtland Report reshaped the key features of the sustainable development debate. While scarcity remained a topic of
concern, the report largely replaced the concept with *natural capital*. In this formulation, the cost of a commodity such as gold or copper or “rare earths” includes the cost of depleting or destroying ecosystem services. Here the concept of natural capital supplanted scarcity as the ultimate value because the concept of scarcity itself has no relationship to the environment where ore or other resources are hosted. Consider as well how we think about climate. We do not talk about the scarcity of clean or carbon-free air. But we do think about the atmosphere’s carrying capacity of carbon and the effect of this on our lives and livelihoods. With the Brundtland Report, the task of defining the environment and identifying the beings affected by its transformation entered the political sphere as a site of debate.

The shift from resource scarcity to *ecosystem integrity* was underwritten by the assumption that economic systems can innovate to: (i) reduce resource intensity (using less raw material in a product); (ii) substitute one resource for another; and (iii) find new sources (e.g., by recycling), among others. Hence, the Brundtland concept of sustainable development is fundamentally based on growth and technological substitution. Where we once believed that economic growth is limited by the Earth’s physical limits, Brundtland taught us to see that our practice of technological innovation constantly expands those limits.

These points are best illustrated through the example of ecological modernization. Like the pre-1970 scarcity and growth debate, the sustainable development debate emerged from a certain political-economic context. The relationship between that particular historical context and the terms of the debate helps us to understand sustainable development as a set of practices as well as goals embedded in a particular context.

**Ecological modernization and sustainable development**

Cold War détente between the NATO countries and the communist bloc, coupled with efforts to contain the geopolitical expansion of the USSR, helped to define the scarcity and growth paradigm of sustainable development. In the 1980s this struggle, though very real as a suite of foreign policies, opened up a new front in domestic debates around economic development and growth. In particular, after the fall of the Iron Curtain in the late 1980s the role of the state came increasingly into question. What was perceived as centralized control of economies, and therefore development, via nation-states began to give way to state restructuring and an increasing role for private enterprise to regulate itself and the market to be the adjudicator of economic, social, and environmental relations, not the nation-state (see Political economy and regional development). These political and economic changes influenced how sustainable development would be implemented. Specifically, the theory of *ecological modernization* motivated and underpinned sustainable development for the first time as a realized policy discourse and not simply a plan.

In the 1980s, ecological modernization theory (see Ecological modernization) was being discussed by a relatively small group of scholars in the social sciences, primarily in Germany and northern Europe. Ecological modernization was, and remains, the theory that environmental problems should be addressed through the transformation of production via the development and implementation of new technologies and processes that were less resource-intensive than their predecessors. This differs from Brundtland in its focus on environmental concerns. Further, economic actors such as entrepreneurs and the private sector, rather than the state, were to be the drivers of this transformation.
A macro-economic structural change, ecological modernization identified sectors capable of combining higher levels of growth with lower levels of material input. For the adherents of this approach, industrialization and technological substitution and innovation offered a way out of ecological crisis. And, unlike earlier responses to this crisis, ecological modernization was more than a theory. In the 1990s it became a key part of the European Union’s Environment Action Programme (see Environment and development). Key aspects of the approach as codified in policy focus on the precautionary principle, integrated regulation (carrot and stick), and voluntary mechanisms. Indeed, countries like Germany, the Netherlands, and Japan are said to be paradigmatic examples of this approach in practice.

Ecological modernization was also rhetorically similar to sustainable development. Advocates for both concepts shared an interest in maintaining the environmental integrity of the Earth through continued but less resource-intensive growth. While the Brundtland approach to sustainable development called explicitly for intergenerational equity, ecological modernization implicitly sought to address these concerns by advocating for the use of fewer resources now so that more will be available in the future (see Conservation and capitalism). Both visions relied heavily on technological innovation to reduce environmental impacts. And, while sustainable development goals appeared in countless official documents worldwide, it was the vision of ecological modernization, of “greening the economy,” that drove practice. Ecological modernization became the operant of macro-level sustainability.

Ecological modernization as a theory of social change and a set of policy prescriptions emerged from established and newer thinking about how the economy works. The Paley Commission could not have anticipated the shrinking role of the government, which by the 1990s had diminished from the architect of economic and social activity to merely one actor among many in a governance structure. A restructured government sits well in ecological modernization. As a result, more recent efforts in sustainable development look very different from earlier approaches. First, ecological integrity has largely been reduced to a series of technological fixes. Technology, ecological modernizers believe, can mediate, replicate, or augment natural processes. Furthermore, prompts for addressing these issues come not from a state regulation but from either social movements or consumer demand, with the market determining which environmental systems are integrated into the economy. When, for example, was the last time we heard of the importance of biodiversity outside the potential benefits that “Big Pharma” can derive from it (“Big Pharma” being a critical term used to describe global pharmaceuticals firms)? Thus abstract forces define what the environment is and whether and how it is integrated into the larger social system of economic activity.

Today, while many politicians, policymakers, and academics would argue that market forces, which are assumed to be based on the decisions of individual consumers, may seem more democratic and thus “just,” evidence suggests that one cannot achieve justice through markets. Some people have fewer economic or social resources now than before; therefore their interests are not well represented among the forces that drive sustainable development. As a result, certain groups – for example, women in Ghana where water is scarce, elderly people in Chicago who are vulnerable to heatwaves, and the world’s non-whites and economically disadvantaged – bore and continue to bear a greater burden of environmental risks in the world’s cities. Brundtland’s sustainable development seeks the inclusion of social justice concerns within these discussions. It
is not, however, capable of changing the broader set of social relations that help to determine who suffers from inequity and who does not.

As a normative construct, Brundtland’s sustainable development established a framework for measuring policy goals. However, as the brief discussion suggests, how those ideals are implemented has not been a straightforward process and has been heavily dependent on a broad social and political-economic context. Sustainable development remains a shaky three-legged stool. Every once in a while policymakers and thought leaders meet in an attempt to repair the design flaws, but these are only addressed conceptually, and not in the political sphere. To further explore this notion and the role of justice in sustainable development, the discussion now turns to local level sustainable development.

From macro- to local-scale sustainable development

A discussion of sustainable development at a local scale is important for a variety of reasons. First, it gives us an opportunity to further ground the ideas from Brundtland. The Earth Summit in Rio in 1992 extended and grounded Brundtland into an actionable agenda both globally and locally. Here, at the largest gathering of high-level officials ever, policymakers deliberated over the goals of Agenda 21 in general, and Local Agenda 21 in particular. This discussion focuses on Local Agenda 21.

Rio, Local Agenda 21, and sustainable development

The Brundtland Report was produced in 1987. Five years later, in 1992, at the Earth Summit in Rio de Janeiro, delegates from around the world discussed Agenda 21, particularly the concept of subsidiarity. They decided that subsidiarity was the principle that decisions should be made at the most local level possible, where decision-makers are closest to the people affected by their decisions. To adopt this principle of subsidiarity, Agenda 21 architects proposed Local Agenda 21 (LA 21). Chapter 28 codified LA 21, and recognized that local governments play a key role in bringing about sustainable development across scales. LA 21 principles emphasized that local authorities needed to make considerable changes to their policy-making approaches so they could incorporate the perspectives and views of a range of interests. Chapter 28 of Agenda 21 states:

Each local authority should enter into a dialogue with its citizens, local organizations and private enterprises and adopt a “LA 21.” Through consultation and consensus building, local authorities would learn from citizens and from local, civic, community, business and industrial organizations and acquire the information needed for formulating the best strategies. The process of consultation would increase household awareness of sustainable development issues. Local authority programs, policies, laws and regulations to achieve LA 21 objectives would be assessed and modified, based on local programs adopted. (UNCED 1992)

Key to LA 21 was a broad-based, multistakeholder planning process that balanced the economy, social equity, and the environment. Proponents believed the success of LA 21 would also turn on the ability of a local authority to redirect its policies, laws, and regulations to align with the principles that emerged from the planning efforts. By 1996, according to LA 21 architects, cities should have engaged the public in a consultation process and achieved consensus around a local sustainability program.

The International Council of Local Environmental Initiatives (ICLEI), the international environmental nonprofit organization, spearheaded the effort to assist communities in
developing their LA 21 activities. Indeed, ICLEI had hatched the LA 21 idea a year before the 1992 Rio Summit. The goal of ICLEI’s LA 21 Campaign is to “to build a worldwide movement of local governments and associations dedicated to achieving sustainable development through participatory, multi-stakeholder sustainable development planning and the implementation of resulting LA21 action plans” (ICLEI 2002).

The process was quite simple. By 1996, 1119 communities in Europe had initiated LA 21 programs. To accomplish this goal, in 1994 ICLEI organized the European Sustainable Cities and Towns Campaign, which led to the Aalborg Charter. Two years later, ICLEI implemented steps for the Aalborg Charter, which was ratified under the Lisbon Action Plan. Since Lisbon, ICLEI has worked with hundreds of communities on their LA 21 plans and organized thousands of communities.

A survey published in 2002 by ICLEI showed that some 6400 communities from 113 countries worldwide had become involved in LA 21 activities over the previous decade (ICLEI 2002). The popularity of LA 21 as a local and regional development strategy was again affirmed when 400 European communities, representing 100 million Europeans from 36 countries, signed the Aalborg Charter in 1994. The Aalborg Charter, which was facilitated by ICLEI as part of their European Sustainable Cities and Towns Campaign, committed its signatories to develop local sustainability action plans in parallel with LA 21.

Another reason for the success of LA 21 in Europe is that its agenda was supported by the functions of the state. Despite calls for fundamental change, the adoption of LA 21 was not a total paradigm shift in Europe. It emerged in the context of existing state functions and regulatory mechanisms. Typically, these occur along two axes, market-oriented “regulation” and state-based command and control. In Europe, state-based regulation, while waning, remained a dominant force that influenced development patterns and land use. This is to say that local, regional, and national authorities have the capacity to clearly direct outcomes of urban development through performance standards and other forms of command and control regulation. The Dutch, for example, set minimum density standards at 33 units per hectare in an effort to promote compact cities with smaller ecological footprints. In the Netherlands, as in other places like Germany and Denmark, the rural fringe of cities is not regarded as transitional and up for grabs for development. Thus, market forces in these countries could be closely regulated so that they align more appropriately with the dictates of the LA 21 process, in particular with considerations of social equity.
One important consequence of neglecting a just and inclusive process is the predictable absence of equitable outcomes when many kinds of stakeholders are excluded from the process. In contrast to European cities and towns, North American cities did not adopt the LA 21 process in large numbers. Roughly 20 US cities are LA 21 cities. This is not to say that US cities did not adopt sustainable development principles. As with other sustainable development policies, US governments at the local, regional, and national scales eschewed the global standard and came up with their own approach. The US approach relied on mechanisms that were incentive-based, voluntary, and largely developer-driven (by the market, not the state), rather than process-driven. This American variant of local sustainability is often referred to as “smart growth” (Krueger 2007). With its roots in the state of Maryland, it spread rapidly across the United States. Over 500 US cities and towns have adopted principles of smart growth. Indeed, smart growth now extends beyond US borders as policy entrepreneurs have exported it to Europe and Asia. To understand not only the rapid spread of smart growth policies and practices but also the absence of concerns about justice, the political-economic context must be considered once again.

Economic engines: urban sustainability, LA 21, and “greening the city”

Many urban theorists have agreed that cities are the main site for economic development. Since the mid-1990s, in the context of an unprecedented development boom in many cities around the globe, the process of urbanization has been a focal point of economic development. The sustainable development discourse has shaped the way many cities have been remade. It is hard to find a city that does not mention sustainability as part of its identity. In the 2000s the mode of urban development – remaking long derelict urban cores into vibrant urban utopias and sites of consumption – was synonymous with urban sustainable development. Development plans go by the monikers of “compact urban development,” “transit-oriented development,” “smart growth,” and the like. They rely on existing infrastructures, they remediate and regenerate brownfields, they often include public transit lines, and they reinvest in communities in need. Coincidentally, these landscapes appealed to the imagery of the urban utopia for the creative class – artists, inventors, entrepreneurs, and so on. It has been argued that the creative class was an important ingredient in urban development because these people are the new raw materials for the entrepreneurial, new economy city (Krueger 2007). Advocates for the sustainable city claimed it as not only a worthy goal but also a driver in shaping a city for the new economy; they proposed that it would stimulate the kind of work needed to support the supposedly less resource-intensive information and service economies, which were the engine of the postindustrial city, or the eco-modern city. Those adopting this development approach also believed that such practices made them more competitive in the global labor market. The Local Agenda 21 process, grounded in environmental and social concerns, had been supplanted by a developer-driven “sustainable city.” Like ecological modernization on the macroscale, urban areas “greened” but did so for purely economic reasons. Urban sustainable development had arrived, but not as it had been imagined by its ethically motivated architects in the early 1990s.

No matter which moniker one chooses – “urban sustainable development,” “LA 21,” “smart growth,” “compact urban development” – sustainable development has been
adopted as a set of policy goals at the urban scale. We now have more mass transit nodes, more “green” buildings, more viable ecosystems in our cities than ever before. These are all good things. The value of being “green” is indisputable in many cities. Freiburg, Germany, proudly calls itself the greenest city in Europe, as does Växjö, Sweden. Despite the accolades and media attention, these cities have not realized what it means to be a “sustainable city.” The actions of these cities have brought economy and environment closer together in ways that are in line with the norms established by Brundtland. Many commentators have noted that for many cities the single most important element in a sustainability effort revolves around environmental concerns (Warner 2002). These environmental aspects coupled nicely with economic development visions, making them palatable to city policymakers and boosters. While environment-led development remains an elusive goal, in the last round of urban regeneration these two goals articulated by Brundtland and operationalized at the local level have more closely aligned visions that, a generation earlier, were seen to be competing.

Reasserting justice and equity in sustainable development?

While economic and environmental concerns have begun to converge in recent years, concerns for social justice have all but disappeared from conversations about sustainable development. Sustainable development, particularly in urban settings, has privileged environmental goals over social ones. An example of a macro-level sustainable development policy is reducing emissions from deforestation and forest degradation (REDD), which is designed to encourage local stewardship. At the urban scale environmental injustice is flourishing in the wake of gentrification (see Gentrification), even when adjacent to sustainable development projects. Environmental justice and sustainable development advocate and scholar Julian Agyeman (2013, 5) notes that “a truly sustainable society is one where wider questions of social needs and welfare, and economic opportunity, are integrally connected to environmental concerns.” With colleagues he coined the phrase “just sustainability” as a label for those activities that consider all three components of sustainability: environment, economics, and justice. Because social equity and justice are not integral parts of the sustainable development agenda, Agyeman and others explicitly remind scholars and practitioners that what often looks like “proper” urban sustainable development is only a creative use of the environmental and economic priorities without any attention to social justice. Environmental justice commentators provide a trenchant critique of sustainable development, especially in urban contexts in Western Europe and North America. By bringing together the sustainability literature with the environmental justice literature, these authors seek to create a vocabulary for political opportunity and mobilization both at the grass roots and in local government. To date, this work has focused largely on the organizational principles of movement leaders rather than the extensive politics of economic development.

There remains a critical need to examine how sustainable development could be mapped onto the current geography of neoliberal capitalism and, more importantly, where the opportunities for broader political engagement with sustainability may present themselves. By recalling that some groups of people are disempowered, marginalized, or silenced in the policy process, and by rendering the concept of justice explicit, we can place justice and equity in an equal position alongside environment and economy. (More on this later.)
Urban greening has been central to the urban sustainable development discourse. Green space has increased and/or improved in many cities in the name of sustainable development. Green space has been preserved from development because of its aesthetic, recreational, and ecological value. In addition to these green infrastructures, bike lanes, bike share programs, shared car schemes, additional miles of trams and public transport, and smarter public transport have been developed. Planners have developed “green infrastructure toolkits” to help mobilize and disseminate how cities might turn unmanaged or derelict space into sources of economic value and cost savings through relying on ecological services. Finally, inner-city redevelopment and brownfield rehabilitation have all contributed to this convivial relationship between green spaces and the city.

Adopting green practices in cities makes sense in terms of transaction costs and other development costs as they contribute to the city’s economic competitiveness. Local and regional urban spaces market their greening strategies to attract new workers and desirable high-tech jobs. Many policymakers believe that, in return, these jobs have broader advantages throughout the local economy. Freiburg, Germany, for example, has developed policies to support its claim to be Europe’s greenest city. The city is known for its extensive network of local and regional bicycle lanes, tram service, high quality of life, and history of progressive politics. Using these as points of evidence, city boosters thus claim that Freiburg represents an ideal sustainable city (for contrary views see Freytag, Gössling, and Mössner 2014).

However, deep injustices accompany urban sustainable development. In the process of gentrification, regenerated and newly “sustainable” property tends to rise in value. In most cases these redeveloped properties were formerly rental units or properties in low-income neighborhoods. Consequently, many residents get priced out of the housing market in their own neighborhoods. This process of gentrification transpires both when the market is left to regulate, as often happens in the United States, and through state-led gentrification, such as in London’s East End. Forced out of marginal housing, these people must move to other marginal housing further from their jobs, causing additional hardships like longer commutes, higher fuel costs, time away from family, and lower-quality housing.

In addition to economic forces, political practices also contribute to the exclusion and victimization of disempowered groups. Picking and choosing which aspects of sustainable development they will adopt to serve their needs, urban elites contribute to the process of victimization begun by impersonal market forces. When business associations, civic leaders, and others come together in the name of urban sustainable development, they introduce green buildings or the like in ways that benefit themselves, not the larger community. Finally, and perhaps most perniciously, the very idea of poor people defending their rights within these debates has been discredited by the notion that urban sustainable development discourses are postpolitical – supposedly no longer about power relations – because justice is now an actual rather than merely a rhetorical component of sustainable development.

Sustainable development … really?

While sustainable development is discussed in city halls around the world, from Bangladesh to Boston and from Casablanca to Carlisle, the concept mutates to fit disparate political, economic, temporal, and geographic contexts. In its most recent and prominent form, in a world that is increasingly wedded to notions
SUSTAINABLE DEVELOPMENT

of market-led development, it is a project of ecological modernization. Whether in local form or in more macro-policy approaches (e.g., Millennium Development Goals), sustainable development has integrated with capitalist social relations while offering the promise of a better world, not business as usual. And, in some ways, it has delivered on this promise: today we are much less concerned about scarcity per se than about finding the next technological alternative (e.g., natural gas, oil shale, nuclear power). At the same time, this cultural shift has reinforced past ideologies, such as technological determinism and continuous growth through innovation (Schulz and Bailey 2014).

Concepts and frameworks, including sustainable development, are useful in that they provide a new set of norms for society to appeal to. However, new frameworks alone don’t always advance us toward the better world we hope to create. To make the best use of new norms, we must recognize how they are introduced and adopted, not only in their own terms, but in the context of the prevailing ideology and conceptual framings of how the world works – understanding, for instance, what happens to considerations of social justice when economic development becomes the driving force of sustainable development. This entry has tried to reveal these relationships and consequences while offering a history of the development and evolution of sustainable development discourse. The final section looks toward a new approach that might lead to a “post”-sustainable society.

Toward a post-sustainable development society?

As the entry has shown, natural and social scientists, and particularly geographers, have, for 40 years, examined sustainable development from the perspective of ecological modernization. For example, economic geographers continue to focus on technological innovation and substitution by examining businesses like green manufacturing and environmental services, as well as supply chains and other economic networks. Scholars thus rely on the traditional development paradigms, which is to say they rely on traditional growth paradigms (or business as usual). For Schulz and Bailey (2014), this focus also dominates most of the recent scholarly work on the economic impacts of climate policy and energy transitions. While focusing on the (spatial) dynamics of emerging industries (e.g., related to renewable energies), underlying innovation processes, regional economic trajectories, or international trade, scholars overlook the implications of these development trends for alternative growth models and sufficiency imperatives. The final section will briefly introduce one of these alternative development scenarios.

Post-growth?

Can our seemingly open-ended attraction to economic growth be sustained, even as more and more people are recognizing that this model creates more problems than it addresses? The push for continuous growth undermines economic security, communities, the environment, a sense of place and continuity, and even mental health. Increasingly, policymakers at a variety of spatial scales are mobilizing new indexes, such as the Happy Planet Index, the Human Development Index, and the Index of Sustainable Economic Welfare.

Alongside these new ways of measuring sustainability and prosperity is an alternative approach to development that eschews growth in its current form. This concept, “post-growth,” should be understood as a departure from dominant growth paradigms in the sense of Serge
Latouche’s *décroissance*: that is, as a rejection of the maxim that private and societal prosperity can be ensured only via a continuous growth of materially and monetarily measurable economic performance. Tim Jackson’s (2009) book *Prosperity without Growth* captures the orientation of a transition toward sustainable lifestyles and economic systems envisioned by the post-growth concept. Jackson and Latouche place strong emphasis on distributive justice in growth and wealth, both at the level of international and development policies and within individual national economies.

Drawing on the work of Georgescu-Roegen, especially his steady-state economics theory, Latouche has refocused the discussion of environmental sustainability, suggesting that the objective of economic growth has endangered the goal of environmental sustainability and banished the principle of justice. His principle of *décroissance*, which rejects growth-oriented forms of production and consumption patterns, has been influential in the Italian, Spanish, and French sustainability movements. In this way, Latouche warns us against the trap of ecological modernization, rejecting its belief that a transition to a sustainable economy can be possible within present market principles. Latouche and the post-growth approach point to a possible way forward, exposing new analytical terrain and the limits of previous work. Bearing in mind this history of sustainable development, its promises and pitfalls, we can begin again to look for new alternatives to what sometimes seems an intractable global challenge.

**Summary**

This entry has examined sustainable development as a historically embedded process that is part of larger social, economic, and institutional contexts, each of which has implications for how sustainable development is defined. Sustainable development has been explored as a historical artifact that takes on different meanings in different places and times (e.g., from Barnett and Morse to Brundtland). The powerful hold some concepts, such as technological determinism, have exhibited as different sustainable development perspectives have evolved has also been explored. Sustainable development has been examined in different contexts, such as ecological modernization. The entry also described how different legs of sustainable development’s three-legged stool are privileged based on their relationship to economic thinking and policy, and concluded with a brief discussion of what are referred to as post-sustainability perspectives. Overall, the entry showed that sustainable development is an elastic concept whose meanings and practical implications reflect varied views on the global environmental problems (and opportunities) facing humanity.

University of Kansas, USA

The concept of sustainable transport

Sustainability has become one of the most important interdisciplinary issues in society. The concept of sustainability has developed with our awareness of the finite nature of many resources and of the negative externalities of our activities. The concept has permutated almost every aspect of society, and the notion of sustainability has become a key component of business and government actions in a wide variety of sectors. The interconnected nature of sustainability likewise makes it a difficult and controversial set of concerns to address.

It is unsurprising, then, that one of the most prominent recent developments in transport has been the concept of sustainable transport. From long-term efforts to regulate emissions to more recent attempts to develop and integrate alternatives to petroleum for fuel, sustainability has become an implicit component throughout transport. Despite this, defining sustainable transport has proved to be a challenge. One of the first definitions comes from Black (1996, 151) who, drawing from the Brundtland Report of 1987, describes it as “transport that satisfies the current transport and mobility needs without compromising the ability of future generations to meet those needs.” Many questions persist as to what constitutes those needs. Most transport modes and activities are sustainable; unsustainability develops when demand for those modes becomes excessive (Black 2010).

Sustainability is often referred to as having three pillars: energy, environment, and equity. These pillars are likewise prominent in discussing sustainability in transport. Most discussions of sustainability in transport begin with describing what makes transport unsustainable. There are three primary realms of issues that contribute to the unsustainability of transport; these are energy issues, airborne issues, and land-based issues, which are briefly summarized in Table 1.

Sustainability issues have a long history in transport. The use of timber for navies and seafaring exploration was linked with deforestation in the United Kingdom and North America, and the use of horses for urban travel was linked with congestion and the disposal of manure. Industrialization placed additional pressures on timber supplies for fuel and as a construction material, and the growing usage of coal exacerbated air pollution. The use of chemicals as materials, such as lubricants, led to new forms of chemical pollution. Rapid urbanization in industrial cities led to congestion and urban air pollution, which were partially mitigated by the development of the first urban transit systems. However, the rapid diffusion of the automobile in the following decades contributed to urban air pollution, climate change, congestion, safety, and energy issues. In the mid-twentieth century governments began to recognize the negative externalities of motor vehicle use and to introduce policies to mitigate them. Marine transport is relatively sustainable, but there are issues with congestion at or near
Unsustainability in transport: airborne issues

Global climate change

To understand the interaction of transport and climate change requires a brief overview of some relevant atmospheric chemistry. There exists a family of naturally occurring chemical components that, when released, become suspended in the atmosphere and create a naturally occurring phenomenon called the greenhouse effect. The greenhouse effect is necessary to keep the planet warm enough to sustain life. However, a problem arises when greenhouse gas emissions exceed the ability of the Earth to absorb these emissions. The resulting increase in the atmospheric content of the gases traps more heat near the Earth’s surface, causing the overall average temperature of the planet to increase. The impacts on the climate and ecology of the Earth from this warming make up the phenomenon called global climate change.

Human activities in transport (or elsewhere) were not enough to influence the greenhouse effect until after the Industrial Revolution, when the burning of fossil fuels for energy began to increase at an unprecedented scale. As transport mechanized, coal and petroleum were developed into its primary energy sources. The incomplete combustion of these fossil fuels results in the emission of greenhouse gases, and over time the worldwide growth of transport has resulted in emissions levels that exceed the Earth’s ability to absorb them, and resulted in an increase in the atmospheric content of these gases. The primary
such pollutant from transport is carbon dioxide, though nitrogen oxides and methane are also contributors. In the United States, transport accounts for 27% of greenhouse gas emissions (EPA 2016).

Complicating the effect is the residence time of gases. Residence time is difficult to calculate because of the varying rate at which gases decay, and the effect of emissions sources and absorption rates on atmospheric content. Carbon dioxide can last in the atmosphere for between 5 and 200 years, nitrogen oxides for over 100 years, and methane for over a decade (IPCC 2014). Because of this, the full effects of efforts to deal with global climate change will not be felt for generations after their implementation.

One impact of increasing global average temperature is the increasing frequency and severity of major weather events. Damage to transport infrastructure will likewise become more frequent and more severe. Facilities that are at low elevations or near bodies of water will also see damage and require repair or relocation. These include much of the world’s port facilities and railway infrastructure. The flow of goods, as well as the travel of individuals, could experience significant disruption as sea levels rise and severe weather events increase in frequency. The movement of agricultural regions in response to changing climate should impact infrastructure usage, requiring new roadway, railway, and terminal infrastructure, as well as the repair of existing infrastructure from additional use.

**Urban air quality**

Emissions from petroleum usage contribute to the degradation of urban air quality. These include carbon monoxide, sulfur dioxide, nitrogen oxides and dioxides, ozone, and solid particulate matter, all of which are released from burning gasoline in internal combustion engines. These “criteria pollutants” are the focus of urban air policy because of their negative impacts on human health when released in amounts that are toxic or lethal, such as impairing the function of the cardiovascular system and damaging the respiratory system. Vehicle emissions are greatest when operating in stop-and-go traffic, when the combustion of gasoline in engines is least efficient. Policies place the burden of compliance on automakers through tailpipe emissions standards, and on urban areas through ambient air quality standards, both of which must be met to receive the necessary federal government funding for roadways.

A major criteria pollutant in the past was lead. Lead was introduced as an additive to gasoline in order to reduce engine knock in the 1930s. Lead exposure has been found to interfere with cognitive development and to induce blood disorders in children. Despite the negative health effects of lead emissions, and awareness of these effects decades earlier, lead was not removed from gasoline completely until the 1970s and 1980s in the developed world. Even then, the primary motivation for the removal of lead from gasoline was its effect on catalytic converters, which it tended to clog.

Urban air pollution has seen significant improvement in the latter half of the twentieth century in the United States and the developed world. In the United States, urban motor vehicle congestion reached critical stages; some of the most notable effects were seen in Los Angeles, California. This led to the state of California developing more stringent air quality standards than had previously existed, standards that have continued to evolve. US states may choose to adopt either the federal Environmental Protection Agency (EPA) standards or the California standards, but they cannot produce their own policy. Currently, nine states have adopted the California policy.
SUSTAINABLE TRANSPORT

Urban air quality is a critical unresolved issue in the developing world, which continues to urbanize rapidly. Automobile ownership rates and usage are increasing precipitously, and emissions standards are far less stringent than those in the developed world. The cities of China are particularly glaring visual examples of the extent of this problem.

Unsustainability in transport: land-based issues

Motor vehicle safety

One of the most implicitly ignored components of sustainability in transport is safety, particularly in the form of fatalities from motor vehicle accidents, which account for 94% of all the fatalities in transport. Automotive accidents claimed 32,719 lives in the United States in 2013 (IIHS 2015), and are among the leading causes of death for children and for adults under the age of 35. Data indicate that there were approximately 1.24 million deaths in motor vehicle crashes worldwide in 2010 (WHO 2015). Despite this, there is relatively muted public and policy attention toward traffic fatalities, except when there are high-profile incidences of malfeasance by government or industry.

Traffic fatalities face two disparate trends. In the developed world, traffic fatalities have been dropping steadily for nearly 50 years, even as vehicle miles traveled have increased. However, worldwide, traffic fatalities are increasing due to increasing vehicle miles traveled in the developing world coupled with more lax safety standards, lower driving education, and poorer road quality.

Traffic fatalities are caused by human error, environmental factors, or design flaws in the vehicle or the roadway. Many countries in the developed world have made significant strides in reducing motor vehicle fatality rates through enhancing safety standards, and automakers have made tremendous advancements in safety through vehicle design and engineering. To address fatalities, a distinction exists in policies that try to reduce fatalities from a crash, and policies that try to reduce the frequency of a crash. Most policies in the United States, for example, have been focused on safety measures that increase the survivability of an accident, while Sweden’s Vision Zero policy plan targets the eventual elimination of all fatalities through both vehicle safety standards and improvements to the environmental and design characteristics of the road network.

Congestion

Congestion is one of the more controversial and challenging aspects of unsustainable transport. This consists largely of motor vehicle congestion, though congestion from other sources such as air travel and surface freight movement raise similar issues. A generally accepted definition of motor vehicle congestion comes from the European Conference of Ministers of Transport (ECMT), which defines congestion as “the impedance vehicles impose on each other, due to speed–flow relationships, in conditions where the use of the transport system approaches its capacity” (Black 2010, 64).

Congestion causes include traffic accidents or roadway incidents, weather, special events, and economic activity. Many tools have been deployed to mitigate or reduce congestion. These have included actions directed toward the road network, such as expansion of the roadway system, improving operational treatments such as traffic signaling and motor vehicle incident clearance, and introducing high-occupancy vehicle lanes, congestion pricing, and toll roads. There is
also an array of strategies to reduce motor vehicle use through behavioral change. These include land-use planning designed to increase the use of nonmotorized modes and transit modes, expansion of the transit system, teleworking, carpooling initiatives, and increasing flexibility in work schedules to alleviate peak period congestion. The evidence indicates that, despite massive investments in roadway infrastructure, we cannot build our way out of congestion, and these can even induce additional travel and congestion. Thus far, most of the efforts to mitigate congestion through behavioral change have had limited effect.

Of particular recent interest are intelligent transportation systems (ITS). Various forms of vehicle automation, including self-driving cars, have the potential to reduce or eliminate human error as a cause of traffic accidents and to reduce the distance between vehicles while still traveling safely, thus increasing road capacity. It may be that we are just scratching the surface of the potential of applications of this type of technology in transport, and its effects on sustainability, while potentially large, are unknown. There is also a line of thinking in transport that congestion is an inevitable by-product of economic growth and development, and that a do-nothing approach will place sufficient pressure on congestion (through the loss of economic activity from congestion) that the problem will eventually solve itself. Some also argue that congestion is inevitable and that losing congestion is undesirable because it represents the loss of economic activity.

**Land use in sustainable transportation**

Land use and transport are interdependent. Transport policy has largely focused on enhancing mobility through facilitating motor vehicle use and the expansion of roadway infrastructure. This is particularly strong in the United States and the developing world, though it is also found in the rest of the developed world. This policy has contributed greatly to the other causes of unsustainability in transport discussed here, particularly in relation to petroleum use, congestion, and fatalities. This has also contributed to inequity issues by, effectively, requiring automobile ownership for participation in society. The land uses that serve automobile-oriented development are described as “urban sprawl,” whereby low-density, single-use development is built with ample land for parking, motor vehicles are the only suitable mode for travel, and improving vehicle flow is done through expansion and management of the roadway system.

Efforts to improve sustainability through land use have gained significant traction since the late twentieth century. In the United States, efforts called “New Urbanism” and “Smart Growth” represent attempts to encourage land uses and transport modes that discourage motor vehicle usage, and replace it with other, more sustainable forms of travel. These development forms are more conducive to walking and biking because they mix land uses and build safe infrastructure for nonmotorized modes of travel. Many of these developments are built in connection with and around new transit stations, and this “transit-oriented development” (TOD) makes public transit trips (often by light rail systems that stop at these stations) more conducive as well.

The evidence supporting the effect of increasing sustainability through modifying land use is, at best, mixed. These developments appear to capture people who are choosing to live in a denser urban form, as well as bringing about modal shifts away from motor vehicle usage. However, these developments are too few in number and too small in size to influence the whole of the city in which they are located, and most of the evidence indicates that they
have done little to mitigate citywide congestion. Many of these types of developments (and the light rail systems built to support them) have been undertaken as much for economic development purposes as for anything related to enhancing transport sustainability. Land-use strategies remain among the most complex and controversial approaches to dealing with sustainable transport.

Unsustainability in transport: energy

Petroleum dependency

Perhaps the primary issue with sustainability in transport is reliance on petroleum as its primary energy source. Petroleum comes from refined crude oil, which is unsustainable because of its being finite in supply, nonrenewable, and polluting. Petroleum deposits exist in a “petroleum window” of underground caverns of numerous shapes and depths. Most of the petroleum that has been extracted is the “sweet crude” deposits that are relatively easy to reach. The remaining supplies that are relatively easy to extract are located in places that are geopolitically unstable. What remains exists in difficult-to-access subterranean pockets that are too expensive to drill unless oil prices are sufficiently high to make extraction profitable. However, North America and parts of Central Asia experienced a boom in supplies in the early twenty-first century due to advances in fracking technology, where water is flushed into these deposits to help draw out the petroleum.

Estimates vary considerably of when worldwide petroleum supplies will be exhausted. A key concept in oil production is “peaking,” where yearly production totals begin to decline after reaching a maximum (or peak) because of dwindling global supplies. Oil production in the United States is believed to have peaked sometime in the 1970s, and global production is expected to peak sometime in the second or third decade of the twenty-first century, though the discovery of new fields and current advances in fracking technology make identifying an exact date difficult.

Most of the world’s transport supply runs on various forms of gasoline, a petroleum derivative. Diesel gasoline, natural gas, and ethanol–gasoline blends are also used. Petroleum is also a heavily used lubricant in the internal combustion engine (ICE), the most common type of engine in transport. Petroleum became the key energy source for transport because of several advantages it has over other alternatives. First, it has the highest energy density of any fuel in transport, meaning it takes the least amount to go the farthest compared to other energy sources. Storage is also relatively easy, and other energy sources, such as electricity and natural gas, have much greater competing uses (such as home and commercial heating and cooling) than petroleum (Greene 2004).

Further driving unsustainability is increasing the worldwide demand for petroleum. Globalization contributes to this by increasing the volume of shipments of goods and services over longer distances to a broader array of locations, and a rise in the overall standard of living in developing countries contributes to increasing the amount of transportation individuals do as well. Globalization also appears to contribute to transport unsustainability through inequity, as much of this economic growth is spatially and socioeconomically segregated.

A final issue influencing transport sustainability with petroleum is its price. The costs of crude oil, gasoline, and natural gas are some of the most influential components of the worldwide economy. Their costs, supply, and demand can be subject to significant fluctuations that in turn influence activity in sustainable transport. Rising costs and tightening demand increase interest in
developing alternatives and efficiency, changing behavior, and extracting remaining crude supplies that were previously too expensive to be profitable. When supply increases and costs drop, interest in these changes subsequently wanes.

Solutions and alternatives in energy issues

Some of this unsustainability in transport is being mitigated by increasing efficiency. This involves increasing the efficiency of the use of the remaining supply of petroleum, and developing alternatives for replacing petroleum – efforts which began decades ago and are still in progress. The regulation of petroleum in transport for sustainability-related purposes dates back to the responses to acute urban air pollution problems, and the oil shortages in the 1960s and 1970s instigated by the Organization of the Petroleum Exporting Countries (OPEC). In this era, regulations were introduced in the United States requiring the average fuel economy of all the cars an automaker sold to meet a certain threshold. Similar regulations were introduced elsewhere in the developed world, though the focus of reducing fuel use through these policies ranges across increasing vehicle efficiency, regulating emissions, and diversifying the fuels an automaker can offer. Lastly, governments are gradually acknowledging the connection between human carbon dioxide emissions and global climate change, and are beginning to use this as motivation for energy policy.

Nonelectric alternative fuels in transport

Natural gas has a relatively long history as an alternative fuel in transport. It is used extensively in commercial freight transport, and in some household vehicles in rural areas. Natural gas offers several advantages that partially explain its longer history of use. It has a higher energy density than other alternatives, one more comparable to gasoline. Refueling and storage procedures are similar to those of gasoline, where an onboard tank can be refilled in a relatively short time. However, natural gas is not a sustainable replacement for gasoline. It is another nonrenewable, carbon-based fuel, and features the same negative externalities as burning gasoline (described earlier). Additionally, it suffers from several existing competing uses, in particular for indoor heating.

Hydrogen and other forms of fuel cells are also on the horizon, and may hold the greatest promise of meeting the energy density requirements of transport that other alternatives currently cannot meet. However, major questions remain about the cost competitiveness and technical viability of hydrogen fuel cells to power individual automobiles.

Key current advancement in sustainable transport: electric alternatives to gasoline

Significant developments have occurred worldwide in electrified forms of surface transportation in the early twenty-first century, making it one of the most notable and widespread activities in sustainable transport to date. Electrification is a rather old concept in transportation. The first and most popular cars of the late nineteenth and early twentieth centuries were electric, and they outperformed other fuels. However, they fell out of favor in the early twentieth century, and experienced numerous false restarts in the 1970s, 1980s, and 1990s. The current rebirth of electric vehicles (EVs) probably began with the introduction of the Prius by Toyota in the late 1990s, which was the first commercially available car to feature a hybrid gasoline–electric powertrain. This powertrain consists of two motors, a gasoline-powered engine and an electric motor powered from a battery pack. The two motors
work in tandem: the battery drives the vehicle when it is sufficiently charged, and, when it is depleted or insufficient to power the car, the vehicle then adds power from or switches over completely to the gasoline engine. The battery is recharged through use of the gasoline engine and through a regenerative system that captures energy from friction applied in braking the wheels of the vehicle. Hybrid engines have increased in application, and major automakers now offer hybrid engines in a variety of models, though large gains in fuel economy have thus far been limited to smaller cars, similar in size to the Toyota Prius.

Vehicle powertrains that rely more exclusively on electricity have recently seen notable advancement. In 2011 two of the first widely commercially available cars were released, highlighting the different approaches to electrification in surface transport. The Chevy Volt is a plug-in hybrid electric (PHEV) compact sedan that runs off of an electric battery which, once depleted, transitions to power from a backup gasoline motor. The motors work independently of each other and not in tandem. The Volt uses the electric motor exclusively until the battery is depleted, at which point it switches over to the gasoline motor for power. At roughly the same time as the Volt was released, Nissan introduced a plug-in electric (PEV) subcompact called the Leaf. It runs off an electric motor exclusively, powered by a battery pack that recharges mostly through being plugged into an external outlet (though it does also recharge to an extent during use through a regenerative braking system).

The sustainability benefits of electric vehicles come from reducing petroleum demand and consumption, and thus reducing the negative externalities from petroleum reliance already discussed. Additionally, maintenance costs on electric motors are considerably less than on ICE motors, as they do not have nearly as many moving parts and don’t require services like oil changes or transmission repair. The user cost of recharging via electricity is currently significantly less per mile driven than refueling with gasoline, and public charging stations also exist on a limited but growing basis.

There are several critical issues limiting the proliferation of electric vehicles. First and foremost is the purchase price of electric vehicles which, even with government incentives to automakers and rebates to purchasers, still remains considerably higher than ICE counterparts. Additionally, electric vehicles face a perception problem that they are small and underperforming, and fit only a niche market of politically and environmentally inclined consumers.

Primary concerns with vehicle use include the distance the vehicle can travel without being recharged. Many current PEV models can only travel less than 100 miles on a single charge, much less than the distance an ICE vehicle can travel on a single tank of gas. Some models, such as those produced by innovative automaker Tesla (which produces only electric vehicles), have ranges up to 300 miles on a single charge, but currently these models are very expensive (retailing from $75,000 to $100,000). Many automakers and battery manufacturers are working to advance technology to extend the battery range and lower the cost of electric vehicles.

Another use issue with EV proliferation is the recharging process itself. EVs currently recharge through one of three different types of power connectors. They can charge through a conventional, 110V outlet (such as is common in US households), but fully recharging the battery can take up to 12 hours. They can also charge through less common but more powerful 240V outlets (such as is common in Europe and many other countries), and this can reduce the full recharge time to 3–6 hours. Lastly, there is “fast charging,” which can replenish a depleted battery in 30 minutes to an hour. However, fast
charging is currently fairly limited, and questions remain as to the long-term effect on battery life.

Electrification of surface transport may be the biggest current activity addressing the unsustainability of transport. Governments throughout the developed world as well as in China have introduced a vast array of policies designed to increase the adoption of electric vehicles. These include setting targets for the proliferation of EVs in their domestic fleet, requiring automakers to produce a certain number of EVs, incorporating EVs to meet fleet fuel economy or emissions requirements, incentivizing consumers to purchase EVs through tax rebates or purchase price reductions of vehicle cost, incentivizing EV purchase through subsidizing user costs such as recharging, parking, high-occupancy vehicle lane access, and registration fees, and, lastly, investing in research and technological development in the automobile, battery, and supply chain sectors to encourage industrial development and economic growth in these sectors.

Despite this activity, serious questions remain about the sustainability impacts of the source of electricity and the effect of increasing electric demand. Most of the electricity in the world comes from the burning of fossil fuels, usually coal. Though in abundant supply, coal is a finite resource that features the same negative externalities as burning other fossil fuels. Additionally, burning coal releases sulfur dioxide, which contributes to acid rain. However, increasing demand for electricity may also continue to drive current existing investments in development of renewable sources of electricity, such as solar and wind power.

Many argue that current energy grids and plant capacities cannot handle increasing demand, particularly at peak daytime periods of usage at the beginning and end of the traditional workday. Initial evidence indicates (and, interestingly, many electric utility providers believe) that much of this increase in demand will be realized not during peak periods but during off-peak periods, such as through charging the car while it is parked overnight on a weekday or at the weekend. There is a significant supply of electricity, particularly through coal-fired plants, that is unused during off-peak periods, and increasing demand for electricity during these times would represent a profit increase without additional infrastructure investment. A way to further incentivize this would be to implement time-of-day charging, where the cost of electricity goes up or down based on the demand for electricity during that time of the day.

There are broader questions about the overall ecological impact, or “carbon footprint,” of the electrification of surface transport. Some evidence indicates that EV proliferation contributes to increasing pollution from generating electricity. EV motors and batteries use certain rare earths and metals such as nickel and lithium, and it is argued that deployment of the resources and equipment necessary to extract these materials results in a larger net impact on the environment than maintaining the status quo. However, calculating a carbon footprint is a complicated and somewhat controversial process, and, to a certain extent, a carbon footprint critique ignores the impacts on resource extraction that were required to become dependent on petroleum in the first place, as well as what would be a necessary transition away from petroleum dependency in transport.

Most of the preceding discussion involves surface transport in motor vehicles. Energy supply as a sustainability question in transport also applies to railroad, maritime, and air transport. Railroad transport is powered primarily by diesel, coal, or externally supplied electricity delivered via overhanging wires. Civilian maritime transport is fueled from on-board diesel, and air transport is fueled from high-octane forms of gasoline.
There is relatively little discussion here of alternative fuels in these modes, partly because there is relatively little in the way of advancement in alternatives for them. Railroad and maritime transport are considered relatively sustainable despite their reliance on nonrenewable energy sources because their distance traveled per unit of fuel used is many times greater than that of motor vehicles. Rail transport is also partially electrified already. Air transport does not have any significant advancement toward alternative fuels at this time, though airplanes have become more efficient and less polluting with time.

Despite the advances in discoveries of existing supplies of petroleum and improvements in efficiency of its use, petroleum faces an undeniable truth of having a finite supply. Sometime in the twenty-first and twenty-second centuries, alternatives to it will be found and petroleum replaced before the supply is exhausted. Whether this happens via a transition made up of technological advancements, policies, and behavioral change, through international conflict to secure remaining supplies, or a combination of the two, remains to be seen.

Sweden: Geografiska Förbundet (GF) (Geographical Association)

Founded: 1918
Location of headquarters: Stockholm
Website: http://geof.se
Membership: 150 (as of 2013)
President: Camilla Eriksson
Contact: geoforbundet@gmail.com

Description and purpose

The Geografiska Förbundet was founded in 1918 and is an organization for anyone interested in geography. It has approximately 150 members and is located at the Stockholm University.

The main purpose of the association is to share geographic knowledge and to encourage young geography students. A scholarship is awarded each year to support students’ traveling, for example, field trips related to studies. The student who receives the scholarship presents his/her work in the form of a lecture for the members of the association. The association also arranges other lectures and excursions.

Current activities or projects

The Geografiska Förbundet arranges several lectures during the year. The lectures cover different areas within the subject of geography and are usually open to nonmembers.

Each year a few guided excursions are arranged to places of physical or human geographical interests, such as national parks or cultural sites. Longer excursions to other countries have been arranged in cooperation with similar organizations. All activities are carried out with a strong geographical focus.

Brief history

The GF was founded by geography students at Stockholm University as the Swedish Society for Geography and Anthropology (SSAG) excluded students from its board. The founders of GF initiated a platform for student-driven activities aimed to promote the development of geography as a discipline.

Sweden: Svenska Sällskapet för Antropologi och Geografi (SSAG) (Swedish Society for Anthropology and Geography)

Founded: 1877
Location of headquarters: Stockholm
Website: www.ssag.se
Membership: 500 (as of December 31, 2013)
President: Sten Hagberg
Contact: ssagmail@yahoo.se

Description and purpose

The Swedish Society for Anthropology and Geography (SSAG) aims to support the development of anthropology, geography, and other closely associated disciplines. SSAG supports interactions between academics in these fields and wider society and has links with similar societies outside Sweden. The protector of SSAG is the king of Sweden and the association collaborates with the Royal Swedish Academy of Sciences. SSAG is governed by an elected council with scholars from different universities in Sweden.

Journals or major publication series

Geografiska Annaler Series A, Physical Geography
Geografiska Annaler Series B, Human Geography
YMER (SSAG’s year book)

Current activities or projects

Among other activities, the SSAG organizes meetings with lectures on topics of member interest. The society stages an awards ceremony on Vega day, April 24, and a symposium is held on a topic chosen by the medalist.

SSAG supports research work through financial grants to primarily young scholars. SSAG also cooperates with local and professional associations of geographers and anthropologists in Sweden and is a member the European Geographical Society (EU-GEO).

Brief history

SSAG was founded under its present name in 1877 as an extension of the activities of the Association for Anthropology founded in 1873. This was a time of great exploratory expeditions and the SSAG took a particularly active part in the scientific description of the Arctic region highlighted by the “Vega” voyage through the passage north of Siberia led by Adolf Erik Nordenskiöld in 1878–1879.

In recent years SSAG is more dedicated to the popularization of the three disciplines and to current topics, for example, environmental degradation, physical planning, political geography, and questions of underdevelopment. SSAG has also become more involved in international relations through outreach activities and the development of Geografiska Annaler to become international research journals.

Description and purpose

The Swiss Association of Geography (ASG) was founded to promote geography in science, teaching, practice, and in the public. The ASG is a member of the Swiss Academy of Sciences (SCNAT; see www.scnat.ch) and represents the concerns of geography under the “Geosciences.” The ASG is also a member of the International Geographical Union (IGU; see www.igu-net.org). The association accomplishes its goal through promotion and sponsorships of young researchers, coordination between the different institutions and organizations of geography, the planning and performance of congresses and excursions together with the departments of geography, the advancement of school geography and corresponding technical didactics, and so forth.

Journals or major publication series

Current activities or projects

ASG activities focus on the coordination among the different geographical societies in Switzerland. Some of these societies are also politically active with respect to the geography teaching at the different school levels. The ASG financially supports young researchers for visiting congresses abroad and also supports national and regional conferences. The ASG collaborates with cantonal authorities with respect to environmental and spatial planning, nature protection, and similar issues.

Specific activities are listed among the individual societies affiliated to the ASG.

Brief history

The ASG is the successor organization of the Verband Schweizerischer Geographischer Gesellschaften that was founded in 1881. It is the coordinating link of several geographical organizations in Switzerland. Among these organizations are the SGAG (Schweizerische Gesellschaft für Angewandte Geographie, founded in 1967), the VSGG (Verein Schweizer
SWITZERLAND

Geografielehrpersonen, founded in 1911), the Swiss Geomorphological Society (founded in 1946), the JUGS (Junge Geographie Schweiz), and all geography departments of Switzerland and the regional (cantonal) societies (among them the Geographic and Ethnological Society Zurich that was founded in 1889).

*Geographica Helvetica* is the official journal and is cosponsored by the Swiss Academy of Sciences (SCNAT). The organizing institutions are the Geographic and Ethnological Society of Zurich (GEGZ) and the Swiss Association of Geography (ASG). *Geographica Helvetica* is part of the cultural heritage of Switzerland and is a multilingual journal (German, French, Italian, English).

The increasing complexity of human activity and its impact on the planet Earth demand a comprehensive understanding of how the various dynamic processes, natural and man-made, interact and, in particular, how they affect the natural and socioeconomic environment we are living in. A fundamental prerequisite in order to gain information about the spatial and temporal variation of phenomena of interest is an adequate means of measuring the current state of our environment at different scales, ranging from the local to regional to global scale. Over the last decades, remote sensing technology and the resulting products have become a major source of spatial information for monitoring and planning tasks assumed by local authorities, governmental agencies, supranational and intergovernmental organizations, as well as private industry.

Envisioning the experience of standing on a high building, a tower, a mountain top, or sitting next to the window on an airplane and looking down at the Earth, it is obvious to everyone that observing the Earth from a distance reveals a wealth of information at a single glance – information that is not readily available when standing on the ground in flat terrain. Thus, capturing this information in a systematic way by means of adequate sensors on board aircraft and spacecraft is a consequential next step to just “looking at the Earth” with our own remote sensing device, the human eye.

Remote sensing encompasses all methods that consist of retrieving information about the Earth’s surface by means of measuring and interpreting (energetic) fields that emanate from the Earth. Thereby, electromagnetic radiation that is back-scattered or emitted by the Earth serves as a carrier of information. These definitions are analogously valid for remote sensing of other celestial bodies. Remote sensing provides a means to not only overcome, by far, the very limited resolving capability of a human eye in terms of both the spatial and the spectral resolution, but it also allows for the capture of information that is carried by the nonvisible parts of the electromagnetic spectrum.

With respect to the source of electromagnetic radiation, two classes of remote sensing systems can be identified: passive remote sensing, where electromagnetic radiation from a natural source (e.g., the sun, thermal radiation, etc.) that is back-scattered or emitted by an object of interest is detected, and active remote sensing, where an artificial source of radiation is part of the remote sensing system. Active remote sensing systems are further distinguished into light detection and ranging (LiDAR) systems and radio detection and ranging (radar) systems. LiDAR systems use a laser device as their source of radiation; thus, they work in the optical domain. With radar systems, microwave antennas are employed for transmitting electromagnetic waves and receiving their back-scattered echoes. Electromagnetic waves within the frequency interval from 300 MHz to 300 GHz are commonly termed microwaves. As the term “ranging” suggests, these two types of active systems measure the time delay between
transmitting a signal and receiving the portion of the signal that is back-scattered towards the sensor. The propagation time is related to the distance (range). By combining this information with the sensor’s position and attitude, the geolocation of the object where the scattering process occurred can be determined. In this basic mode, the cross-range resolution of the system is governed by the beam footprint, which is a function of the wavelength, the aperture of the sensor, and the range distance. In the context of radar remote sensing, the resolution obtained in this way is typically low as a consequence of the large wavelengths of microwaves (m to mm), as compared to the wavelengths in the optical domain (μm to nm), for instance. In the next section a concept termed aperture synthesis that alleviates this adverse property is discussed in some detail. The high-resolution imaging radar technique based on this concept is called synthetic aperture radar (SAR).

When thinking of remote sensing as an operational monitoring tool, imaging radar technology has a number of attractive assets. The source of radiation, the radar antenna, is man-made and, therefore, well controlled. It can be deployed in the required manner, limited only by the degree of freedom and mission constraints of the aircraft or spacecraft that carries it. As a further consequence of the artificial source of radiation, the data acquisition schedule is not restricted by external factors such as daylight or weather conditions. Microwaves experience very little attenuation when they propagate through the Earth’s atmosphere. But while only being mildly attenuated, microwaves are subject to polarization rotation (Faraday rotation) and propagation delays in the ionosphere depending on the total electron content; they are subject to propagation delays in the troposphere as a function of the hydrodynamic condition. Microwaves penetrate clouds and, within a substantial range of the microwave frequency band (at wavelengths of the order of decimeters and larger), radar imaging is possible even in case of heavy precipitation. Further, synthetic aperture radar, unlike optical remote sensing, is the only imaging remote sensing technique where the spatial resolution of the resulting imagery is not a function of the distance between the sensor and the object of interest.

**Aperture synthesis in a nutshell**

In this section, a short overview of the general concept of aperture synthesis is given. In particular, aperture synthesis within the context of radar remote sensing is highlighted. These explanations are accompanied by a brief sketch of further relevant basic concepts of radar imaging. For an in-depth treatment of the subject, there are a number of excellent and comprehensive textbooks on synthetic aperture radar signal processing (Curlander and McDonough 1991; Carrara, Goodman, and Majewski 1995; Soumekh 1999; Cumming and Wong 2005) and on Fourier array imaging (Soumekh 1994). Unless indicated otherwise, the subsequent paragraphs are based on material compiled from Soumekh (1994), Born and Wolf (2009), and Demtröder (1999).

**Diffraction**

For many applications it is critical that remote sensing data are available at a high level of detail. Striving for a high spatial resolution has, therefore, always been one of the key challenges in remote sensing. As for any imaging system, there is a fundamental physical limit that determines the maximum resolving performance that can theoretically be achieved by a remote sensing
system. This limit is imposed by the physical phenomenon of diffraction. Waves of any kind (electromagnetic waves, sound waves, ocean waves, etc.) are subject to diffraction when they interact with an object. In the context of the fundamental resolution limit of imaging systems, the diffraction pattern that occurs when a wave front impinges on a slit, a rectangular, or a circular aperture, is of interest. The real-world equivalents would be the antenna array (real aperture) in the case of radar or the slit dimension in optics.

For remote sensing systems, where the physical aperture $D$ is typically very small compared to the distance $R$ from the object under examination, a type of diffraction called Fraunhofer, far-field, or plane-wave diffraction defines the fundamental theoretical resolution.

According to the Huygens–Fresnel principle (Born and Wolf 2009), every point on a wave front is a source of a secondary wavelet. Assuming a 1-D or 2-D aperture, which lies in the tangent plane of the spherical wave, and assuming the far-field case, a planar wave front “impinges” on the aperture at one instance of time. Thus, an infinite number of secondary radiating point sources, which oscillate in phase, occupy the planar wave front within the planar aperture $S$. The radiation stemming from a secondary radiating point source within the aperture $S$ experienced at a point in space with position vector $r$ is then:

$$E_{sec} = \frac{1}{R} a(l) e^{i\omega t - ik |\vec{r} - \vec{r}_s(l)|} dl$$  \hspace{1cm} (1)$$

where $R = |\vec{r} - \vec{r}_s|$. $\vec{r}_s$ is the center of the aperture, $a(l)$ is an amplitude function, $i$ is the imaginary unit, $\omega$ is the angular frequency, $t$ is the time, $k = 2\pi/\lambda$ is the wave number, $\lambda$ again is the wavelength, and $dl$ represents an infinitesimally sized patch of the planar aperture $S$. Hence, the total radiation experienced at the spatial point defined by $\vec{r}$ is obtained by integrating over all secondary radiating point sources within the aperture $S$:

$$E(x, y) = \frac{1}{R} \int_{S} a(l) e^{i\omega t - ik |\vec{r} - \vec{r}_s(l)|} dl$$  \hspace{1cm} (2)$$

which is called the Fresnel–Kirchhoff diffraction integral. Plane waves that are subject to diffraction when passing an aperture (optical case) and planar wave fronts that impinge on, or are transmitted, by a planar antenna are equivalent and, therefore, yield similar diffraction patterns.

In terms of the fundamental resolution of remote sensing systems, we are interested in the diffraction patterns that occur in the far-field case. (A more general (using neither the Fresnel nor the Fraunhofer approximation) treatment of the radiation pattern for dish-type radar antennas can be found in Soumekh (1999).) Essentially, the far-field case is obtained by approximating the nonlinear dependence of equation 2 on

$$R = |\vec{r} - \vec{r}_s(l)|$$

$$= \sqrt{(x - x_s(l))^2 + (y - y_c(l))^2 + (z - z_c(l))^2}$$

using a Taylor series expansion. Choosing the coordinate system in such a way that $z_c(l) = 0$, that is, the $z$-axis runs orthogonal to the aperture plane, then the Taylor series expansion of $R$ yields:

$$R = \sqrt{z^2 + (x - x_s(l))^2 + (y - y_c(l))^2}$$

$$= z \left(1 + \frac{(x - x_s(l))^2}{2z^2} + \frac{(y - y_c(l))^2}{2z^2} + \ldots\right)$$  \hspace{1cm} (3)$$

Stopping the expansion after the quadratic terms, the Fresnel, or near-field, diffraction is obtained ($E$ is the electric field strength) (equation 4):

$$E(x, y, z) = \frac{e^{i\omega z}}{az} \int_{S} E(x_c(l), y_c(l)) e^{ik((x - x_s(l))^2 + (y - y_c(l))^2)/2z^2} dl$$  \hspace{1cm} (4)$$
SYNTHETIC APERTURE RADAR

The Fraunhofer, or far-field, diffraction is obtained by expanding the quadratic terms of the second-order Taylor series expansion of \( R \) (equation 5):

\[
R \approx z \left( 1 + \frac{x^2 - 2xy}{2z^2} + \frac{y^2}{2z^2} - \frac{xy}{z} - \frac{y^2}{z^2} + \frac{x^2 + y^2}{2z^2} \right)
\]

\[
E(x, y, z = z_0) = E_0 \sin \left( \frac{\pi D_X}{\lambda z_0} x \right) \sin \left( \frac{\pi D_Y}{\lambda z_0} y \right)
\]

Similarly, for a circular aperture of diameter \( D \) the Fraunhofer diffraction pattern is obtained

\[
E(r, z = z_0) = E_0 \frac{2J_1 \left( \frac{\pi Dr}{\lambda z_0} \right)}{\pi Dr}
\]

where \( r = \sqrt{x^2 + y^2} \) and \( J_1 \) is the Bessel function of the first kind, integer order one.

An interesting and, in practice, a very useful property of Fraunhofer diffraction is the fact that the amplitude distribution of the Fraunhofer diffraction pattern is directly proportional to the Fourier transform of the aperture shape.

This becomes obvious when equation 8 is rewritten for the rectangular aperture case, for instance (equation 12)

\[
E(x, y, z = z_0) = E_0 \int_{-D_y/2}^{D_y/2} \int_{-D_x/2}^{D_x/2} \frac{e^{-i(kx_0 + ly_0)}}{\sqrt{x_0^2 + y_0^2}} \sin \left( \frac{\pi D_X}{\lambda z_0} x \right) \sin \left( \frac{\pi D_Y}{\lambda z_0} y \right) dx_0 dy_0
\]

which is easily identified as the 2-D Fourier transform of the rectangular function \( \text{rect}(x, y) \):

\[
\text{rect}(x, y) = \begin{cases} 
1, & |x| \leq D_x/2, |y| \leq D_y/2 \\
0, & |x| > D_x/2, |y| > D_y/2
\end{cases}
\]

In Figure 1, the intensity distributions of the Fraunhofer diffraction patterns are shown for three different shapes of apertures: a single vertical slit, a rectangular aperture, and a circular aperture. The following is notable: a constant field amplitude within a rectangular aperture of the dimensions \( D_x, D_y \) yields the same diffraction pattern as two orthogonally running slits of infinite length and widths \( D_x, D_y \), respectively. The horizontal apertures of both the single
Figure 1  Fraunhofer (far-field) diffraction patterns obtained from the following planar apertures: (a) a single vertical slit of horizontal width $D_x = D$ and infinite vertical extension $D_y = \infty$; (b) a rectangular aperture of dimensions $D_x = D$, $D_y = 2D$; (c) a circular aperture of diameter $D$. The grayscale map has been adjusted to increase the visibility of the diffraction pattern.

slit and the rectangular aperture, which lead to the far-field diffraction patterns shown in Figures 1(a) and 1b, are of the same size, $D_x = D$. Thus, the central, or main, lobe of the diffraction pattern has the same width in the horizontal dimension in both cases. The vertical extension $D_y = 2D$ of the rectangular aperture, however, is twice the size of the horizontal aperture, which leads to a main lobe that is only half as wide as compared to the horizontal dimension. The far-field diffraction pattern depicted in Figure 1c results from a circular aperture of diameter $D_r = D$.

In conclusion, for rectangular apertures the intensity distribution of the far-field diffraction pattern is sinc-squared-shaped ($\sin^2(\xi) = \sin^2(\xi)/\xi^2$) in either dimension, and a circular aperture leads to a pattern in the form of the so-called airy function $(2J_1(\rho))^2/\rho^2)$. In the following, the Fraunhofer diffraction pattern is also called the point spread function (PSF) or the impulse response function (IRF) of an imaging system.

The fundamental resolution limit of imaging systems

In the context of imaging systems, the resolution is a measure for the separability of two point targets (dirac pulses). The width of the main lobe of the Fraunhofer diffraction pattern defines the fundamental resolving performance of an imaging system. Looking at the diffraction patterns given in Figure 1, it can be observed that the first dark line or circle defines the width of the main lobe. In terms of mathematical expressions, the dark lines correspond to the roots of the sinc and airy function, respectively. The roots of the sinc function are found at:

$$\xi_0 = \pm n\pi, \quad \text{for } n = 1, \ldots, \infty \quad (13)$$

The outer boundary of the main lobe can be expressed in terms of the aperture $D_x$ and the wavelength $\lambda$ A by combining equation 9 and equation 13:

$$\frac{\pi D_x x}{\lambda z_0} = \pi \quad (14)$$
SYNTHETIC APERTURE RADAR

Further, using \( x/z_0 = \sin(\delta_\theta) \), where \( \delta_\theta \) is called the divergence angle, equation 14 can be rewritten as:

\[
\sin(\delta_\theta) = \frac{\lambda}{D_x} \quad (15)
\]

In optics, a common empirical definition of resolution is the so-called Rayleigh criterion. According to the Rayleigh criterion, two point sources are considered to be just resolved if the center of the main lobe of the IRF of the first point source coincides with the first root of the IRF of the second point source – a circular aperture is assumed. The first root of the airy function is found at \( \rho_0^0 = 1.220\pi \) (Born and Wolf 2009). Analogous to equation 15, this yields

\[
\sin(\delta_\theta) = 1.22 \frac{\lambda}{D_x} \quad (16)
\]

where \( \delta_\theta \) is the angular resolution that could theoretically be obtained if no other resolution-degrading effects were present.

In radar remote sensing (and also for other modern imaging systems) a slightly different definition of resolution is used, as the sensitivity of these devices is usually better than imposed by the Rayleigh criterion. Commonly, and also throughout this work, the \(-3\,dB\) width of the main lobe of the intensity distribution of the Fraunhofer diffraction pattern is used as a definition of the angular resolution, which is obtained by solving

\[
10\log_{10} \left( \frac{I(\pi D/\lambda \sin(\delta_{\theta dB}))}{I_0} \right) = -3 \quad (17)
\]

for \( \sin(\delta_{\theta dB}) \). \( I(\cdot) \) is the intensity distribution of the Fraunhofer diffraction pattern. For the rectangular aperture case, and considering the two-way propagation the relationship is then

\[
\sin(\delta_{\theta dB}) = 0.64 \frac{\lambda}{D} \quad (18)
\]

where \( \delta_{\theta dB} \) is the \(-3\,dB\) angular resolution and \( D \) is the size of the aperture in the particular dimension of the rectangular aperture. The threshold of \(-3\,dB\) corresponds approximately to half the maximal intensity \( I_0 \).

In remote sensing, one is eventually interested in the spatial resolution, that is, the resolution that is achieved when observing an object from a particular distance. The spatial resolution \( \delta_{3dB} \) that is obtained by illuminating an object using one single radar antenna of aperture \( D \) at a distance \( R \) is

\[
\delta_{3dB}(R) = a \sin \left( 0.64 \frac{\lambda}{D} \right) R \quad (19)
\]

With respect to radar remote sensing, two basic essentials can be drawn from these reflections:

1. A smaller aperture (antenna) has a lower directivity, a lower angular resolution, and a larger beam width.
2. The final spatial resolution is directly proportional to the distance of observation \( R \), which means that the spatial resolution deteriorates with increasing distance of observation.

Synthesizing a larger aperture

The basic concept of aperture synthesis involves appropriately combining the electromagnetic waves, which are back-scattered from an object of interest, as they are measured at different sensor locations. Thereby, an aperture that is a hundred to several thousand times larger in size than the actual aperture of a real antenna can be simulated. As a consequence, the main lobe of the synthetic antenna is extremely narrow, leading to a high resolution in the dimension where the aperture synthesis is performed. In SAR remote sensing, this is usually the direction of the motion vector of the sensor, called the azimuth direction. In multibaseline SAR configurations, such as SAR...
In synthetic aperture tomography, a synthetic aperture is also built in the normal direction, which is the direction orthogonal to both the azimuth direction and the line of sight.

Bearing in mind the Huygens–Fresnel principle once more, where the real aperture is thought of as being composed of an infinite number of secondary wavelets, which radiate in phase, this thought can be extended to subsequently placing antennas to form an array, where for all individual antennas an infinite number of secondary wavelets radiate in phase. However, as the synthetic aperture increases, the Fraunhofer approximation is no longer valid. As a consequence, the phase of the electromagnetic waves that are recorded at the different sensor locations has to be altered such that the wave fronts that are echoed by the object of interest interfere constructively for the location at which the object is situated.

Given that premise, the beam divergence angle $\theta_{SA}$ obtained for the synthetic aperture of length $L$ can be written, analogously to the real aperture case (equation 15), as:

$$\sin(\theta_{SA}) = \frac{\lambda}{L} \quad (20)$$

Using the fact that $x/z_0 = \sin(\delta_\theta)$ and setting $x = L/2$, the length of the synthetic aperture $L$, which varies as a function of the range distance, can be expressed in terms of the wavelength $\lambda$ and the aperture $D$ of the real antenna:

$$\frac{L/2}{z_0} = \sin(\delta_\theta) = \frac{\lambda}{D} \quad (21)$$

Combining equation 20 and equation 21, gives the following expression (neglecting tapering factors) for the divergence angle $\theta_{SA}$ of the synthetic aperture:

$$\sin(\theta_{SA}) = \frac{D}{2z_0} \quad (22)$$

The maximal spatial resolution $\delta_{SA}$ obtained with the full synthetic aperture is then:

$$\delta_{SA} = \sin(\theta_{SA})z_0 = \frac{D}{2} \quad (23)$$

Hence, the beneficial characteristics of aperture synthesis can be summarized as follows.

- A very high spatial resolution of half the aperture size of the real antenna is obtained in the dimension in which the synthetic aperture is built. A smaller real aperture (antenna), which has a lower directivity, that is, a larger beam width, is favorable in order to obtain a higher resolution because individual radar echoes measured at different azimuth positions can be combined only as long as the object lies within the beam width of the real antenna.
- Most importantly, the resolution is independent of the distance of observation.

This analysis is valid for an imaging mode called stripmap mode and the additional constraint is that the direction in which the antenna is pointing is orthogonal to the synthetic antenna array during the whole data acquisition period. In contrast, in spotlight mode imaging the antenna beam is steered, mechanically or electronically, such that the scene of interest is illuminated over a longer period and, thereby, the resolution in azimuth direction can be further enhanced (Soumekh 1999; Carrara, Goodman, and Majewski 1995).

Similar to aperture synthesis in the azimuth direction, a synthetic aperture can also be formed in the normal direction, thus yielding a 2-D synthetic aperture. This concept is called multibaseline SAR interferometry or SAR tomography. In practice, the main difference lies in the fact that multiple sensor trajectories, ideally running parallel, are required to build the synthetic aperture. This topic is not discussed here.
So far, discussion has been about imaging resolution in two dimensions of the planar antenna, assuming that an infinitesimally short pulse consisting of a monochromatic wave accurately indicates the propagation delay to the object of interest. For pulsed radar systems, a high resolution in range direction (line of sight) is obtained by typically using a frequency-modulated pulse (chirp) of a length of several microseconds; each radar echo is then compressed later by matched filtering with a replica of the original frequency-modulated pulse. Without going into further detail here, the resolution $\delta_r$ in range direction for the case of a linear frequency modulation leading to a resolution that is inversely proportional to the bandwidth $B$ is:

$$\delta_r = \frac{c}{2B}$$

where $c$ is the propagation speed of the electromagnetic wave.

This brief introduction to aperture synthesis and imaging resolution concludes here but a detailed introduction to the signal model of synthetic aperture radar systems is available elsewhere (Curlander and McDonough 1991; Carrara, Goodman, and Majewski 1995; Soumekh 1999; Cumming and Wong 2005).

Radar remote sensing is only one of many fields where imaging by aperture synthesis is performed. Examples of such imaging systems include very large baseline interferometry (VLBI) in radio astronomy, synthetic aperture sonar (SAS) in the maritime environment, ultrasonic synthetic aperture systems in noninvasive diagnostic medicine, as well as seismic sounding in geophysical exploration (Stolt 1978). In astronomy, even optical aperture synthesis (OAS) using an array of telescopes is possible today, a notable difference being that the large aperture cannot be synthesized by digital post-processing but has to be correlated by a dedicated optical system (e.g., the Very Large Telescope, VLT).

Case studies have also been made for future OAS Earth observation systems from a geostationary orbit. Similar concepts are found in speech and acoustic signal processing and wireless communication systems, mostly under the name of direction-of-arrival estimation (DOA). The fundamental framework of all these techniques is called array signal processing.

As diverse as are the fields where aperture synthesis is applied, so too is the terminology. Thus, a number of terms that essentially all describe resolution enhancement by means of aperture synthesis are used; they are listed here nonexhaustively: (azimuth) focusing, (digital) beamforming, matched filtering, correlation with a reference function, wave equation migration, back-projection, and direction-of-arrival estimation.

**Imaging paradigms in synthetic aperture radar data processing**

Imaging essentially means inverting the measurement process in an adequate way in order to obtain a representation of the objects of interest.

Over the years, a number of different algorithms have been developed or adapted for SAR image processing. This section gives a very brief overview of three imaging paradigms that are commonly used in SAR signal processing. An in-depth review of available SAR focusing algorithms is outside the scope of this entry but a number of excellent textbooks are available that cover this topic at length and in great detail: Curlander and McDonough (1991) and Cumming and Wong (2005) highlight and compare a number of focusing algorithms from a spaceborne SAR perspective and, therefore, predominantly for narrow band width and narrow beam width systems. Carrara, Goodman,
and Majewski (1995), Jakowatz et al. (1996), and Soumekh (1999) all treat SAR signal processing from an airborne SAR perspective. Thus, compensation of irregular motion receives considerable attention in these works.

Basic focusing steps

With the exception of the chirp-scaling-based algorithms, all SAR imaging techniques can be split into a sequence of focusing the data in the range (fast-time) direction (range compression, range-matched filtering) and synthesizing a large aperture in the azimuth (slow-time) direction. In Figure 2 an example of an airborne SAR dataset is given; it visualizes the SAR data as amplitude representations at different stages of the image formation process: (a) before any manipulation, that is, the data are displayed as taken by the sensor before focusing (raw data); (b) at an intermediate stage, after range matched filtering (range-compressed data); and (c) after aperture synthesis has been performed (azimuth-focused data).

In the range-compressed data representation shown in Figure 2b, the 2-D hyperbolic nature of the target signal history becomes obvious: the target appears to be smeared along a hyperbolic trajectory. This nontrivial range/azimuth coupling is exactly what makes synthetic aperture imaging a challenging task. The signal contributions of a point target appear at range distances that vary from pulse to pulse along the azimuth direction, an effect called “range cell migration” (RCM), or “motion through resolution cells.” In addition, perturbation of the signal history in the airborne case, caused by irregular motion of the sensor and varying propagation delays due to atmospheric conditions, further complicate the image inversion.

In the following sections, the most common SAR imaging algorithms are discussed briefly in the context of three imaging paradigms: the range-Doppler paradigm, the wave number domain reconstruction paradigm, and the tomographic paradigm.

Range-Doppler paradigm

Following this paradigm, efficient processing is achieved by making use of the fact that, in SAR remote sensing, the sensor is in motion. Thus, the signal of a point target experiences a Doppler frequency shift depending on the projection of the relative velocity vector onto the connecting line between the sensor and the target. Algorithms that can be assigned to the range-Doppler paradigm are the range-Doppler algorithm (Cumming and Bennett 1979; Wu, Liu, and Jin 1982; Barber 1985), the chirp scaling algorithm (Raney et al. 1994), as well as further extensions of the chirp scaling algorithm such as for squinted geometry (Davidson, Cumming, and Ito 1996), the airborne case including motion compensation (Moreira and Huang 1994), and a more generalized formulation for processing of air- and spaceborne stripmap SAR data and even ScanSAR data (Moreira, Mittermayer, and Scheiber 1996). Another chirp-scaling-based framework for higher order approximation of the hyperbolic range equation, called the generalized frequency domain algorithm, is described by Zaugg and Long (2009).

The basic range-Doppler algorithm involves the assumption of a narrow band width and a narrow beam width, as well as a parabolic approximation (corresponding to the Fresnel approximation of the diffraction pattern) of the hyperbolic shape of the signal history. A further, distinct feature of the range-Doppler algorithm is that the range cell migration correction (RCMC) is performed in the range (time)-Doppler (frequency) domain where targets lying at a certain range distance are superposed as they have the same Doppler
Figure 2  Exemplary SAR data representations (SAR data acquired by the airborne E-SAR sensor of the German Aerospace Center (DLR)): (a) raw data, as measured by the sensor; (b) range-compressed data (i.e., after range-matched filtering); (c) azimuth-focused data (i.e., after aperture synthesis). Note the hyperbolic shape of bright objects as they appear at different range distances in subsequent pulses within the range/azimuth geometry of the range-compressed image. Evidently, the signal processing steps that are needed to build the synthetic aperture are of a 2-D nature (in contrast to the 1-D range compression).
characteristics. RCMC is performed using an interpolation scheme, the choice of which considerably affects the quality of the final image.

The chirp scaling algorithm avoids that critical and time-consuming interpolation step. It involves basically multiplying the SAR data in the range-Doppler domain with a quadratic phase function (chirp scaling) in order to equalize the range cell migration to a reference range, followed by a range compression and a secondary range compression (SRC) in the wave number domain. The SRC is strictly correct only for one reference range and it is updated as a function of the Doppler frequency. The SAR data are imaged without any data interpolation within this focusing procedure. The chirp scaling algorithm in its standard formulation employs a parabolic approximation of the hyperbolic range history. Varying the Doppler rate with range is possible. The RCMC is carried out differentially by means of the chirp scaling operation in the range Doppler domain.

The accuracy of both, the range-Doppler algorithm and the (extended) chirp scaling algorithm, is limited for higher band widths and wide beam widths. While the generalized frequency domain algorithm is theoretically suitable to process SAR data from systems with wide beam widths, large band widths, or low carrier frequencies, no concept that can handle severe deviations from a linear sensor trajectory has been presented so far.

In Walker (1980) the so-called polar format algorithm was introduced; this algorithm was later reformulated from a tomographic point of view. The polar format algorithm is particularly useful for spotlight mode SAR data processing.

**Wave number domain paradigm**

The wave number domain algorithm, also called range migration algorithm, or \( \omega - k \) algorithm (Rocca 1987; Cafforio, Prati, and Rocca 1991; Soumekh 1992; Milman 1993) allows for an approximation-free image reconstruction based on the exact inversion (as far as the phase history is concerned) of the wave equation. The only approximation involved in this reconstruction scheme is the principle of stationary phase, which is used for an explicit evaluation of the Fourier transform of the signal model. The principle of stationary phase is valid in the standard monostatic scenario except in the extreme case of frequencies close to zero (Zaugg and Long 2009). Another exception where the principle of stationary phase is not valid is an extreme bistatic case, such as a combined spaceborne-airborne bistatic data acquisition Wang et al. (2008).

The characteristic feature of this algorithm is a nonlinear coordinate transform also termed Stolt mapping (Stolt 1978), which stems from a seismic migration technique.

Theoretically, the \( \omega - k \) algorithm is a very elegant and approximation-free solution of the SAR image reconstruction problem. In practice, however, several drawbacks become evident; for instance, the exact \( \omega - k \) algorithm lacks the possibility to account for a range varying adjustment of the Doppler rate, which renders it to be an option only for airborne SAR remote sensing. Therefore, approximations of the exact \( \omega - k \) algorithm have been developed for small band width and narrow beam width spaceborne systems. One of these approximative solutions is called monochromatic \( \omega - k \) developed by Rocca, Prati, and Monti–Guarnieri (1989). It is an approximation of the strict \( \omega - k \) algorithm in two ways: The nonlinear Stolt interpolation is replaced by a linear phase term in the range-Doppler domain. Consequently, only the carrier frequency is mapped correctly; hence, the attribute is monochromatic. In addition, a quadratic approximation is used instead of the exact transfer function. The main advantage of
the monochromatic $\omega - k$ algorithm is that it needs no interpolation and, therefore, is very efficient.

Another interpolation-free imaging algorithm deduced from the wave number domain algorithm is the range stacking algorithm (Soumekh 1998), where a (range-varying) matched filter is explicitly calculated for each range bin, followed by a slow-time inverse Fourier transform. In the original wave number domain algorithm, by contrast, the matched filter is applied in the 2-D wave number domain for one reference range. Thus, the Stolt mapping of variables $k_r = \sqrt{4k^2 - k^2_u}$ requires a delicate interpolation of nonlinearly spaced data points to regular grid points in the $(k_r, k_u)$ domain. The range stacking algorithm is computationally more expensive than the wave number domain algorithm, but due to the fact that the azimuth focusing can be performed independently for each range bin, the image formation can be parallelized with ease. In addition, it features the advantage that no interpolation artifacts are present in the final image.

In the airborne case, however, another problem may occur in the sense that strong deviations from a linear trajectory, especially in combination with rugged terrain, cannot be corrected for adequately.

**Tomographic imaging paradigm**

In a pioneering paper, Munson, O’Brien, and Jenkins (1983) highlighted the similarity of spotlight mode SAR data and tomographic data as obtained from, for example, X-ray computerized tomography devices. They gave a 2-D formulation of spotlight SAR imaging in terms of the projection slice theorem known from computer-aided tomography (Kak and Slaney 1988). The signal received at each antenna position is interpreted as a portion of the Fourier transform of a central projection of the imaged area. This interpretation allows for a geometry-based or Radon-transform-based understanding instead of a Doppler-shift-based understanding of the synthetic aperture imaging process. In that paper (Munson, O’Brien, and Jenkins 1983), the polar format algorithm (Walker 1980) originally formulated in a range-Doppler sense is reinterpreted and opposed to a back-projection algorithm. Jakowitz and Thompson (1995) have extended the 2-D view towards a 3-D tomographic formulation of spotlight mode SAR. However, the polar format algorithm is again an approximation of the exact image formation process in the sense that a plane wave approximation is used. This limits the scope of application to narrow beam width systems and spotlight processing of limited-sized patches in terms of the target area (Soumekh 1999).

Another instance of the class of tomographic imaging algorithms is called time-domain back-projection (TDBP). In contrast to all frequency-domain based reconstruction methods, TDBP theoretically allows for a nonlinear aperture shape and incorporation of terrain models into signal processing in a stringent way (Frey *et al.* 2009). The idea of back-projecting the measured data pulse by pulse onto a 2-D or 3-D image space is a very natural solution of the inversion problem: For each sensor position, the range-compressed signal is spread (back-projected) along the spherical shape of constant range in the monostatic case, or along the ellipsoidal shape of constant bistatic range in the bistatic SAR case. Basically, the coherent superposition of the back-projected signals at different range distances and for all antenna positions within the synthetic aperture (as obtained at the pixel locations of the reconstruction grid) yields the final focused SAR image.

It has been stated by Ulander, Hellsten, and Stenstrom (2003) that for airborne wide beam width systems, in particular, an extreme case is
the CARABAS II sensor (Hellsten et al. 1996): the TDBP supersedes the frequency domain algorithms. The TDBP can be regarded as a generalization of the standard beam forming or delay–and–sum approach, on the one hand, or matched filtering of a known signal embedded in Gaussian noise by means of a spatially varying reference kernel for each pixel location on the reconstruction grid, on the other hand.

In summary, depending on the parameters of the SAR sensor (carrier frequency, band width, beam width), platform type (spaceborne, airborne, ground based), and type of application, the appropriate SAR imaging algorithm must be selected. The fast frequency-domain-based algorithms, which rely on simplifications that trade an accurate model of the azimuth reference function for speed, are typically valid for spaceborne narrow band width, narrow beam width SAR sensors, and standard data acquisition modes, such as monostatic stripmap SAR. At the other end of the wide spectrum of SAR imaging algorithms, the time-domain back-projection-based algorithms are found. These algorithms are typically used for airborne sensors (subject to nonlinear platform motion), very wide band width, wide beam width SAR sensors at low carrier frequencies, as well as for intricate data acquisition geometries such as curvilinear or circular SAR, bistatic SAR imaging, or, potentially, for future geosynchronous SAR systems.

Further reading

The discipline of system dynamics was founded by Jay W. Forrester when he utilized principles of control theory to inform hiring, inventory, and production decisions in industrial systems (Forrester 1961). Following from this foundation, the problem-solving approach of system dynamics has been widely applied to the study of business and managerial problems in industrial systems. Forrester’s work became well known when his WORLD model (Forrester 1971) was described in *The Limits to Growth* (Meadows et al. 1972). The WORLD model characterized the global socioeconomic system to study the impact of population growth and consumption on society and the environment. A central insight was that exponential population growth would overshoot and collapse due to resource constraints if no action were taken to avert this scenario. This unpopular conclusion garnered media attention and induced a vocal backlash from critics. However, the book’s fundamental tenet that unlimited growth is not possible on a finite Earth has withstood the test of time: recent editions of the book have updated the original model with new information about population growth and resource use.

System dynamics offers a powerful way to aid human decision-making. Humans make assumptions about the causes and effects of phenomena in a system as well as how the system functions. These assumptions, also known as mental models, help individuals make sense of the system and, thus, influence the decisions to regulate or intervene in the system. Limitations of the human mind for attention, memory, recall, and information processing about dynamically complex problems often produce deficiencies in mental models, such as incomplete causal reasoning and misperceptions about feedbacks. System dynamics provides a way to address these deficiencies with specific methods for representing, testing, and ultimately modifying mental models. Information about a system may be processed and interpreted using different strategies, resulting in very different decisions. Over time, these decisions will change system structures and the subsequent system behavior. A central principle of system dynamics is to study a problem from different perspectives so as to broaden the boundaries of mental models to design better strategies and structures.

The methodology of system dynamics is used to address problems embedded in systems that exhibit dynamic complexity. Complex systems often exhibit dynamic and nonlinear behavior. Such system behavior produces uncertainties, complicating efforts to understand and regulate complex systems. Policy changes and corrective actions can lead to unintended consequences because of feedback processes and delays in the system. A system dynamics model may be used to explore policies for management of these systems.

Complex systems exist in many forms: physical, biological, social (human), natural, or coupled human–natural (variously termed...
Socioecological, human–biophysical, human–environment). Complexity research often involves explorations of the resilient and adaptive capacity of systems in response to stresses and shocks. Familiar to geographers who use geographic information systems (GIS), the term “system” refers to a set of interacting components connected in a distinctive structure. The system forms a boundary-maintaining entity that can be embedded within other systems, establishing a hierarchical structure. A functional system is one that balances the overall purpose with the subpurposes of individual system components and embedded systems.

A system’s behavior is generated by interactions among its elements and the context in which they operate. The model’s structure, in terms of stocks and flows interconnected via feedback loops, determines its characteristic behavior over time. Common patterns of system behavior are exponential growth, decay, goal seeking, oscillation, S-shaped growth, and combinations such as overshoot and collapse.

Central to system dynamics are the concepts of stocks and flows. Stocks are accumulations that integrate their net inflows (the sum of all inflows minus outflows) and, therefore, change only in response to their flows. Stocks are also known as state variables, levels, buffers, inventories, compartments, reservoirs, reactants, or reaction products. Stocks may represent tangible (e.g., water level in a reservoir) or intangible (e.g., customer satisfaction) quantities. Flows refer to rates of change over time and are expressed in the units of the stocks to which they are connected per unit time (i.e., days, months, years). Flows are encoded as actions that increase or decrease the quantity contained in the stock. Because flows occur over time, they are not directly observable. In contrast, stocks reflect the state of the system so that if a snapshot were taken of the system, the stocks would be observable (if also visible). Since they characterize the state of the system, stocks provide information as a basis for action that ultimately feeds back to affect future flows. Those flow rates, in turn, affect future values of the stocks, completing a feedback loop.

Given linkages between stocks and flows, system dynamics models facilitate exploration of time delays that occur when there are time lags between inputs and outputs. Delays tend to introduce instability into the system, affecting material as well as information flows in a system. Material delays are produced by capacity constraints on the flows into and out of stocks, such as those of a manufacturing process. Information delays reflect the time needed to adjust public perceptions or beliefs in response to new information about the state of the system as contained in the stocks. All delays involve stocks, so that stocks endow the system with inertia and memory.

A common metaphor invoked to convey the meaning of stocks and flows is the level of water in a bathtub (stock) as a function of input/outputs of water (flows). As an open container with flows into and out of it, a bathtub creates a stock with water levels changing as water flows into and out of the bathtub. The faucet (water flowing in) and the drain (water flowing out) together regulate the amount of water in the bathtub, which characterizes the state of the system and is observed as level (depth) of water in the bathtub. The flows into and out of the bathtub are controlled by the humans who turn the faucet on or off and close or open the drain. Information about the depth of the water in the bathtub relative to its size is used to decide when to turn off the faucet.

Mathematically, stocks are expressed as integrals that integrate their net inflow for each time step. The equation for the quantity of the stock at time $t$ is as follows:

$$\text{Stock}(t) = \int_{t_0}^{t} [I(s) - O(s)]ds + \text{Stock}(t_0)$$
In this equation, $I(s)$ and $O(s)$ indicate the inflow and outflow rates at any point in time, $s$, between the initial time ($t_0$) and the current time ($t$). In an equilibrium condition, the corresponding differential equation would be expressed as: \[ \frac{d(\text{Stock})}{dt} = I(t) - O(t). \]

While a system dynamics model is mathematically equivalent to a system of coupled ordinary differential equations, it is also characterized by the use of descriptive variable names, visual icons that distinguish stocks from flows and auxiliary variables, and causal information arrows that identify the presence of complete feedback loops. Figure 1 illustrates this iconography, with a box to represent the stock of population, pipeline icons with valves for flows, curved arrows for causal information mechanisms, and cloud icons to indicate sources or sinks. Sources and sinks function as stocks of infinite capacity that are beyond the scope of the problem being represented.

Linear systems can be split into subsystems whose behaviors can be expressed with exact analytical solutions (general solutions to systems of equations). For linear systems, the rate of flow into a stock is constant over time and the sum of parts (the behaviors of subsystems) is equal to the whole (the behavior of the overall system). In contrast, for nonlinear systems the parts connect in such a way that their sum does not equal the whole.

Simulation modeling is well suited to the study of nonlinear behavior. For example, the simulation experiments of Edward Lorenz led to the complexity principle of “sensitive dependence upon initial conditions” or path dependence (Lorenz 1963). These simulation experiments demonstrated that a third-order deterministic system of ordinary differential equations interconnecting three weather state variables could generate chaos if their parameters were perturbed slightly from the rounding of digits when printing simulation results after each day’s worth of experiments.

System dynamics models usually operate under deterministic assumptions, although probabilistic functional forms are feasible. Embedding stochastic behavior into a system dynamics model renders it harder to interpret. Rigorous methods of parameter variation, sensitivity testing, and calibration are instead performed to build confidence in the structure and conditions of a system dynamics model.

Various computer software platforms (i.e., Vensim, Powersim, Stella/iThink, AnyLogic) are available to construct computer simulation models via the graphical language of system dynamics. These software platforms facilitate the practice of system dynamics using a graphical interface with distinct iconography for stocks, flows, and information feedback. Vensim was used to construct the models represented in the figures of this entry.

As a simplified representation, a system dynamics model has utility when it can explain why characteristic behavioral patterns are being produced by the system. Identifying which structures and conditions generate the observed behavior reveals leverage points for policy change. Leverage points signal opportunities to intervene in the system where relatively small changes can be introduced so as to encourage larger-scale changes in system behavior to
achieve desired goals. System dynamics models can be used to assess the impact of different courses of action in the short term and long term. A fundamental insight of system dynamics, and systems thinking more generally, is that the problems and the solutions are often endogenous to the system in that the most effective change comes from within.

The modeling process

Although there are different ways to model a problem using system dynamics, the general modeling process usually involves the following steps (Sterman 2000):

1. defining the problem;
2. developing a dynamic hypothesis (causal map) of the problem;
3. formulating the model with stock and flow structures;
4. calibrating and testing model boundaries;
5. considering the impact of different policies and scenarios.

The stages of the modeling process may be interwoven, as it may prove valuable to revisit hypotheses (step 2) after beginning the model formulation (step 3), or to perform model testing (step 4) on scenarios (step 5) that have been articulated. Some system dynamics practitioners begin with stock–flow structures (step 3), and different steps are emphasized depending on the purpose of the modeling effort. The process of modeling is iterative, with each cycle of model design and experimentation resulting in new insights for modelers, model users, and problem stakeholders. In addition to the model itself, the modeling process can provide a mechanism for gaining insights about how a problem came to exist and what actions should be taken to address this problem. After a model is developed, discrepancies in simulation results and expectations may motivate new hypotheses and additional experiments to better understand alternative hypotheses.

In step 1, the problem is defined and characterized as dynamic in nature. The system dynamics approach emphasizes modeling of a particular problem, not the system itself (which would be more difficult to bound without a problem orientation). Useful system dynamics models are those designed to investigate policy issues to solve a specific problem that exhibits dynamic behavior.

To define the problem, system variables relevant to the problem of interest that exhibit dynamic behavior are first identified. Identifying system variables (elements that vary over time) helps determine the model scope, that is, what to put in the model. Drawing out reference modes and time horizons for system variables is part of articulating the problem dynamically. Observed behaviors over time are characterized graphically as reference modes from which to compare simulation results. Reference modes, also known as behavior over time graphs, characterize the dynamic pattern as a point of reference during the modeling process. The x-axis of the reference modes spans the time horizon to be simulated. The length of the time horizon will influence the perspectives on the problem. Longer time horizons allow for consideration of system delays and long-term impacts of feedback processes that contribute to unexpected system behaviors, which are often overlooked. The y-axis of the behavior over time graph should represent a magnitude either on a continuous scale (e.g., 0–100) or a categorical scale (e.g., low, medium, high). It is common practice for different trends over time to be charted for hoped, feared, and expected behaviors of key state variables in the reference modes.
An illustration of reference modes is provided for the example of technology diffusion in Figure 2. Diffusion, also referred to as dispersal or spillover, is a dynamic process. The reference mode for the diffusion process is the S-shaped curve, as for the population of adopters (green line) in Figure 2. The S-shaped (sigmoidal) curve or logistic growth curve is characterized by a slow initial incline, followed by a rapid, uniform acceleration until about the midpoint of the curve, at which point there is continuous rise that progressively decelerates until leveling off at an upper limit. S-shaped growth is generated by a system where the interaction between reinforcing and balancing loops is nonlinear; there are no significant time delays in balancing loops; and the upper limit is fixed. The “tipping point” of diffusion processes occurs when there is a shift in loop dominance from reinforcing feedback (growth) to balancing feedback (market saturation). This point is characterized by the maximum adoption rate (dotted line) in Figure 2.

Dynamic patterns of system behavior are produced by time delays and interactions between feedback loops, particularly nonlinear interactions. As outlined in Ford (2010), common reference modes characterizing patterns of system behavior include reinforcing feedback for exponential growth; balancing feedback for exponential approach (goal-seeking behavior); negative feedback with significant time delays for oscillation; nonlinear interaction between reinforcing and balancing feedbacks with no significant time delays and a fixed upper limit for S-shaped growth; S-shaped growth, but with significant time delays for S-shaped growth with overshoot; and S-shaped growth, but with a diminishing upper limit over time for overshoot and collapse.

In step 2, a dynamic hypothesis is developed as a plausible explanation for system behavior. Causal maps (also known as causal loop diagrams) provide a systematic way to develop dynamic hypotheses and identify important feedback loops. Because the modeling process is iterative, the dynamic hypothesis serves as a working theory that may be modified in future iterations. As a conceptual framework, the dynamic hypothesis provides an important link between theory and model design.

The system dynamics approach aims to find endogenous explanations for observed phenomena within the structure of the system. Therefore, causal maps of dynamic hypotheses are composed of cycles created by linking variables through causes and effects to create feedback loops.

The process of building a causal map generally begins with the identification of which variable best characterizes the state of the system. This variable is then rendered endogenous by linking relevant system variables in cause and effect relationships. Upstream factors or causes are identified, followed by the downstream factors or effects that are associated with the problem. Lastly, links are made between upstream and downstream factors. In terms of downstream factors, modelers using system dynamics should...
think beyond expected and immediate outcomes. During this step of the modeling process, modelers should consider the difference between short-term and long-term outcomes, as well as possible unintended consequences of policy changes. The linking of downstream and upstream factors should yield complete feedback loops. Richardson (1991) illustrates numerous examples of feedback mechanisms implicit in social theory.

In causal maps, links between variables are represented with arrows that indicate the direction of causation. Each arrow between pairwise relationships is also labeled with a polarity, a positive (+) or negative (−) sign. The polarity denotes whether variable X increases or decreases relative to variable Y, ceteris paribus (i.e., holding all else equal). For each pairwise relationship, the modeler asks: if X were to increase, would Y increase or decrease compared to what it would otherwise have been? A positive sign (+) can be interpreted as follows: all else remaining equal, an increase in variable X increases variable Y above what it would otherwise have been. A negative sign (−) can be interpreted as follows: all else remaining equal, an increase in variable X decreases variable Y below what it otherwise would have been. These relationships hold when the system is responding to a decrease in variable X, so that a positive causal link means the effect variable Y decreases it below what it would otherwise have been. Similarly, a negative causal link means that the effect variable Y increases in response to a decrease in X. An even number of negative (opposite) relationships or a positive product of polarities indicates a reinforcing feedback loop, whereas an odd number of negative (opposite) relationships or a negative product of polarities indicates a balancing feedback loop. An important check when constructing causal maps is to think through the logic of a feedback loop to determine whether it is reinforcing or balancing.

When appropriately presented, causal maps can reveal and communicate potential mechanisms driving the dynamic behavior via feedback loops. An example causal map is illustrated in Figure 3 for a hypothesis of the diffusion behavior depicted in Figure 2. The left-hand loop is denoted “B” for balancing feedback in the saturation of the potential market as increased adoption rate (a flow, in units of people per year who adopt the technology) reduces the stock of potential adopters and, thereby, diminishes the pool of potential adopters not previously
exposed to the technology. The right-hand loop is labeled “R” for reinforcing feedback exhibited by growth of the market due to word of mouth as an increase in adopters fuels the probability that a potential adopter will encounter adopters, further increasing the adoption rate.

System variables may be exogenous or endogenous. Endogenous variables are embedded within the system boundary, whereas exogenous variables impinge upon the system from outside the system boundary. The variables in the causal map expressed in Figure 3 are endogenous. In step 3, each endogenous variable mapped in step 2 is formally related to its causes with an explicit equation. Exogenous variables are defined as parameters that can be controlled to create distinct simulation experiments. Units are assigned and checked for dimensional consistency.

In step 3, a computer simulation model is formulated using stock and flow structures interconnected with feedback loops. Formulating a computer simulation model involves specifying assumptions as parameter settings and equations encoding decision rules.

Figure 4 illustrates the full stock–flow model corresponding to the causal map depicted in Figure 3. Particularly, the diminishing stock of potential adopters is seen to be part of the balancing feedback loop, and the growing stock of adopters fuels the reinforcing feedback loop through word of mouth about the innovation that is modulated with the contact rate parameter. This example is adapted from Sterman (2000).

The equations for the innovation diffusion model depicted in Figure 4 are:

\[ A(t) = \int_{t_0}^{t} [ar(s)]ds + A_0(t_0) \]
\[ P(t) + A(t) = n \]

\[ P(t) = \int_{t_0}^{t} [-ar(s)]ds + n - A_0(t_0) \]
\[ ar(t) = cr \times i \times P(t) \times \left( \frac{A(t)}{n} \right) \]
where: \( A \) = number of adopters (people); \( A_0 \) = initial number of adopters (people); \( n \) = total population (people); \( P \) = number of potential adopters (people); \( ar \) = adoption rate (people/day); \( cr \) = contact rate (people/person-day); \( i \) = probability of adoption after exposure to innovation (dimensionless); \( P_0 \) = initial number of potential adopters, \( n - A_0 \) (people); and \( j \) = probability of encountering adopters, as fraction \( A/n \) (dimensionless).

Variables are classified as stocks, flows, auxiliaries (intermediaries), and parameters (Table 1). By definition, the functional form of a stock is an integral of the net inflow. In addition, each stock is assigned an initial condition.

Auxiliaries, such as “encounters made by potential adopters” and “probability of encountering adopters” in Figure 4 and Table 1, are intermediate variables used for representing a part of the problem that corresponds to particular mathematical operations. By breaking down larger equations into smaller ones, auxiliaries enable the model logic to be more transparent and intuitive to the model user.

Because it involves transforming a conceptual model into clearly defined structures and decision rules in a computer simulation model, step 3 may expose gaps in problem articulation (step 1) and resolve potential discrepancies in the logic of the causal map (step 2). Modifications may need to be made, as there may be limitations in estimating parameters and initial conditions, but the model purpose and model boundary should guide the construction of the simulation model.

Attention should be given to checking the consistency of units, referred to as dimensional analysis, when formulating the model. Unit checking is a standard option in system dynamics software. After the model equations are completely formulated and the model has been checked for unit consistency, the model is simulated.

Although modelers often justly derive much satisfaction in getting their models to run after investing effort into model design, it is critically important to budget sufficient time for the last two steps of the modeling process, namely testing and analysis. Step 4 involves model testing. In

this step, model boundaries are first tested by adjusting parameter values to extreme settings to determine where the model logic holds and where it breaks down. Then the simulation model may be calibrated by adjusting or “tuning” parameter values to match an objective function comparing the simulated results to empirical data, as in the case of time series. There are several tests that can be performed but the fundamental tests are comparison of simulated behavior to historical behavior (reference modes), robustness under extreme conditions, and sensitivity of uncertain parameters. These tests are conducted to assess model performance and utility, that is, to determine where the model performs well and where the model breaks down. Shock tests for model robustness involve setting extreme model parameter values, while sensitivity tests involve setting a range of model parameter values. In both robustness and sensitivity testing, of interest is observing how the simulated behavior over time responds to different parameter changes and its comparison to the reference mode. Model testing can indicate structural flaws in the model, such as errors that were introduced when formulating the model (step 3), or critical model components that are missing. Furthermore, in addition to evaluating model credibility, documentation of results from model testing improves the transparency of the model.

The graph in Figure 5 illustrates a sensitivity test indicating outcomes for the stock of adopters that occur when changing the parameter setting for contact rate. Confidence intervals for the range of outcomes are shown with the color legend. Increasing contact rate to the maximum value hastens market saturation to about 20 days, but slowing it to the minimum value slows the pace beyond the 120-day horizon of the graph.

Model calibration is appropriate if a model is expected to provide a forecast (as opposed to used for exploratory or pedagogical purposes). The base case under default model settings is illustrated in Figure 5 with a single blue line saturating soon after 30 days. This behavior is faster than the reference mode depicted in Figure 1. Therefore, a step toward calibration in this case would be to lower the average contact rate until the base case slows enough to match the reference mode.

Once confidence in the model has been established through the process of exploring model behavior, the model can become useful as tool for decision support and policymaking. In step 5, policies and scenarios are designed and analyzed. In this stage of the modeling process, the model is used to explore how system behavior responds to alternative policies and scenarios. Here, policies refer to system-wide interventions, whereas scenarios refer to particular plausible cases of interest (e.g., hoped and feared market behavior in response to a new technology). Because the modeling process is iterative, scenario development can be undertaken at the beginning of the modeling process, along with problem definition. Scenario analysis, however, involves the use of a reasonable model to explore implications of policy shifts.
Scenario analysis is performed to recommend policy shifts that would induce desired outcomes. Sensitivity testing on a wide range of scenarios should be performed because interactions of different policies may produce unanticipated interferences or synergies. High-leverage policies are often system interventions that can change dominant feedback loops and delays. An important objective at this final stage of a modeling effort is to design proactive rather than reactive policies, which can alter system structure to address the root of the problem.

Advanced system dynamics analysis involves identification of which feedback mechanisms dominate behavior at different points in time. In the example of technology diffusion, reinforcing feedback of market growth precedes the dominance of balancing feedback from market saturation. Feedback loop dominance can have a profound impact on the equilibrium or end state of the system, especially in two interesting ways, through tipping points and path dependence. Shifts in dominance of reinforcing feedback loops to balancing feedback loops (or vice versa) create tipping points, also known as bifurcation points. Path dependence is present when small changes or random system shocks early in the process significantly impact the equilibrium or end system states. Path dependence tends to arise when there are dominant reinforcing feedback loops in the system.

Outlook and extensibility

System dynamics is one of several methods of computational modeling employed in systems science (others include GIScience, ABM and social network analysis) and, as such, may be fruitfully applied to the study of complex systems. Simulation models provide a way to conduct experiments in a virtual world that may be unethical, harmful, or too resource intensive to conduct in the real world.

Since models are necessarily simplifications of real-world systems, all aspects of the system may not be captured in models. The utility of models is in the identification of the core elements and processes of the system associated with the problem of interest. The difficulty of addressing problems in complex systems is, in part, due to the distance in space and time between the causes and outcome. An advantage of computer simulation models is the compression of space and time.

Whether tangible (e.g., water level in a reservoir) or intangible (e.g., trust in a relationship), stocks reflect aggregate or average attributes at a specific scale. Although the contents of each stock are assumed to be homogeneous and randomly mixed, stock and flow structures are often replicated to represent distinct population subgroups. Such subgroups can be used to reflect spatial distribution of population by neighborhood or region.

Stocks can be considered as compartments or containers with an implicit spatial dimension and scale. Therefore, stock–flow system dynamics may be spatially extended to represent quantities like population that vary with place. The stock–flow structures of system dynamics may be extended using interlinked cellular automata to enable raster-compatible simulation (BenDor and Metcalf 2006). These structures may also be embedded in individual agents, or may characterize the environment in which agents interact. Standard agent-based modeling software (RePast, NetLogo, AnyLogic) now includes the capacity for representing stocks, flows, and information feedback. BenDor and Kaza (2012) explore the potential for characterizing spatially explicit reference modes for use in models involving spatial system dynamics.
Because the path dependence of complex systems is attributable to their sensitive dependence on initial conditions, an argument can be made for the importance of characterizing environmental context when simulating such systems. In a system dynamics model, geospatial context would affect the initial level of the stocks, even if the hypothesized feedback mechanisms were considered universal.

Description and purpose

The GSC-Taipei serves to publish the Zhong guo di li xue hui hui kan (Bulletin of the Geographical Society of China); organize local conferences, coordinates research and teaching, and special lectures; organize local and international excursions; and organize international conferences. In addition, the GSC-Taipei provides logistical support for our members who undertake research and educational endeavors.

Journals or major publication series

Zhong guo di li xue hui hui kan (Bulletin of the Geographical Society of China)

Current activities or projects

IGU conferences that have been organized by GSC-Taipei include Transnational Lives: Feminist Perspectives on Citizenship, Home and Belonging in 2007, Island Development in 2013, and Geomorphology & Society in 2014.

In 2014, the society supported projects such as a training program of environmental education for Yehliu Geopark (from the Ministry of Transportation and Communications) and the Geography Olympiad for Senior High School Students in Taiwan (from the Ministry of Education.)

Brief history

GSC-Taipei was founded in 1934 in Nanjing and reestablished in 1951 in Taipei 2 years after the civil war in China. It was formally registered with the Ministry of Interior, Republic of China in Taiwan, in 1977, with the goal of developing geography as a scientific discipline.

Technology and development

James T. Murphy
Clark University, USA

In the public’s perception, technology and development are commonly viewed as being in lock-step with one another, with development driven by technology and technology serving as a key indicator of development. In reality this somewhat tautological relationship belies the fact that technological change is often highly problematic with respect to its socioeconomic and environmental implications as it may exacerbate inequality, uneven development, ecological degradation, and/or social exclusion. A critical understanding of the drivers, dynamics, implications, and geographically uneven distributions of technology and technological change is thus an important component of development studies and practice, and an area in which geographers contribute critical insights.

While there are many definitions of what technology is, it is perhaps best understood as an expansive and multifaceted phenomenon as Metcalfe (2010, 154) notes:

By technology, we can mean a body of understanding of cause and effect in human minds, as with the codified realizations of productive knowledge in operating manuals, blueprints, recipes, scientific papers and so on; the capacities and skills that permit action, whether individually or in cooperation with others, not all of which is written down; and the purposefully organized and designed built structures within which action takes place – the realized, human built world.

Viewed in this manner, technology is much more than simply artifacts, computer algorithms, and/or built systems or facilities, it is cognitively and often tacitly constructed and embedded deeply in social, cultural, economic, and political systems. Moreover, technology is an inherently geographical phenomenon in that it emerges out of particular contexts, is often diffused spatially, can be scaled up or down (e.g., from the local to the global), and has uneven geographies of use, significance, and impact.

With respect to development, technology is viewed by most as an essential driver and determinant of socioeconomic, cultural, environmental, and political change. Economically, technology can increase productivity through improvements to the efficiency of production, exchange, logistics, and service-provisioning activities while speeding up innovation-development and knowledge creation processes. Alternatively, technology can exacerbate socioeconomic (e.g., class) differences, create uneven development within and between countries, and/or further the exploitation of labor through more intensive, real-time monitoring of workplaces. Culturally, technology has a profound effect on the norms, conventions, identities, and traits that help to constitute particular social groups, often destabilizing these and creating generational divisions. Environmentally, technology can contribute in significant ways to greener and more sustainable societies or exacerbate ecological degradation through intensified or expanded impacts locally and globally. Politically, technology can have democratizing effects (e.g., see the so-called Facebook revolutions in the Middle East) or it can facilitate enhanced forms of repression or surveillance by
TECHNOLOGY AND DEVELOPMENT

state authorities. All told, the impacts of technological change on development are complex, contingent, sometimes unpredictable, and often highly uneven geographically. Technology can thus serve as a valuable lens through which one can examine the context-specific and multi-scalar drivers of, and obstacles to, more even, sustainable, and just forms of development.

Neoclassical views on technology and its role in/for development

The most prevalent perspective on technology is that it is principally an economic phenomenon; one that is a key driver of economic growth created in response to scarcity or in pursuit of profit. Neoclassical (orthodox) economists generally view technological change as manifest in productivity improvements – in the form of labor savings, increased output, decreased costs, and/or scale economies that enhance the efficiency of production. Early frameworks (Solow 1957) viewed technology as an external factor (or residual to) in econometric models, but one that plays a crucial role in shifting national production functions such that higher levels of output (i.e., GDP) are possible. With Romer’s (1990) work this perspective shifted somewhat as technological change (understood in part as human capital) was conceptualized as being endogenous to the economy, determined in large part by investments in education, research, and innovation. As knowledge – a nonrival good manifest in increasing levels of human capital – becomes more widespread, it creates positive externalities able to sustain long-run growth (development) through measureable productivity improvements driven by market forces and profit-maximizing entrepreneurs and firms.

Although countries that are early innovators or leading technological centers have an initial advantage with respect to their development, the neoclassical perspective holds that there will be, over time, a “natural” convergence between lower-tech and higher-tech places provided the former increase their rate of capital (human, physical) investment such that productivity rises at a higher rate than that of so-called mature economies. Increasing productivity will enhance growth, increase national output, and reduce poverty as all boats are lifted through the surpluses generated. Particularly important for this developmental process are productivity improvements in agriculture which can free up labor for work in manufacturing sectors able to add more value, accelerate the pace of technological change, and create the kinds of localization and urbanization economies that enhance a country’s comparative advantage in global trade. In sum, the neoclassical view of the technology-development nexus conforms to Rostow’s modernist perspective of a singular/linear trajectory; one that reflects the evolution of advanced industrial economies during the nineteenth and twentieth centuries.

Contextualizing technological change: institutional, systemic, and constructivist perspectives

In the neoclassical view, technology is essentialized in four significant and problematic ways. First, technologies, manifest as productivity improvements and are seen as being inevitably positive/progressive given that they drive economic growth (i.e., development). Second, technologies are developed by utility or profit-maximizing agents who make rational decisions about how to resolve socioeconomic challenges with only the most productive solutions surviving in the context of market-based competition. Third, technologies are principally
artifacts, skills, algorithms, and so forth that quantifiably increase productivity and/or the scale/scope of economic production; thus meaning that they are best understood as tangible/codified “things” that can be diffused or spread from one context to another with the same effect or outcome. Fourth, the economic impacts (i.e., productivity contributions) that a technology makes are generally assumed to be the same everywhere, thus making the neoclassical view by and large ageographical.

Such perspectives on technology have been challenged effectively by social scientists who view them as acontextual, oversimplified, abstract, and/or narrowly focused on codified (patented, westernized) scientific discoveries and discontinuous shifts in production functions, rather than more incremental or tacit changes that are often not manifest in tangible or material innovations (Rosenberg 1976). The push-back against neoclassical understandings of technology and its role in development emerged in response to the many failures – environmental, social, public health, and economic – that accompanied modernization and rapid technological change/diffusion in the post-World War II period (e.g., thalidomide and DDT poisoning). Rather than deterministically assuming that modern technology must create development, new questions emerged regarding who technologies were for, how/why they are made/developed, and what their constitution and impacts can tell us about societies and economies more generally. Such inquiries began as explorations by heterodox economists into the evolution of technologies and innovation-development systems, eventually leading to the emergence of the field of science and technology studies.

For heterodox economists, the direction, pace, scale, and impacts of technological change are shaped fundamentally by the institutional and geographical environments where innovations are developed; the paradigm, cognitive frame, or “gaze” that technologists deploy in developing their ideas; and forces and factors in the wider societal context (Dosi 1982). Context-sensitive perspectives such as these provide a helpful foil to technologically deterministic frameworks as they shift the focus from artifacts to institutions, culture, built and natural environments, political economies, and sociotechnical systems wherein technologies are developed, innovation diffusion occurs, and/or path dependencies or development trajectories evolve. Particular emphasis is placed on the governance of national and regional systems of innovation, networks, and institutions within and through which new technologies and industries are developed (Freeman 1995). The development of such systems is shaped by multiscalar and context-specific relationships and struggles between state agencies, policymakers, firms, civil society actors, universities, and innovators who seek to reproduce or transform national or regional economies through technological change. In-depth analyses of these networks, institutions, and governance processes can provide key insights regarding the challenges of overcoming path dependencies and so-called lock-ins that make alternative development trajectories difficult to achieve.

Heterodox perspectives on the evolution of regional economies helped to spawn the emergence of the field of sociotechnical transitions research with its particular emphasis on the prospects for more environmentally and socially sustainable forms of development (Truffer and Coenen 2012). This work assesses the prospects for, and potential drivers of, technology-driven and systemic shifts (transitions) away from business-as-usual development pathways; trajectories that generate excessive waste, pollution, and other environmental and social externalities (e.g., climate change, inequality, poverty).
Transition researchers examine the regimes and innovation systems associated with key service-provisioning sectors – such as energy, water, housing, sanitation, food, and transportation – in order to determine if and how greener technologies might destabilize and redirect them toward more sustainable outcomes. Importantly, this work contextualizes regimes and technological innovation systems in the wider context of countries, regional authorities, societies, and the global economy in order to more fully understand the obstacles to, and potential drivers of, sustainable development (Geels and Schot 2007).

A key question for transition scholars is how to coordinate and manage the diverse actors, infrastructures, institutions, and markets governing a sociotechnical regime such that business-as-usual technologies are replaced by greener alternatives that might enable a transition toward long-run sustainability. Work in this regard has examined increasingly transitions processes in the Global South in order to determine, in particular, if developing regions can establish alternative sociotechnical systems such as those that are not dependent on carbon-based fuels.

Beyond innovation systems and sociotechnical transitions research, others have contextualized technologies by critically examining the ways in which they are developed and embedded in particular social, cultural, political, and historical contexts that shape significantly the direction and substance of their contributions to development. Considered in this manner, technologies are seen as social constructions developed, promoted, supported, and/or diffused by states, firms, and societal groups to achieve or reproduce desired power relations, profits, and/or socioeconomic conditions. Through analyses of these dynamics, constructivist perspectives strive to overcome technologically deterministic views in order to understand the coevolution of technological change and socioeconomic development at a variety of scales – from individual artifacts to sociotechnical systems and cultures (Bijker 2010). Research in the constructivist tradition typically focuses on one or more of the following analyses: (i) deconstruction of the technology itself in order to understand different interpretations of its use; (ii) an assessment of how the technology was constructed in the first place; and/or (iii) an examination into the role that particular social groups played in framing and constructing the technology.

Constructivist studies reveal critical insights regarding the contingent origins of technologies, their persistent use despite better alternatives, the unexpected ways in which they are absorbed into contexts that differ from where they originated, and their contribution to path dependencies with respect to industrial, regional, and community development. For example, although ultrasound imaging technologies have proven to be highly significant tools for prenatal medical care, their diffusion into some societies (e.g., India) has led to higher incidences of sex selection given that male children are more valued in patriarchal settings. Other examples include the persistence of the QWERTY keyboard in a post-typewriter world, despite its inefficiencies, and the ways in which energy, production, and transportation systems worldwide are generally locked in to carbon-based fuels despite our knowledge of the climate-change crisis and the other negative social and environmental externalities associated with fossil fuel extraction, processing, and consumption. Through in-depth, qualitative analyses of such lock-ins and path dependencies, constructivist perspectives demonstrate the challenges of overcoming dominant technological paradigms through the diffusion and deployment of improved technologies, particularly in contexts that differ in significant ways from those where they were developed. Such insights are crucial in order to move beyond deterministic
views of technology’s role in development and to design more appropriate (i.e., context-specific, distributive) technologies to meet the needs of the poor and disempowered.

**Radical and alternative perspectives on technology’s role in/for development**

Beyond contextualized and constructivist analyses of the technology-development nexus there is a significant body of work that takes a much more critical view, particularly of technology in its mainstream or dominant forms. Radical (Marxist), feminist, and postcolonial/postdevelopment scholars have made important contributions in this regard, reminding us of technology’s tendency to (re)produce repressive, unequal, and/or exploitative socioeconomic systems. Moreover, such scholarship highlights the ways in which technologies and knowledges situated/produced outside the westernized, capitalist context are marginalized by mainstream development institutions and states. In response to such failures some have called for alternative technology development and diffusion systems, ones that value indigenous knowledge, welfare distribution, the environment, and community wellbeing above growth, profit, and individual measures of productivity.

For Marxists, the technologies produced and diffused in the context of capitalism are fundamentally the outcome of the class struggles associated with control over the means of production (Smith 2010). As capital increased its power historically, its need to extract surplus value from labor has resulted in technological changes that tend either to substitute machinery for workers or to deskill them such that wages can be compressed. The net result is that technology helps to disempower the working classes and enhance the ability of capitalists to reap profits through the exploitation of living and so-called dead labor (i.e., that which is embodied in the machinery used in industries). Absent a class revolution whereby workers take control over the means of production, and the scientific/technological apparatus, capitalist-driven technological change will reproduce and exacerbate inequality, deprivation, and exploitation despite the improvements that seem to accompany modern innovations.

Rather than focusing on class, feminist analyses reveal the sociocultural embeddedness of technologies and their subsequent bias or tendency to reproduce patriarchal systems that essentialize or marginalize women’s roles in society. For Merchant (1980), such biases and inequalities accelerated during the Enlightenment as a new value system emerged in the West, one that sought to order society and nature as if they were machines which could be technologically engineered in rational, predictable, and productive ways. Women’s role in the societal machinery was reduced to that of social reproduction (e.g., child rearing, household labor) with the powers-that-be in society valuing technologies that sustained this status quo by restricting women’s personal freedom, access to technology, and mobility in all its forms. Feminist scholars further demonstrate that technologies – artifacts, the built environment, and knowledge in all its forms – should be understood as phenomena inscribed with valences or biases that reflect societal values regarding gender roles and relations, among others (e.g., class relations) (Wajcman 2010). Consideration of such biases or tendencies, and their embedded nature in particular contexts, is essential in order to understand the implications of technology development and diffusion for women’s empowerment and wellbeing. Rather than viewing technology as being inevitably problematic with respect to such concerns, some (e.g., Haraway 1991)
view today’s hyper-technological/information age as one laden with political, economic, and social possibilities for women, manifest in new identities and opportunities that can destabilize essentialized notions of gender roles and create political space for difference and diversity.

A third major critique of mainstream views on technology-for-development is concerned with the ways in which the Western scientific and technological project marginalizes subjects and knowledges existing/produced in the Global South. These critiques began with concerns over the loss of indigenous forms of knowledge (IK) that evolved in situ, but which were devalued or delegitimized by Western science and its prioritization of universal, globalized, and rationally engineered technologies (Agrawal 1995). More recent work has been inspired by postcolonial and actor-network theory (ANT) which seeks to disrupt the “purity” of Western science and technology through studies that demonstrate its messy, contingent, and often highly subjective nature, while highlighting the value of IK and alternative forms of knowledge as means to create more emancipatory, distributive, and collective technologies in/for development. A key concern of these scholars has been attempts by mainstream development institutions to co-opt, codify, and decontextualize these technologies in ways that make them more compatible with Western science and development practices (Briggs and Sharp 2004). For example, some have raised concerns over initiatives such as the World Bank’s “Knowledge Bank” (https://openknowledge.worldbank.org), a database that strives to collect, codify, and centralize information about successful livelihood, production, and development practices such that they are available globally. Critics charge that initiatives such as these can either distort the often tacit and localized knowledge associated with such practices such that it adheres to the ideology and priorities of mainstream development institutions (e.g., growth, individual productivity, market-led development), or exclude altogether practices associated with radical or alternative perspectives on development.

Beyond offering critiques of mainstream and capitalist-oriented views of the technology-development nexus, radical, feminist, and postcolonial perspectives have inspired initiatives to protect IK and support appropriate technologies to empower the poor and disadvantaged. In general terms, appropriate technologies are those designed to meet the direct/subsistence needs of people and their communities better, rather than foster economic growth and individuated forms of productivity. Inspired initially by E.F. Schumacher’s (1973) book Small is Beautiful, appropriate technologies privilege public/social utility, human values, justice, accessibility, and context specificity over scale, universality, and market driven forms of diffusion. As such, they are often associated with social movements and grassroots organizations which seek to delink the wellbeing of communities and their environments from the technologies and forces of global (corporatized) capitalism such that livelihoods can become more autonomous and resilient. Developing appropriate technologies demands a finer grained geographical understanding of the wider social, cultural, and political contexts wherein livelihoods are practiced, one that puts the priorities, capabilities, and wellbeing of communities first (e.g., see Via Campesina’s notion of a peasant agroecology at http://viacampesina.org/en/). Some have called for the development of a postcolonial technoscience as a means to more systematically develop technological alternatives to facilitate more just, distributive, and progressive forms of socioeconomic development in the Global South and beyond (Anderson 2002).
Development through technology diffusion: from modernization to translation

For geographers and others, a traditional concern with respect to the technology-development nexus has been the processes through which technologies diffuse across space and over time. This is a fundamentally geographical question, one that spawned the “diffusion of innovations” literature starting the 1950s. Early diffusion theorists – E.M. Rogers (1962) and Torsten Hägerstrand (1967) – emphasized the cultural and behavioral drivers of technology diffusion, arguing that the geographical spread of modern innovations depends upon whether individuals in peripheral places are able to embrace change and shift away from traditional practices and understandings of their place in the world. Viewed from this perspective, the (technological) diffusion of modernization is dependent upon changes in individual behavior that can, over time, aggregate into community and regional-scale transformations. In spatial terms, à la Hägerstrand (1967), information and social communication are crucial and it is essential for practitioners (e.g., agriculture extension officers) to establish centers or hearths from which an innovation can spread. For Rogers (1962), technology driven development objectives can be achieved through a process of getting local opinion leaders and others to adopt and effectively use new technologies such that other community members follow suit and eventually replace the “old” ways (e.g., peasant farming) with modern, productive, and efficient techniques.

As Figure 1 demonstrates, the early diffusion literature (especially Rogers 1962) presumed that there is a “normal” diffusion pattern or distribution of behavioral types in any given setting, one that determines the pace and scale of a technology’s spread. The goal for development practitioners is to find ways to increase adoption levels (i.e., to provide sufficient information or communication in order to change behaviors) such that a majority of the population uses the technology consistently and effectively. Once an (early) majority is reached, the diffusion process can proceed in a more “natural” fashion as late adopters and so-called laggards eventually take up the innovation. Considered in this manner, technology diffusion – as a means for development – depends to a large extent on spatial and

---

social proximity, spurred on when neighbors or individuals of similar standing copy one another's behavior. Such forms of proximity thus serve as central explanatory factors with respect to the diffusion of innovations across space and over time.

Diffusion studies were further enhanced by Brown (1981) who extended early frameworks in order to better account for the context wherein adoption occurs. Rather than focusing solely on the demand-side of technology adoption (i.e., individual behaviors), Brown's framework considers supply side factors such as markets, institutions, and infrastructure in determining one's access to new innovations. Moreover, his work sought to explicitly address the implications of innovation diffusion for development and to assess the impacts that levels of development have on the diffusion process. This work highlighted and conceptualized both the contingent nature of the technology-development nexus and the context-specific factors that create sometimes highly uneven patterns of technology uptake, particularly in the Global South.

In many respects, the behavioral perspective in diffusion studies remains pervasive in mainstream development studies despite numerous critiques of the technological determinism and binary categorizations (e.g., traditional versus modern) built into Rogers's framework. More critical, poststructurally inspired, studies of technology diffusion emerged along with the radical and alternative perspectives discussed above. In addition to explaining why certain social and cultural groups (e.g., poor people, women, etc.) “fail” to adopt modern innovations despite their efficiencies and utilities, this work provided in-depth, contextualized, and ethnographic research into technology adoption and absorption processes. Particularly important is work inspired by ANT which, among other things, examines critically the ways in which technologies move across space and how they are integrated into distanced social, political, and economic systems such that they contribute to new or existing forms of order (Law 1992). Considered in this manner, diffusion occurs through a process of “translation” whereby the technology is “assembled” with other aspects of the social and material worlds actors inhabit such that it helps to generate positive or negative development outcomes. Importantly, the ANT perspective, while bestowing a degree of autonomy and agency on technologies themselves, is keen to understand and describe the power relations that enable translation to occur, and the effects these have on material and social outcomes.

For example, de Laet and Mol's (2000) careful, ANT inspired, analysis of the diffusion of the Zimbabwe bush pump in Africa reveals the technology’s origins and fluid meanings as it is “translated” across space and over time. Through a detailed ethnography of this seemingly “modest” technology, they demonstrate its adaptability and flexibility with respect to the contexts where it is distributed. Such fluidity, as they term it, means that the pump can be translated or “enrolled” into a diversity of cultures, communities, and sociotechnical systems throughout Africa and thus help to generate effects such as cleaner drinking water, fewer water-borne illnesses and disease, and the social capital that comes with the collective endeavor of installing and maintaining the pump (see Figure 2). As such, they demonstrate how the effective and widespread diffusion of so-called appropriate technologies depends on their “firmness” or mutability with respect to geographical context, the latter of which is preferable as it makes technological absorption more likely.

To conclude, the technology–development nexus is by no means a unidirectional or predictable relationship given the myriad factors and contingencies that shape innovation and
diffusion processes. For human geographers this is thus an important area of inquiry given its unevenness, the multiscalar nature of technology development processes, and the crucial role that spatial relationships play in shaping diffusion dynamics. The ability to move beyond neoclassical and modernist abstractions regarding what technologies are, and how they contribute to development, has been made possible through geographically sensitive and critical inquiries into the nature of technologies themselves, the drivers of their development and diffusion, and the context-specific factors that determine their accessibility, utility, and appropriateness.

Technology spillover

Yifei Sun
*California State University, Northridge, USA*

Peilei Fan
*Michigan State University, USA*

Technology spillover refers to the unintentional technological benefits gained by firms due to the actions of other firms. Though spillover can happen among firms that belong to the same industry, geographers are most concerned with spillover that occurs among firms co-located in the same geographical space. As such, technology spillover is a phenomena associated with agglomeration. Most research has focused on spillover of foreign direct investment (FDI) on domestic firms in emerging economies. It is hoped that FDI can strengthen the technological capabilities and innovation of domestic firms in developing countries so that such sustainable development can be achieved in the long term. Domestic firms in developing countries can benefit from FDI through competition, demonstration, supplier–client networking, and labor mobility. First, domestic firms can imitate foreign products in order to reduce market uncertainties. Domestic firms can also learn the management practices and marketing strategies of the foreign competitors. Second, the spillover effect can also be fulfilled through labor turnovers from foreign firms to local firms. When workers are relocated to local firms, they can apply the management experiences and skills that they learned from foreign firms. However, there could also be negative impacts; domestic firms may lose highly skilled labor because foreign firms in general offer higher salaries and better working conditions than domestic firms and so attract local talent. Third, domestic firms can benefit from FDI spillover through backward linkages (contracts between foreign affiliates and domestic suppliers) or forward linkages (interactions between foreign suppliers of intermediate input and domestic suppliers) with foreign firms. Domestic firms can learn from foreign customers on product development, quality control, and technological improvement. Domestic firms can also improve their product quality by using intermediate products from foreign companies. Finally, foreign firms also stimulate competition in the domestic market. Fierce competition can urge domestic firms to use more advanced technologies or new technologies and
resources in order to survive the competition, which may also lower the demand for local products or even force domestic firms out of the local market.

Absorptive capabilities, the technological gap, and technology spillovers

Empirical results on spillovers have shown conflicting results, from positive impact to no impact and negative impact. The most consistent results concern the moderating effects of a firm’s absorptive capabilities (Cohen and Levinthal 1990, 128), which refers to “a firm’s ability to recognize the value of new, external information, assimilate it, and apply it to commercial ends.” Absorptive capability is more than just effort and investment in research and development (R&D) but more importantly includes a firm’s combinative capability, which is a function of the firm’s level of prior related knowledge. Absorptive capability is more than just the sum of individual skill or knowledge levels, and can be acquired, retained, and updated through an accumulative process.

Most recent research on spillovers along this line has further examined the technological gap between foreign firms and domestic firms. It is argued that there may exist a nonlinear relationship between the technological gap and spillover effects. Spillover reaches a peak when the technological gap is of medium size: if the technological gap is either too big or too small, the potential spillover will be lower. When the technological gap is too big, the technology becomes too advanced for the local firms to learn. When the technological gap is too small, local firms become less interested/motivated to make efforts to learn from foreign firms.

Technology spillover: a social process

Technology spillover is a social process that involves multiple actors situated in a particular social context. Research has demonstrated that organizational and cultural proximity between the sending and receiving firms are important in understanding the process of technology spillovers. Technology spillover relies on a shared “interpretation system,” “shared systems of meaning,” and shared “organizational focus,” since people “interpret, understand and evaluate the world differently” (Nooteboom et al. 2007), and such dimensions are summarized as “cognitive proximity,” which denotes “a broad range of mental activity, including proprioception, perception, sense making, categorization, inference, value judgments, emotions, and feelings.” However, the relationship between cognitive proximity and technology spillovers is not necessarily linear, and it is argued that the relationship between absorptive capability and cognitive distance may follow an inverted U shape; however, such research is only preliminary and more solid work is needed to clarify the issues here.

Geographical context and technology spillover

Traditional research on spillover has been spaceless and assumes that spillover occurs among firms that are located in the same industry within a country. Knowledge spillover tends to be geographically bounded within regions where the new economic knowledge was created (Feldman and Audretsch, 1999). Geographical proximity enhances the interactions between local and foreign firms and the spillovers should be affected as well. Demonstration or imitation effects are more likely to occur when foreign
and domestic firms are co-located. It is easier for local firms to learn advanced technologies or collect market information from their neighbors. Similarly, frequent labor turnover between foreign and domestic firms is more likely to occur when they are located in proximity to one another. Geographical concentration can also enhance interfirm linkages. Domestic firms are more likely to become the suppliers or customers of foreign firms. Similarly, firms are likely to experience competition from local competitors, foreign or domestic. Recent research has examined FDI spillover at different geographical scales: from the national to regional and local scales (Sun and Du 2010; Zhang et al. 2010). It is interesting to note that studies at different geographical scales reveal great differences in their findings, even studies that are situated in the same country.

Conclusions

Technology spillover is a social process of learning. It does not occur automatically and does require intentional and sustained efforts made by the receiving firms. As such, it requires firms to invest in internal capabilities that enable them to identify the opportunities and internalize the technologies that are in their geographic and relational space. Research on spillovers should expand from the firm-centered perspective to the social perspective that incorporates the geographical context in which the learning takes place. Such research has the potential to further our understanding of spillovers from foreign firms to domestic firms. Finally, the current research that focuses on spillovers of foreign firms from advanced economies to firms in developing countries should be expanded. With more and more firms going global, it is necessary to examine how foreign and domestic firms can learn from each other.

References

From *tekhnē* (meaning craft, or art) and *logos* (the application of reason), technology might suggest the “art of reason.” But it has just as often tended to mean quite the reverse, referring instead to the rational principles that govern the construction of artefacts, “the reason of art rather than the art of reason” (Ingold 2000, 294). In some senses, this reversal in meaning captures the ambivalence of technology. For many, technology signifies hope, freedom from drudgery, and the chance for a better life. But the application of technological reason to human dealings with themselves and with the planet can also lead to dehumanized and environmentally damaging results. Hydroelectric dams, IT networks, genetic modification – indeed anything we choose to call technology – can suggest tragic outcomes as well as hope for a better future.

Part of the problem is that technology, as the downstream “application” of reason or science to real-world issues, can imply a particular and rather reductive understanding of the world. It can tend to treat the Earth as a vast machine, and “through a rational scientific understanding of its principles and functioning, this machine [can] be harnessed to serve human interests and purposes” (Ingold 2000, 294–295). While this machine metaphor seems to suggest a human mastery over nature and continued human progress, the lessons from the last century have been that the world rarely behaves in this fashion, and the social and ecological costs of technologies are as common as its benefits.

An inspiration for this kind of critique of technology comes from the twentieth-century German philosopher Martin Heidegger. While Heidegger saw technology as ambiguous, he nevertheless wrote of the tendency for technical rationality to produce an impoverished understanding of the world and an instrumental treatment of both humans and nonhumans. For Heidegger, technical rationality can degrade the Earth and humanity, producing a “tear in being” and “enframing” living beings and other components of an environment as mere resources or what he called standing reserve (Heidegger 1978). He was writing in part in opposition to Bolshevist and other ideological investments in technological modernity. His warnings were meant to disrupt any blind faith in technological solutions to problems of scarcity, hunger, and labor. For Heidegger, technology was descent as much as ascent, and we need to remember this ambiguity lest we fall into the trap of technological optimism.

More starkly, perhaps, for recent interpreters of Heidegger, technology seems inevitably to divide Being from beings (or entities), and sets up a distinction between the proper and the improper, the hand-written and the typed, “man” and human. This distinction involves an ordering of both human and nonhuman lives that makes it easier to take or disqualify those lives (so technology makes everyone and everything look the same, and in so doing we enter a world of expendable, dehumanized beings). In biopolitical renderings (see Biopolitics), technology is something that makes some human and nonhuman lives of lesser value and able to
be sacrificed for some supposedly greater good. It is a dark side to technology that can help us to think through the atrocities and tragedies of the disastrous twentieth century. The holocaust, ethnic cleansings, mass animal slaughter, and environmental disasters all characterize this most technological of centuries.

These dehumanizing effects of technologies remain key debates in geography. As the question of technology is posed less in terms of a debate between Bolshevism and National Socialism, and more so in terms of neoliberalism (see also Neoliberalism and the environment), globalization, and disaster capitalism, there has been a return to an interest in the essences of technology, and a thanatopolitical (or towards death) reading of technology and biopolitics. At the same time, though, more affirmative treatments exist, in some ways reinvoking the notion of technological progress as, for example, the widespread adoption of social media and Internet technology provide the conditions of possibility for new kinds of politics (Hardt and Negri 2005). The former offers warnings concerning technical rationality (for instance, in relation to geoengineering) while the latter looks for the political openings that a change in technological consciousness may present.

The problem with some of these accounts is that the future already seems mapped out, for better or for worse. Some would regard this as technological determinism, or the ascription of essential qualities to a technology that then dictates how it will be used. Such a view denies geographical variation and seems to foreclose political action. In contrast, more empirically grounded work, which attends to the role of technologies in generating or transforming political situations in ways that are not preset or determined in advance, seems to offer an alternative. Indeed, it may be that the more recent attempts in geography and cognate social sciences to bring together the lively materialisms associated with feminist inspired science and technology studies, such as those of Donna Haraway (Haraway 1985), start to open up a technopolitics that is both situated and attenant to the dynamics of socially embedded technologies (see also Feminist geography). This more empirically focused work tends to return “technology” to an art of reasoning and involves attending to the broad sweep of activities involved in generating knowledge (which is already in this sense technological), and is part and parcel of acting in the world. Technology, here, becomes hopeful once again, though certainly not in an idealistic or utopic sense. Aiding from ethnographic studies concerned with the practical “doing” or “enacting” of science and technology, we start to see the art of reasoning as an embodied, distributed, and often fraught process. Technologies can, in this sense, open up debate and politics, and can form the issues over which technological publics come into being.

Studies of science and technology in practice foreground the interrelations and intra-actions between people, tools, machines, and other nonhumans, showing how their assembly, or configuration, has significant effects on outcomes (Barad 2007) (see also Actor-network theory). Underestimating the complexity of entanglements between people, electricity grids, financial investment, and climate can, for example, lead to catastrophic failures. Realizing the agency of all these and more can help to re-enchant and possibly improve such relations (Bennett 2001). Technology in this sense is no more than the quality of its relations. As a result, an intermaterial analysis or a more spatial, empirically focused geography of technology has taken shape with a concentration on the uncertainties and indeterminacies of technologies in complex and power-laden fields.
Technology as a process, one that of necessity requires listening to and acting with a whole range of both human and nonhuman others, is indeed an art. More significantly, its futures are not already determined as there is scope here for doing technology in ways that are more, as well as less, progressive. Rather than technological determinism (the sense that a particular technology always leads to particular outcomes), here the politics of technology, while always dangerous, monstrous, and liable to co-option, is nevertheless more open and to be worked out.

Tectonic geomorphology

Lewis Andrew Owen
University of Cincinnati, USA

Tectonic geomorphology is one of the youngest branches of geomorphology, clearly merging the study of geomorphology and the relative new geologic discipline of tectonics. Not only does tectonic geomorphology combine these two immense fields, but it also incorporates the study of geodesy, geophysics, geochemistry, geochronology, archaeology, and paleoclimatology. In essence, tectonic geomorphology examines the relationship between Earth’s internal (tectonic/endogenetic) and external (surface/exogenic) processes, their role in landscape development, and their implications for tectonic and geomorphic hazard mitigation. Owen (2013b) provides a perspective on the development of tectonic geomorphology as a discipline and emphasizes how this evolving area of study has provided a far deeper awareness of the importance of tectonics in helping to drive the study of landscape development and surface processes. In addition, tectonic geomorphology has helped force awareness of the strong relationships between endogenetic and exogenic processes, which have in turn led to many new geologic and geomorphic paradigms.

As Owen (2013b) points out, there is no formal definition for tectonic geomorphology, but it is broadly defined as the study of landforms produced by tectonic processes such as faulting, warping/tilting, folding, uplift or subsidence, and the application of geomorphology to the study of landscape evolution and tectonic problems. Some authorities include volcanic processes and landforms under the heading of tectonic geomorphology (Owen 2013a), while others do not (Burbank and Anderson 2012/2001). Tectonic geomorphology as a term did not become part of the geosciences lexicon until the 1980s and it was not until 1998 that it was used as a keyword for articles cited in ScienceDirect (Owen 2013b). Moreover, tectonic geomorphology was not mentioned, or only given fleeting consideration, in encyclopedias and textbooks until the middle of the first decade of the twenty-first century, when it became a more widely recognized area of study.

Tectonic geomorphology has been enhanced and boosted since the late 1990s with the development of new technologies including remote sensing, GIS science, geophysical exploration methods, enhanced microcomputing, and geochronology. A search for tectonic geomorphology in ScienceDirect today yields more than 13,000 articles and more than 80,000 results listed in a search of Google Scholar. The publication of Burbank and Anderson’s textbook, Tectonic Geomorphology in 2001 helped establish tectonic geomorphology’s place in the mainstream of geomorphology and tectonics. The Treatise on Geomorphology (Shroder 2013) published in 2013 dedicates one of its 14 volumes solely to tectonic geomorphology (Owen 2013a).

Although considered a young branch of geomorphology, the study of tectonic geomorphology (but not called that, of course) has been an integral part of landscape evolution studies for some time. Such concepts as the “Davisian cycle of erosion” and various models of “landscape evolution” have included the role of uplift and subsidence driven by endogenetic processes.
Aspects of tectonic geomorphology have also been included under the broader themes of neotectonics and active tectonics during the latter part of the twentieth century. Of particular note was Vita-Finzi’s (1986) book, *Recent Earth Movements*, which provided a modern overview of neotectonics and included many aspects of tectonic geomorphology, though not specifically referred to by name. Keller and Pinter’s (1996) book, *Active Tectonics*, also provided a wealth of information on tectonic geomorphology, including a chapter called “Landforms, Tectonic Geomorphology, and Quaternary Chronology,” with other chapters focusing on geomorphic indices, rivers, coastlines, and mountain building, all pertinent to tectonic geomorphology.

Quaternary science, particularly the study of rates and magnitude of climate change, underwent a mini-revolution during the latter part of the twentieth century which continues into this millennium. The realization that climate change throughout the Quaternary was very rapid and often of high magnitude, influenced thoughts and studies on the likely responses of surface processes to these changes and helped drive renewed interest in climatic geomorphology. As a consequence, researchers began to explore the connections among climate, tectonics, and landscape evolution. This helped strengthen interest in tectonic geomorphology and studies of landscape development, particularly the polygenetic origin of landscapes.

Today, tectonic geomorphologists have an impressive arsenal of tools at their disposal. Most tectonic geomorphic studies begin with a detailed analysis of landforms and the landscape, which usually requires the acquisition of topographic and/or other remote sensing data (Figure 1). Topographic data such as LiDAR can be digitally manipulated to enhance and reveal subtle topographic features. In recent years, the development of Google Earth has proved particularly useful, and in many cases has replaced more the more traditional analysis of landforms using stereoscopic aerial photography (Figure 2). Improved global positioning systems are also enabling very quick and accurate maps to be constructed, and comparisons to be made over time. In recent years, stereoscopic analysis of photographs can now be easily and quickly done on microcomputers, in particular enabling maps to be made quickly and accurately without the need for expensive surveying equipment.

Improvements and advances in Quaternary geochronology have been a particular boon for understanding the ages of landforms and the rates of processes underlying tectonic geomorphology; these include the use of radiocarbon-dating, terrestrial cosmogenic nuclides (TCN), optically stimulated luminescence dating, U-series geochronology, and various systems of thermochronology. The ability to accurately and precisely date tectonic landforms is critical to assessing rates and styles of deformation, and landscape evolution. In essence these methods are used to determine the timing of formation or deformation of landforms. Some of the methods can be used to quantify rates of denudation and the timing and duration of sediment burial, such as those using TCNs. Thermochronology allows exhumation histories to be determined for large-scale topography. In all cases, the power to unravel the tectonic geomorphic history of a study area comes from combining high-fidelity age control with high-resolution remotely sensed imagery and/or surveying/map-making. Only by combining these two datasets can the tectonic geomorphic history be fully understood.
Tectonic landforms are diverse and pervasive throughout the world but are most evident along active plate margins (Figure 1). In fact, it may be argued that all landscapes are essentially a consequence of tectonics because tectonic processes are partially responsible for the distribution of the bedrock that constitutes the ground on which landforms develop. However, tectonic landforms are generally considered to be those landforms that have formed in direct response to geologically young crustal movements. The definition of “geologically young” can vary given different perspectives and geologic/geographic locations. A good definition may be a landform/landscape that has formed over a timescale of about $10^{-3}–10^7$ years, the duration over which geomorphic processes are considered to operate.

Continental-scale (around $10^{3–4}$ km$^2$) tectonic landforms include mountain ranges, plateaus, volcanic island arcs, ocean trenches, basins, great escarpments, drainage systems, and linear valleys, among others. Such features can be readily observed from space and in the field (Figure 1). On a regional-scale ($10^{1–3}$ km$^2$), tectonic landforms include marine terraces, fault-bounded mountain fronts, transverse and longitudinal drainages, grabens and volcanic centers (Figure 2). Local-scale (around $10^{-3}–10^{-1}$ km$^2$) tectonic landforms include fault scarps, shutter ridges, sag ponds, landslides, sand
Figure 2  Regional-scale tectonic landforms. (a) LiDAR data (gray) overlain on an oblique Google Earth image of the part of the right lateral strike-slip Banning Fault near San Gorgonio Pass in Southern California. The Banning Fault is part of the San Andreas Fault system, and this image illustrates offset alluvial fans, impressive fault scarps, and fault valleys. This example illustrates some of the rapidly evolving geographic and geodetic technologies/tools that are enabling tectonic geomorphology to be more readily studied. (b) View south along the San Andreas Fault near Wrightwood in Southern California. The San Andreas Fault runs along an impressive valley at this location, with the Mojave Desert to the east and the San Gabriel Mountains to the west. The city of Palmdale can be seen in the Mojave Desert in the middle part of the view. The relative motion between the North American (to the east) and the Pacific Plate (to the west) is about 30 mm/year along this stretch of the San Andreas Fault. (c) View northwards into Death Valley. As the lowest point in North America, Death Valley is a pull-apart basin formed by normal and strike-slip faulting that bound its eastern margin.
blows, volcanoes, lava flows, and river terraces (Figures 2 and 3). The smallest-scale (around $10^{-1}$ m$^2$ and less) features include such phenomena as fissures, cracks, individual rock falls, displaced streams, small terraces (marine or river) and liquefaction structures (Figure 3). These tectonic landforms have been described in much detail with appropriate examples in Burbank and Anderson (2012/2001) and Owen (2013a).

Owen (2013a, 2013b) identified several main areas of emphasis within tectonic geomorphology. These are modified and summarized below.

**Landscape and tectonic evolution of active plate margins**

Tectonic geomorphic studies have been undertaken on nearly every, if not all, active plate margins. In particular, there has been much interest in quantifying geomorphic rates ($10^0$–$10^5$ years) of vertical and horizontal crustal displacement to help define tectonic models and for seismic hazard assessment. Much emphasis has been placed on comparing geomorphic with geologic ($10^2$–$10^6$ years) and geodetic ($10^{-1}$–$10^2$ years) rates of displacement, particularly along fault systems such as those along the Gulf of California–San Andreas transform plate boundary, for seismic hazard mitigation (Frankel and Owen 2013). Other areas of focus include the development of landscape evolution models, most notably for the Himalayan–Tibetan orogen and southern and southeastern Alaska (Koons, Zeitler, and Hallet 2013).

**Mountain building**

Tectonic geomorphic methods have been applied in numerous mountain belts to help understand their evolution and to help identify which areas are more tectonically active. In recent years, it has become increasingly apparent that young mountain belts are the product of localized interactions among tectonics, climate and erosion (Koons, Zeitler, and Hallet 2013). A major focus of interest is whether steady state can be achieved in mountain belts and whether tectonics and/or climate control the width and asymmetry of mountain belts. Tectonic geomorphic studies are adding much to this debate, as discussed in detail in Koons, Zeitler, and Hallet (2013). Moreover, it is becoming apparent that tectonic geomorphic evidence, for example, in the form of topography, terraces, and drainage systems may provide important insights into possible influences of crustal flow on the geomorphic and tectonic evolution of continental plateaus such as Tibet and the Colorado Plateau (Koons, Zeitler, and Hallet 2013).

**Development of fault and fold systems**

The development of fault and fold systems has attracted much attention on a variety of scales ($10^2$–$10^8$ m$^2$). The tectonic geomorphology of many continental-scale strike-slip faults has been studied in much detail, including those along the Pacific–North American plate boundary and those within the Himalayan–Tibetan orogen (Frankel and Owen 2013). Measuring and dating offset landforms has enabled rates of displacement to be quantified on geomorphic timescales. Particular emphasis has been placed on what geomorphology can reveal about fold development, especially for seismic hazard mitigation because of the growing recognition that large earthquakes occur within fold belts, often on blind thrusts. In addition, examining drainage development as well as the deformation of river terraces along traverse drainages has been particularly insightful.
for understanding the relationship between deformation and landscape development.

Evolution of passive margins, continental interiors, and plateau uplift

Tectonic geomorphic studies of passive margins, continental interiors and plateau uplift have provided important new insights into how continents evolve. Of particular note has been the study of continental-scale landforms, such as great escarpments and plateaus, along passive margins. Blenkinsop and Moore (2013) summarize the diversity of passive margins and discuss how they reflect variations amongst thermal, isostatic, flexural, buckling, and dynamic (mantle) sources of stress that affect margins.

Study of the evolution of continental interiors has focused much on the very long-term geomorphic evolution of shield areas, particularly examining how drainage systems develop. Examining plateau development has also benefited greatly from tectonic geomorphic studies. This has included studies that aim to define rates of plateau uplift, quantify paleoelevation, and document drainage development. Many mechanisms have been proposed for plateau uplift including denudational unloading, and uplift associated with hotspots and delamination; these are discussed in detail in Blenkinsop and Moore (2013). A further area of research related to plateau development concerns the feedback between plateau uplift and global climate change.

Volcanic landforms and processes

Volcanoes are among the most dynamic landforms on our planet, yet tectonic geomorphic studies on volcanoes are still very much in their infancy. Nevertheless, the tectonic geomorphology of volcanoes has provided important insights into our understanding of the evolution of volcanic islands and continental volcanic arcs along subduction zones. Moreover the development of volcanic centers over hotspots has provided valuable information for tectonic modeling. Studies often focus on volcanic hazards, particularly as there is a growing awareness of the potential for volcanoes to have local, regional and global catastrophic effects. Volcanic eruptions may trigger other catastrophic

This landslide was triggered during the October 8, 2005 Kashmir earthquake resulting in the burial of three villages and more than 700 fatalities. (h) View looking across the city of Orotava in Tenerife. This city is built within a giant landslide scar that formed on the slopes of the Rico de Teide, a volcano that rises to 3728 m above sea level. The submarine run-out from this landslide stretches for about 100 km beneath the sea and the volume of debris is about 1000 km³. The landslide age is younger than about 0.78 Ma and may even be younger than 0.2 Ma.
Figure 3
TECTONIC GEOMORPHOLOGY

tectonic-geomorphic hazards including landsliding and tsunami. As such, real-time monitoring by such research group/organizations such as US Cascade Volcano Observatory is becoming increasingly important, especially in areas near large population centers such as in the Pacific Northwest of the United States, Japan, Indonesia, and the Philippines.

Paleoseismology and seismic hazard assessment

Over the last few decades paleoseismology has emerged as its own subdiscipline within geology, aimed at determining the timing and magnitude of past earthquakes. Ultimately, paleoseismology can be used to help determine earthquake recurrence intervals for seismic hazard mitigation. Much paleoseismological work depends on tectonic geomorphology to identify active faults that can be trenched to provide a record of past earthquakes by measuring and dating displaced sedimentary strata. However, paleoseismology has been also extended into the use of landslides, rock falls, and precariously perched boulders to determine the timing of past earthquake events.

A holistic knowledge of geomorphology is essential for seismic hazard mitigation. The effects of earthquakes on people, their animals, and property extend far beyond the shaking and collapse of structures, and can include landsliding, liquefaction, flooding, and tsunami. In particular, earthquake-triggered landslides can be particularly devastating, as was illustrated by the 2005 Kashmir and the 2008 Sichuan earthquakes that resulted in many thousands of fatalities. Earthquake-triggered landslides may also block drainages to create metastable dams behind which large lakes may form. These have the potential to fail catastrophically, as was the case with the Hattian Bala slide produced by the 2005 Kashmir earthquake in Pakistan (Figure 3g). The construction of a sluice through the Hattian Bala helped drain the lake and reduced the effects when the dam eventually burst. Careful geomorphic mapping can help identify slopes that might potentially fail. In addition, mapping may aid in identifying flood zone and run-up zones for tsunami, and areas of potential liquefaction. Such maps may become integral parts of geographical information systems that may be used by planners, policymakers, and relief agencies to help reduce the impact of tectonic hazards.

Tectonics, climate change and erosion, and polygenetic landscapes

Arguably the most exciting aspect of tectonic geomorphology is the growing realization of the polygenetic nature of landscapes, and the complex interactions between endogenetic and exogenetic processes. This is particularly well illustrated with the tectonic aneurysm model that was initially developed to help explain the exceptionally high topography and rapid exhumation rates of the Nanga Parbat–Haramosh syntaxis at the western end the Himalaya. This model argues for localized uplift caused by enhanced glacial and fluvial erosion and the exhumation of metamorphosed crustal rocks, weakening the lithosphere, and further enhancing bedrock uplift (Koons, Zeitler, and Hallet 2013). Key issues in the evolution of polygenetic landscapes include examining the role of tectonic and isostatic uplift, the nature of exhumation rates, climate control and the distribution and timing of erosion, the role of glaciers and relief production, focused erosion and spatial coincidence, geomorphometry and erosion modeling, and equilibrium concepts such as topographic steady state. In addition, human influences are now contributing to the development of polygenetic landscapes and
this factor poses greater challenges for predicting the nature of future geomorphic change.

In summary, tectonic geomorphology is an exciting and expanding new branch of geomorphology, which has added much to our understanding of the dynamics and interplay of Earth’s interior and surface processes. In particular, it is allowing the complex variability between regions at different scales, and over different timescales (particularly ranging from $10^0$–$10^6$ years) to be examined in great detail and more holistically. The broader impact of tectonic geomorphology is great, as it has the potential to aid in tectonic hazard assessment and mitigation. This is important as human population increases dramatically in tectonically active areas. In particular, the largest population on our planet live in areas that are likely to experience exceptionally large earthquakes and volcanic eruptions, notably, China, India, Indonesia, Japan, Philippines, and western United States.

Temperate forest ecosystems

Shannon McCarragher
The University of Tennessee at Chattanooga, USA
Lesley S. Rigg
University of Calgary, Canada

Temperate forest ecosystems are found throughout the middle latitudes in both the Northern and Southern Hemispheres, although they occur much more extensively throughout the northern mid-latitudes than the southern. Temperate forests are perhaps the most exploited and degraded in the world, primarily as a result of unsustainable harvesting and development, clearing for agriculture and livestock, pollution, and introduced pathogens.

There are seven major mid-latitude regions in which the temperate forests of the world can be found: Europe, eastern North America, Asia (specifically North China, Korea, Japan, and far-eastern Russia), southern South America, southeastern Australia, Tasmania, and New Zealand. For the purpose of this entry, these regions will be broadly discussed by hemisphere: Northern Hemisphere and Southern Hemisphere.

Generally, the mid-latitude temperate forest communities can be classified into three broad categories:

- temperate deciduous forests, dominated by broad-leaved trees that lose their leaves seasonally and support a wide and complex variety of flora and fauna;
- temperate coniferous forests, composed of evergreen trees and a simple two-layer vegetation structure; and
- temperate mixed forests composed of both coniferous and deciduous trees.

Biomass is the total mass (usually dry weight) of the vegetation within a forest and is often used to estimate the amount of energy stored in the vegetation. The rate at which biomass is produced by the forest plants each year is known as net primary productivity. Generally, biomass and net primary productivity levels vary from location to location. North American temperate forests, for example, have high biomass levels that steadily increase until the community is about 200 years old and a net primary productivity that ranges from 500 to 1200 g/m²/year. By comparison, the net primary productivity of a rainforest is 1000–1500 g/m²/year, while deserts can be as low as 150 g/m²/year.

Temperate forests’ underlying bedrock, geology, and soils differ from region to region. The two most common soils found beneath the temperate forests of the world are Alfisols and Ultisols. Alfisols, which tend to be found in cooler regions, are grayish in color at the surface due to the loss of some minerals as water moves through the soil. They have a relatively thin topsoil layer, clay accumulations at depth, and generally have a high fertility. Ultisols, on the other hand, tend to develop in warmer regions on stable landscapes and have red or yellow hues from the iron oxides present within them. They are usually less fertile, since many of their primary minerals have been broken down and removed as a result of a process called weathering. One of the most important
aspects of soil is the nutrients which the plants use for growth. In temperate forests most of the plant nutrients (nitrogen, calcium, sodium, etc.) are contained in the leaves.

Northern Hemisphere

The Northern Hemisphere contains most of the world’s temperate forests. The following are common families of trees, listed alphabetically by genus, that make up these forests: maple (Acer spp.), birch (Betula spp.), beech (Fagus spp.), oak (Quercus spp.), willow (Salix spp.), and elm (Ulmus spp.). These broadleaf deciduous trees lose their leaves every fall and don’t resume growth until the following spring when increasing temperatures and day lengths trigger their leaf development (see Figure 1). Prior to this trigger, light levels are high on the forest floor. Spring ephemerals or short-lived plants that lack woody tissue in their stems (also known as herbaceous) take advantage of the high light levels by growing quickly and flowering in early spring before the leaves on the deciduous trees fully develop and shade the understory. Some conifers or evergreen trees, such as fir (Abies spp.), red cedar and juniper (Juniperus spp.), spruce (Picea spp.), pine (Pinus spp.), cypress (Taxodium spp.), and hemlock (Tsuga spp.) can also be present within the northern temperate forests.

Physical environment basics

The temperate forests in the Northern Hemisphere have four changing seasons (i.e., winter, spring, summer, and fall) and are the second rainiest biome after rainforests. The average yearly precipitation in temperate forests is 75–150 cm (30–60 in). Since precipitation is usually abundant due to high summer rainfall and large winter snowfall events, the vegetation is generally affected more by temperature than by precipitation.

The average temperature in temperate deciduous forests is 10°C (50°F). Typically, winter (November–April) in the north is characterized by cold weather, but conditions are strongly influenced by latitude and continental characteristics. Summers are mild, averaging about 21°C (70°F), while winter temperatures are often well below freezing. In North America, cold dry arctic air dominates the winter months.
TEMPERATE FOREST ECOSYSTEMS

and the average winter temperature can be as low as −10 °C (14 °F) or up to 10 °C (50 °F), depending on the location. Summer averages are usually warm and humid with July averages ranging from 20–23 °C (68–73 °F). In Europe, winter temperatures can range between 0.6 and 7 °C (33–45 °F) while summer temperatures tend to range from 11–20 °C (51–68 °F) and rarely exceed 30 °C (86 °F). Europe is wettest in the western regions and becomes progressively drier in the regions to the east that are located on the continent’s interior. The coastal zones of Asia from equatorial Southeast Asia to the subarctic eastern Siberia have sufficient rainfall and, as a result, have given rise to a sequence of five forest formations, two of which are temperate: cool temperate deciduous broad-leaved forest and warm temperate evergreen broad-leaved forest.

**Major communities**

In general, the deciduous forests in the Northern Hemisphere have five distinct layers. The first layer is the canopy trees, which range from 18 to 30 m (60–100 ft) tall. Maple (Acer spp.), elm (Ulmus spp.), and oak (Quercus spp.) trees are just some examples of those that can be found in the canopy. Beneath the canopy is a distinct subcanopy, composed of younger, small trees and saplings. The shrub layer sits below the small trees and saplings and includes mountain laurel (Kalmia latifolia), huckleberries (Gaylussacia spp. and Vaccinium spp.), dogwoods (Cornus spp.), viburnum (Viburnum spp.), and many others. The herbaceous layer occurs below all the others and is made up of small non-woody plants such as wildflowers, ferns, and grasses. Many short-lived herbaceous species, called spring ephemerals, have early leaf development that permits them to complete important stages of their lives prior to full tree canopy development; these include trilliums (Trillium spp.), trout lilies (Erythronium spp.), and mayapples (Podophyllum peltatum) (see Figure 2). Mosses and lichens often form a blanket ground layer on the forest floor, depending upon moisture and canopy cover.

In Europe, many of the forests have been highly disturbed or entirely cleared by human activity and agriculture production (see Figure 3). Most of the remaining forests in Europe can either be classified as mixed temperate forests, primarily found in Western Europe, or temperate evergreen woodlands, primarily located in the mountainous and Mediterranean regions of central and southern Europe. The European temperate forests are generally composed of fewer species when compared to other Northern Hemisphere forests, even though their densities (number of trees per unit area) and basal areas (area occupied by tree trunks and stems) are reported to be similar to those of old-growth forests in eastern North America.

Oaks, particularly pedunculate oak (Q. robur), dominate regions with lower elevation throughout Britain and northwest Europe. As elevation increases, beech (Fagus sylvatica), sessile oak (Q. petraea), and birch species (i.e., Betula pendula and B. pubescens) become dominant. A variety of oaks (i.e., Q. lusitanica, Q. pubescens, Q. trojana, and Q. cerris), chestnut, and beech (Fagus spp.) dominate the southern Mediterranean temperate forests of Europe. The dominance of oak throughout Europe is in part a result of centuries of planting monospecific oak stands. Other common tree species found throughout Europe include hornbeam (Carpinus betulus), field maple (Acer campestre), and elm (Ulmus procera), although many were damaged by Dutch elm disease (Ophiostoma ulmi). Often, an open shrubby understory can be found below the European temperate forest canopy.

The North American and Asian temperate deciduous forest communities are much more diverse than their European counterparts. Between 100 and 150 different deciduous tree
species compose the North American temperate forests, each with their own unique distribution. In the north, American beech (*Fagus grandifolia*) and maples (*Acer saccharum, A. saccharinum, A. rubrum, A. platanoides*) mixed with some conifers, specifically eastern hemlock (*Tsuga canadensis*) and others, are abundant in the forests, with conifers becoming more dominant as the community transitions into the immense boreal forests of Canada. In the south, oak (*Quercus alba, Q. rubra, Q. marilandica*), hickory (*Carya cordiformis, C. ovata*), maple (*Acer saccharum, A. saccharinum, A. nigrum, A. rubrum*) and American basswood (*Tilia americana*) dominate the forests. This general forest pattern is due to a north–south temperature gradient and further species differentiation occurring along an east–west moisture gradient, with more drought tolerant species dominating the western edges of the ecosystem. Deciduous trees become restricted to wetter drainages and open woodlands, eventually transitioning in the west into what was formerly a tall-grass prairie. On the northern and southern fringes of the community evergreen trees dominate with needle-leaf conifers in the north and broad-leaved evergreens in the south.

This distinct pattern of forest species assemblages has shifted through time. Forest responses to past climate change are well documented and significant. At the height of the most recent glaciations much of the area in North America, Europe, and Asia that is currently occupied by the boreal and mid-latitude forests was ice covered. As climates warmed, tree species migrated northward out of their southerly refuges (an area where populations of species can survive during unfavorable environmental conditions) and shifted into geographic locations and ranges currently associated with the mid-latitude forests. Studies of pollen distribution demonstrate that plant species in North America shifted range in response to natural climate warming over the past 18,000 years. Pollen records found in North America show that maple (*Acer* spp.) and birch (*Betula* spp.) species reached their current northerly limit approximately 6000 and 7000–10,000 years ago, respectively (Davis 1983). By 7000 years ago, within the Great Lakes region of North America, beech (*Fagus* spp.) had migrated into the oak/hickory (*Quercus* spp./*Carya* spp.) forests of lower Michigan, and hemlock (*Tsuga* spp.), beech (*Fagus* spp.), and white pine (*Pinus* spp.) formed extensive stands throughout southern Ontario. In Europe, the extent of the shift was more pronounced than in North America with only pockets of boreal and
Figure 3  An example of a highly disturbed and cleared area used for agricultural and grazing purposes in Europe (Ireland). Source: Photo by Shannon McCarragher.

deciduous species surviving in small populations within protected locations. Pollen studies similar to those conducted in North America suggest that the past 10,000 years of forest change in northeastern Sweden, showed a northward expansion of species (Quercus spp., Ulmus spp., and Tilia spp.) associated with warmer climates. Ultimately, this shift was mediated by a cooler period around 3200 years ago during which spruce (Picea spp.), pine (Pinus spp.), and birch (Betula spp.) established.

However, projections of human-induced climate change over the next several hundred years suggest that warming may be much faster than tree species have experienced in the past 18,000 years – in fact, probably over the past two million years. This rapid rate of climate change may severely impact many species’ ability to reproduce and persist in regions where they are currently found. Most significantly, numerous species may ultimately be unable to migrate to locations more suited to their species-specific ecological tolerances. Collectively, this problem may result in altered forest communities comprised largely of species with wide ecological tolerances. For example, sugar maple (Acer saccharum), an ecologically and economically important species that ranges across much of eastern North
TEMPERATE FOREST ECOSYSTEMS

America, will most likely be affected by altered climates. Increases in temperature could eventually lead to increased growth rates for adult sugar maple (Goldblum and Rigg 2005) and potential migration over longer time frames. In Scandinavia, East Asia, and North America, a northward movement of mid-latitude deciduous forest is modeled to occur at the expense of the southern boreal forest.

Adaptations and disturbances

Due to the marked cold winter season, nearly all plants in the Northern Hemisphere have a winter dormant season. For many shrubs and trees, the dormant season includes the loss of their leaves. During the shorter days and cooler weather of autumn, green chlorophyll in the leaves is reduced and begins to decompose, leading to discoloration that reveals brilliant oranges, yellows, pinks, and reds (variable by plant species) (see Figure 4). Actually, these colors were present in the leaves all year long, but had been hidden by the green pigment of the chlorophyll. Toward the end of the growing season, deciduous trees try to recover as many nutrients (such as nitrogen, phosphorus, and potassium) from leaves as they can before they drop them. The cycle of deciduousness relies upon the decomposition of the leaf litter deposited on the forest floor and the return of any remaining nutrients back to the soil for use by soil fauna (e.g., insects, earthworms, amphibians) and flora (e.g., trees, wildflowers, shrubs). The combination of retracted and stored nutrients allows for new leaf production each spring when the longer days and warmer weather signal to the trees that it is time to begin photosynthesizing again. Spring also triggers the growth and germination of various plants in the herbaceous layer.

If trees in the northern temperate forests did not undergo this deciduous cycle and instead kept their leaves throughout winter, the water in the leaves would freeze into ice, damaging the leaves and leaving the plant vulnerable to pathogens. In colder biomes, where species retain their leaves (needles) throughout the cold season, the plants are equipped with adaptations that prevent freezing. The short growing season within these colder biomes, however, inhibit the ability of nutrients to be returned to the soil via decomposition. Long-lived leaves are common in temperature extremes, both cold and hot, where tree species produce very high quality leaves. Trees in the deciduous forests produce comparatively low quality leaves that are easily decomposed on the forest floor when dropped. The herbaceous plants growing in the temperate forests do not simply lose their leaves; instead, they completely die back to the ground surface during the winter and regrow each spring.

Fire is not very common in North Hemisphere mid-latitude forests, except on the fringes (for
example, along the North American western and northern boundaries). Rather, the dominant forms of disturbance in the Northern Hemisphere are storms (Fischer, Marshall, and Camp 2013). Typhoons and hurricanes are common in both East Asia and northeastern North America, while windstorms occurring in the winter are dominant in central Europe. Tornados are also a destructive force within mid-latitude forests, especially in North America, although their damage tends to be confined to narrow strips of land that lie within their paths of movement. Ultimately, storm events tend to have a fairly isolated impact on the vegetation, leveling anywhere between a single individual to several hundred trees, but in doing so they create openings in the canopy, known as canopy gaps. The disturbance patches in central Europe tend to be the smallest when compared to East Asia and North America, respectively. Even though these gaps occur infrequently (1% per year), the increased light levels within them tend to play an important role in promoting germination and seedling development. The subcanopy, composed primarily of trees in varying stages of succession to the canopy, usually benefits the most from the increased sunlight within these gaps. However, many herbaceous species are also well adapted to take advantage of the conditions within canopy gaps. Ultimately, these gaps occupy about 10% of the forest area and support turnover within the forest community, whereby older trees are replaced by younger, newly established trees. As a result of this turnover, Northern Hemisphere temperate forests are generally composed of unevenly aged stands of trees, rather than the evenly aged stand of trees that may develop in regions where larger disturbances, like fire, cause an entire community to reestablish all at once.

Temperate forests are one of the most altered biomes on our planet, having been seriously affected by human settlement and clearing. While early human populations most likely played a key role in altering forest structure, it is the movements, more recently, of colonial and postcolonial Europeans that have had the greatest impact on these forest communities. In both Europe and North America, the northern boreal forest remains largely intact, while the mid-latitude forests have been extensively utilized for many centuries for farming and habitation. This is not to say that the boreal forest, especially at its southern margins, is not highly managed for timber and other activities, but in comparison, the history of human land use is more pronounced in the temperate forests.

These activities have led to the decline of this biome throughout most of the world. In the early eighteenth and nineteenth centuries, enormous tracts of forest land were cleared for agriculture, but the ground was rocky and soils were minimal. Following the opening of the American Midwest, nearly all the northeastern farmlands were abandoned and many of them have since returned to second growth forests. However, there are very few remnants of original forests remaining from which to piece together the original character of the forest. The American chestnut (Castanea dentata) was previously a canopy dominant tree in these forests until its virtual extinction in the 1930s due to a fungal disease (Cryphonectria parasitica). Evidence suggests that the chestnut blight fungus may have been accidentally carried in on Chinese chestnut trees being imported through New York. After entering the United States, the spores of the fungus were quickly carried by the wind and spread throughout the rest of the temperate deciduous forests. Today, American chestnuts exist only in small numbers as shrubs and rarely survive to maturity.

Pollution is a key factor within the temperate forest as exposure to subtle, but long-term,
TEMPERATE FOREST ECOSYSTEMS

pollutants such as acid deposition weakens trees leaving them susceptible to disease, insect outbreaks, and extremes in weather conditions. Researchers monitoring sugar maple forests in southeastern Canada and northeastern United States note changes in nutrient levels in the woody tissue of the trees (Jones 2006). They have linked these changes in wood chemistry to changes in environmental chemistry, specifically the progressive acidification of forest soils due to increased amounts of acid precipitation at higher latitudes. The long-term impacts on forested communities include forest decline due either to nutrient deficiencies or soil toxicity and dieback of species that are particularly sensitive to changes in soil environmental chemistry or species growing in marginal soils. Many commercially important tree species (e.g., maple, pine, and spruce) are experiencing decline, and in many areas the affected trees are the dominant tree species in their respective forest communities. Their decline not only results in changes to the relative distribution and dominance of those tree species within the forest community, it also impacts the ecological network of species that rely on them. For example, in some declining sugar maple stands, researchers have noted a decrease in the number of early season butterflies and moths, while others have reported increased stress in birds nesting in the canopies of declining sugar maple stands due to increased exposure.

The introduction of exotic or non-native plant and animal species to temperate forests can create a disturbance, as the new arrivals compete for food and habitat space, and can potentially displace and threaten native species. An introduced species becomes known as an invasive species when it is non-native to the ecosystem in which it has established, has the ability to become the dominant species within that community, and is causing, or is likely to cause, harm to human health, the environment, and/or the economy (Devine and Fei 2011). Ecosystem services, or the processes and natural cycles by which ecosystems fulfill and sustain humanity, are often also disrupted. Kudzu (Pueraria lobata), mile-a-minute or knotweed (Persicaria perfoliata), and Amur or bush honeysuckle (Lonicera maackii) are a few examples of exotic invasive plants that present an ecological threat to regions throughout North American temperate forests (see Figure 5). Invasive insect outbreaks are quite common in northern temperate forests and often result in an increased vulnerability or exposure to pathogens and diseases. The gypsy moth (Lymantria dispar) was accidentally introduced to the United States in the late 1860s and has since caused the defoliation (removal of leaves) of over 80 million acres of forested land. Dutch elm disease has negatively affected most elm trees growing within all Northern Hemisphere temperate forests and was spread by a variety of bark beetles that transmitted the spores of the fungus (Ophiostoma ulmi, formerly Ceratocystus ulmi) to healthy elm trees. Asian longhorned beetles (Anoplophora glabripennis), walnut twig beetles (Pityophthorus juglandis), and the emerald ash borer (Agrilus planipennis) are a few more examples of pests that pose serious threats to the hardwood trees found within northern temperate forests. It is important to note that not all exotic species are invasive; some actually prove beneficial to the environment and economy, such as cattle, potatoes, and honeybees. Multiple strategic management programs have been developed and initiated in order to detect, prevent, and control the harmful invasive biological disturbances.

Southern Hemisphere

The temperate forests of the Southern Hemisphere differ significantly from those in
the Northern Hemisphere and are not as geographically extensive. They are characterized by milder winters and are composed of evergreen broad-leaved forests, rather than deciduous broad-leaved forests found in the cooler Northern Hemisphere. Tree species in the Northern Hemisphere also exhibit a higher degree of frost hardiness than those in the Southern Hemisphere, but lack the fire tolerance that is necessary for life in the south.

**Physical environment basics**

Temperate forests in the Southern Hemisphere span climates from coastal maritime (South America and New Zealand) to drought prone (interior South America and Australia). The coastal maritime climate of the Southern Hemisphere is characterized by a mild temperature range and high annual precipitation (greatest in the winter). The summer drought becomes less severe as precipitation increases from north to

**Figure 5** An example of the invasive species Amur honeysuckle (*Lonicera maackii*) found in a northern temperate forest understory. The inset shows its distinguishing characteristic: the flower/fruit stems are shorter than or equal to the leaf stem lengths. Source: Photos by Shannon McCarragher.
TEMPERATE FOREST ECOSYSTEMS

In the south, average monthly precipitation can exceed 100 mm (4 in.) even during the driest months. The wettest conditions prevail on west-facing slopes, which catch onshore clouds.

In South America, the slopes of the Andean Cordillera receive more than 4000 mm (157 in.) of precipitation per year. Above about 800 m (half mile) on the Coastal and Andean Cordillera, winter precipitation falls as snow. When moist, warm air flows over a mountain range, it condenses to form clouds and precipitation on the windward slopes. After the precipitation falls, the air continues to flow over the mountain range and descends down the leeward side, becoming warm and dry. The warm, dry air produces what is called a rainshadow effect – significantly lower rainfall totals and higher air temperatures on the leeward side of the mountain range and beyond, as compared to the windward side. In South America, the Argentinean side of the Andes mountain range and the central depression beyond are examples of regions that have significantly lower rainfall totals as a result of the rainshadow effect. Average annual temperatures in this region range from 6–10°C (43–50°F).

In New Zealand, temperatures range between around 5°C (41°F) in the winter to around 14°C (57°F) in the summer. In some areas of New Zealand, annual precipitation levels can reach 9670 mm (381 in.) while the temperate forest regions of western Tasmania, Australia, are considerably drier and rarely receive annual precipitation levels over 4000 mm (157 in.).

Major communities

Plant communities on the Australian continent, over the geologic time scale, have largely evolved with tropical climatic regimes. Australia's vegetation has a very high proportion of endemic species, many of which can resist drought, fire, or both. Two genera dominate the tree communities: there are more than 700 species of *Eucalyptus* and over 900 species of *Acacia*. The broad-leaved temperate forests of Australia are some of the most distinctive in the world. They display a remarkable uniformity in that the principal tree genus, *Eucalyptus*, dominates. In no other region of the world does one genus so dominate the forests. They range from some of the tallest hardwoods in the world, mountain ash (*E. regnans* – 100 m; see Figure 6), to small woodland species found across Australia and form the treeline at elevation in the mountains of the southeast. In eastern Australia, the deciduous snow gum tree (*E. pauciflora*) defines the boundary between the subalpine forests and the treeless alpine zone.

Due to the aridity of Australia, large areas are without tree cover. The total forested area of Australia is 147 million ha, which represents approximately 19% of the continent. The greatest area of Eucalyptus forest occurs in eastern Australia in a nearly continuous band from the Tropic of Cancer in Queensland to South Australia and extending to Tasmania – an amazing 3000 km (1864 mi.) extent, north to south. River red gum (*E. camaldulensis*) occurs along river courses in the more central portions of Australia. The temperate eucalyptus forests in Victoria and Tasmania are composed primarily of *Eucalyptus* varieties, such as mountain ash (*E. regnans*), white gum (*E. viminalis*), and Australian oak (*E. oblique*), while tree ferns and small trees dominate the understory. In southwestern Australia, karri (*E. diversicolor*; see Figure 7), marri (*E. calophylla*), yellow tingle (*E. guilfoylei*), and red tingle (*E. jacksonii*) dominate. These forests have similar understories to those found in Victoria, mostly tree ferns, small trees, and shrubs. Conifers in these forests include Patagonian cypress (*Fitzroya cupressoides*), which grow in poorly drained lowland sites or in wetter mountain zones and can live to an age of 3000 years.
TEMPERATE FOREST ECOSYSTEMS

Figure 6  Mountain ash forest near Wallaby Creek in Victoria, Australia, with trees reaching over 90 m tall and a person for scale. An understory of tree ferns, small trees, and shrubs can also be seen. Source: Photo by Lesley S. Rigg.

The coastal temperate forests (in Australia, South America, and New Zealand) are dominated by the southern beeches (*Nothofagus* spp.). Myrtle beech (*Nothofagus cunninghamii*) is found in Tasmania and parts of southern Victoria. These Australian forests have a close affinity with other Southern Hemisphere forests of the same genus in Chile, New Zealand, and Argentina. Tasmania has the highest percentage of forest cover of any Australian state. In the Australian wet temperate forests other dominant species include the following conifers: king billy pine (*Athrotaxis selaginoides*), huon pine (*Lagarostrobus franklinii*), and celery-topped pine (*Phyllocladus asplenifolius*).

The temperate broad-leaved forests of New Zealand are characterized as podocarp-hardwood forests, meaning they are primarily composed of trees from the *Podocarpaceae* taxonomic family. Common species include matai (*Prumnopitys taxifolia*), rimu (*Dacrydium cupressinum*), kauri (*Agathis australis*), and kahikatea (*Dacrycarpus dacrydioides*). The forests have multistoried canopies with a podocarp dominant emergent (or tallest) layer that can reach 40–60 m (131–197 ft) high and a main canopy below that can reach 25–30 m (82–98 ft). Common subcanopy trees include kamahi (*Weinmannia racemosa*), rata (*Metrosideros robusta*), and mountain beech (*Nothofagus solandri*) in the wetter regions. In general, these forests are found at low altitudes toward the north of the country where rainfall is greater and soils are more fertile. The south island of New Zealand is primarily composed of beech (*Nothofagus* spp.) forests that tend to form in the subalpine areas in pure stands. Beech and podocarps are found coexisting in the warm and moist areas of New Zealand.

The temperate evergreen forests of South America occur primarily in Chile with minor extensions into neighboring Argentina. The temperate forests range from 37°S to about 46°S. The northern limit of this forest is determined by aridity while the cold temperatures determine the southern limit. This region of Chile varies topographically from west to east. The Cordillera mountain range (1000 m or 3280 ft) occur near the western coast, while the Andean Cordillera mountain range lies on the eastern portion of Chile and is twice as high as its western counterpart. Between these two mountain ranges lies a valley, known as the central depression, in which the elevation ranges from 100–300 m.
Three broad categories of plant communities exist within these ranges. Forests dominated by evergreens, such as Chilean laurel (*Laurelia sempervirens*), and tineo (*Weinmannia trichosperma*), occur in the central depression and low elevation forest of the coastal Cordillera. The deciduous roble beech (*Nothofagus obliqua*) is also found scattered throughout the central depression and low elevation forest, but the evergreen species are more common. As the altitude increases in the Andean Cordillera, coígües (*Nothofagus dombyri*) and Chilean tepas (*Laurelia philippiana*) become the dominant forest species. Epiphytes (plants that live on other plants) and lianas (woody vines) cover the tree trunks.

**Adaptations and disturbances**

Fires are the dominant disturbance in the southern temperate forests and they have been occurring since before the arrival of humans. The most common fires are surface fires that kill the ferns/grasses/shrubs, but merely burn the bark on the trees. Intense fires, called bushfires in Australia, kill the canopy tree species and are responsible for clearing massive areas of forest during the dry season. Many species in these forests are dependent on fire for regeneration and have therefore developed adaptations to survive them. Some trees have highly flammable bark and leaves that, in combination with the accumulation of leaf and woody litter, assist in their ability to burn. Other adaptations to fire include thick bark and the ability to resprout.
from lignotubers (a protected outgrowth at the base of the trunk containing vegetative buds). Stand-destroying fires of the Southern Hemisphere result in large, evenly aged stands of trees, in contrast to the unevenly aged stands in the temperate forests of the Northern Hemisphere.

Following fires in the temperate evergreen forests of South America, bamboo (Chusquea auila) will occupy the site for some years until trees reestablish. Beyond fires, South American forests are prone to earthquakes, which in turn trigger large mass movements (landslides) on the steep slopes that are found in the Andes. Landslides in South America are similar to fires in Australia as large even-aged stands regenerate after the disturbance. Evidence from disturbed forests where Nothofagus species are growing suggests that these trees require large-scale disturbance to regenerate. Agricultural practices in South America required open land, which in turn required the clearing and destruction of vast areas through Southern Hemisphere temperate deciduous forests. Nothofagus forests were hit particularly hard by clearing for agriculture, while other trees, particularly the raúlí (Nothofagus alpina) and roble beech (Nothofagus obliqua) were selected and cleared for use in charcoal production and ship building.

The Southern Hemisphere forests are prone to other disturbances, such as avalanches, cyclones, and introduced grazers (e.g., possums and deer). In New Zealand, the introduction of exotic animals to the island habitat by both Maori and Europeans (Australia) has wreaked havoc on the temperate forests. The tree species were adapted to grazing by native birds, including the flightless Moa whose extinction was linked to human arrival, but they were not adapted to grazing by arboreal possum or deer. Browsing by the introduced Australian brush-tailed possum (Trichosurus vulpecula) is generally accepted by most ecologists as the main sources of forest dieback, especially for forest dominated by rata (Metrosideros spp.) and kamahi (Weinmannia racemosa).

TEMPERATE FOREST ECOSYSTEMS

Temperature measures the intensity of heat within the physical world and thereby determines, influences, or limits most geographic features and processes. As primary examples, temperature (1) determines the solid, liquid, or vapor state of water, (2) influences heating and cooling needs within the built environment, and (3) limits the geographical range and distribution of many plant and animal species. Temperature also is a critical variable in analyzing climatic variability and change.

While heat refers to the total reservoir of kinetic energy of a substance, temperature refers to the average kinetic energy of a substance. As a comparative example, the water in a small lake in northern Wisconsin during summer will have a higher temperature than that of the water in nearby Lake Superior, but Lake Superior has a far greater overall heat content.

In many cases, what is referred to as “temperature” is the air temperature, usually measured at a standard height of about 1.5 m above the ground. Many other measures of temperature are routinely made and these include (1) profiles of air temperature from the near-surface to the upper atmosphere (made with instruments on weather balloons known as radiosondes), (2) sea-surface temperature (measured either by satellite sensors or by “in situ” sampling), and (3) soil or deep-earth borehole temperature profiles. The focus here primarily will be on near-surface air temperature; however, many of the concepts can be extended to other measures of environmental temperature.

Controls on temperature

Within the natural environment, air temperature is most closely related to the availability of solar radiation. Therefore, temperature has strong relationships with variables that influence solar radiation, such as latitude, cloud cover, aerosols, and surface albedo. The annual and daily cycles of solar radiation availability create corresponding cycles of temperature, although the peaks of the annual and daily temperature cycles lag the solar radiation cycles, as temperature is more closely related to net radiation than solar radiation alone.

The initial heating or cooling of air temperature near the Earth’s surface occurs via conduction with the surface below. While incoming solar radiation (insolation) is the primary heat source for the atmosphere, reflection and long-wave radiation emission by the surface offsets solar input. These factors added together are known as net radiation. Net radiation indicates the overall amount of radiative heat gained or lost by the surface. A net radiation gain generally means warming and net radiation loss generally means cooling of the surface and, subsequently, of the atmosphere that is in contact with the surface.

The thermal climate of the Earth over recent millennia has varied only slightly, primarily because the amount of solar radiation reaching the Earth is relatively stable. In addition, the incoming and outgoing radiation from the Earth’s surface as a whole are nearly in balance.
Figure 1 Time–latitude plot of top–of–the–atmosphere (extraterrestrial) solar radiation (left) and annual mean of top–of–the–atmosphere solar radiation (right), both expressed as a percentage of the solar constant. The tropics receive relatively uniform solar input, while many higher latitude regions have high solar inputs during summer months only when sun angles are higher and day length is particularly long. At high latitudes, substantially longer path lengths of radiation through the atmosphere (not shown) further reduce incoming solar radiation.

However, large variations in solar radiation occur daily and seasonally because of the geometry of the Earth and its orbital characteristics within the solar system. These characteristics – such as the Earth’s orbit around the sun, axial tilt, and rotation, along with latitude – govern the angle at which solar radiation enters the Earth–atmosphere system. When totaled over the course of a day and expressed as a percentage of the solar constant, insolation at the top of the atmosphere at the poles varies from near zero during the winter solstices. Contrastingly, tropical areas receive nearly 30% of the solar constant at nearly all times of the year, resulting in year–round homogeneous temperatures (Figure 1).

By governing the amount of absorbed and reflected solar radiation and the amount of absorbed and emitted longwave radiation, characteristics of the Earth’s surface and atmosphere exert a strong influence on temperature. The greatest influence of the surface on net radiation is albedo. Snow is the most effective natural reflector of sunlight, whereas most land surfaces
and open water are efficient absorbers. Even small differences in land-surface albedo, however, can be great enough to cause large spatial variations in temperature during sunny days.

Emissivity is another important surface property because of its influence on longwave radiation. The amount of longwave radiation emitted by a surface \( E \) is dependent on both its temperature \( T \), in Kelvin, and its emissivity \( \varepsilon \) and is given according to the Stefan–Boltzmann law as

\[
E = \varepsilon \sigma T^4,
\]

where \( \sigma \) is a constant \( 5.67 \times 10^{-8} \) W m\(^{-2}\) K\(^{-4}\). Emissivity varies from 0 to 1, with natural surfaces generally having higher values than man-made surfaces (see Oke 1987, table 1.1). The effects of emissivity are at work 24 hours a day, whereas albedo is only a factor when sunlight is present. As a result, emission of longwave radiation plays a particularly important role in cooling processes at night but is overshadowed by the effects of solar radiation during the day. Higher nighttime temperatures often occur in areas with lower emissivity than adjacent areas where it is higher. Snow has a very high emissivity, which, combined with its high albedo and ability to insulate the atmosphere from ground heat below, makes it a very efficient cooling device in the climate system. Inversion of the Stefan–Boltzmann law to solve for temperature,

\[
T = \left[ \frac{E}{\varepsilon \sigma} \right]^{1/4},
\]

is used to estimate land- and sea-surface temperature from satellite- or aircraft-based sensors that measure longwave (thermal infrared) emission.

Like the Earth’s surface, the atmosphere has a variable albedo and emissivity. Clouds and other atmospheric constituents, such as small atmospheric particles or liquid droplets known as “aerosols,” typically increase albedo and act as cooling processes. Conversely, greenhouse gases – such as water vapor, carbon dioxide, and methane – affect the absorptivity and emissivity of the atmosphere and act as warming processes. Even though greenhouse gas concentrations are relatively low, they have important direct radiative effects that are compounded by positive feedback mechanisms – processes that have acted to make Earth substantially warmer and more habitable than it would be without greenhouse gases. As a result, changing concentrations of greenhouse gases and atmospheric aerosols are very influential in regional and global climate change.

Water vapor is the most influential of the greenhouse gases in the atmosphere because of its high concentration compared to the others. Water vapor that is converted to liquid or solid form in the form of clouds, however, typically increases atmospheric albedo. The net effect of clouds on near-surface temperature is dependent on their optical thickness and their height. For instance, high cirrus clouds tend to lead to higher temperatures over clear-sky conditions because of their transparency to solar radiation and ability to absorb longwave radiation and re-emit it to the surface. Low clouds tend to be less transparent and have a higher albedo, leading to lower temperatures compared to clear-sky conditions. In addition, natural and anthropogenic aerosols and particles can linger for hours to days and lead to cooling. Volcanic eruptions can result in large-scale atmospheric albedo increases and temporary global cooling. The most influential of these volcanoes inject gases and particles into the stratosphere where they persist for months to several years.

The physical geography of the Earth’s surface affects temperature spatially through topography and the distribution and configuration of land and water bodies. An important property of water is its role in dampening temperature variation. This is because of its high specific heat, which is about five times that of most land surfaces. Water absorbs energy when there is a surplus of net radiation and re-releases it when there is a deficit of net radiation, acting to
DECREASE THE RATE OF TEMPERATURE CHANGE RELATIVE TO SURFACES WITH LOWER SPECIFIC HEATS.

WATER ALSO PLAYS A KEY ROLE IN MODULATING TEMPERATURE VIA LATENT HEAT EXCHANGE. WHEN WATER CHANGES PHASE, AN EXCHANGE OF ENERGY IS INVOLVED THAT CAN OFFSET BACKGROUND TEMPERATURE TENDENCIES. PHASE CHANGES FROM A LOWER ENERGETIC STATE TO A HIGHER ONE – SUCH AS MELTING OR EVAPORATING – CONSUME LATENT HEAT ENERGY SO THE WARMING THAT LEADS TO THE PHASE CHANGE IS OFFSET. EVAPORATIVE COOLING IS A GOOD EXAMPLE: FORESTS OR OTHER VEGETATED AREAS OFTEN HAVE A LOWER TEMPERATURE THAN ADJACENT NONVEGETATED AREAS BECAUSE THE TRANSPERSION PROCESS LOWERS THE AIR TEMPERATURE AS WATER IS EVAPORATED. CONVERSELY, PHASE CHANGES FROM A HIGHER ENERGETIC STATE TO A LOWER ONE – SUCH AS CONDENSING OR FREEZING – RELEASE LATENT HEAT ENERGY SO THAT THE COOLING IS OFFSET. CITRUS FRUIT GROWERS MAKE USE OF THIS PROCESS BY SPRAYING LIQUID WATER WHEN TEMPERATURES APPROACH THE FREEZING POINT. THE FREEZING PROCESS ADDS LATENT HEAT TO THE ATMOSPHERE AND RESULTS IN A LOCAL WARMING OF THE AIR THAT PROTECTS THE FRUIT CROPS. THROUGH THESE LATENT HEAT PROCESSES, THERE IS NO RESULTANT CHANGE IN TOTAL ENERGY IN THE SYSTEM, DESPITE A CHANGE IN TEMPERATURE. AS A RESULT OF THESE PROPERTIES OF WATER, LOCATIONS THAT ARE NEAR OR DOWNWIND OF WATER BODIES, OR THOSE WHERE ATMOSPHERIC HUMIDITY IS HIGH FROM EVAPORATION OR TRANSPERSION FROM VEGETATION, HAVE LOWER ANNUAL AND DIURNAL VARIATIONS IN TEMPERATURE. SEMIARID AND ARID REGIONS HAVE A VERY HIGH DIURNAL TEMPERATURE RANGE BECAUSE OF THE LACK OF WATER VAPOR, VEGETATION, AND TRANSPERSION.

DIFFERENTIAL HEATING OF THE EARTH’S SURFACE AND THE RESULTING TEMPERATURE CHANGES GIVE RISE TO WIND AND AIR CIRCULATION FROM LOCAL TO GLOBAL SCALES. COLD AIR IS DENSER THAN WARMER AIR, WHICH MEANS COLD AIR TENDS TO DISPLACE WARM AIR VERTICALLY WHEN THEY ARE ADJACENT. AT THE GLOBAL SCALE, TRANSPORT OF COLDER AIR FROM THE POLES EQUATORWARD AND WARMER AIR IN THE TROPICS POLEWARD SERVES TO ALTER TEMPERATURE FROM THAT WHICH NET RADIATION ALONE WOULD PRODUCE AT THE SURFACE. ATMOSPHERIC CIRCULATION ALSO INFLUENCES AND INTERACTS WITH OCEAN CURRENTS, WHICH EXCHANGE LARGE AMOUNTS OF HEAT LATITUardinALLY. IN ADDITION TO THE LATITUDINAL GRADIENTS OF OCEAN TEMPERATURE, THE ORIENTATION OF THE OCEAN BASINS AND CONTINENTS HELPS TO DIRECT OCEAN CURRENTS AND PRODUCE THE PATTERNS THAT WE SEE TODAY. FOR INSTANCE, THE GULF STREAM TRANSPORTS WARM WATER FROM THE TROPICS TO WESTERN EUROPE, HELPING TO PRODUCE A CLIMATE THAT IS MUCH WARMER THAN AREAS AT SIMILAR LATITUDES IN EASTERN CANADA OR EASTERN RUSSIA WHERE COLDER OCEAN CURRENTS EXIST (FIGURE 2).

TOPOGRAPHY HAS A STRONG INFLUENCE ON TEMPERATURE BECAUSE OF THE EFFECTS OF ALTITUDE ON PRESSURE (AND THEREFORE TEMPERATURE), BUT SURFACE FEATURE SHAPES AND SIZES ALSO PLAY A ROLE. THE SLOPE AND ASPECT OF A SURFACE CAN ALTER THE INCIDENCE ANGLE OF SOLAR RADIATION, SUCH THAT SLOPES THAT FACE AWAY FROM THE SUN ARE COOLER THAN SLOPES FACING TOWARD THE SUN. THIS EFFECT CAN BE SEEN IN MID-LATITUDE REGIONS WHERE STEEP SLOPES FACING EQUATORWARD ARE WARMER AND OFTEN HAVE VEGETATION INDICATIVE OF A DRIER AND WARMER CLIMATE THAN SLOPES FACING POLEWARD, PRIMARILY BECAUSE EVAPORATION IS DIRECTLY RELATED TO TEMPERATURE.

AT HIGHER ELEVATIONS, THE MEAN TEMPERATURE IS COOLER BECAUSE ATMOSPHERIC PRESSURE IS LOWER, AND THEREFORE THERE IS LESS MOLECULAR KINETIC ENERGY AT THESE ALTITUDES. HOWEVER, BECAUSE THE ATMOSPHERE IS THINNER, GREATER INSOLATION OCCURS AT HIGH ELEVATIONS DURING THE DAY AS THERE IS LESS ATMOSPHERE ABOVE TO REFLECT OR SCATTER INSOLATION. ON THE OTHER HAND, THERE IS A GREATER LOSS OF LONGWAVE RADIATION AT NIGHT BECAUSE THE THINNER ATMOSPHERE DOES NOT ABSORB AND RETURN AS MUCH OUTGOING LONGWAVE RADIATION. THESE PROCESSES OFTEN RESULT IN A GREATER DIURNAL TEMPERATURE RANGE AT HIGH ELEVATIONS. FACTORS LIKE PERSISTENT CLOUDS THAT LIMIT NET RADIATION OR WINDS IN EXPOSED MOUNTAIN
slopes that enhance atmospheric mixing, however, can reduce the diurnal temperature range.

Topography and elevation can work together to increase the diurnal temperature range. Valleys and enclosed basins tend to collect cool air at night, since it is denser than warmer air and thus drains to topographic lows. During the day, surface heating usually mixes this chilled air and then is further warmed from positive net radiation. These conditions require clear skies
and dry air for a greater temperature variation with the presence of wind, clouds, or high water vapor concentrations dampening the effect. Valley environments can experience large seasonal temperature differences from surrounding areas, especially where winter snow or enhanced cloud cover occurs. The effects of snow and cloud on surface and atmospheric albedo give rise to the extreme annual temperature variation seen in nonglaciated cold environments, such as the interior regions of Asia and North America, where atmospheric humidity is normally low.

Global patterns of air temperature

Global-scale maps of monthly mean values of near-surface air temperature clearly show the influence of latitude, topography, and proximity to water bodies discussed above (Figure 2). In response to solar radiation variations, isotherms (lines of equal temperature) tend to be predominantly east–west. Major mountain ranges such as the Andes in South America, the Himalayas in Asia, and the Rockies in North America are very influential in global-scale patterns of temperature. Beyond the expectation of lower temperatures at high latitudes, the high elevations of the ice sheets on Greenland and Antarctica act to further reduce air temperature substantially. Some of the largest spatial gradients of air temperature occur in North America and eastern Asia during January – primarily because solar radiation gradients are largest in the winter hemisphere and both of these continents have vast interiors that are distant from oceanic sources of heat and water vapor. North America and eastern Asia also have substantial snow cover at higher latitudes, which further cools northern regions relative to southern ones. A quantitative example from North America shows that the rate of change of air temperature with latitude during January is about 1.0 to 1.5°C per degree of latitude, whereas July air temperatures decrease only 0.4 to 0.6°C per degree of latitude (Figure 3). These latitudinal rates of change of air temperature are the cause of variability in weather systems across the continent, but also are influenced by the same weather patterns, illustrating the nonlinear nature of the climate system.

Temperature and climate change

Changes and variability in near-surface air atmospheric temperature are among the most important and tangible indicators of climate change. Reliable liquid-in-glass thermometry developed in the mid-eighteenth century produced relatively consistent instrumentation during the historical record. High-quality data from microwave-based satellite sensing of temperature are available from about 1979 onward (Hurrell and Trenberth 1996). As temperatures have a wide range of variability, the analysis of temperature changes with time is simplified by averaging it over space and time. Global and hemispheric-scale averages of monthly or annual averages of temperature are typically used to monitor the energetic state of the near-surface environment. Often, these large-scale spatial averages are integrations of air temperature over land and sea–surface temperature over the oceans. Latitudinal and topographic influences on temperature are usually considered to be independent of climate change. As a result, to reduce the spatial variability associated with latitude and topography, air-temperature anomalies are created by removing a local mean from an air-temperature time series. Converting air temperatures to anomalies produces a smoother spatial field while preserving the temporal variability of each location. The temporal variability of nearby locations that are at very different elevations,
Figure 3  Latitudinal transects of monthly mean air temperatures during January and July at 120°W and 90°W in North America (same data as Figure 2). The gradient of air temperature with latitude (slope) in January is 2–3 times that of July. In both months, the more westerly transect (120°W) shows a weaker latitudinal gradient due to its closer proximity to the Pacific Ocean. Data from Willmott and Matsuura (2009).

The data, for instance, becomes much more comparable after conversion to anomalies (Figure 4). Once temperatures are converted to anomalies, they can be interpolated to a regular grid and averaged accordingly. Analysis of global-scale air-temperature anomalies show that global
Figure 4  Time series of January mean air temperature (°C) at two locations in Colorado, USA, from 1903 to 2012 (data from Historical Climate Network, National Climatic Data Center). Boulder is located at an elevation of 1672 m while Dillon is at 2763 m. The two locations have January mean air temperatures that differ by approximately 9°C, but removing the long-term January mean produces anomaly time series that have similar interannual variability. As a result, air-temperature anomalies are used for comparative analysis and to estimate climatic change across regions that have wide ranges in elevation or latitude. Data from Historical Climate Network, National Climatic Data Center.

and hemispheric rates of recent warming range from 0.05 to 0.25°C/decade (Figure 5; Morice et al. 2012). Concentrations of greenhouse gases are increasing and they are mixed well in the atmosphere, but changes in temperature in the historical record have been larger during nights and winters, especially at high latitude where net radiation often is negative (Meehl et al. 2009; Robeson 2004; Seneviratne et al. 2012).

Human alterations of land cover also influence temperature, primarily by changing surface albedo, emissivity, and the availability of surface water for evaporation and transpiration (Pielke et al. 2011). For instance, many urban heat islands arise from the introduction of materials and urban geometry that result in increased absorption of solar radiation, decreased longwave radiation loss, and decreased evapotranspiration relative to natural landscapes. These processes, along with anthropogenic waste heat, frequently combine to increase air temperature over cities, with the effect usually being larger at night (Oke
Figure 5  Time series of globally and hemispherically averaged temperature anomalies from 1881 to 2012 (HadCRUT4 data from Hadley Centre at UK Met Office and Climatic Research Unit at University of East Anglia). Both hemispheres have similar interannual variability, but the Northern Hemisphere has warmed slightly more rapidly in recent decades.

1987). Other larger-scale anthropogenic changes to the land surface include deforestation and agricultural activities. The direction in which temperature is forced is dependent on what landscape was altered because albedo, emissivity, and evapotranspiration can be either increased or decreased. For instance, irrigated farmland in a desert environment can lower the temperature through increased evapotranspiration. Deforestation can increase daytime temperature and decrease nighttime temperature through decrease in evapotranspiration and subsequent water vapor concentrations. Overgrazing removes vegetation and exposes soil, which reduces transpiration and water vapor while also lowering emissivity, with the net effect being higher daytime and nighttime temperatures.

Meanings are not fixed but are historically, geographically, and socially specific. This simple, but insightful lesson of the postmodern and poststructural turn seems quite appropriate when looking at the notion of “territory.” In its original Latin use, *territorium* referred to the agricultural and grazing land surrounding a human settlement. With the rise of the modern state in Europe, around the fifteenth century, the term has increasingly been associated with the state. Among Anglo-American geographers, territory is today often conceptualized as a bounded space over which a form of political authority is exercised, although it can also be used as a generic synonym of place and region. A similar multiple usage can also be found in French and Italian, but within these geographical traditions territory tends to be treated as a lived space more than as a space monopolized by a politico-institutional power. And yet, if we move out of the Western world, we will see how territory cannot be easily translated into other languages. “Territory” is therefore a polysemic term and the fact that it is a key notion in several disciplines (geography, law, ethnology, ecology, anthropology, etc.) makes the task of pinning down its meaning even more dependent on the context within which it is used. For the purpose of this entry, territory will therefore be analyzed within a limited disciplinary and linguistic scope. Preference will be given to the geographical literature in English and French. This choice might sound too confining, but within both the anglophone and francophone geographical literature territory and territoriality have been extensively researched, producing the prevailing interpretations that are more widely used today within the international scientific community.

**Early steps on territory**

In his historical account of the political and legal institutions of the Western world, Carl Schmitt (2003, 74), echoing the linguist Jost Trier, affirmed: “In the beginning was the fence. Fence, enclosure, and border are deeply interwoven in the world formed by men, determining its concepts.” *Nomos*, the legal principle around which, according to Schmitt, the first political institutions were created, is a spatial term which recalls indeed the notion of fence. *Nomos* stands for the primeval form of land appropriation and delimitation – the first partition and classification of space, which gives orientation (*Ortung*) and order (*Ordnung*) to space.

This interpretation is particularly relevant in considering territory, which today is still mainly defined as a portion of the Earth delimited by borders, over and through which some form of power is exercised. In one of the first geographical reflections on the notion of territory, Jean Gottmann (1973) implicitly echoed Schmitt’s definition of territory as the fruit of partitioning and organization through political processes. In the interpretation of this cosmopolitan geographer, born into a Jewish family in Ukraine, raised in Paris, and active in the United States, France, and England, territory
TERRITORY AND TERRITORIALITY

is the basic unit in the political organization of space that defines the relationships between a group of people and their habitat. Gottmann treats this relationship in psychological terms, as a “psychological reflex” that characterizes all people, thus suggesting, somewhat uncritically, that territorialization is a sort of inescapable condition of humanity. Further elaborating on this point, Gottmann talks of territory as a psychosomatic device – a rather obscure notion that, in the intention of its author, should capture people’s psychological oscillation between a search for security and a search for opportunities. These are indeed the two functions with which Gottmann believes territory is endowed: territory serves as both a shelter and a springboard of opportunity. While the former clearly resonates with forms of control and exclusion, the latter opens up terrain for collaborations and relationships across boundaries. Territory in this latter sense is a space associated with a socioeconomic project, namely the pursuit of the “good life” of people, their happiness, and their wellbeing. In Gottmann, territory is therefore not only a bounded space imposed by a sovereign power on a portion of the Earth that constrains and encages people. True, for Gottmann there can be no territory without sovereignty, as the two are intimately linked; however, territory is something more than a state space; it is a peopled space. Territory comes into existence first and foremost thanks to and for people. It is less a top-down than a bottom-up construct, as it aims to satisfy the needs of those who inhabit it. This is an important point which has gone astry in later academic production, often concerned with the oppressive character of territory. Equally important is the fact that, although territory signals a unique relation between a group of people and the land they inhabit, this relationship is not necessarily cast in identity terms. Rather, what is generated is a shared modus vivendi, which, along with shared interests, works as a common denominator among fairly diversified peoples – an insight equally lost in the successive treatment of territory as mere national homeland.

Another important early step on the notion of territory was Edward Soja’s (1971) essay on the political organization of space. For the American geographer, this organization revolves around three main functions: (i) control over distribution, allocation, and ownership of resources; (ii) maintenance of order and enforcement of authority; and (iii) legitimization of authority through societal integration. Human or social territoriality is a primary basis for the political organization of space. Territoriality provides an essential link between society and space, in terms of identity, concentration of activities, and exclusion of undesirable outsiders. Although Soja believes that men (sic) are territorial animals and that territoriality affects human behavior at all scales of social activity, he also cautions against making direct analogies between animal and human territoriality. He argues that human territoriality is a cultural and behavioral phenomenon that varies historically and geographically in its structure and functions. Similarly, the boundaries that define territory as a demarcated space should also be evaluated in historical perspective, as they might not necessarily coincide with precise lines on the Earth’s surface.

Both Gottmann and Soja stand as isolated contributions within an academic production that most often treated territory and territoriality as self-explanatory terms. Their emphasis on territory as organizational space made by and for people did not find a large following, as scholars largely looked at territory as the product of the state, often at the expense of people, and as a defining principle of nationhood.
Human territoriality

In the Anglo-American geographical literature, territory has long been treated as a juridico-political concept associated with sovereignty—that is, a key component of the modern state. Not surprisingly, it has been monopolized by political geographers. According to Kevin Cox (2002), territory and territoriality actually should be regarded as the defining concepts of political geography. Ironically, though, the most compelling reflection on these two terms came in the 1980s from someone who was not a political geographer, Robert D. Sack (1986).

Before his seminal work on human territoriality opened up the notion of territory to a plurality of scales and actors, both terms referred mainly to the state.

For Sack (1986, 1), human territoriality can be best understood “as a spatial strategy to affect, influence or control resources and people, by controlling an area.” This means that human territoriality cannot be considered as a natural instinct. Since the 1960s, the majority of social scientists had approached territoriality with the lenses of ethology. Following the insights of Konrad Lorenz, territoriality was regarded as an innate feature of all living species, humans included. Also, Soja – whose definition of territoriality as a behavioral phenomenon associated with the organization of space into demarcated territories clearly anticipated Sack’s definition – felt obliged in his essay (Soja 1971) to offer a lengthy review of the literature on animal territoriality. Within this scholarship, the most cited work was *The Territorial Imperative* by the American anthropologist Robert Ardrey (1967). For Ardrey, human beings are driven by an inherent need to occupy, control, and defend the space which they inhabit—a territorial imperative that would inevitably lead to aggressive and conflictual relations between groups. Similar considerations were also present in another influential book of the time, *The Hidden Dimension*, by the American anthropologist, Edward T. Hall (1966), who introduced the notion of proxemics, which was to prove very popular among geographers.

Moving from a behaviorist approach, Sack argues that territoriality should be regarded neither as an instinct nor as an essentially aggressive move. Territoriality is instead a spatial strategy, and therefore it can be turned on and off according to the circumstances and the interests of the given actor. In other words, the same space can be a territory, that is, a bounded controllable place, at one time and not at another time. Let’s imagine, for instance, an open green space in the outskirt of a city. It might be assumed that usually this space can host a variety of leisure activities: lying, strolling, playing games, and so on. The day a ticketed event is organized, this space might become a territory: a fence is built to delimit the event area and the flow into this area is regulated by a given authority. In Sack’s (1986, 19) words, territoriality is “the attempt by an individual or group to affect, influence, or control people, phenomena, and relationships, by delimiting and asserting control over a geographic area. This area will be called the territory.” The importance attributed to both scale and boundaries is clear in this definition. Contrary to that strand of political geography, which has long associated territory with the scale of the state, Sack introduces a plurality of scales at which territory can be conceived. Potentially, any space can become a territory: from the microspaces of the home (e.g., a given room declared off-limits to children by their parents) to large supranational spaces (e.g., the Schengen Area). Similarly, the actors involved are not only state actors, but any individual or group that can produce and enforce a territorializing strategy. This involves the demarcation of
clear boundaries, which, once trespassed, might lead to various consequences to the trespasser, including their physical removal or suppression. Territory is the result of bounding strategies, and its existence is dependent on the establishment, maintenance, and enforcement of boundaries. These boundaries are a form of social communication, as they are indeed signs that give meaning to place, mediating the interaction between individuals, groups, and organizations. According to Sack, territoriality is a form of spatial behavior associated with some universal traits, as they occurred throughout history and across most of the world, and with some specific traits as well, which are distinctive to historical periods and geographical contexts. In this sense, territoriality and territories are not given, but they are the product of people’s conscious agency – what Sack calls the social construction of territoriality. This idea was developed further in the seminal studies of Anssi Paasi (1996), who detailed the social construction of territories around four interrelated processes: the physical shaping of a territory, its symbolic constitution, its institutionalization, and its final establishment.

**De- or reterritorialization**

With the emergence of poststructuralism as a major paradigm in geography in the 1980s and 1990s, territory underwent a severe criticism. The fact of being defined by a physical boundary was clearly at odds with the new understanding of place as an open, unbounded, relational space. Territory was too structural a notion in an epoch that started privileging ideas of hybridity, porosity, and blurriness. While place was regarded as progressive and empowering, territory was dismissed as a site of oppression, exclusion, and confinement. The inside/outside demarcated by a territorial boundary came to be questioned by a growing numbers of scholars. International relations (IR) theorists in particular challenged the analytical purchase of a modern, exclusive form of territoriality. Going beyond this Westphalian model of state territoriality, they suggested the notion of “unbundled territoriality” as a more insightful way to explore the condition of postmodernity in international politics (Ruggie 1993). Associated with this notion was the idea of the emergence of a plurality of overlapping and competing authorities and jurisdictions, giving way to a sort of new medievalism. This post-Westphalian or postmodern territoriality was seen to best capture governing practices adopted within the European Union (EU), which was heralded as the first postmodern or postnational polity, articulated around a form of nonhierarchical, multilevel governance, which defied any separation between domestic and international politics.

In geography, the most sustained critique of modern territoriality came from John Agnew (1994), whose “territorial trap” exposed the ahistorical and decontextualized view of a world reified into fixed units of sovereign space – a view also labeled “methodological nationalism.” Within this conception, the territorial state was thought to exist prior to and as a container of society. To be accurate, Agnew’s criticism was not targeting territory per se but the conceptual isomorphism between state, sovereignty, and territory. One of Agnew’s later major arguments would indeed be the idea that effective sovereignty is not necessarily predicated on and defined by the strict and fixed territorial boundaries of the state.

In the 1990s the excitement over the end of the Cold War and the transformations broadly associated with globalization produced new narratives calling for “the end of history,” “the end of geography,” and “the end of territories.” Transnationalism and cosmopolitanism gained
momentum, also spurred by the perception that the economic, political, and ecological risks societies were facing were too large to be effectively addressed by individual states. Responding to this deterritorializing frenzy, geographers observed, echoing Deleuze and Guattari, that the claim that territories were disappearing was wrongly placed, and that deterritorialization was necessarily associated with reterritorialization, as these were two sides of an ongoing territorialization process. Thus, on the one hand, geographers, among other scholars, acknowledged the “hollowing out” of the state caused by processes of denationalization, destatization, and internationalization. Yet, on the other hand, they mapped the emergence of new territories at the supra- and subnational scales, paying particular attention to (world) cities and regions. In this sense, globalization entailed not the implosion of territories but their explosion, with the territory of the state now being only one of many competing territories.

**Territoire**: a francophone perspective

While anglophone geography has clearly privileged a statist understanding of territory, francophone geography has followed a different path. Loosely informed by the Vidalian tradition of regional geography, with its focus on the unique relationship between a group of people and the space they inhabit, *territoire* (the French term for territory) has emerged mainly as a social and symbolic concept. True, the legal-political connotation – territory as the space divided, possessed, and controlled by a political authority – has also been present in francophone geography. But some of its most renowned representatives (e.g., Claude Raffestin, Joël Bonnemaison, Bernard Debarbieux, Jacques Lévy, Guy Di Méo, and Jean-Luc Piveteau) have generally preferred exploring notions of *territoire* and *territorialité* beyond their connection to the state. Overall, *territoire* has been theorized as a cultural space of belonging, imbued with geo symbols and individual and collective memories: a lived space (*espace vécu*), wherein people are linked to their habitat in an ecological relationship. Within this perspective, *territoire* is defined not so much by a principle of material appropriation, as it is in anglophone geography, but by a principle of cultural identification. It has to do with being more than having, since it is a central concept in processes of identity formation. As a *milieu de vie* (living environment), *territoire* allows people to give sense to their lives and to make sense of what surrounds them. *Territoire* is permeated by ethical, spiritual, symbolic, and affective values, and at times it is conceptualized, as it is in Gottmann (1973), as the product of a presocial, psychological human need for rootedness. This ecological and cultural territory is generally kept separated from the political territory, and in some instances it is also said to precede it. The focus, rather than being on the production of territory by political institutions, is on the everyday production of territories (*territoires du quotidien*), in a move which takes territory away from political geography and places it at the center of social and cultural geography.

It is clear that the francophone conception of territory comes close to how place has been conceptualized in anglophone humanistic geography. Not surprisingly, both share the same Heideggerian perspective on the human subject’s mode of being, which is always being-in-the-world or being-in-place (*Dasein*); however, while anglophone geography has in time moved away from an essentializing link between culture and place, also introducing issues of power, economy, and politics in the making of place, a great deal of francophone geography
TERRITORY AND TERRITORIALITY

still seems to approach both the notion of identity and the relationship between identity and territory in a rather unproblematic way.

One of the most interesting departures of francophone geography in relation to mainstream anglophone geography is its understanding of the notion of territoriality. Instead of a strategy to control people and goods by controlling an area, *teritorialité* is a relational and semantic system: it is aimed not at keeping people and things off a space, but at making space meaningful. This view first originated in the work of Claude Raffestin (1980), a Franco-Swiss geographer who, earlier and more than others, offered a comprehensive study of *territoire* and *teritorialité*. Combining Lefebvre’s insights into the production of space with Foucault’s notion of power relations, Raffestin conceives of *territoire* as the result of the projection of labor – understood as a combination of energy and information – by an individual or collective actor onto a given space. For Raffestin, *territoire* is constructed out of a pre-existing space on the basis of an actor’s program (a set of intentions and objectives) which signifies that space. Largely influenced by semiotics, Raffestin pays particular attention to the system of signs (“semiosphere,” to use Yuri Lotman’s term) which is available for any given culture and from which the actor draws the informational resources necessary for action. Thus, *territoire* is first and foremost a semiotized space, which can manifest itself at a plurality of scales. This emphasis on the system of signs also explains why Raffestin overlooks the notion of physical boundaries. While these are essential in a political-institutional understanding of territory, they are treated by Raffestin instead as a mere subset of the more general notion of “limit.” Quoting Wittgenstein, Raffestin (1980, 170) affirms that “the limits of my world are the limits of my language.” The extension of a *territoire*, therefore, is not necessarily geographical but semantic. Similarly, *teritorialité* is defined by Raffestin as a system of relations, exchanges, and flux that the territorializing actor entertains with both the physical environment (exteriority) and the social environment (alterity). There is here an explicit attempt to rewrite geography in light of social theory, anticipating the path which also anglophone geography would have then followed. Yet, until recently, Raffestin’s ideas have remained largely confined within francophone geography, with the only relevant exception of Italy, whose geographers have been the first to build on and to add empirical evidence to Raffestin’s theoretical framework.

**Territory: a new renaissance?**

After living in the shadow of place from around the mid-1990s, territory has since 2009 attracted new interest among geographers. This revival has taken various directions, from historical accounts of its origin and use to reconceptualizations aimed at overcoming its strict governmental character. One of the most ambitious projects on the historical excavation of the notion of territory is *The Birth of Territory* by Stuart Elden (2013). In this book and in numerous earlier journal articles, Elden proposes putting territory back in its historical context. Criticizing the largely ahistorical treatment of territory and territoriality in the social and political sciences, Elden offers a meticulous history of the notion, meaning, and use of territory by surveying an extensive amount of historical, political, and literary texts, from ancient Greece to eighteenth-century Europe. On this basis, Elden argues that in Western thought the modern concept of territory is closely tied to the notion of jurisdiction first theorized in the late Middle Ages by the Italian glossators of Justinian’s *Corpus Iuris Civilis* and then refined, in terms of exclusive sovereignty, in seventeenth-
and eighteenth-century Europe. In his reading, territory is a historically and geographically specific form of political organization associated with the gradual emergence of the modern state. Moving onto a more conceptual digression, Elden maintains that territory is both “land” and “terrain,” but also more than them. As a land, territory stands for a relation of property, providing sustenance to its people. As a terrain, territory is both the stage and the stake of conflict over land. Yet, neither a political-economic nor a political-strategic understanding can fully capture the specifics of territory as a political technology for measuring land and controlling terrain. Territory as a technology is the historical product of a series of advances in geometry, cartography, and land-surveying that have allowed for the effective establishment of linear boundaries. This quantification and measurability of space is what made territory possible (although in his book Elden specifies how territory as a political technology should be understood, in a Foucauldian sense, as an art or technique of the political rather than mere technology). For this reason, Elden maintains that boundaries are a second-order problem when it comes to territory, as territory is primarily a product of calculable space – although it might be argued that between the introduction of these calculable techniques in the seventeenth century and the emergence of a state system based on modern, exclusive territoriality in the nineteenth century, as the most recent historiography suggests, there is an important gap, which demands further historical investigation. Moreover, as maintained by Antonsich in an exchange with Elden in Progress in Human Geography, to exclusively associate territory with modern techniques of calculability risks obliterating other forms of territorial organizations that existed before, during, and after the rise of modern territory (Antonsich 2011; Elden 2011). True, The Birth of Territory also surveys a great deal of these political spatial arrangements. Yet, in the name of a rigorous etymology, Elden avoids labeling them territory.

The value of Elden’s work, though, consists not only in offering a comprehensive historical account, but also in reading territory in light of the Foucauldian analysis of power. Territory is about the reification and naturalization of space – as well as of the sociospatial relations that insist on it – by the state. This Foucauldian “territory effect” has been read by Elden in conjunction with the etymology of “territory,” whose Latin term, territorium, derives from the verb terrere, meaning to frighten, to terrorize. Although Elden (2009) engages with the debate surrounding this etymology, he privileges an analysis of the concrete, practical link between territory and terror as a way to interrogate more broadly contemporary geopolitics in an epoch of “war on terror.”

An alternative excursus in the history of political institutions is offered by Saskia Sassen (2006). For Sassen, territory equates with a bordered space imbricated with authority and rights into what she calls organizational assemblages. Contrary to Elden, she takes territory as a transhistorical category which cannot be reduced to the modern state. Her concern is therefore to map variable instantiations of territory across time. Once liberated from its exclusive association with the modern state, territory acquires for Sassen an analytical power that would allow exploring the formation of new types of bordering capabilities in the age of globalization.

A similar approach also characterizes the work of Marco Antonsich (2009). His aim is to rescue territory in an epoch where place has emerged as the dominant scientific paradigm. However, rather than reproducing notions of territory as a symbolic resource in nationalist discourses or as a control device in the hands of the state,
TERRITORY AND TERRITORIALITY

Antonsich proposes looking at territory as a space of political belonging beyond the sociospatial congruence of nation and state. This approach would also pay due attention to the agency of people, who are not passive pawns waiting to be controlled, contained, or disciplinized by the state but active players in the reproduction of territories.

Another attempt at reconceptualizing territory is that of Joe Painter (2010), who, along with Jessop, Brenner, and Jones (2008), suggests exploring its construction in close relation to the notion of network. Rather than treating territory and network as two rival principles of spatial organization, Painter shows how the former is actually the product of networked sociotechnical practices, building on his consolidated investigation of prosaic geographies of the state.

Besides a continuing interest in more traditional aspects of territory (Murphy 2012), the revival of this notion can also be associated with the “discovery” of Raffestin by anglophone geography (see Klauser 2012). The relational approach to territory pioneered by the Franco-Swiss geographer has also found new interpreters (Brighenti 2010), who further push the idea that territory does not revolve around space but revolves around a program of relatedness between individuals and that, in order to be implemented, territory has to be grounded.

Finally, a newly published journal, Territory, Politics, Governance seems to confirm the new interest surrounding the notion of territory today. Even in this case, territory is treated in a pluralist vein as a signifier of a political spatial arrangement not exclusively associated with the state. According to the journal’s editors, territory should be regarded not as a mere cage within which people are contained by the state, but as a medium for fulfilling positive projects from changing society to administering public goods. Forty years after Gottmann’s (1973) original

reflection on territory, this move has brought us back to where we started.

Text and intertextuality

Jonathan M. Smith  
Texas A&M University, USA

Geographers began to use “text,” “textuality,” and “intertextuality” as theoretical terms in the late 1980s, as part of what was then called the new cultural geography. These terms denoted concepts that had originated more than 20 years before in literary theory, and were adopted by geographers who felt a need to go beyond the humanistic hermeneutics of the 1970s. Geographers employed these terms and concepts in the interpretation of a wide range of objects, including scientific and literary documents, geopolitical discourses, maps, and landscapes, one result being a spreading conviction that the meaning of such objects is arbitrary, constructed, and endlessly contestable. Because the theory of which these terms were part represented meaning as unstable, provisional, partial, and vulnerable to deconstruction, these geographic studies were said to be poststructuralist. In its early days, Marxist geographers were among the harshest critics of poststructural geography; however, over the course of the 1990s, the two traditions merged to form critical geography.

The concept of text was not invented by literary theorists in the late 1960s. Nor was textual interpretation unknown among geographers prior to the late 1980s. Indeed, the concept of a text as an object of interpretation has a long history in the Christian and humanistic scholarship of the West.

In traditional hermeneutics, a text is a document subject to critical analysis and elucidation.
TEXT AND INTERTEXTUALITY

most often sacred scripture, but also, at times, a classical manuscript or legal document – and the commentary or interpretation was either an exposition of recondite terms and obscure passages, or an application of the “principal truth” of the text to a contemporary question of thought, taste, or conduct. This pattern began to break down for three reasons.

First, critics began to regard many more documents as texts, which is to say, as documents worthy of critical interpretation. At first they turned their attention to works of modern literature, many of which were replete with difficult points and obscure passages, and then later, in the late 1960s, they extended their commentary to anything – verbal or nonverbal – that could be made an object of interpretation. Thus critics began to speak of buildings, events, images, and landscapes as “texts.”

Second, the didactic authority of texts was diminished, and sometimes denied. The word “lesson” originally denoted a reading from scripture, and the relation between readers and texts such as the Bible or Plato’s Republic was understood as a tutorial relation. The authors of these texts were authorities, in one instance God himself, so men read these texts in the expectation of learning something from them. Under modernism, with its condescending view of the past and admiration for science, the relation between reader and text changed from a tutorial relation to what might be called an interrogatory relation. The text was not an oracle; it was a specimen.

Third, criticism became a creative activity. In the classical pattern, the critic was a humble conduit who conveyed the meaning of a great authority – perhaps the greatest authority – to a modern audience. His job was to make sure nothing had been added to, or subtracted from, the original, oracular message. In the modern period, however, it was common for a critic to discover in a text meanings the author of the text had never dreamed of. The exaltation of the critic over the author was complete when theorists such as Julia Kristeva and Roland Barthes began to challenge “authorial intention” and to speak of the author as a fiction produced by his or her text.

With this background in hand, we can define the theoretical terms “text,” “textuality,” and “intertextuality” as they have been used in geography since the late 1980s. A text is simply an object of interpretation, whether or not it has any words in, on, or beside it. An artifact becomes a text when a critic subjects it to interpretation. It makes no difference what the persons who fabricated the artifact were trying to express when they fabricated it, or whether they were trying to express anything at all, since authorial intentions are, at best, one reading among many. A text is not a product of authorial intention, but rather of critical intention.

Textuality is the property of being susceptible to interpretation. Applied to an artifact of verbal communication such as a book, it denotes the semantic properties of the book, as distinct from its physical properties, such as its weight, or economic properties, such as its price. The term is, however, most frequently employed to denote the property of being susceptible to interpretation in artifacts that were not intended, and are not generally recognized, as communicative gestures or utterances. To say that a landscape or an event has textuality is, therefore, simply to assert that it can be read or interpreted.

Critics coined the term “intertextuality” in the late 1960s to denote the state, allegedly common to all texts, of being joined in a dynamic and interrelated galaxy comprising all possible texts. The galaxy itself is called the intertext or social text. More specifically, the theory of intertextuality proposes that the meaning of any particular text is produced, and changed, by its shifting relations to other texts in the intertext. Text is,
of course, broadly defined, so the intertext takes in, not only verbal documents, but also images, objects, and events. In fact, it has often been claimed, most famously by Jacques Derrida, that there is “nothing outside the (inter)text.”

In theory, the texts of the intertext are represented as seething and stirring like particles in the vortex of Epicurus, their ever changing resonances, reactions, and relations resulting in an “endless play of signification.” The metaphor of a “semiotic machine” is sometimes used to suggest the robotic production of meaning by the revolutions of the intertext, which acts autonomously. In practice, of course, it is the critic who constructs (and deconstructs) the meaning of a text because it is the critic who proposes (or dismisses) the context in which the text is interpreted, and who thus produces (or deactivates) the signifying resonances, reactions, and relations. As we have seen, criticism has become a creative activity.

The main point to notice about the doctrine of intertextuality is that, on this doctrine, a meaning is never absolute. Another way to say this is that no meaning is a true meaning. Every meaning is partial, provisional, and dynamic. An “endless play of signification” means that it is impossible to fix or establish the significance of any text. No reading should be “privileged,” which is to say regarded as authoritative or correct, because every reading is the result of placing the text in an arbitrary context. As one geographer described it, “the appeal to context … involves the installation of borders that provide a secure frame within which calculations of an otherwise unbounded textuality can be contained,” but such borders are always arbitrary because “textuality has no beginning or end, it is … limitless” (Barnett 1999, 280–281, 284).

This arbitrariness of context gives rise to what is often called the “indeterminacy of meaning.” An early discussion of the idea by geographers described this as “the liberation of meaning in the post-modern world, the freedom of intertextuality with which we characteristically invert signs and symbols to recycle them in different contexts and thus transform their reference” (Cosgrove and Jackson 1987, 98). Another geographer similarly wrote that “intertextuality accounts for the apparent instability of meanings because their contexts change so rapidly” (Burgess 1990, 144). It was the idea of the arbitrariness of context and the indeterminacy of meaning that caused scholars in the 1980s to speak of a “crisis of meaning,” and the general theory that supposedly captured this crisis of topsy-turvy significance was called, expressively enough, antifoundationalism, poststructuralism, or deconstruction.

It must be understood that poststructuralist geographers did not look on this “crisis of meaning” with despondency and alarm. On the contrary, far from toiling to resolve the crisis, poststructuralist geographers did everything they could to make it worse.

This is why.

When we look out on the world, it appears to us fraught with meanings, and it appears that these meanings are stable, structured, and grounded in the very nature of things. We produce this meaningful world in an act of interpretation that places the objects of our interpretation (i.e., texts) in what we are accustomed to believe are their proper contexts. Taken together, these customary contexts or frames of interpretation are the structure or foundation of our interpreted world. However, according to the theory of poststructuralism, this world is an illusion because there are no proper contexts, and hence no true or stable meanings. What is more, this illusory world is a sinister illusion because it is constructed by powerful social interests, who enforce these customary contexts, and who thus stabilize these apparent meanings, in a form that they find satisfying or advantageous. As one
TEXT AND INTERTEXTUALITY

ageographer put it, “effects of social power are understood to take the form of wholly arbitrary stabilizations of the necessary indeterminacy of meaning” (Barnett 1999).

The purpose of poststructural geography, therefore, is to destabilize or “deconstruct” such meanings by announcing the arbitrariness of “proper” contexts, destroying the appearance of true foundations, and transporting humankind beyond the structure and into the “freedom of intertextuality.” Poststructuralism may therefore be thought of as a republication of Nietzsche’s “transvaluation of values,” not only because it aims to overthrow the established order (which it posits as arbitrary), but also because it ultimately grounds meaning in the will. When the will aims to produce aesthetic satisfactions, we may speak of the poetics of poststructural interpretation; when the will aims to produce rhetorical advantages, we may speak of its politics.

Much of what geographers have written about text, textuality, and intertextuality is at a very high level of abstraction, but these concepts have also been put into practice in several lines of empirical research. There were, for instance, several inquiries into the textual practices, hermeneutic protocols, and reading strategies that were dominant in geography’s research literature, travel writing, and geopolitical discourse. In the last instance there was mention of “deconstructing the textuality of foreign policy” by exposing the arbitrary and tendentious “discursive expressions” and “representational practices that are foreign policy” (O Tuathail 1993).

Poststructuralism also stimulated interest in critical readings of the “textuality of maps.” A map is, of course, a symbolic representation that conveys meaning much like a verbal text, but poststructural geographers were not concerned with map reading as conventionally understood. To read a map as a representation of a portion of the Earth’s surface was, after all, to read it in the context of the “discourse” of scientific inquiry. But a map could be read, and poststructural geographers believed that it should be read, in the context of ideological suspicion and exposure. It should be read as a representation that serves some powerful interest by stabilizing meaning in a form that satisfies or serves that interest.

The textual metaphor was most often employed by geographers who were interpreting landscapes. When they spoke of landscape as a text, they were, first of all, drawing attention to its textuality or susceptibility to interpretation. This was not an altogether original idea, since geographers had long spoken of “reading” or “interpreting” the cultural landscape, but using the term “text” allowed them to adopt (some might say smuggle ashore) the entire apparatus of poststructural interpretation, with its doctrines of intertextuality, indeterminacy, and the construction and deconstruction of meaning by power. The method was used most effectively by the geographers James and Nancy Duncan, who applied the poststructural concepts of text and intertextuality to landscape and thereby represented landscapes as transformations of ideology. The textual approach to landscape was thought especially promising because, viewed in this manner, the landscape appeared not only as an ideological representation, but also as a uniquely cunning representation that masked its ideological content. This was because “the cultural landscape serves to naturalize or concretize – to make normal – social relations as embodied in the various discourses and their combinations” (Schein 1997, 676).

Not all geographers welcomed the textual metaphor and its attendant theoretical doctrines. Many traditional cultural geographers scoffed at the jargon, which they dismissed as a pretentious way to talk about the established practice of reading the landscape. They were, no doubt, sometimes correct about the pretension, but
they were slow to grasp the radical implications of indeterminacy and deconstruction. The most strenuous objections to the textual metaphor and its attendant doctrines were raised by Marxist geographers who complained that it is a form of idealism that diverts attention from material relation, that encourages a life of ironic detachment rather than revolutionary action, and that cannot, in any event, explain anything.

On Marxism, meanings are mere reflections and shadows of material social relations. They are, as it were, symptoms of an underlying disorder; so to explain material social relations as a consequence of textual meanings is, on Marxism, to get causality backwards. It is an error akin to explaining an infection as an effect of inflammation. This is why, rather than speaking of the textuality of physical objects, Marxists urged geographers to speak of the “physicality of texts.” When they did this, they were encouraging greater attention not to the size and weight of books, but rather to the material relations that, according to Marxism, produce the consciousness of the authors and the content of books.

Ultimately the dispute between Marxists and poststructuralists was overcome in a dialectical synthesis that combined textuality and physicality in a hermeneutic cycle. This synthesis began with a denial of the “structural binary that separates discourse and materiality into separate ontological domains,” and ended with an affirmation that “in all practices, textuality and materiality are inextricably intertwined” (Braun 1996, 717). As with all dialectical syntheses, the validity of this argument is far from self-evident, but the utility of combining Marxism and poststructuralism is obvious. Both theories are subversive and revolutionary, both operate on an assumption that the world of appearances is an evil sham sustained by power, and both proceed in the faith that this evil sham can be exposed and defeated through theoretical redescription and critical analysis.

“Text,” “textuality,” and “intertextuality” are still used as terms of art in the geographic literature, but they are no longer seen as daring or new. The term “intertextuality” retains currency because it is so well adapted to describe the production of meaning in cyberspace and our ubiquitous media environment, neither of which existed when it was first coined (e.g., Cupples and Glynn 2013). The general theory of intertextuality also continues to underwrite claims that interpretation is characterized by “essential incompleteness,” that “ultimately, there is no final, “true” reading,” and that “texts are apt to be received, reworked and resisted” according to the “presuppositions” – which is to say, the contexts – in which they are read (Tyner 2005; Eriksson 2008).

TEXT AND INTERTEXTUALITY

Therapeutic landscapes

Allison M. Williams
McMaster University, Canada

The concept of therapeutic landscape is recognized by health geographers as one of the key contributions made to the study of health. Wilbert Gesler is credited as the pioneer of the idea, defining therapeutic landscapes as those changing places reputed to have an “enduring reputation for achieving physical, mental and spiritual healing” (1993: 171). He highlighted a number of therapeutic landscape themes, which he categorized as those having either “inner/meaning” (i.e., natural setting, built environment, sense of place, symbolic landscapes) or “outer/societal context” (i.e., beliefs and philosophies, social relations and/or inequalities, and territoriality). Gesler examined these themes in a number of traditional healing sites, including Epidauros (Greece), Lourdes (France), and Bath (England). Gesler’s thinking was subsequently embraced by a growing number of geographers and other health researchers (representing such diverse disciplines as nursing, kinesiology, medical anthropology, and sociology), many of whom were interested in present-day places for health. Although initially intended to encompass landscapes known for their therapeutic qualities, and therefore of interest to those experiencing ill-health, the concept has evolved to include places recognized as having health-promoting effects (Williams 2007). The idea has provided health geographers and others with a tool to better understand the characteristics of place that contribute to the making of healing places and symbolic landscapes, and to the marketing of such places.

Building on Gesler’s original work, scholarship has encompassed a large number and range of present-day applications, such as natural wilderness environments, and environments characterized as having a mix of natural and built attributes, such as monastery retreats, holy wells, pilgrimage sites, children’s camps, and yoga ashrams. Further, there has been a call for exploring sites that provide relief from the fast-paced, stress-filled lifestyles that characterize the Western world. These many contemporary applications continue to highlight the therapeutic place characteristics that contribute to healing; such characteristics are many and wide-ranging, contributing to better understanding the lesser-known mental, social, and spiritual elements of these sites.

Much of what has been learned from the physical places known for health has informed the practical application of the concept to a wide range of health-care sites and services. Some of the more common sites for exploration have included hospitals, residential care facilities, continuing care retirement communities, purpose-built residential homes for young adults with complex disabilities, respite centers, and the home as a setting of care. Research on hospital design for the mentally ill in the United Kingdom (Wood et al. 2013) provides an excellent application. A recent application of these ideas involves medical tourism sites, where forms of health care are combined with travel and leisure. Addressing the health-care spaces and places for particular groups, often in unique sites, frequently focuses on marginal and special populations, including addicts. Further, a small number of applications
THERAPEUTIC LANDSCAPES

have been made to specific cultural groups, such as indigenous peoples.

The symbolic component of the therapeutic landscapes concept is central to research on “fictive geographies,” as this is what reflects people’s perceptions and meanings of both illness and health. Employing literary analysis of fiction, a tool borrowed from cultural geography, has equipped health geographers to interpret literature using the therapeutic landscape concept as an analytic framework to better understand how place impacts health.

The variable nature of landscapes, with regard to their capacity for restoration and/or risk, suggests that places can be simultaneously healthful and hurtful. Such uneven landscape perceptions clearly illustrate the everyday nature and variable therapeutic qualities of place, while also recognizing the larger social, political, and economic context in which they are situated. For example, Masuda and Crabtree (2010), in their work on Vancouver’s (Canada) highly stigmatized Downtown Eastside, reveal a contradictory therapeutic response to environmental injustice, illuminating how the inner-city landscape operates as both restorative and risky for society’s most marginalized.

The performative nature of therapeutic landscapes is more recently highlighted in the rituals involved in the use of places characterized as therapeutic (i.e., healing rituals related to water, song, prayer). Similarly, there is a growing literature examining the mobile and embodied construction of therapeutic landscapes via walking modalities and other forms of travel.

The emergent topic of bluespace highlights the specific importance of water and sky in healing places, accentuating the known healing properties of water as one of the most important landscape elements.

Thiessen polygons

Ikuho Yamada  
Chuo University, Japan

Thiessen polygons, also known as Voronoi polygons, are generated around a set of points in a given space by assigning all locations in that space to the closest member of the point set. Any location in a Thiessen polygon is closer to the corresponding point inside it than to any other member of the point set. A spatial tessellation generated in this way is called a Voronoi diagram. The Voronoi diagram, as well as the Delaunay tessellation, which is its dual (as will be explained below), is an interdisciplinary concept that has been used extensively in many different fields including, but not limited to, archaeology, astrology, cartography, computational geometry, ecology, geography, geology, marketing, meteorology, physics, and urban and regional planning. Because the concept of the Voronoi diagram is fairly simple and has potential use in many applied fields, there is no surprise that it has been discovered independently in different contexts and that a variety of terms have been coined for it. While some of the terminologies will be introduced later in relation to a brief history of the Voronoi diagram, Voronoi-based terminology will be used hereafter since it seems to be the most extensively used in the literature.

Each Voronoi polygon may be seen as an area of influence of a point in a given set. For example, Voronoi polygons generated for a set of points representing fast-food restaurants can be used as approximated market areas of the restaurants given that foods and services provided by each restaurant are practically the same so that it is reasonable for customers to visit the nearest one. The concept of the Voronoi diagram is also utilized for the purposes of spatial interpolation, point pattern analysis, and locational optimization, as well as for models of spatial processes.

Brief history

As mentioned above, the concept of the Voronoi diagram has such a broad range of potential applications that it has been developed and (re)discovered independently in many research fields. This section discusses a brief history of the concept of the Voronoi diagram, mainly relying upon a comprehensive textbook on the Voronoi diagram by Okabe et al. (2000).

Diagrams that resemble the Voronoi diagram are found in the work of French philosopher and mathematician René Descartes (1596–1650). The diagrams are used in his discussion on cosmic fragmentation, but with no specific explanation about their construction. The first comprehensive presentations of the concept can be traced back to Peter Gustav Lejeune Dirichlet (1805–1859), a German mathematician, and Georgy Feodosevich Voronoy (1868–1908), a Ukrainian mathematician. They utilized a special form of the Voronoi diagram in their studies on positive definite quadratic forms. “Dirichlet domain” and “Voronoi region,” each reflecting their names, respectively, are arguably the most frequently encountered terms for the concept of the Voronoi polygon.

A more practical application is found in the work by Alfred H. Thiessen, an American meteorologist, after whom the term
“Thiessen polygon” was created. He used Thiessen/Voronoi polygons to obtain an improved estimation of regional rainfall averages (Thiessen 1911), which is one of the first examples of using the Voronoi diagram for spatial interpolation. Meteorologists as well as geographers and social scientists in related fields tend to prefer the term Thiessen polygons in their two-dimensional applications. Application of the Voronoi diagram for spatial interpolation has also been carried out in the context of estimation of ore reserves from observations at bore holes. In this type of application Voronoi polygons are simply called “area of influence polygons.”

The concept of the Voronoi diagram was rediscovered by Eugene Wigner and Frederick Seitz, Hungarian and American physicists, respectively, in their study of metallic sodium (Wigner and Seitz 1933). The term “Wigner-Seitz regions” is commonly used among physicists. Independent development of the concept of the Voronoi diagram continued in the fields of crystallography, cryptography, ecology, biology, and astronomy until the late twentieth century. While computational burdens of constructing Voronoi diagrams for large-scale data had long limited empirical applications, advancement in computational geometry that was stimulated by that in computer science since the 1960s has facilitated development of efficient algorithms starting around the 1980s.

Whereas the development and early applications of the concept of the Voronoi diagram mostly occurred in natural sciences as outlined above, applications in social sciences can also be found as early as the late nineteenth century in epidemiology and linguistics: a study of a cholera outbreak in London and a study of dialect variations in southwest Germany, respectively. Analyses of service/market areas, human territorial systems, and point patterns remain the major areas of applications in social sciences. In epidemiology, for example, the Voronoi diagram has been used to estimate service provision areas of medical facilities. Zwarenstein, Krige, and Wolff (1991) used such service provision areas to evaluate inequality in medical services between racial groups, and Tanser et al. (2001) used them to assess the hypothesis that patients choose the nearest medical facility, both in South Africa.

### Definition and use of the Voronoi diagram

For a given set of distinct, isolated $n$ points, $P = \{p_1, \ldots, p_n\}$, in a Euclidean plane, $R$, a Voronoi diagram is constructed by assigning all locations in $R$ to the closest member of $P$. An example of the Voronoi diagram is shown in Figure 1. This construction is referred to as “Voronoi tessellation.” The Voronoi diagram consists of $n$ polygons, each associated with a point in $P$. The polygons are referred to as “Voronoi” or “Thiessen polygons,” and each of the Voronoi polygons is convex with possible exceptions along the boundary of $R$. They

![Figure 1 Voronoi diagram.](image)
THIESSEN POLYGONS are collectively exhaustive in $R$ and mutually exclusive except for their boundaries; in other words, the Voronoi polygons exhaustively fill the plane $R$ with no overlap. In construction of the Voronoi diagram, a location that is equally close to two or more members in $P$ is assigned to the multiple members, which collectively form the boundaries of the Voronoi polygons. A boundary of the Voronoi polygon consists of line segments, which are referred to as “Voronoi edges.” Two Voronoi polygons that share the same Voronoi edge are considered to be “contiguous.” A vertex of a Voronoi polygon, that is, an end point of a Voronoi edge, is referred to as a “Voronoi vertex.” The points in $P$ are called “generators,” “generator points,” or “sites” in some literature, and the set $P$ is called the “generator set.” The related terminology is indicated in Figure 1.

Mathematically, the Voronoi polygon associated with $p_i$ (or simply, the Voronoi polygon of $p_i$), $V(p_i)$, is defined as shown in equation 1.

$$V(p_i) = \{x \mid ||x - x_i|| \leq ||x - x_j|| \text{ for } j \neq i, \ j \in I_n \}$$ (1)

where $x$ is a location vector for a point, $p$, $||x - x_i||$ is a distance between points $p$ and $p_i$, and $I_n$ is a set of integers from 1 to $n$. Then, the Voronoi diagram generated by $P$ (or simply, the Voronoi diagram of $P$) is given by the set

$$\mathcal{V} = \{V(p_1), \ldots, V(p_n)\}$$ (2)

So far, the Voronoi diagram has been discussed in relation to the two-dimensional Euclidean plane. However, the concept can readily be extended into the $m$-dimensional Euclidean space. The Voronoi tessellation in this case splits the space into nonoverlapping, space-filling polyhedrons instead of polygons. Moreover, Voronoi diagrams may be constructed in a space different from the Euclidean space; for example, Voronoi diagrams on a sphere, a cylinder, or a cone are possible. Because the majority of applications in geography and related fields remain in the planar Euclidean space, the following discussion focuses on the planar situations.

A dual diagram of the Voronoi diagram is called the “Delaunay triangulation.” For a given planar Voronoi diagram with three or more generator points that are not on the same line, a Delaunay triangulation is constructed by joining all pairs of generator points of which Voronoi polygons share the same edge. Figure 2 shows the Delaunay triangulation that corresponds to the Voronoi diagram in Figure 1. The resulting Delaunay diagram consists of nonoverlapping triangles, which are referred to as the “Delaunay triangles.” The Delaunay triangles are known to be as close to equilateral as possible. Edges and vertices of the Delaunay triangles are referred to as “Delaunay edges” and “Delaunay vertices,” respectively. Every Delaunay vertex is a generator point in $P$ by definition. The Delaunay triangulation is widely applied in the context of spatial interpolation of a spatially continuous variable. For instance, suppose that the generator set $P$ represents a set of weather stations taking rainfall measurements. Then imagine that each station is assigned a height that is proportional to
the measurement at that station. The Delaunay triangles whose vertices are projected to these heights form a surface estimating a continuous distribution of rainfall.

A Delaunay triangulation may also be constructed directly from the set of points \( P \). For each possible pair of members of \( P \), examine its circumscribed circle. Only when there are no points inside the circle, connect the two members. A resulting diagram after all possible pairs have been examined is the Delaunay triangulation. As a dual diagram of the Delaunay triangulation, a Voronoi diagram can be constructed from a given Delaunay triangulation, too. More specifically, it can be defined by perpendicular bisectors of the edges of the Delaunay triangles as Voronoi edges and corresponding circumcenters as Voronoi vertices.

Since the Voronoi tessellation assigns every location in a given space to the closest generator, one of the most straightforward uses of the Voronoi diagram is to identify the closest facility among a set of facilities given as a generator set. A facility location problem is thus a natural application field of the Voronoi diagram. As mentioned earlier, a market area analysis is another application field assuming that customers are likely to visit the closest store. The Voronoi polygons may be used as approximated market areas of generators so as to estimate the number of potential customers and/or to plan a location of a new restaurant.

In cartography, the Voronoi diagram is used to create a choropleth map. When each generator is given a certain property value, a choropleth map may be based on the value itself or on a density measure computed with the area of the Voronoi polygons if the property value is a count of some spatial objects, like a population. In the simplest case that each generator represents a single object like a person, 1 divided by the area of the Voronoi polygon indicates a density, for instance, a population density. The Voronoi diagram can also be used to solve the largest empty circle problem. For a given set of points \( P \), the problem is to find the largest empty circle of which center is in the convex hull of \( P \). Such a circle is given as the largest of the largest empty circles centered at the Voronoi vertices generated by \( P \). When \( P \) represents retail facilities, for example, the largest empty circle suggests an area that is the most inconvenient for shopping. Furthermore, Voronoi-like diagrams are often found in natural structures, so that Voronoi diagrams can be used to model spatial processes to form them. Crystallization is an example of such processes. Further applications will be introduced later in conjunction with extended versions of the Voronoi diagrams.

Extensions of the Voronoi diagram

The Voronoi diagram discussed so far is the most fundamental form of its kind and it has been extended in many directions since the early 1970s. This fundamental form of the Voronoi diagram is referred to as the “ordinary Voronoi diagram.” The basic idea to form a Voronoi diagram is that every location in a space is assigned to a member of a generator set, and resulting sets of locations assigned to all members of the generator set are collectively exhaustive and mutually exclusive except for their boundaries. Various forms of Voronoi diagrams are therefore possible depending on the rule of assigning a location to a generator and the generator set. An element in the generator set may be a point, a set of points, a line, a polygon, and so on. They may also be weighted differently reflecting a certain property that they possess; for example, the population of a city and the number of beds in a hospital. In the case of the ordinary Voronoi diagram, the assignment rule is to assign
THIESSEN POLYGONS

a location to the closest generator and the type of generator is a point with an equal weight.

The line Voronoi diagram is a Voronoi diagram generated for a generator set, \( L = \{L_1, \cdots, L_n\} \), of which elements, \( L_i \ (i = 1, \cdots, n) \), are line segments or geometric elements consisting of connected line segments. Line segments \( L_i \) may be curved, but they are assumed not to intersect with one another. Defining that the distance from an arbitrary point, \( p \), to a line segment \( L_i \) is the shortest-path Euclidean distance and denoted as \( d_i(p, L_i) \), the line Voronoi region associated with \( L_i \) is given by equation 3.

\[
V(L_i) = \{ p | d_i(p, L_i) \leq d_j(p, L_j) \text{ for } j \neq i, j \in L_i \} \tag{3}
\]

Note that the term “Voronoi region” is used instead of “Voronoi polygon” because each resulting region in this case is not necessarily a polygon. The area Voronoi diagram can be defined analogously. Okabe and his colleagues illustrate how the line and the area Voronoi diagrams can be utilized in the context of urban analysis to define areas of influence of road segments and parks, respectively. Okabe and Yoshikawa (1989), for instance, applied the line Voronoi diagram to investigate the potential impact of vehicle emissions on roadside trees along highways.

While the ordinary Voronoi diagram deals with a set of points \( P \) as a generator set, a family of Voronoi diagrams named the “higher-order Voronoi diagrams” considers a set of all possible subsets of \( k \) \((2 \leq k \leq n)\) points out of \( P \). Letting \( P_i^{(k)} \) be a subset of \( k \) points in \( P \), that is, \( P_i^{(k)} = \{p_{i1}, \cdots, p_{ik}\} \) and \( p_{ij} \in P \), a Voronoi polygon, \( V(P_i^{(k)}) \), of the “order-\( k \) Voronoi diagram” is composed of all locations that are closer to points in \( P_i^{(k)} \) than to any other points in \( P \). The order of the \( k \) points is not indifferent here; that is, point \( p_{i1} \) may be the closest from a location \( p \) in \( V(P_i^{(k)}) \), or it may be the \( k \)-th closest. When the order is taken into account, the resulting diagram is referred to as the “ordered order-\( k \) Voronoi diagram.” Applications of the higher-order Voronoi diagrams may be found in a facility location problem where identifying the \( k \) nearest facilities is critical; for example, a system to dispatch emergency vehicles would require identifying the second-nearest station when more than one vehicle is needed and/or vehicles in the closest station are unavailable.

Another direction of extensions is to consider an assignment rule based on the \( k \)-th nearest member of the generator set \( P \), rather than the nearest one. A Voronoi diagram constructed by assigning all locations in a space to the \( k \)-th nearest member of \( P \) is called the “\( k \)-th nearest-point Voronoi diagram.” A special case of \( k = 1 \) corresponds to the ordinary Voronoi diagram, and that of \( k = n \) is referred to as the “farthest-point Voronoi diagram.” Such Voronoi diagrams can also be used in the facility location problem mentioned above; the farthest-point Voronoi diagram in particular may be found in applications with a min-max criterion.

Other families of extensions can also be achieved by modifying the way in which a distance between two locations is determined. The Voronoi diagrams discussed above are based on the Euclidean distance, which almost implicitly assumes that one can take a straight path between any two locations in the space. The “shortest-path Voronoi diagram” is developed to deal with a situation where there exist some obstacles that prevent straight-line movement between locations. The obstacles may be natural geographic features such as rivers and lakes or artificial ones such as gated communities and large parks that one cannot go through. The underlying concept of the shortest-path Voronoi diagram can further be extended to handle a Voronoi diagram constructed in a bounded region for which a shortest path traversing

...
outside of the region is unrealistic. An obvious example in the context of geography is an island.

The distance between two locations may be weighted according to a certain property assigned to the locations. A family of Voronoi diagrams constructed based on a weighted distance is referred to as “weighted Voronoi diagrams”; the multiplicatively weighted distance and the additively weighted distance are often used. Other types of distance measures such as Manhattan distance and network distance facilitate further extensions. A Manhattan distance is defined as the sum of the absolute differences in the x- and the y-coordinates; a Voronoi diagram with the Manhattan distance would reflect a situation where movement between locations is restricted to a grid-like street network like the one in Manhattan. A network distance is measured along a street network, which may be seen as a more generic, realistic representation of movement in a city than the Manhattan distance. A Voronoi diagram in a network space is referred to as the “network Voronoi diagram.”

While construction of the network Voronoi diagram is much more complex than the ordinary Voronoi diagram, recent advancements in geographic information systems (GIS) have greatly contributed to practical implementation of its construction algorithms. SANET (Spatial Analysis along Networks), a toolbox for network-based spatial analysis in GIS, provides a tool for the network Voronoi diagram (Okabe, Okunuki, and Shiode 2006).

Time geography and space–time prism

Harvey J. Miller
The Ohio State University, USA

Time geography is a constraints-oriented approach to understanding human activities in space and time. Time geography recognizes that humans have fundamental spatial and temporal limitations: people can physically only be in one place at a time and activities occur at a sparse set of places for limited durations. Participating in an activity requires allocating scarce available time to access and conduct the activity. Constraints on activity participation include the location and timing of anchors that compel presence (such as home and work), the time budget for access and activity, and the ability to trade time for space in using mobility or information and communication technologies (ICTs). Time geography is a physical not a behavioral theory; it highlights the necessary spatiotemporal conditions for human activities, but does not explain the sufficient events that lead to specific activities. But since these necessary conditions vary by individual and situation, time geography supports an approach to understanding human and environmental systems that recognizes individual histories and the importance of geographic context.

Time geography is consistent with some core ideas in fields such as geography, transportation, urban science, social sciences, and environmental sciences. These include an integrated perspective on human and physical phenomena, the need to build macro-level explanations from micro-level processing, and situating human activities within context. Basic time geographic concepts, such as events being sparsely distributed in time and space, limited time availability, and trading time for space to access activities, seem mundane, since they are common and correspond with everyday experience. But this is why time geography is needed: these seemingly banal but utterly crucial factors in our scientific explanations of human behavior should not be neglected. Time geography provides a framework that demands recognition of the fundamental constraints underlying human experience and also provides an effective conceptual system for keeping track of these conditions.

Time geography originates from Professor Torsten Hägerstrand (1916–2004), a Swedish geographer who spent his career at the University of Lund. He nurtured the ideas for a long time, but time geography emerged dramatically to the international scientific community with a now-famous 1969 presidential address to the Regional Science Association (Hägerstrand 1970). Hägerstrand was concerned that human geography and regional science were neglecting much of what comprises a livable world. He also wanted to provide a counterbalance to increasing specialization and fragmentation in science, technology, and administration by offering a more holistic view of human activities. Hägerstrand believed in the integrative power of the regional approach in geography, but felt that it needed to be more inclusive and rich. Time geography upgrades the regional approach by describing the “bare skeleton” of spatiotemporal conditions and constraints that emerge from the interplay of historical and geographical factors.

Time geography is an active and flourishing research domain one half-century after its initial
conceptualization in the 1960s. This ranks time geography among elite and enduring scientific ideas. Time geography has endured for good reasons. It is beautiful: the geometry of the space–time path and prism (discussed below) and their relationships are intuitive and appealing. It is elegant: it can help to explain much with few basic principles. It is robust: it can help us understand a wide range of phenomena in human and linked human-environmental systems. It is sensitive: it treats people as individuals and recognizes social differences across a wide range of factors (gender, age, socioeconomic status, culture) as well as geographic context. It is ecological: it connects the individual to the aggregate, balancing nomothetic law seeking with context and situation, as well as balancing agency and structure. Finally, it is practical: Hägerstrand was prescient when thinking about how to keep track of the basic spatial and temporal existential facts of human activities. It is now possible to collect, store, manage, and analyze individual-level data on mobile objects and human activities with ease and power that would seem magical from the perspective of the 1960s.

Classical time geography

Time geography recognizes three major types of constraints on human activities. Capability constraints limit the activities of individuals through their own physical capabilities and/or available resources. People need to conduct maintenance activities such as eating and sleeping; these require time and place. Also, individuals with private automobiles can generally travel faster than individuals who walk or rely on public transportation. Coupling constraints define where, when, and for how long an individual has to join with other individuals for shared activities such as work, meetings, and classes. Authority constraints are fiat restrictions over particular space–time domains. For example, a shopping mall or gated community can make it difficult and illegal to enter at designated times, while a public street cannot.

Space–time path

Activities such as personal and domestic maintenance, work, shopping, health care, education, and recreation are sparsely distributed in time and space; they are available for limited duration at relatively few locations. Participating in activities requires trading time for space to access these locations at their available times. The space–time path highlights these requirements. Figure 1 illustrates a space–time path between activity stations. Stations are places where activities can occur; classical time geography treats these as tubes designating their locations in space and availability in time (e.g., work hours, operating hours for a store, appointments, scheduled lectures). The classical space–time path focuses on physical mobility and interaction. Virtual interaction via ICTs is possible; for example, a telephone call can be represented as a connection between two space–time paths. However, virtual interaction is muted relative to physical interaction in the classic theory.

Time geography also classifies activities based on their flexibility for an individual. Fixed activities are those that cannot be easily rescheduled or relocated (e.g., work, meetings), while flexible activities can be more easily rescheduled and/or occur at more than one location (e.g., shopping, recreation). These categories can be arbitrary; for example, a software developer can code in an office or a cafe. Nevertheless, the dichotomy provides an effective means for understanding how the location and timing of some activities condition accessibility to other activities. Fixed activities act as space–time anchors because other
activities must occur at the temporal gaps between fixed activities.

**Space–time prism**

The *space–time prism* (STP) highlights the influence of space–time anchors on the ability to participate in flexible activities. The STP is the envelope of all possible space–time paths between known locations and times. Figure 2 illustrates a planar STP. In this case, two *space–time anchors* frame a prism. Anchors correspond to known locations and times for the mobile object. These are often (but not always) the locations and times of fixed activities that compel presence. A maximum travel speed represents the object’s mobility capabilities; in classic time geography this is a uniform across space and time. (Time geography uses the term “velocity,” but this is incorrect since velocity implies magnitude and direction. “Speed” implies magnitude only and is, therefore, the more appropriate term.) Given these anchors and the speed limit, the prism defines the envelope all possible space–time paths between the anchors. The spatial footprint of the STP is the *potential path area* (PPA); this is the region in space that is accessible to the moving object.

The prism in Figure 2 is general since it accounts for stationary activity time and has two anchors that are spatially separate. A prism without stationary activity time consists only of its *time-forward cone* rooted at the first anchor and its *time-backward cone* rooted at the second anchor. The STP will have a larger volume and PPA, as no stationary activity means more time to be mobile. The two anchors may also be coincident spatially; this prism consists of two right cones instead of oblique cones as in Figure 2. A prism may also have only one anchor. An STP with its first anchor only is a time-forward cone delimiting all destinations that can be reached from that origin within a specific time limit. Conversely, a prism with its second anchor only is a time-backward cone delimiting all origins that can reach that destination within a specific time limit.

The STP measures *accessibility*: the ability for an individual to travel and participate in activities and the amount of time available for activity participation at locations. An activity at a station is not feasible unless that station intersects with the prism spatially and temporally, the latter for at least as long as the minimum activity time required. This delimits the subset of opportunities in an environment that is available to a person based on their STP constraints.

The STP provides a dramatically different image of accessibility than place-based accessibility measures, such as those based on spatial interaction (“gravity”) models or simply counting the number of opportunities near a person’s...
home and work location. The locations and timings of fixed activities vary by age/life cycle stage, socioeconomic status and culture. For example, STP-based accessibility measures capture gender differences in accessibility due to household organization that are missed by place-based accessibility measures such as home–work commute length. Place-based accessibility measures assume everyone at a place, such as home and work, has the same space–time scheduling constraints, while people-based measures derived from the space–time prims recognize individual capability constraints that are masked through homogenization by place. Time geography also facilitates understanding how the temporal organization of service and trading hours can have differential impacts beyond the locations of services and businesses.

Bundling and intersections

Time geography recognizes two types of relationships between paths and prisms. Bundling refers to the convergence in space and time of
two or more paths. Path bundling is necessary (although not sufficient) evidence of shared activities and individuals meshing their space–time activities to participate in projects. Bundling can occur when objects are in motion or stationary; examples of the former include public transportation and ride-sharing. Intersection is the condition of two or more time geographic features sharing some locations in space with respect to time. Two or more people cannot physically meet unless their STPs intersect, or a path is within an STP.

Bundling and intersections are necessary conditions for the emergence of broader space–time activity systems, such as a university or a city. Time geography is an ecological theory; it considers interactions between individuals and between the individual and the aggregate. Bundling and intersections require individuals to synchronize (coordinate over time) as well as synchronize (coordinate over space). Coordination also occurs at multiple scales. Individuals must conduct projects consisting of sequenced activities linked by mobility events to meet larger goals such as hosting a dinner party. Cities and regions are time systems balancing the supply of available time and demands on that time. This is a rich and intricate conceptualization of cities and societies; Alan Pred memorably referred to a “ballet of adjustments” as disruptions propagate through a time system due to activities and projects changing to meet the new space–time requirements for participation and interaction.

Analytical time geography

Classical time geography is conceptually rich but limited analytically. The rise of geographic information systems (GIS) motivated renewed interest in time geography, particularly in relaxing strict assumptions such as the maximum speed constraining an STP being uniform in space and time. The development and deployment of location-aware technologies (LATs), such as the global positioning system (GPS), mobile phones, and radiofrequency identification (RFID) chips, have greatly expanded capabilities for collecting data on mobile objects and have led to the development of mobile objects databases and mobility mining or exploratory analysis of mobile objects data. These scientific and technological developments led to the development of analytical time geography and supporting GIS software.

Path analytics

Location-aware technologies do not generate space–time paths directly; they generate a temporal sequence of spatial locations that are used to construct the path. There are several ways to generate this temporal sequence. Event-based recording captures the time and location when a specified event occurs; for example, a person texting or calling using a mobile phone. Time-based recording captures mobile object positions at regular time intervals; this typifies GPS receivers. In change-based recording a capture occurs when the position of the object is sufficiently different from a previous location; this includes dead-reckoning methods as well as some mobile objects data technologies that avoid recording locations to manage data volume. Location-based recording occur when a mobile object comes close to locations where sensors are located; examples include stationary radiofrequency identification and Bluetooth sensors.

The simplest and most common way to generate a path is linear interpolation: assume the object followed the straight-line segment between recorded locations. This works well for time-based and change-based recording with high capture frequencies. Event-based recording creates more issues since events are often not
very frequent, and the spatial resolution can be coarse and variable; this is often the case with mobile phone data resolved only to membership in a service cell. Even coarser are paths derived from location–based recording; these are often simply sequences of visits at the sensor locations. Space–time paths can also be matched to other spatially referenced data such as transportation networks.

The ease of collecting space–time path data from location-aware technologies often comes at the expense of path semantics: details about the moving objects such as the reasons for mobility behavior. Semantics can be recovered by overlaying paths with other georeferenced data. This method can produce errors related to data inaccuracies and intrinsic ambiguities. For example, GPS positional error means that it can be hard to tell if a person is inside or outside of an activity location, for example, a coffee house. If the person is inside the coffee house, what was she doing – dining, working, socializing, or some combination of the above? Often, there is no unambiguous link between locations and activities, especially in an era with near-ubiquitous access to information and communication. Methods for recovering path semantics include decomposing the trajectory into a sequence of moves and stops, and annotating these sequences based on map matching with background geographic information. Also available are advanced data mining techniques such as machine learning algorithms.

Table 1 summarizes the fundamental measurements available from space–time paths. The primitive position allows the derivation of distance, direction, and spatial extent in the object’s movement; an example is spatial range methods. From these primary derivatives the spatial distribution of the object, changes in direction, and the path’s sinuosity can be derived. From the temporal primitives instant and interval the duration of the object’s movement and its speed, as well as the temporal distribution of the object’s movement and changes in duration, can be derived. Primary derivatives from combining spatial and temporal intervals include the object’s speed (a scalar) and velocity (a vector), and corresponding secondary derivatives acceleration and an approaching rate with respect to a location, boundary or region.

**Prism analytics**

It is difficult to analytically describe the entire STP. However, it is easy to describe its spatial extent at a moment in time; this can serve as

the basis for a wide range of prism analytics. STP parameters are \( \{x_i, x_j, t_i, t_j, s_{ij}, a_{ij}\} \) where \( x_i, x_j \) are the first and second anchor locations with associated departure and arrival times \( t_i, t_j \) respectively, \( s_{ij} \) is the maximum travel speed, and \( a_{ij} \) is the stationary activity time. At a moment in time \( t \in (t_i, t_j) \), the spatial extent of an STP (denoted by \( Z_{ij}(t) \)) is the intersection of three convex spatial sets: (i) the future disc \( f(t) \) comprising all locations that can be reached from the first anchor by time \( t_i + t \); (ii) the past disc \( p(t) \) encompassing all locations at time \( t \) that can reach the second anchor by time \( t_j - t \); and (iii) the geo-ellipse \( g_{ij} \) that constrains the prism locations to account for any stationary activity time:

\[
Z_{ij}(t) = \{f(t) \cap p(t) \cap g_{ij}\}
\]

(1)

\[
f(t) = \{x \mid \|x - x_i\| \leq (t - t_i) s_{ij}\}
\]

(2)

\[
p(t) = \{x \mid \|x - x_j\| \leq (t_j - t) s_{ij}\}
\]

(3)

\[
g_{ij} = \{x \mid \|x - x_i\| + \|x - x_j\| \\
\leq (t_j - t_i - a_{ij}) s_{ij}\}
\]

(4)

Figure 3 provides an illustration. This definition of the STP is not limited to 2-D space. In 1-D space, the sets described by equations (2)–(4) are line segments. In 2-D space, the discs are circles and the geo-ellipse is an ellipse. In 3-D space, the discs are spheres and the geo-ellipse is a spheroid. There are scalable methods for calculating these objects and their intersections. Also, only one or two of the sets are relevant at any time, since the future and past disc change in size and may be enclosed by the other two objects. For example, with a general prism as in Figure 2, it is only necessary to solve (in the following order) a disc, a disc–ellipse intersection, an ellipse, a disc–ellipse intersection, and finally a disc. Similarly, finding path–prism intersections only requires testing if a point lies within a disc, ellipse, or a disc–ellipse intersection. Finding a prism–prism intersection requires solving for the intersection of two, three, or four of the sets based on the prisms’ morphologies at that moment in time. The worst case is a four-set intersection involving two discs and two ellipses (Miller 2005).

Over time, the future disc traces the time-forward cone with an apex at the first anchor, the past disc traces the time-backward with an apex at the second anchor and the geo-ellipse is a cylinder. Over time, the prism in space is a lens-like set that traces the PPA footprint. These dynamics can be computed at discrete moments in time using the static construction described above and reconstruct the corresponding spatiotemporal region for the prism.

Error and uncertainty in paths and prisms

Error in space–time paths results from two sources. Measurement error occurs when the recording of a mobile object’s location has noise or uncertainty. The left-hand side of Figure 4 illustrates this for one segment of a space–time path; the captured locations have some degree of spatial error. This is equivalent to the problem of error in line segments and polylines, a well-established topic in the GIS literature. Sampling error occurs when the captured locations undersample an object’s movement pattern. This creates a spatial uncertainty region equivalent to the STP over time. Therefore, a space–time path with sampling error can be viewed as a sequence of linked STPs. The right-hand side of Figure 4 illustrates this; the black curve is the actual path of the mobile object, the dashed red polyline indicates the interpolated movement, and the blue ellipses indicate the spatial uncertainty region surrounding each paired sample locations.
Combined measurement and sampling error in a space–time path is equivalent to an STP with measurement error. Therefore, if it is possible to solve the measurement error problem for STPs it is also possible to solve the problem of combined measurement and sampling errors in space–time paths. One strategy is Monte Carlo simulation, which involves generating multiple prism realizations based on sampling from the stochastic error distributions. Monte Carlo simulation is effective for theoretical investigations but it is cumbersome for applications: it is awkward to run prism error simulations when executing STP-based mobile objects database queries or measuring accessibility in a model.

Spatial error propagation theory provides an analytical strategy for analyzing prism error. Given a direct geographic measurement \( \mathbf{x} = \mu_x + \varepsilon_x \), where \( \mu_x \) is the true location vector and \( \varepsilon_x \) is an error vector, it must be determined how that error propagates through a geographic operation \( \mathbf{y} = f(\mathbf{x}) \). If \( f(\mathbf{x}) \) is nonlinear, the error propagation is approximated using the first-order partial derivatives of the function. In the case of the analytical prism, the relevant functions are the intersections of the boundaries of spatial objects described by equations (2)–(4). These boundaries are:

\[
\begin{align*}
f_i : & \quad \|\mathbf{x} - \mathbf{x}_i\| - (t - t_i)s_{ij} = 0 \quad (5) \\
p_j : & \quad \|\mathbf{x} - \mathbf{x}_j\| - (t_j - t)s_{ij} = 0 \quad (6) \\
g_{ij} : & \quad \|\mathbf{x} - \mathbf{x}_i\| + \|\mathbf{x} - \mathbf{x}_j\| - (t_j - t_i - a_{ij})s_{ij} = 0 \quad (7)
\end{align*}
\]

A problem is that equations (5)–(7) define these boundaries implicitly rather than explicitly (that is, in the form \( f(x, y) = 0 \) rather than \( f(x) = y \)), meaning that solving for the intersection points requires finding the roots of high order polynomials. This difficulty can be resolved using implicit function methods that allow calculation of the required first order partial derivatives without having their explicit functions. This allows the error propagation from STP parameters to the constructed STP and to STP intersections to be estimated analytically. However, some of the required circle and ellipse intersection cases are
still unsolved and the techniques are not tractable beyond two STP intersections. Still required are scalable approximations and heuristics for STP error based on these analytical techniques. The analytical techniques can also serve as bounds for improving the efficiency of simulation-based techniques.

The methods discussed above estimate error propagation from measured STP parameters to the constructed object. Another strategy is to construct objects that encompass the possible STP consistent with the prism parameters and their errors. A rough STP consists of the upper and lower bounds on an STP. A reliable STP is the set of space–time locations where an individual can conduct an activity and meet the second anchor constraints with a specified probability.

Properties of the prism interior

The STP is traditionally a binary concept; all locations within the prism interior are considered to be equally accessible. However, this is a simple characterization that masks intricate properties of the prism interior. Intuitively, it would be expected that the distribution of visit probabilities would be unequal: locations that are near the space–time axis connecting the prism anchors are more likely to be visited than locations near the prism boundary since there are more possible paths through the former.

One way to model visit probabilities within a planar STP is to use the theory of random walks (RWs). An RW is a stochastic process in discrete space and time; given a spatial lattice of discrete locations, an RW involves, at each time step, a random choice of direction. Results from RW theory confirm intuition that locations near a prism anchor in a forward-time or backward-time cone are more likely to be visited; visit probabilities follow a bivariate multinomial distribution centered on the prism anchor.

However, movement within an STP with two anchors is not completely random; the object needs to move from the first prism anchor to second anchor within the time budget. A directed random walk (DRW) is an RW process with directional biases. A DRW process constrained by an STP requires updating the RW direction biases at each step to account for the remaining time to travel to the second anchor given the speed limit. This suggests a visit probability distribution similar to a bivariate normal distribution that is centered on the axis connecting the anchors and moves along that axis with respect to time.

A technique for modeling directed movement in continuous time and space is Brownian bridges (BBs). A BB is a continuous stochastic process between two known values; it has been applied widely to model animal movement between recorded locations. While BB can capture directionally biased random movement between prism anchors, it is not constrained by a maximum speed and, therefore, does not capture the STP boundary; it is still possible for the object to travel outside the prism boundary. A truncated Brownian bridge (TBB) imposes a maximum speed on a BB process, fully representing STP constraints. Figure 5 illustrates visit probabilities at a moment in time within the PPA of a planar STP based on a TBB process. Figure 5 shows the two prism anchors with the spatial projection of the space–time axis connecting the anchors. The gray area is the PPA for the STP; these locations have zero probability of being occupied at this moment in time. The blue, yellow, orange and red colors show increasing probability that the locations may be occupied by the object at that moment in time. These results are also consistent with the assumption of a bivariate random distribution whose center moves with time along the axis connecting the
anchor points; however, rather than assumed it is derived from fundamental movement principles.

Another strategy for estimating visit probabilities within planar STPs is to use spatial interpolation to infer unknown object locations from the known locations at the prism anchors. This assumes that the most likely locations are along the axis between the anchors, but as seen above this assumption is consistent with theory. *Time-geographic density estimation* (TDE) integrates kernel density estimation with the constraints imposed by an STP. This method can generate the fine-grained movement patterns of objects between anchors derived from sparse tracking data.

**Other types of space–time prisms**

A planar STP has interesting properties and is useful for applications where it can be assumed that objects move in constrained space with a uniform maximum speed. However, in some applications the assumptions of unconstrained space and uniform maximum speed are unrealistic; examples include vehicles within a transportation network or movement across terrain. In addition, the STP assumes unrealistic motions such as infinite rates of acceleration and deceleration.

A *network time prism* (NTP) is a prism subject to network routes and allowable speeds that vary by network arc and, possibly, time. Figure 6 illustrates an NTP for a network embedded in 2-D space with time along the third orthogonal dimension (Kuijpers and Othman 2009). The green subportion of the network arcs is the *potential network area* (PNA), the network analog of the planar PPA; these are the accessible locations within the network. The red polygon comprises the full NTP; this is the envelope of possible space–time paths between the anchors constrained by the network.

Calculating an NTP involves three steps. A precomputation step uses the planar PPA as an upper bound on the NPA; this speeds computation by eliminating network nodes that cannot possibly be in the NPA. It then solves for the shortest path tree in this subnetwork twice: once for travel from the first anchor and a second time for travel to the second anchor. The procedure assigns the earliest arrival time and latest departure time at each node. The second step builds the spatial footprint of the NTP by testing if only one of an arc’s end nodes is included in the NPA and (if so) solving for the NPA boundaries within the edge. The third step computes the full spatiotemporal region of the NTP based on the earliest arrival times and latest departure times at network vertices. These arrival and departure times dictate, for each node incident to an arc, whether the mobile object can traverse the full arc to an adjacent node or can only traverse partway and return to the original node. These cases correspond to the
Figure 6  A network time prism.

rectangular and triangular regions in Figure 6, respectively. The computational bottleneck in the algorithm is the shortest path trees in the precomputation step; although this is only applied to a subportion of the network, this subnetwork can be large, as can the number of prisms to be processed. However, the Boolean query about whether two NTPs intersect can be solved analytically.

Similar to an STP, the parameters of an NTP can also be measured with uncertainty. An anchor region is the set of all possible locations and times for a prism anchor within a network arc. These regions are not necessarily continuous in space or time and can have nonuniform probabilities. There are two ways to calculate an NTP with anchor regions. The first way is to calculate the envelope of all NTPs having an anchor point within a given anchor region. The second way is to calculate, for any space–time point, the probability that an NTP with given anchor regions contains that point. As with the standard NTP, the computational bottleneck is the precomputation phase involving shortest path calculations.

TIME GEOGRAPHY AND SPACE–TIME PRISM

A field time prism (FTP) is a planar STP where travel speeds (magnitude) or velocities (magnitude and direction) vary continuously across space. Fields are useful for describing movement across terrain or through water and air that are subject to currents. Fields can extend the NTP by treating edges as 2-D regions with continuously varying speeds or velocities due to factors such as traffic. In these cases, space–time paths have unobserved components corresponding to minimum cost curves through an inverse speed or velocity field rather than straight line segments through a uniform plane. The FTP generalizes the prism concept: the STP and the long standing concept of isochrones (curves of equal travel time) are special cases of the FTP. It also links time geography to the continuous transportation or urban fields tradition in quantitative geography and regional science.

Space–time prisms as described above are physically impossible; they assume that the mobile object can instantly accelerate and decelerate at locations such as the prism anchors and the prism’s sharp corners. Physical limitations on acceleration and deceleration mean that an STP is an overestimate of the true space–time region accessible to the object. While this may not matter for some STP applications, kinetics can make a difference for applications such as microscale movement (e.g., pedestrians, athletes), active transport modes such as bicycling, movement through media such as airplanes and ships, and animal behavior. It can also make a difference for applications in sustainable transportation, as vehicle fuel consumption and emissions are often dominated by acceleration events.

A kinetic time prism (KTP) is the set of all possible kinetic paths between two locations and times, where a kinetic path is a space–time path that obeys physical limits on acceleration and deceleration. Figure 7 illustrates a KTP in
1-D space and time, overlaid with a classic STP. Solving a KTP is scalable in 1-D space and time but complex in 2-D space. In 2-D space, only one-quarter of the prism must be solved; the remainder can be obtained through point and reflection symmetries. But calculating the first quarter of the KTP requires solving parametric functions describing the 1-D prism rotating around the line connecting the prism anchors. This can only be accomplished if it is assumed that the object’s initial heading is unknown; still open is the case where the object’s initial heading is known.

Path and prisms collections

With the proliferation of location-aware technologies generating mobile objects data, it is often the case that there are large collections of space–time paths and prisms to analyze. With these collections, it is often useful to summarize the paths or prisms through clustering (finding groups of similar paths or prism) or aggregation (forming a composite representative paths or prisms). It may also be desired to search through a collection of paths and prisms for other cases that resemble a reference path or prism. This requires methods for calculating path and prism similarity.

Path similarity is the degree of correspondence between two space–time paths. Geometric similarity measures focus only on the geometry, ignoring sequence and time; these include Euclidean and Hausdorff distances. Euclidean distances, such as the average, minimum and maximum distance are intuitive and scalable; however these measures are sensitive to noise and outliers. The Hausdorff distance is the maximum distance from a location in one path to the closest location in the other path. However, the Hausdorff distance can be misleading, as it does not take into account the temporal sequence of the path locations, only their geometry.

Dynamic similarity measures include Fréchet distance, dynamic time warping, longest common subsequences, and edit–distance functions. Unlike Hausdorff, the Fréchet distance takes into account the sequence of locations in the path and is, therefore, better suited to mobile objects. One way to think about the Fréchet distance is to imagine two space–time paths representing a person walking a dog: the Fréchet distance is the shortest leash that connects the two. Dynamic time warping measures the similarity between two sequences or trajectories based on the effort involved to stretch or compress time to get the sequences to match. Least common subsequence (LCSS) measures similarity based on the length of least common subsequence between two sequences. Edit-distance functions are a generalization of LCSS; these measure similarities between sequential patterns based on the cost of the insertion, deletion, and substitution operations required to transform one sequence into the other.

Other methods for analyzing collections of space–time paths include path clustering methods and spatial field methods. Path clustering methods find groupings of similar space–time...
paths in collections of mobile objects; these are often based on path similarity measures such as the ones already discussed. Spatial field methods translate movement patterns of objects into fields or surfaces that summarize mobility and activity frequency by geographic location, allowing the identification of “hot spots” or locations with high mobility activity.

Similar to space–time paths, it may desired to analyze a collection of space–time prisms for patterns. This may involve clustering or aggregating prisms based on morphology, finding prisms similar to reference prism, and summarizing and aggregating prisms to discover synoptic patterns. However, to date there has been little research on these questions; it is a much less developed research topic than path comparison and summarization. A fundamental problem is to develop efficient numeric measures that summarize meaningful prism properties. It is easy to calculate basic properties such as prism volume and PPA size for classic prisms, as these have an elegant geometry consisting of cones and cylinders. More generally, measures are required that can capture a wide range of morphological properties. These properties may be straightforward for classic prisms, but more complex prisms such as NTPs, FTPs, and KTPs, or prisms with fuzzy or probabilistic boundaries have more complex shapes and, consequently, are more difficult to describe analytically.

One possible strategy for measuring planar space–time prism morphology is shape analysis or quantitative measures summarizing geometric form. Shape analytical techniques typically reduce geometric forms to a single numeric indicator or a small set of indicators; for example, roughness, perforation, and elongation. However, most shape measures are specific to 2-D space: required are scalable shape measures that can handle 3- or 4-D space (treating time as static) and the evolution of shape (treating time as dynamic).

A possible way to summarize NTP structure is through network indices based on graph theory. Network indices summarize network properties such as connectivity, the distribution of arc lengths/costs, and properties of shortest paths and tours within the network. Graph theory and network analysis is a very well established field that has been newly reinvigorated due to the rise of network science to analyze phenomena such as social network and cities. A research frontier is determining which existing network indices describe relevant properties of NTPs, and the development of new network indices tailored for NTPs.

Joint accessibility and time ecology

As mentioned, time geography recognizes bundling and intersections among paths and prisms as indicators of shared activities. The next step beyond calculating bundles and intersections are the higher-level properties associated with space–time coordination and dynamics.

Collective motion methods focus on individual object movement patterns within the context of a larger group of mobile objects. Distance-based measures search for collective patterns, such as flocks, by searching for moving objects that are densely connected in space given user-defined distance and time thresholds. Relative motion methods consider the individuals’ directions to detect collective patterns such as flocking, leadership and convergence in a group of moving objects. Joint accessibility measures use prism–prism intersections as a basis for analyzing the potential benefits to coordinated activity participation.

Static measures of collective motion and joint accessibility do not directly address the ultimate
goal of understanding the dynamic processes though which shared and interlinked activities form and intertwine in space and time. This highlights a weakness of time geography: its inability to specify an explanation of human activity that goes beyond the implications of space–time constraints limiting possible activities. Time geography can explain why infeasible activities did not occur, but it cannot explain why some feasible activities occurred while others did not. However, it would be difficult to build a dynamic, processes-based time ecology theory based only on the negative space implied by prisms and stations. A more promising way forward is to link time geography with modeling approaches such as activity-based travel demand models and agent-based models that naturally capture the emergent properties associated with individuals’ interactions over space and time. The natural fit between activity-based analysis and time geography is well recognized and well utilized in many models. However, the linkages between time geography and agent-based modeling are less developed, somewhat surprisingly given their complementarity.

**Time geography and virtual interaction**

Classical time geography recognizes the possibility of virtual interaction; for example, Hägerstrand (1970) shows a telephone call between two space–time paths. However, virtual interaction is neglected relative to travel and physical interaction in classical time geography. This is understandable given the era when time geography was initially formulated. But in the contemporary world virtual interaction is more pervasive and cannot be ignored when discussing physical mobility and activities.

Table 2 is a typology of possible communication modes based on space–time constraints.

<table>
<thead>
<tr>

</tr>
<tr>
<td>Geocaches</td>
<td>Webpages</td>
</tr>
</tbody>
</table>

*Synchronous presence* (SP) includes face-to-face conversations; this requires people involved to be physically present or proximal at the same time. *Asynchronous presence* (AP) requires co-location in space but not coincidence in time; examples include notes left on an office door or in a geocache. *Synchronous telepresence* (ST) requires coincidence in time but not in space; it includes media such as telephones, television, radio, and teleconferencing. *Asynchronous telepresence* (AT) does not require co-location in space or coincidence in time; it includes mail, e-mail, messages, and webpages. Classical time geography focuses on SP, recognizes but does not develop ST, and mostly ignores AP and AT.

There are at least two strategies for incorporating the wider range of communication modes into time geography. One strategy is to treat these as spatial and temporal relationships between space–time paths and prisms. SP requires the prism to intersect both spatially and temporally, while AP interactions only require spatial coincidence between the prisms (in other words, they share the same locations but at different times). ST requires temporal but not spatial coincidence.
(the prisms share some interval in time but not locations in space), while AT only requires one prism to precede the other in time.

Another strategy for extending time geography is to make communication technology explicit using time geographic entities and derive space–time constraints based on those entities. A portal is a type of space–time station (Figure 1) where a person can access communication services. It includes a point location, and an access range and time intervals when the service is available. Portals correspond to real world entities such as wired Internet connections (a point location with zero range), wireless access points, and cellular telephone base stations (both characterized as point locations with different ranges). An individual can access a communication service only if his or her paths or prism intersect with the service footprint of an appropriate portal. When this occurs, it generates a message window or an interval of time when a message could be sent or received. Message windows can be compared using temporal predicates such as before, during, and after to determine which communication events are feasible. This approach is consistent with the perspective that temporal constraints dominate spatial constraints on telepresence.

Discovering time geographic knowledge

As the size of mobility datasets become richer and voluminous, the challenges move beyond developing scalable techniques for computing low-level time geographic properties and relationships to discovering higher-level time geographic knowledge. Mobility mining is a set of activities and techniques for discovering novel knowledge hidden in moving objects data. This involves three major activities: (i) trajectory reconstruction and management; (ii) space–time knowledge discovery; and (iii) space–time knowledge delivery.

Trajectory reconstruction and management requires processing the raw mobility data to obtain the space–time paths of the mobile objects as well as data structures and access methods for processing these paths efficiently. These include specialized data warehouse designs, mobile object indexing methods, and semantic trajectory compression methods for reducing storage requirements. Preserving locational privacy through security, anonymization, and other protocols is also a concern.

Space–time knowledge discovery involves processing the trajectories to discover patterns such as clusters and behavioral rules. As noted, path and prism similarity methods can be used in conjunction with clustering methods to provide synoptic summaries of large mobile objects databases. Collection motion methods can also scale to large mobile databases. Another technique is space–time association rule mining that discovers rules describing how objects move among a set of regions over time. Sequence mining techniques search for temporal patterns in mobile objects data. Periodic pattern mining search for recurrent patterns in sequential data includes finding locations that are repeatedly visited by mobile objects and the recurrent movement patterns between these locations. Under specific conditions, causal relationships can also be inferred from sequential pattern in movement data.

Space–time knowledge delivery from movement data requires methods for transparent management of the knowledge discovery process and linking discovered knowledge to real-world semantics. A strategy for managing mobility mining is through visual analytics. Visual analytics is an extension of scientific visualization, but rather than seeking insights into data, visual analytics seek insights into how data are processed during exploration and analysis. Visual
analytics for moving objects include techniques for analyzing and comparing entire trajectories, the distribution of properties within trajectories, synoptic visualization, and investigating movement within geographic context.

Connecting movement patterns to real-world movement semantics requires a conceptual system for describing low-level patterns and their relationships with higher-level behavior. System dimensions can include movement parameters (direct measures and derivatives; Table 1), the number of objects (one, group, or a cohort of similar objects such as people aged 20–30 years), path type (semantically continuous or discontinuous), influencing factors (the object’s intrinsic properties, spatial constraints on movement, environmental factors, and the influence of other agents), and scale/granularity of the data (spatial and temporal scales, temporal granularity). Generic patterns are low level and shared with many different types of mobile objects. These can be primitive (based on a single mobility parameter) or compound (based on multiple primitives and/or inter-object relations). Behavioral patterns are high level and specific to the object type. Examples include pursuit/evasion, fighting, flocking, and leader/follower. Unlike generic patterns, behavioral patterns are open-ended and can be added to the framework as more empirical movement patterns are discovered in different domains (Dodge, Weibel and Lautenschütz 2008).

Time–space convergence

Donald G. Janelle
University of California, Santa Barbara, USA

Time–space convergence (TSC) refers to the rate at which the travel time between places declines in response to transport innovation (Table 1). Analogous to the velocity concept, it is a surrogate for the impact of technological investments in overcoming distance. The original formulation of TSC was linked to the concept of spatial reorganization of settlement systems and socioeconomic institutions (Janelle 1969) and to the enhancement of place utility (the ability of a place to capitalize on its location in meeting its needs and to compete successfully within its local region and more broadly within national and global contexts).

As a component of the process of spatial reorganization, TSC is seen as a significant motivating factor in reshaping the relationships between places and in altering socioeconomic landscapes at local through global scales. The reciprocal concept of human extensibility is, in essence, the dual of time–space convergence, in that it considers how space-adjusting technologies (transportation and communication) are used by individuals and institutions to extend their presence and influence beyond their immediate geographical locations.

TSC has been used to evaluate equity in accessibility gains through public transport services at urban and regional scales and to investigate information diffusion and the historical transformations in the hierarchy of places in shaping emergent urban systems. Cost–space convergence was documented by Abler (1975) and convergence measures have been used to document advances in place connectivity through communication and virtual technologies. TSC is often characterized as one of the forces contributing to time–space compression – a separate concept introduced by David Harvey to invoke the experiential impress of capital accumulation on people and places.

Average rates of change (as shown, e.g., in Table 1) do not fully capture the complexities of the convergence process. Convergence is uneven across space and time because of variation in the abilities of places to attract transport and communication investment, and because of temporal discontinuities in the process of technological innovation, thereby benefiting some places over others. Whereas convergence takes place primarily at regional and global levels, time–space divergence is more common at urban scales owing to congestion. Also, regional variation in patterns of convergence and divergence frequently align with the socioeconomic status of individuals, groups, and places. These TSC attributes and their implications for research in the social sciences are reviewed in Janelle (2014).

Tobler’s first law of geography

Nigel Waters
University of Calgary, Canada

This discussion of Tobler’s first law (TFL) of geography begins with a formal definition and an account of its origins in an article published by Tobler in 1970. This is followed by a section that parses and explains the implications of all the components of TFL: whether it was/is the “first” law, whether it is a “law,” and how distance and relatedness might be measured. The extent to which TFL can be accommodated within the classic models of human and urban geography is considered next. TFL can be made operational through spatial interpolation techniques and these are explained in the ensuing section. TFL has been considered to be highly original but the subsequent segment examines “first laws” in other disciplines. Finally, consideration is given to geographical contexts and circumstances where TFL fails and where other intellectual frameworks and methodologies are more informative. Throughout the discussion reference is made to observations and commentaries of the Forum published in the Annals of the AAG (Association of American Geographers) in 2004 which remains the most detailed examination of TFL to date (Sui 2004; Barnes 2004; Goodchild 2004; Miller 2004; Phillips 2004; Smith 2004). It seems fitting to allow Tobler to have the last word and so concluding section is devoted largely to Tobler’s “Reply” to the participants in the AAG Forum (Tobler 2004).

Definition of Tobler’s first law of geography

Tobler’s first law of geography was originally “promulgated” (this seems more appropriate than the more mystical “invoked” preferred by Sui (2004)) in a paper published in the journal Economic Geography (Tobler 1970). Tobler’s article described a model of population growth for Detroit from 1910 to 2000. The model produced a simulation that was presented as a wire-frame, three-dimensional block diagram. Tobler suggested that if the simulated surfaces were viewed at 16 frames per second then a new surface should be generated for every month of the simulated time period in order to maximize viewing effectiveness. Many of the spatial characteristics of the model were provided in a paper published a year earlier and cited in the 1970 article. A total of 1150 grid cells were used, each being 1.5 miles square. To operationalize his simulation, Tobler stated that he would “invoke the first law of geography: everything is related to everything else, but near things are more related than distant things.” Tobler had earlier argued that “everything is related to everything else” but he added the additional proviso to make the model more localized and thus more tractable. Temporal influences on the population at a particular point in time came from the population during the previous decades, declining by 50% for each passing decade. Spatial influence came from the adjacent cells and this influence was modeled.

Tobler’s paper and his first law have been immensely influential. His 1970 paper has now been cited over 3700 times in the academic and research literature. In June 2003, a Google search
TOBLER’S FIRST LAW OF GEOGRAPHY

of “Tobler’s first law of geography” produced “at least 150 returns” (Sui 2004, 274), but in April 2016, the same search produced almost 8000 returns. Interest in TFL appears to have been growing exponentially.

The law unmasked, deconstructed, and parsed

To understand the importance of Tobler’s law we must question what exactly a first law in the discipline of geography might imply, and ask if other academic disciplines have laws and, more specifically, if they are the most important laws, that is, “first laws.” We should ask whether this was the “first” such law in geography. We need to know what is meant by “everything.” We need to ask how we determine whether two “things” are “related” and what we mean by a “thing.” Finally, we should make explicit how we measure distance and what is “near” as opposed to being more “distant.”

Determining the importance and law-like status of TFL

When Tobler said that this was “the first law of geography,” he was not suggesting that this was the first law to be declared. He was arguing that this was the most important law in geography and that distance was the most important variable governing the influence of one entity on another. In his case study of Detroit, the variable of interest (the “thing”) was persons aggregated into populations, but the implication of TFL is that most geographic variables would show a distance-decay effect.

It is important to determine whether others had suggested there should be laws in geography. Therefore the question must be asked whether this was the first time any scholar had suggested that there be a “first [most important] law” in geography. The answer is that possibly it was, but in the years before 1970 there had been an intense interest among scholars in defining laws and theorems in geography. This concern for formulating laws was a consequence of the increasingly bitter debate between Richard Hartshorne and William Bunge about the nature of geography (Lewis 1965). Hartshorne maintained that geography’s role was to describe the uniqueness of geographical regions and that, according to Lewis (1965, 24), “geographers study individual cases rather than construct scientific laws.” Bunge argued that entities studied in geography were not unique, in the sense that they had similarities that could be studied and characterized and that these similarities could be measured and exploited allowing for the construction of functional models that produced informative explanations and predictions, and therefore a scientific approach to geography. Bunge maintained that the traditional science disciplines did not always seek to argue that cause and effect or deterministic laws were essential. Thus, it might be reasoned that a stochastic law could yield useful predictions in a more scientific, mathematically formulated approach to geography. This is fundamentally the view of Miller (2004, 284), namely “that science accepts the concept of empirical laws, or compact descriptions of patterns and regularities … [that] are not required to be immutable truths.” Phillips (2004, 290) also argues for a less rigid definition of a “law,” citing Cole and King’s classic text, Quantitative Geography, which provides six definitions of a law that “are used in geography, several of which would apply to TFL.” Neither Miller nor Phillips is particularly concerned with the fact that Tobler claims his proposition to be a “law,” but for Smith (2004, 294) this is a primary concern. He argues that had Tobler claimed his proposition to be a rule rather than a law then it would have attracted little attention.
TOBLER’S FIRST LAW OF GEOGRAPHY

Measuring distance

To understand TFL it is important to recognize that there are various ways to measure distance. For many years, geographers have recognized that models and analysis can be formulated in both Euclidean and network space. From the earliest days, location-allocation models have been formulated in both types of space. For example, Leon Cooper formulated his solutions in Euclidean or continuous space while Seifollah Louis Hakimi determined optimal facility locations on a graph or network that is in discrete space (Waters 1999). Most of the classic, theoretical models of human geography (see discussion below) were formulated in continuous space. More recently, due to the availability of software such as SANET (Spatial Analysis on a Network) and the network analyst routines in ArcGIS, human geographers have evaluated distances along networks such as transportation routes. SANET, for example, permits network autocorrelations to be evaluated allowing the researcher to determine if “near things,” such as traffic accident densities, are “related” or spatially autocorrelated along the links of a transportation system.

Regardless of whether we choose Euclidean distance or network distance, it is crucial to be able to discriminate between what is a near thing and what is a more distant thing. Measuring distance is much more complicated than simply making a choice between continuous space and discrete space. It is so much more complicated that in 2006 Michel Marie and Elena Deza produced a comprehensive and exhaustive Dictionary of Distance. This was quickly replaced, in 2009, by an even more extensive survey, the Encyclopedia of Distances (EOD), and a second edition followed three years later (Deza and Deza 2012). Deza and Deza demonstrate that measuring or estimating the distance between two points is of fundamental interest to researchers in a wide variety of disciplines and that these disciplines include...
TOBLER’S FIRST LAW OF GEOGRAPHY

those that are interested in using estimates of
distance in the physical world where distance
may be measured in spatial units (e.g., miles) or
in time or cost of travel, and those disciplines that
use distance as a measure of similarity or related-
ness in a virtual or variable space (the latter being
commonly used for finding clusters of observa-
tions). Of special interest to geographers in the
EOD are the sections on: Distances in the Inter-
net and Web (characterized by links in virtual
networks); Distances in Ecology, Biogeography,
and Ethology; Distances in Geography; Distances
in Economics and Human Geography (p. 561
references Tobler’s first law); and Distances and
Similarities in Data Analysis (especially, for
example, cluster analysis – see below).

Measuring similarity, dissimilarity,
and association in space

If a researcher is to determine that “near things
are more related than distant things” then
the researcher must be able to establish this
relationship using an objective, reproducible
statistic that measures “relatedness.” This statistic
might be some form of correlation coefficient,
such as Pearson’s product moment correlation
coefficient, $r$, or Spearman’s rank correlation
coefficient, $r_s$; a measure of association, such as
Goodman and Kruskal’s $\lambda$ or Cramer’s $V$; or a
measure of dissimilarity between two locations,$x$ and $y$, determined as the sum of the values
obtained from their differences on each variable
$i$ standardized to have a mean of zero and a
standard deviation of 1.0, to insure that each
variable has potentially the same influence in
calculating the dissimilarity (relatedness) between
the locations. With correlations and measures of
association (i.e., measures of similarity), a larger
number indicates that the two locations are more
positively related. With dissimilarity measures, a
larger number means that the two locations are
less “related,” that is, further apart in a single or
multivariable space. Correlations and measures of
association may be used as measures of strength
of the relatedness of a variable or variables at
two locations, and are usually constrained to a
range of $+1.0$ through $0.0$ to $−1.0$ or from $+1.0$
through to $0.0$, allowing for easy comparisons
of, in this case, the relatedness between different
pairs of locations. Correlations and measures of
association are commonly accompanied by an
associated statistical test (for $r$ and $r_s$ this is a $t$
test and for $\lambda$ and $V$ a chi-squared test or $G$
test) allowing the researcher to determine whether an
observed statistic is statistically significant or not.

Gould (1970) was the first to cite TFL in a
paper, in the same issue of Economic Geography.
He noted a problem with traditional measures
of relatedness such that, when used with spatial
data, they frequently violated the assumption of
independence. Indeed TFL states that spatial data
are defined by their spatial dependence or spatial
autocorrelation. Researchers in geography have
had two responses to this conundrum. We can
use TFL and the spatial dependence in our data as
an opportunity to model spatial autocorrelation
as in kriging (see below), or by calculating and
interpreting local indicators of spatial association
(LISA) statistics to gain insights as to what this
implies for our understanding of the variable(s)
under investigation. Alternatively, we can remove
the spatial autocorrelation using more recent
methodologies such as spatial regressions, as
exemplified in software packages such as GeoDa.
An alternative approach to the modeling of
near things is to use geographically weighted
regression (GWR) models (and, more recently,
geographically weighted discriminant analysis
(GWDA) and geographically weighted principal
component analysis (GWPCA)), which allow the
researcher to model local influences using dis-
tance or a predefined number of points that spec-
ify exactly what is “near” and what is “related.”
The Center for Spatial Studies at the University of California at Santa Barbara maintains a webpage on spatial statistics and spatial econometrics software resources including GeoDa. For R-coded software packages that perform spatial statistical analysis, researchers can access the Comprehensive R Archive Network (CRAN) where they can download the R software for various operating systems (Linux, OS X, and Windows) as well as the CRAN Task View for the analysis of spatial data, a website maintained by Roger Bivand (Bivand 2015). This is the most comprehensive set of routines for the analysis of spatial relatedness available anywhere and includes R code for most of the procedures mentioned here. Spatial autocorrelation is thus both a problem and an opportunity for the researcher using geographical data, but with so many new spatial analytical software tools now available and often embedded in geographic information system (GIS) packages such as ArcGIS, the former has become increasingly less of a concern.

Tobler’s first law and the classic models of human and urban geography

The classic models of human geography, including Von Thünen’s model of agricultural activity around a centralized market town in an isolated state, Christaller’s central place theory (CPT) defining the settlement geography of hierarchical urban systems, and Lösch’s *The Economics of Location*, all produce economic landscapes where TFL is consistently shown to be insufficient. Distance is important in Von Thünen’s model, but the model produces rings of agricultural specialization that are homogeneous internally but where the land use between adjacent rings (land-use patches which are indeed very “near things”) may be quite unrelated. CPT produces a hierarchy of settlements superimposed on a background of uniform agricultural activity. Thus a large urban center will be located within a rural setting and the largest centers will be spaced the furthest apart, and it is these centers where similar “high-order” goods and services will be found. A hierarchy is inimical to TFL, at least in terms of *geographical* distance, and so are borders and boundaries (see below for further discussion of these topics). Lösch’s analysis produced sectors of economic activity which alternated between high and low densities of settlements and thus, according to Lösch’s theoretical analysis, adjacent sectors would be less similar in this respect and, presumably, in their population and other socioeconomic characteristics.

Geographers and other social scientists have identified a number of models to characterize the internal structure of cities. The best known of these are the concentric ring model of Burgess, the sector model of Hoyt, and the multiple nuclei model of Harris and Ullman, all three of which were reconciled by Bourne and Murdie’s factor analysis of the internal structure of the city of Toronto, Canada (Perry, Crew, and Waters 2013). It might be argued that TFL applies within the Burgess rings, or within Hoyt’s sectors, or inside Harris and Ullman’s ethnically homogeneous nuclei, but again, on the borders of these zones, there might be radically different residential communities or zones of economic activity living adjacent to each other. These inconsistencies in the validity of TFL are in part a function of scale. When a researcher concentrates on the “big picture” and “zooms out” from the map, variables that exhibited a gradual decline with increasing distance from a given location may, at a more detailed scale, simply appear as uniform concentrations with sharp boundaries where the spatial autocorrelation declines to zero. Thus first-order trends may appear as second-order concentrations.
TOBLER’S FIRST LAW OF GEOGRAPHY

Less theoretical, more applied, empirical models have fared better, especially those used in transportation geography. Step 2 of the four-step transportation planning model (Waters 1999) is based on the premise that commuters moving out of trip production zones where they live and toward trip attraction zones where they work will attempt to minimize the length of their journey to work. Trip distributions are a practical example of TFL that is based on the concept of a doubly constrained, spatial interaction model where trip numbers are directly proportional to the product of the number of commuters in a production zone and the number of jobs in an attraction zone, and, most significantly, inversely proportional to some power of the distance between the two zones. Put simply, the shorter the distance between the production and attraction zones, eteris paribus, the more commuter trips will result; all traffic analysis zones (TAZs) are related but near zones are more related than distant zones.

Spatial interpolation and TFL

Spatial interpolation is the science of estimating the values of a surface at unsampled locations within a region based on a set of sampled values at various locations and is commonly found in GIS software such as ArcGIS and Idrisi. The value of a surface at an unsampled location is dependent on the values at nearby sampled locations. Spatial interpolation is a way to operationalize TFL. It assumes that the values of a surface exhibit some form of spatial autocorrelation.

Distance-weighted averaging

A common method of spatial interpolation is to use a distance-weighted average. Decision variables in a distance-weighted average involve the number of sampled values to include, usually four, six, or eight. In Tobler’s original words, this determines just how “parochial” or localized the estimating function should be (in kernel-based spatial interpolation the kernel can be limited by distance or number of points used) – the more localized, the more irregular the surface of estimated points. A second decision variable is whether there should be a spatial bias in choosing the nearest four, six, or eight points, that is whether they should be the nearest point in each one of four quadrants, six sextants, or eight octants, respectively, the object being to reduce directional bias in the estimation. The distance-weighting function may be exponential or simply 1/d where d is the distance from the unsampled point or 1/d^n where n is some power of distance. This allows “near things to be more related than distant things.” The degree to which a distance-weighted interpolation is parochial depends on both the number of points included in the averaging process and the distance function used. In theory, all sampled points might be included (where everything is related to everything else) and this would produce a relatively smooth surface, the degree of smoothness being a function of how quickly the influence of distance declined. Trend surface analysis uses a global polynomial with two independent locational variables (X and Y; easting and northing; longitude and latitude) to estimate values of the dependent variable (elevation, population, as it was in Tobler’s 1970 paper, or some other spatially varying variable) using a single equation. The polynomial can be first, second, or third order, or some higher number producing surfaces with additional inflections each time the order increases. Tobler referenced Richard Chorley and Peter Haggett’s early use of such trend surface models.
Kriging

Kriging is another commonly used method of spatial interpolation. Kriging allows the researcher more objective control over the variables implicit in TFL, more objective control, that is, than the subjective choices used in distance-weighted averaging. Specifically, in kriging everything is not “related to everything else” because the “relatedness” ceases when the range is reached. The range is a distance over which points no longer covary. The extent to which points covary is measured by the covariance function that is estimated by a variogram. The variogram can take a large variety of functional forms, similar to the changing influence of distance in a distance-weighted averaging. The variogram is an estimation of just how strongly “near things” are related. It also shows how quickly “relatedness” declines to zero. Universal kriging (as opposed to simple kriging) allows the geographic researcher to model the influence of spatial trends in the data since “near things” in one direction may be “more related” than near things in another direction. For example, data in a north-south direction might be more highly correlated than in an east-west direction.

In many instances, near things may be related not only spatially but through the influence of one or more variables. Thus population density in a city such as Detroit might be influenced by many variables. Yeates (1965) found that land values at any given location in Chicago were influenced by distance from the central business district, distance from the nearest regional shopping center, distance from Lake Michigan, distance from the nearest elevated subway system, population density, and percentage of nonwhite residents at the given location. Thus the land values at any location might be “related” to the land values at nearby locations, as TFL states, but this relationship would be influenced by these other variables and would thus be better modeled by co-kriging than by simple kriging or regression as suggested by Yeates.

First laws in other disciplines

The idea of a first law may be found in other disciplines, often with partially humorous intent. Examples abound on the Internet: “The first law of Politics is that it is always about politics”; the first law of sociology: “Some do, some don’t.” Science provides some rigorous, universally accepted examples, such as the first law of thermodynamics. Geologists have given the name “uniformitarianism” to the idea that the natural laws governing geological processes that operate today also operated throughout geological history. More wittily, one researcher has suggested that the first law of geology should be that “the rocks remember while liquids and gases forget.” Since kriging and, to a large extent, geostatistics were developed in geology, it is not surprising that TFL has recently been claimed by geologists, without acknowledgement: “According to the first law of geology ‘everything is related to everything, but near things are more related than distant things’” (Bayraktarli and Faber 2011). It has been suggested that biology’s first law should be that there is a tendency for diversity and complexity to increase in evolutionary systems. It is interesting to note that evolution itself is hindered by TFL, for the primary method of speciation, allopatric speciation, requires the isolation of two breeding populations by geographical barriers (mountains, rivers, oceans), migration, or habitat fragmentation. Perhaps TFL should be classified as a dangerous idea, since, like globalization, it inhibits diversity and complexity. Tobler (2004) himself cites a number of “first laws” from other disciplines (some closely allied to geography and some not) including Ernst Georg Ravenstein’s well-known laws of migration and George Zipf’s
**TOBLER’S FIRST LAW OF GEOGRAPHY**

law, which stated that the frequency of a word in a large corpus of text would be inversely proportional to its frequency rank. This is also known as a power law or the rank-size rule, the latter suggesting perhaps more reasonably a diminished status. Power laws have been applied extensively to the population ranks of cities in numerous countries and to the study of social networks in geography to detect scale invariance, but unfortunately they can be derived in many different ways and therefore tell us little about generative processes (Waters 2013).

**Spaces where Tobler’s first law fails**

**Borders, boundaries, and barriers**

TFL will fail (or provide an incomplete explanation) wherever there are natural barriers similar to those that have aided the process of evolution discussed above. It will also fail wherever there are political or administrative barriers. A striking example may be found in the land use on the border between some parts of Haiti and the Dominican Republic, on the island of Hispaniola. Even the land use north and south of the forty-ninth parallel of latitude, forming the border between the United States and Canada, may show dramatic differences. In many countries, census divisions and political constituencies have boundaries that are deliberately constructed to maximize internal homogeneity and external heterogeneity in terms of socioeconomic characteristics and voting behavior. Ordinarily, having a political unit composed partly of an urban area and partly of a rural area would be considered to be gerrymandering. Finally, some countries may erect barriers between themselves and neighboring countries. Examples include the former Berlin Wall separating East and West Berlin, the Mexico-US barrier or border fence, and the Israeli West Bank and other separation barriers. The existence and impact of such separation barriers have been prominent in fiction, including the celebrated work of Gloria Naylor who, in her first and second novels respectively, located the African American communities of Brewster Place and Linden Hills bordering each other but separated by a wall. “Linden Hills is a posh upper-middle-class settlement, Brewster Place the last stop on the road to the bottom in American society… with a great distance between them even as they are both black” (Christian 1990). TFL stops at the wall in both the real and the fictional world. TFL does not readily explain ethnic segregation (Perry, Crew, and Waters 2013). Having noted these examples at micro-geographical scales, it is important to state that some researchers have found evidence suggesting “that national cultures are organized geographically; similar cultures are found in neighbouring countries, and dissimilar cultures in countries that are far apart” (Gelade and Dobson 2009).

**Hierarchical spaces and networks**

Diffusion and migration processes often progress hierarchically. Thus a diffusion of an innovation may be passed and adopted from one individual of influence to another. Once these individuals have adopted the innovation it may then be adopted by a process of filtering down through the hierarchy of their networks of influence. Such hierarchical diffusion may also occur across space. Thus an innovation may be adopted by higher-order centers in a central place hierarchy and may then, in a second wave of adoptions, be embraced by individuals in lower-order centers. Indeed, the whole adoption process might filter down through the entire urban system in a hierarchical fashion. Geographical research (Bowen and Laroe 2006) has shown that the temporal spread of diseases such as severe acute respiratory syndrome (SARS), which, in 2003, spread from...
its origins in China to 25 other countries and to Taiwan, is primarily due to airline network accessibility. Bowen and Laroe estimated the parameters of a multiple regression model where the dependent variable was the number of days from the first case of the disease in a newly SARS-infected country (SIC) until the disease was contained on July 5, 2003. Thus the higher the number of days, the earlier the outbreak, that is to say, the more quickly the disease moved from China, its origin, to the country concerned. Six independent variables were included in the regression model: the number of Chinese ancestry residents of a country as a percentage of the total population; a binary variable that was assigned a 1 for the 11 countries with the highest foreign direct investment in China and a 0 for the remaining countries; per capita gross national income; a country’s 2003 population; a measure of accessibility from Beijing using airline network schedules; and distance between the SIC and China. Only the airline network accessibility and the number of Chinese ancestry residents as a percent of the total population were statistically significant. Distance itself was not, and so it can be argued that TFL did not apply to the diffusion of the 2003 SARS outbreak unless we measure “distance” as a function of network accessibility. In addition, the medical geographer would need to take past migration patterns into consideration as well. Bowen and Laroe cite other examples of disease propagation via transportation routes, including the transmission of the fourteenth-century outbreak of bubonic plague along sea trade routes and three outbreaks of cholera in the United States during the middle of the nineteenth century along existing trade routes. A county not on a trade route would not be infected, regardless of “nearthiness.”

Social media and social networks

Social media (SM) and social networks (SNs) have weakened the influence of distance, contributing to the so-called death of distance and the weakening of TFL. Waters (2013) has reviewed both the literature on the death of distance, including Cairncross’s book on this topic, and the research on the impact of SM and SNs on distance-decay functions within social networks. The primary attraction of SM and SNs, and even the Internet itself, has been to weaken or eliminate the influence of geography and distance and, if this were true, Waters (2013) has argued that a second law of geography might replace the first: “Everything is connected to everything else, but things more closely connected [in network space] are more related — and geography may well be irrelevant.” In SN space there is also a problem with defining what is local. Christakis and Fowler (2011) have discussed this issue and describe research that demonstrates that it is our friends’, and friends of friends’, and friends of friends of friends’ behavior that affects us, and it is these linkages that determine whether we are obese, happy, or smoke, or have heart disease, and presumably other characteristics as well. We may be connected to everyone else in the network, but influence ceases to be significant with three degrees of separation (Waters 2013). Sociologists have identified homophily as “the principle that a contact between similar people occurs at a higher rate than among dissimilar people” (McPherson et al. 2001). Although their observation relates to social networks they argue that Geography is the most important of a number of influential independent variables.

However, the question remains as to whether distance is now irrelevant. Or perhaps more alliteratively: “Is spatial special when it’s social?” (Waters 2012). The existing research (which is expanding rapidly as SN companies such
as Facebook and LinkedIn utilize their own research teams) implies that the more “social” as opposed to “professional” the SN is the more distance still matters. Tobler (2004, 308) himself suggested a second law that “the phenomenon external to [a geographic] area of interest affects what goes on in the inside” – essentially a problem of system closure presumably because “everything is related to everything else.”

Various researchers (for a complete discussion see Waters (2013)) have fitted distance-decay functions to “friends” and connections within SNs. For example, the probability that two cell phone users are connected is proportional to the Euclidean distance separating them raised to the power $-2$. This is the classic distance-decay function used in a gravity model and is reminiscent of the findings of Mackay (1958). Mackay’s seminal study of long-distance phone calls between cities in the Province of Quebec, Canada, showed a distance-decay exponent of $-0.9$, but between cities in the Province of Ontario it was $-1.7$, a steeper distance-decay function. Rapid drop-offs in call interactions occurred between Quebec-Ontario city pairs in which case the telephone traffic was about one-fifth what it was between pairs of cities in Quebec. An even more dramatic drop-off was noted between Quebec-US city pairs, where the traffic was about one-fiftieth of the Quebec pairs. Such differences presumably occurred because there were fewer contacts across provincial and national borders and because of higher long-distance charges. Cell phone rates may also influence such long-distance interactions and cross-jurisdictional calls. These provincial and national borders do not prevent interaction; rather, they modify the process making it impossible to use a single function to model it. Waters (2013) notes that one study of the SNs, LiveJournal, determined that the average user had eight friends and that, again on average, 5.5 were “geographically influenced” and lived nearby with a distance-decay function where the exponent of distance was approximately $-1$, while the remaining 2.5 friends were a result of nongeographic processes, the former geographically influenced connections being a partial vindication of TFL. Other research cited by Waters also suggests that SNs are influenced by a mix of geographic and social influences. Such research has suggested that “node locality” or network-based metrics be combined with “geographic clustering metrics” (and presumably socioeconomic factors similar to the past migration patterns elucidated by Bowen and Laroe) to provide a modeling framework with exceptionally high explanatory power but lower generality than Tobler’s Detroit model.

Tobler: the last word on Tobler’s first law

Daniel Sui, the convener of the 2003 AAG panel session on TFL, asked Waldo Tobler to review and respond to the participants’ written reviews of his law. Tobler (2004) introduced his comments by saying that the goal of his model and of TFL was to emphasize simplicity and therefore generality. This allowed Tobler to predict population growth in Detroit, a modest goal but a goal that is most useful in transportation planning and for urban budgeting wherever these budgets are based on population numbers. Tobler states that Barnes was correct in observing that he was “restricting … [himself] … to local effects.” Unfortunately, this is not what the law states when it declares “that near things are more related than distant things,” implying a gradual decline in relatedness with no sharp break. However, spatial interpolation methods such as kriging, with its concept of the range, spatial smoothing’s use of kernels and geographically
weighted regressions, discriminant analysis, and principal component analysis all allow analysis to be restricted to the local. Tobler confines his subsequent comments to three issues: (i) What defines a law and does TFL satisfy the definition? (ii) Is it true “everything is related”? (iii) How should “near” be defined?

Laws

Unlike Smith (2004), Tobler is satisfied with, and quotes, Richard Feynman’s relatively undemanding definition of a law from his 1967 book, *The Character of Physical Law*, as an educated guess, where the consequences have been computed and then tested by experiment, experience, or observation. If the test conforms to reality then it is a law, and if not, the scientist must guess again. This is a very low bar and would not satisfy Smith’s criteria described above. Tobler’s definition of a law is simply based on predictive power, not explanation, but this, according to Tobler himself, and also Miller (2004), was enough for Newton’s law of gravity to be universally accepted. However, Tobler does not appear to have validated his own predictions for his Detroit population model.

Tobler admits that other well-known social scientists and geographers have found the idea of laws in social science to be simply unacceptable (e.g., Anthony Giddens and Bent Flyvbjerg, references in Tobler (2004)). Nevertheless, it is difficult not to conclude that often what passes for a law might be better referred to as a principle (e.g., Zipf’s principle of least effort), or perhaps a rule (e.g., the rank-size rule now known as one form of the power law), or simply an empirical generalization such as Roger Shepard’s observation concerning multidimensional scaling: “if a solution exists, probably it exists in two dimensions” (cited in Tobler 2004).

Everything is related

Tobler concedes that everything is not usually related to everything else and, if it is, then the influence of the most distant relationships is usually not significant or meaningful. So TFL is not strictly correct and geographers have long accepted this in their modeling activities by applying locally constrained models, measures of association, and spatial interpolations including LISA, GWR, GWDA, GWPCA, and variations on kriging and distance-weighted averaging, all of which have been mentioned above.

Near things

Tobler admits that his use of the term “near things” was “equally ambiguous” (Tobler 2004, 306). He noted that distance can be measured in a variety of ways but was, of necessity, unaware of the Dezas’s contribution since both their *Dictionary* and *Encyclopedia of Distance* were published subsequent to Tobler’s “Reply.” Tobler does, however, note that the variogram (see above) is a way to assess both relatedness (covariance) and nearness (range). Tobler commends Goodchild (2004) for speculating on other “laws” and “principles” that are fundamental to geographic information science and for contemplating situations where TFL does not apply, which might include the chaotic drainage in the landscapes of southeastern Alberta, South Dakota, and New Mexico.

Tobler concludes, modestly, by noting how the eminent statistician Sir Ronald Fisher made a similar statement to TFL in 1935. He also expresses his surprise that TFL should have aroused so much debate when he was “just having fun doing an animation” (Tobler 2004, 308).

Topological relations

M. Andrea Rodríguez
Universidad de Concepción, Chile

Topology is typically seen as the most abstract spatial structure. It is considered essentially qualitative because it is independent of quantitative measures such as the distance or length of common boundaries. Topological relationships, such as “C is inside D” or “C touches E,” are those relations that are invariant with respect to continuous transformations of the underlying space, namely, translation, rotation, and scaling. They represent basic notions of connectivity between spatial objects and have spurred much research in the spatial information community.

Formalization of topological relations

In the formalization of topological relations there are two well-known approaches: axiomatic theories (generally logic of first order) and point-set theories.

The region connection calculus (RCC) by Randell, Cui, and Cohn (1992) is a well-known axiomatic theory based on a single binary relation and a set of axioms. The primitive “connected” relation $C(x, y)$ is true if the topological closures of the nonempty spatial regions $x$ and $y$ are connected. Then, other relations can be formally defined as expressions in first-order logic using the relation $C$. This formalization derives a set of eight topological base relations (Table 1), which are called the RCC-8 set of relationships. While this theory is rich in its expressive power and has captured the attention of the research community, it falls short under considerations of computational implementation.

The same set of topological relations between connected regions (i.e., regions with connected boundaries and connected interiors) was independently proposed by Egenhofer and Franzosa (1991) as being very important for geographic information systems (GIS) and spatial databases. In point-set theory, an object is represented by its point-set topological elements. The basic strategy is to determine the point-set intersection between an object’s topological elements and then to derive constraints to filter out impossible cases.

Egenhofer and Franzosa defined binary relations according to the emptiness and nonemptiness of the four intersections between interiors (○) and boundaries (δ) of regions; hence, it is called the 4-Intersection Model. The empty/nonempty topological invariant is the simplest and most general invariant, so any other invariant may be considered a more restrictive relationship classifier.

It is straightforward that the sixteen possible intersections between interiors and boundaries form a jointly exclusive and pairwise disjoint (JEPD) set because, for any pair of regular regions, one and only one of the relations holds. However, if spatial regions are defined as regular nonempty proper subsets of $\mathbb{R}^2$ with connected interiors, then only eight of the sixteen relations are realizable in the plane. This set of eight relations is called the high resolution set or the base set of topological relations. The eight relations are: “$x$ is disjoint or disconnected from $y$” (Disjoint), “$x$ touches $y$” (Meet), “$x$ overlaps $y$” (Overlap),

</tr>
</tbody>
</table>

“$x$ is equal to $y$” (Equal), “$x$ is covered by (or a tangential proper part of) $y$” (Covered_by), “$x$ is inside (or a nontangential proper part of) $y$” (Inside), and the converse of the two latter relations (Covers and Contains). The definitions can be found in Table 2 and are illustrated in Figure 1. For example, for nonempty regions $x, y$, Meet($x, y$) is true if and only if all of $\delta(x) \cap \delta(y) \neq \emptyset, x^c \cap y^c = \emptyset, \delta(x) \cap y = \emptyset$ and $x^c \cap \delta(y) = \emptyset$ simultaneously hold.

As the eight relationships correspond to the eight base relationships of the RCC-8 theory, there seems to be a natural agreement about what is considered to be a high level of resolution of topological relations. However, there are other sets of topological relations that are obtained by the disjunction of high resolution relations. For example, a relation Within captures the Equal, Inside, or Covered_by relation of the high resolution set. A smaller set in this condition is said to be a coarse resolution set of topological relations.

The 4-Intersection Model was later revised to incorporate the analysis of regions, lines, points, and combinations of them using an algebraic topology with primitive geometric objects called “cells” and their aggregation into cell complexes. In this model, a point is a 0-cell in $\mathbb{R}^2$, a line is a sequence of connected 1-complexes in $\mathbb{R}^2$, and a region is a 2-complex in $\mathbb{R}^2$ with a nonempty connected interior. The binary topological relation between two cells is derived from the
set intersection of the interior (\(\,\)), boundary (\(\partial\)) and exterior (\(\,\)) of cells, which was called the 9-Intersection Model (equation A).

\[
M(x, y) = \begin{pmatrix}
\delta(x) \cap \delta(y) & \delta(x) \cap y^+ & \delta(x) \cap y^- \\
x^- \cap \delta(y) & x^+ \cap y^- & x^+ \cap y^+
\end{pmatrix}
\]

(1)

Based on the set intersections, it is possible to identify \(2^9\) mutually exclusive combinations from the nine intersections, where each of these intersections has two possible values: empty and nonempty. This leads to 8 realizable topological relations between arbitrary regions, 10 between regions with disconnected boundaries, 33 between lines, and 19 between a line and a region.

Notice that by taking into account the efficiency to derive topological relations, the 4-Intersection Model (i.e., intersections that consider only the interior and boundary) can be sufficient for modeling topological relations between \(n\)-cells if their boundaries are connected and codimensions are zero, that is, cells are of the same dimension. However, when objects are embedded into higher dimensional space, it is necessary to examine whether or not boundaries and interiors are subsets of the other objects' closure.

Addressing the analysis of topological relations on a surface, which is neither the planar 2-D nor the 3-D space, the work in Egenhofer (2005) systematically derives the topological relations between two nonempty regions on the surface of a sphere. It analyzes first if all eight topological relations in \(\mathbb{R}^2\) could be realized on the sphere and then it analyzes the completeness of this set by examining constraints on the 9-Intersection combinations that could lead to new topological relations. A first conclusion of this work is that the 9-Intersection Model serves to distinguish the same eight relations on the sphere. However, new topological relations between regions on a sphere are found. Indeed, there are eleven, instead of eight, topological relations between regions on the sphere. Figure 2 shows examples of the three additional topological relations realizable on the sphere, which are characterized by the fact that the union of regions forms the entire sphere.

Taking a more general approach, the 9\(^+\)-Intersection Model in Kurata (2010) is an extension to the 9-Intersection Model that distinguishes topological relations between arbitrary objects by patterns in nested matrices. It defines a set of constraints on this matrix, which are applicable to arbitrary pairs of objects in various spaces. In the 9\(^+\)-Intersection Model, matrices are of the form \(M^+\) in equation 2, where the bracketed elements are matrices by themselves and \(\delta_i(x), x_i^+,\) and \(x_i^-\) are the \(i\)-th subparts of an object \(x\).

\[
M^+(x, y) = \begin{pmatrix}
\delta_i(x) \cap \delta_j(y) & [\delta_i(x) \cap y^+] & [\delta_i(x) \cap y^-] \\
[x_i^+ \cap \delta_j(y)] & [x_i^- \cap y^+] & [x_i^- \cap y^-] \\
[x_i^- \cap \delta_j(y)] & [x_i^- \cap y^+] & [x_i^- \cap y^-]
\end{pmatrix}
\]

(2)
An example of this model is shown in Figure 3 (Kurata 2010). It shows $M^+(x, y)$, where $x$ is a directed line (DLine) with distinguished start and end points of the boundary and $y$ is a region.

The 9+-Intersection Model derives nine general constraints upon which it defines a set of admissible intersection matrices. Table 3 shows a summary of the number of topological patterns derived by this model in the 2-D ($\mathbb{R}^2$), 3-D ($\mathbb{R}^3$), and on a 2-D sphere ($\mathbb{S}^2$).

There are also efforts to translate the topological relationships in a continuous space (i.e., vector space) into relations in a discrete space and applicable to a raster representation of the space. The raster space $\mathbb{Z}^2$ is seen as a rectangular array of points or pixels. The work in Egenhofer and Sharma (1993) defines a raster object as an extended object that is bounded. An extended object is a finite proper subset of $\mathbb{Z}^2$, where two points in the extended object are connected if there is a connected path between them (i.e., a path formed through the 4- or 8-neighbors). In this context, a boundary of a raster region is a Jordan curve that separates the interior from the exterior. For this work, raster regions have nonempty boundaries and interior, and their

**Figure 4** The boundary, interior and exterior of a raster region: (a) admissible raster region with four-connected interior and boundary and (b) inadmissible raster region with disconnected interior. Adapted from Egenhofer, M.J., and J. Sharma. 1993. “Topological Relations Between Regions in \(r^2\) and \(z^2\).” In Advances in Spatial Databases, Third International Symposium, SSD’93, 316–336, © With permission of Springer.

interior and exterior are four-connected, that is, they are composed of cells that are adjacent by row or by column (Figure 4).

From the analysis of the set intersection in the discrete space, all eight JEPD topological relations defined by the 9–Intersection Model that can be realized between two regions in a continuous space can be also realized between two raster regions. In addition, there are eight more topological relations between bounded raster regions. Even more, another three topological relations can be identified in \(\mathbb{Z}^2\) if considering whether or not empty boundary–boundary intersections are neighbors. Figure 5 shows topological relations for raster regions that are not realizable in the continuous space, excluding those cases that can be distinguished when boundary–boundary intersections are neighbors. This figure omits converse relations, which can be derived from cases Figure 5a, Figure 5b, and Figure 5c, respectively.

The work in Egenhofer and Sharma (1993) identifies the following mappings of relations from the raster to the vector space: Relation (a)
in Figure 5 and its converse relation map to the Inside and Contains, respectively. In a similar way, relation (b) and its converse relation map to Covered by and Covers, respectively. Finally, relations (b), (c) and their converse relations in the raster space map to the Overlap in the vector space.

Despite the wide use of the 9-Intersection Model and its extensions, the model is not exempt from suffering some criticism. In the 9-Intersection Model, not all intersections are possible and there may be several object intersections that are topologically equivalent. The 9-Intersection Model was originally designed for 2-D objects and cannot distinguish a large number of topological relations between complex 3-D objects because it ignores that the interiors, boundaries, and exteriors may also be complex objects. Even more, it has been argued that the 9-Intersection Model suffers a basic contradiction in the definition of boundaries and interiors when objects of lower dimensions are embedded into higher dimensions. In particular, when a line, which is a 1-D entity whose boundary is composed of the two end points, is embedded into a 2-D space, the interior is connected to the exterior. This contradicts that the boundary separates the interior from the exterior of an entity. To overcome this previous drawback of the 9-Intersection Model, other point-set formalisms for topological relations consider other topological invariants that can distinguish more topological relations (Zlatanova, Rahman, and Shi 2004).

A different formalization of topological relations replaces the exterior of an entity by its Voronoi diagram. This results in thirteen relations between areas, eight between lines, thirteen between a line and an area, three between points, four between a point and a line, and five between a point and an area. Later, a Voronoi-based algebra was also proposed. This formalization utilizes set operators (i.e., union, intersection, difference, difference by, symmetric difference) to distinguish spatial relations between neighboring spatial objects, and several values are the results of these operators: content, dimension, and number of connected components.

From a mathematical point of view, the extended model for topological relations (EMTR) defines topological relations between any two objects in GIS. From this perspective, a topological relation is basically an equivalence relation that splits the relation between two objects into different partitions. Instead of using the value of empty/nonempty of the 9-Intersection Model, the EMTR uses for convex sets \( x \) and \( y \) the number of connected components of elements in the matrix:

\[
\begin{pmatrix}
  x \cap y & x \setminus y \\
  y \setminus x & \delta(x) \cap \delta(y)
\end{pmatrix}
\]

</tbody>
</table>

For nonconvex sets \(x\) and \(y\), this model also considers the fundamental group of \(x \cup y\). The fundamental group is a concept of the algebraic topology that captures information about the basic shape or holes of a topological space. By considering the property of connectivity and fundamental group, the topological relations between objects can be described by an infinite sequence of matrices.

The dimensional model is another model for representing spatial relations. The model is based on the dimensional elements of spatial objects and their dimensional relations. The \(\alpha\)-dimensional element of an object \(A\) corresponds to the set of all points of \(C\) that have order 0. For example, a triangle in \(\mathbb{R}^2\) contains points of order 0 that are vertices of the triangle, points on the edges are of order 1, and points inside are of order 2. Consequently, elements in the 3-D space are of order 0, 1, 2, and 3. Then, to define the topological relations between spatial objects \(A\) and \(B\), the dimensional relations between elements in \(A\) and \(B\) are checked from the highest to the lowest dimensional order. The dimensional relations can be partial, total, or not existing, depending on the intersection between dimensional elements. They can also be classified by distinguishing basic relations that consider whether or not the dimensional elements intersect, extended relations that consider the dimension of the intersection, and simplified relations where some dimensional relationships are aggregated.

The major drawback of the alternative approaches to the 9-Intersection Model is that there is no clear semantic interpretation of all relations derived from these models and, in consequence, how they relate to common sense in practical use.

Topological relations in query languages and for information retrieval

Topological relations are very important components of spatial query languages in databases. Topological relations are inserted as filter conditions of join or range queries. For example, they are useful to specify a join query that retrieves rivers that cross a city. They also serve to specify the valid states of a database through the definition of integrity constraints. For example, it could be specified that the boundary of two counties must be disjoint or touch each other. Thus, every time there is an update on the database, the system should check if there is a pair of counties that are internally connected. These types of constraints are called semantic integrity constraints, which are typically implemented by using query languages.
TOPOLOGICAL RELATIONS

Current spatial database management systems have adopted the standard by the Open Geospatial Consortium (www.opengeospatial.org/). Table 4 provides the definitions of the topological relations extracted from the Open Geospatial Consortium simple feature specification. In this table, given a geometry \( x, \partial(x) \) indicates its boundary, and \( \dim(x) \) its dimension, where \( \dim(x) = 0 \) if \( x \) is a point, 1 if it is a curve, and 2 if it is a surface.

It can be seen from this table that current query languages use a coarser set of topological relations than the set defined by the 9-Intersection Model. These relations, such as the coarser relation Within, are not part of the basic and pairwise disjoint basic relationships of models. However, they are useful in practical cases.

In common spatial databases, retrieval by spatial relations is done on the basis of information consisting of objects stored in relational tables and organized by thematic layers with spatial indexing methods (e.g., R-Tree). This technique answers queries as cascaded spatial joins and is restrictive to the type of objects and relations. Unlike querying databases where data are retrieved by an exact matching between the query and the stored data, spatial-information retrieval focuses on similarity-based searching of spatial configurations. In this context, queries can be specified with a visual language that represents a scene by a set of objects and a set of constraints defined by the topological relations between objects. Similarity-based search has a common strategy: (i) definition of the set of spatial relations that can be used in a query, (ii) definition of a similarity measure of spatial relations, and (iii) implementation of a search algorithm for similarity retrieval.

In the typical similarity-based retrieval of spatial configurations, similarity measures compare the topological relation between objects with respect to a topological constraint. Using relations defined by the 9-Intersection Model or RCC, a similarity measure compares topological relations using the semantic distance between relations as defined by a conceptual neighborhood graph (Egenhofer and Al-Taha 1992). This type of measure suffers the disadvantage that it does not distinguish pairs of objects that, holding the same topological relation, correspond to different spatial configurations. For example, it does not distinguish between a pair of disjoint objects very close to one another and a pair of disjoint objects very far apart. Other types of similarity measures use a quantitative approach to compare relations between objects based on distances, angles, or overlapping areas (Godoy and Rodriguez 2004). This later type of measure can only be applied when comparing pairs of geometries.

In general, spatial information retrieval for a variable number of objects and constraints is a hard computational problem due to the size of the search domain of possible solutions. This means that there is no algorithm that can run in a reasonable time and that finds the set of objects that best match the query. As a consequence, studies take approximation approaches. Most of these studies use heuristics and approximation algorithms based on evolutionary algorithms. They start with a set of possible solutions and then apply heuristics and transformations on the initial solutions to improve the solutions in each iteration of the algorithm.

Reasoning about topological relations

Two important reasoning problems with topological relations are the topological consistency problem and the realizability problem (Grigni, Papadias, and Papadimitriou 1995). These are important problems in applications where you
have to derive possible scenes from qualitative descriptions based on topological relations or when you want to evaluate the consistency of specifications.

A set of topological relations defined over a set of spatial objects is said to be topologically consistent if there are no contradictions among the topological relations. For example, three objects $A$, $B$, and $C$ and the relations Covers($A$, $B$), Covers($B$, $C$), and Disjoint($A$, $C$) are topologically inconsistent, as the first two relations imply that $A$ and $C$ cannot be disjoint.

A fundamental concept to topological consistency is the notion of composition of topological relations. The composition of two topological relations $T_1(A, B)$ and $T_2(B, C)$ over a common object $B$, denoted $T_1(A, B) \otimes T_2(B, C)$, enables the derivation of the topological relation between objects $A$ and $C$. The composition of the eight base topological relations between regions is shown in Figure 6, which is the same derived from the 9-Intersection Model and RCC. In Figure 6, each topological relation is represented as a dark node in a graph. If, for example, Overlap($A$, $B$) and Covered_by($B$, $C$) are true, then from the composition table it is obtained that either Overlap($A$, $C$), Covered_by($A$, $C$) or Inside($A$, $C$) is also true. The composition between two relations, say Overlap and Covered_by, is denoted by:

\[
\text{Overlap} \otimes \text{Covered_by}\\
= (\text{Overlap} \lor \text{Covered_by} \lor \text{Inside})\\
= \{\text{Overlap, Covered_by, Inside}\}
\]

A more formal definition of topological consistent is then defined by a consistency network as follows. Given a set of spatial objects $Ob$ and a conjunctive expression of the form $\psi = \bigwedge_{i=1}^{n} T_i(A_i, B_i)$, where each $T_i$ represents a disjunction of base topological relations between objects $A_i$ and $B_i$ belonging to $Ob$ (i.e., alternative base topological relations between $A_i$ and $B_i$ — recall that base relations are the high relations (JEPD) topological relations), $\psi$ is said to be topologically consistent if there exists a network of base topological relations (denoted by $\pi$), that is, if there exists a function $TR : Ob \times Ob \pm \pi$ such that:

1. A topological relation $T$ is defined for every $A, B \in Ob$.
2. For every $A \in Ob$, $TR(A, A) = \text{Equal}$.
3. For every $A, B \in Ob$ such that $T(A, B) \in \psi$, $TR(A, B) \in T$.
4. For every $A, B, C \in Ob$, $TR(A, C) \subseteq TR(A, B) \otimes TR(B, C)$.

The following example illustrates a case where topological consistency is satisfied. Given a set of objects $Ob = \{A, B, C\}$, the topological expression $\psi = T'(A, B) \lor T(A, C)$, where $T' = \{\text{Meet, Equal}\}$ and $T = \{\text{Equal, Inside, Covered_by}\}$, is topologically consistent because there exists a function $TR$ that can be defined such that $TR(A_i, B_i) = \text{Equal}$ for every $A_i$ and $B_i$ in $Ob$. Indeed, $TR(A, B) = \text{Equal} \in T'$, $TR(A, C) = \text{Equal} \in T$ and for every $A_i$, $B_i$, and $C_i$ in $Ob$, $TR(A_i, C_i) \subseteq TR(A_i, B_i) \otimes TR(B_i, C_i)$ because $\text{Equal} \subseteq \text{Equal} \otimes \text{Equal}$.

The following example, in contrast, illustrates a case where a set of topological relations does not satisfy topological consistency. Consider the set of spatial objects $Ob = \{A, B, C, D\}$ and the topological expression $\psi = \text{Covered_by}(A, B) \land \text{Covered_by}(B, C) \land \text{Inside}(C, D) \land \text{Covers}(A, D)$. The possible topological relations between $A$ and $C$ must be defined by the common relations in the compositions $\text{Covered_by}(A, B) \otimes \text{Covered_by}(B, C)$ and $\text{Inside}(C, D) \otimes \text{Covered_by}(D, A)$. However, by the composition table (Figure 6), $\text{Covered_by} \otimes \text{Covered_by} = \{\text{Covered_by},$
TOPOLOGICAL RELATIONS

Inside} and Covers \( \otimes \) Includes = \{Includes\}. Since Covered\_by \( \otimes \) Covered\_by \( \cap \) Covers \( \otimes \) Includes = \( \emptyset \), there exists no function TR that satisfies the conditions for consistent network.

There are some cases in which, even if the topological relations are consistent, the spatial objects may not be realizable due to reasons of planarity, that is, there are no objects that can be

---

Figure 6 Composition of basic topological relations. Adapted from Egenhofer (1994). © 1994, with permission from Elsevier.
drawn on a plane and satisfy topological relations. The problem of determining if these objects exist is the realizability problem (Grigni, Papadias, and Papadimitriou 1995). The conjunctive realizability problem consists in determining if there exists a planar model that satisfies a conjunctive topological expression like $\psi = (\text{Equal}(A, B) \land \text{Disjoint}(B, C) \land \text{Disjoint}(A, C))$.

Formally, given a set of objects $Ob$ and a conjunctive topological expression $\psi = \wedge_{i=1}^{n} T_i(A_i, B_i)$ where each $T_i$ represents a disjunction of base topological relations between objects $A_i$ and $B_i$ belonging to $Ob$, the realizability problem consists of determining whether there exists a planar model for each object that satisfies $\psi$.

If a topological expression is not topologically consistent, then it directly follows that it is not realizable. There are some cases, however, where the expression is topologically consistent but it is not realizable on a plane. From a computational point of view, there is no known algorithm that can efficiently determine if a topological expression is realizable. Consequently, the topological consistency problem is generally used as a good approximation algorithm for the realizability problem.

Another interesting concept when reasoning about topological relations is the notion of a conceptual neighbor. The conceptual neighbor refers to relations that are semantically closer to each other. This is useful for grouping relations and detecting similar relations, which have practical applications to compare spatial configurations and select appropriate terminology when people communicate about specific spatial configurations. Figure 8 shows the eight base topological relations organized in a graph that connects conceptual neighbors derived from the concept of gradual changes (Egenhofer and Al-Taha 1992). For example, Disjoint and Meet are two neighboring relations in this graph and, therefore, they are conceptually closer than Disjoint and Overlap. Using this graph a similarity measure compares topological relations using the semantic distance between relations.

In a similar way, there exist conceptual neighboring of relations between lines or between regions defined by interval relations in $\mathbb{R}^1$, region relations in $\mathbb{R}^2$ and regions on the sphere $\mathbb{S}^2$.

**Natural-language spatial relations**

With the goal of making GIS closer to the way users communicate about topological relations, the work in Shariff, Egenhofer, and Mark (1998) studies the geometry associated with natural-language spatial terms. Understanding
TOPOLOGICAL RELATIONS

the use of natural-language spatial terms is important when trying to capture the common-
sense knowledge about the physical world, which is a central area of naive geography.

Focusing on the 19 region–line relations defined by the 9-Intersection Model, three types
of measures model the metric refinements of the topological relations between regions and lines:
(i) splitting, which determines how the interior, boundary, and exterior of a region is divided
by the interior and boundary of a line, and vice versa; (ii) closeness/nearness, which deter-
mines how much in common two regions have; and (iii) approximate alongness, which assesses
the length of the line and perimeter when the interior of a line does not coincide with
the boundary of a region. In total, they define six different measures of splitting, four of closeness,
and two of alongness. To clarify the idea of these metrics, Figure 8 shows one measure for each
type that is defined as a dimension-neutral ratio.

This model of metric refinements over the topological relations was calibrated for 59
English–language spatial terms (Shariff, Egenhofer, and Mark 1998). Major conclusions of
this work are that topological relations are more important than metric refinements when char-
acterizing spatial terms and that many spatial terms fall in the same topological relation but
not with equal metric parameters.

The work in Xu (2007) also studies natural-
language spatial terms but focuses on linear
objects. It uses the 9-Intersection Model and
metric indices to formalize natural-language spatial terms between two line objects. Metric
indices in this case are direction (local and global angles), splitting (i.e., intersect splitting, along-
ness splitting, and interior traversal splitting), distance (i.e., short and long distances), and
overlap ratio. Unlike the work in Shariff, Egen-
hofer, and Mark (1998), however, in this case topological and metric indices are used together
to classify spatial terms with a decision tree. Only
the indices that are found to better classify terms
are then used in spatial queries. As a conclu-
sion, this work found that topological relations
together with metric indices are better to classify
spatial terms than just topological relations alone.

Place names weld together language and territory. Place names that label, denote, and identify places belong to the language of space and to the poetics and politics of the landscape. Importantly, as elements of language spoken and inscribed in gazetteers and ordinances and on maps and public signs, place names are enmeshed in a web of significations.

Intended to call attention to the existence of particular places, the primary function of place names is to signify geographical features, such as countries, seas, mountains, creeks, towns, or streets, and thereby differentiate between them. Giving a name to a place entails that the place is recognized as an entity distinguishable from other places. Essentially, place names are signs of civilization: geographical features belonging to elemental wilderness are largely nameless. However, conceiving geographical features as places entitled to be named possibly entails a degree of abstraction. Can a mountain be definitively delineated? What constitutes a street? Where exactly is the source of a river? Moreover, while “real” place names signify places in the physical world, real and imaginary place names also flourish in the fictional worlds of literature, cinema, and computer games.

Many place names such as Long Island, Dead Sea, or Yellow River are descriptive, which can be potentially misleading. The Pacific Ocean can be stormy. The Red Sea is not red. Myriad place names commemorate events or other places, such as Alexandria, Egypt; Washington, DC, USA; Piazza Venezia, Rome; and Pariser Platz, Berlin. Place names do not necessarily designate the properties and character of the place they refer to. They may be words that are intrinsically void of lexical sense. However, since place names are associated with human experiences and agendas, they not only denote locations but possibly also connote reputations and call to mind certain images and associations. This is clearly evident in the case of (in)famous places, whose names have become household names. As a place name, Las Vegas denotes a city in Nevada and connotes its reputation as Sin City. A reference to New York City also connotes its reputation as a vibrant metropolis that never sleeps. Sometimes place names connect with events and are invested with historical memories. Examples include Verdun (a battlefield in France, 1916) or Yalta (conference, 1945). Place names may also become metaphors for social milieux, cultural phenomena, and lifestyles that, at least in their early evolution, were connected with the location. The meanings associated with place names are historically dynamic; place names may acquire new connotations, while older ones may lose their power of evocation.

Naming is a prerequisite for converting space into place. Place names are not mere signifiers but are actively involved in place-making. The place-making capacity of place names are manifest in their power to stir the imagination, to evoke the idea of place, and to conjure a sense of place. It is evident in their ability to elicit personal and communal memories that associate places with real and fictional biographical and cultural experiences.
Human curiosity and fascination with the origin and meaning of place names are manifest in stories societies tell about the origin and meaning of place names. In Maori lore, stories about the journeys of ancient heroes also recount the names they gave to features of the land. The Old Testament contains numerous etiological stories about the origin and meaning of place names.

As it developed in the nineteenth century, linguistic orientation and philological discipline underlie the traditional European approach to the study of place names (Stewart 1975). The aim of such research has mainly been to establish etymology: tracking the development of place names since their earliest documented occurrence and possibly unearthing the provenance of place names in relation to patterns of migration and settlement. With its overwhelmingly linguistic orientation, the traditional European approach to the study of place names has been fixated on older names and almost exclusively focused on taxonomy and etymology. For lack of historical records and documentary sources, etiology, namely the causes underlying name-giving, was almost inevitably a highly speculative matter.

That place names belong to the academic discipline of geography seems self-evident, yet within academic geography studying place names was traditionally consigned to the margins of scholarship (Rose-Redwood, Alderman, and Azaryahu 2010). Whereas the kind of “applied” toponymy advanced by national boards and United Nations agencies has focused, respectively, on the standardization of toponymic nomenclatures nationally and internationally, academic geographers interested in social theory largely considered the traditional approach to the study of place names as not worthy of serious scholarship.

The resurgence of academic interest in toponymy since the 1980s has largely been anchored in and connected to applying a critical approach to the study of place names and especially procedures and patterns of place naming, where issues of power reign supreme (Berg and Vuolteenaho 2009; Rose-Redwood, Alderman, and Azaryahu 2010). The “critical turn” in toponymy as a field of academic study has largely been concerned with recent, well-documented place-naming procedures. Notably, it has also been manifest in the growing number of studies dedicated to issues related to the potentially contested urban and possibly national politics of street naming. Being a feature of urban modernity, street names had almost completely been ignored by traditional toponymic studies.

Crossing disciplines, the critical approach to the study of place names has been applied by geographers inspired by earlier works on landscape symbolism as well as by historians, political scientists, sociologists, and anthropologists. Underlying the critical approach to the study of place names is the insight that place names belong to structures of power and discourses of identity. The critical orientation of geographic inquiry into toponymy has treated place naming as an arena of politics. Accordingly, recent critical scholarship on toponymy has directed attention to how the politics of place names and place naming in particular reproduce power relations and ideological agendas in public space.

This line of research has shed light on the relationship between place (re)namings and identity politics, such as when contested place names and place-naming patterns are embedded into larger struggles for recognition and legitimacy and are emblematic of them. Studies have yielded significant insights into the shaping of toponymic regimes in colonial societies and in nationalist contexts. Along this line of research several studies have focused on toponymic changes following power shifts, most conspicuously in postcolonial and post-communist societies. When belonging
to the symbolic politics of regime change, the renaming of streets demonstrates how processes of political change and ideological reorientation at national level are instrumental in reshaping urban geographies of everyday life.

Within the growing literature on critical toponymy, several studies have focused on toponymic commemoration and especially on street naming as a strategy of public commemoration where possibly competing visions of history shape (re)naming priorities and practices. These studies have shown that when invested with commemorative capacity, toponymic inscriptions become urban sites of memory that weld together power, remembrance, and language in public space. Some recent studies have directed attention to the politics of displaying toponymic inscriptions in public signage in bilingual societies. Another line of investigation has explored the commodification of toponyms in conjunction with tourism and as a place-branding strategy and the association of place-naming practices and priorities with creating social distinction and prestige for communities and commercial ventures.

Based on the understanding that (re)naming is an expression of power, critical toponymy emphasizes the politics underlying place naming as a potentially contested spatial practice susceptible to involvement in struggles for symbolic control of public space. Importantly, the emphasis on (re)naming procedures that direct the formation of modern toponymic regimes has introduced unequivocal etiological concerns and considerations into current theoretically informed and critically oriented study of place names.

Tourism

Daniel H. Olsen
Brigham Young University, USA
Dallen J. Timothy
Arizona State University, USA

Tourism entails temporary travel outside people’s usual place of residence from one area of the Earth to another and all the elements of supply and demand at home, in transit, and in the destinations that facilitate this mobility and create an experience. People have traveled for leisure and other purposes for centuries. The foundations of modern tourism have been attributed to the Grand Tour, wherein wealthy Europeans traveled to various European countries for education, health, and pleasure. While travel for leisure purposes initially was an elite activity, increases in discretionary income, the development of cheaper and more efficient transportation, the growth of various tourism market niches, and the institutionalization of the act of travel into Western cultural lifestyles and schedules (e.g., spring breaks, reading weeks, gap years, and the growing number of holidays and paid vacation days) has led to the democratization of tourism for virtually all socioeconomic classes in the Western world.

Since World War II there has been a dramatic increase in domestic and international travel. In 2015, 1.185 billion international tourist arrivals were reported, generating approximately US$1.241 trillion in international tourism receipts (see Table 1). Tourism also represented 6% of the world’s exports, contributing to approximately 1 out of every 11 jobs worldwide, or 8.7% of total employment (including jobs indirectly supported by tourism) in 2015. With international travel expected to increase 3.3% a year until 2030, and with emerging destinations expected to see a 4.4% increase in international arrivals during the same timeframe, tourism has become a crucial component in the economic development strategies of national, regional, and local governments in their quest to diversify economies and enhance employment opportunities (World Tourism Organization 2015).

While geographers were among the earliest tourism scholars, the academic study of tourism has become increasingly multidisciplinary, in part because of the increasing complexity of various types of human mobility, the emerging industries that have been organized to cater to their needs, and the increasing economic, sociocultural, and ecological impacts of tourism. Considering that tourism is inherently a spatial phenomenon, and while geographic concepts such as complementarity, intervening opportunity, transferability, distance decay, and gravity models are key in understanding tourism flows between and within destinations, the study of tourism as a subject of analysis seems to occupy a liminal or relatively minor specialist position within academic geography (Gibson 2008). This is no doubt so because many tourism geographers are employed outside of geography departments (e.g., in business, tourism and recreation, community development, sport management, environmental planning, and cultural studies), even though many of them continue to undertake geographical research.

Geographic research on tourism began in the 1920s, and contributions by geographers

to the study of tourism continue to grow and influence contemporary thinking, with some of the best known, prolific, cited, and respected tourism scholars being geographers. In the early twentieth century, geographic studies of tourism were highly descriptive, like many human geography studies of the time. The 1950s saw the beginnings of tourism-focused research in area studies, human–environment interactions and spatial analyses, which tended to dominate tourism research by geographers until the 1980s. The 1980s and 1990s saw an additional shift in focus to the sociocultural, economic, and environmental effects of tourism’s growth (Butler 2004), tourism planning and policy, and community–based development. The 1990s and the new millennium saw the expansion of research by tourism geographers into many emerging themes, including safety and security, cultural heritage management, indigenous rights, poverty alleviation, rural development, urban renewal, niche tourism in relation to gender, sexuality, spirituality, and religion, and amenity migration, addressing a range of issues central to geography such as power and empowerment, human mobility, globalization processes, neoliberalism, and technology.

While geographers continue to contribute to the increasingly fragmented study of tourism through various theoretical and applied perspectives and approaches (see Wilson 2012), many of these traditional and modern contributions can be categorized into at least three key areas: explaining the spatial complexities of tourism development, human–environmental interactions in tourism, and critical and sensuous geographies of tourism.

The spatial complexities of tourism

Because of the importance of tourism in Western economic and capitalist economies, early work by geographers revolved around the economic elements of tourism. Initially, geographers described, mapped, and modeled the spatial patterns of domestic and international travel patterns and flows, segmented tourist attractions, and identified different tourism niche markets based on people’s motives for travel and geographic origin. They explained the marketing and promotion of new tourism spaces and discussed how increasing numbers of travelers affected the creation of new commodity chains and tourism labor markets. Geographers have studied the role of international law, the supranationalization of the world, and the neoliberal growth factors that either facilitate or inhibit international tourism. Geographers have also tried to explain the effects of tourism on changing land-use patterns within urban and rural contexts, tourism development in wilderness areas and along coastlines, and the
spatial dimensions of tourist attraction systems. Different forms of land-use development unique to tourism, such as tourism zones, resorts, and touristic enclaves have also been examined as well as a number of issues related to tourism planning, growth and destination management, destination life cycles, community-based tourism, entrepreneurial behavior, transportation development, and the rise of second homes in the context of the particularities of different places.

Tourism is supposed to improve the livelihoods of people in destinations through the improvement of a country’s balance of payments, the attraction of both local and foreign investment, the creation of new economic linkages, the “multiplier effect” beyond tourism zones and related businesses, and increased employment opportunities; but such is not always the case. Transnational tourism businesses and cruise lines, for instance, tend to encourage high levels of economic leakage in many lesser developed destinations, and considering that most jobs in the tourism sector are highly seasonal, and therefore usually part time, and consist of low-wage, low-skill, and frequently dangerous work, tourism is therefore seen as contributing to, rather than helping with, current global spatial and economic disparities. Therefore geographers investigate pro-poor tourism and bottom-up approaches to development as a way to understand tourism as a potential tool to help alleviate poverty in developing countries.

Place is an essential ingredient of tourism, particularly from the perspective of destination development and marketing. Geographic approaches have led to increased knowledge about people’s attachment to place and sense of place in tourism settings, both from tourists’ and residents’ perspectives. From a marketing perspective, place branding has come to the fore in recent years as a critical factor in a location’s success as a tourist destination. Place-making and location branding, as well as meanings and identities associated with place attachment, while initiated by geographers and embracing geographical concepts and spatial complexities, have gained significant currency among non-geographers as well and form a common thread in tourism planning and marketing studies.

Finally, technological developments have provided methodological and virtual tools and cyber spaces for contemporary geographic research in tourism and elucidate additional spatial complexities in global tourism. Geographic information systems (GIS) are currently routine tools for assessing impacts and locational valuations. Social media, including Facebook, blogs, Youtube, photo sharing sites, Google Earth, and other neogeographic spaces are overflowing with volunteered geographic information about destinations and travel experiences and are now among the most popular cybernetic laboratories for tourism research. Global positioning systems-based technology, for example, has been used in recent years by geographers to understand tourists’ spatial behavior patterns in parks, historic cities, and in other heritage contexts.

Human–environment interactions in tourism

While the competitive economic elements of tourism continue to dominate much tourism scholarship, because of their interests in human–environment interactions, geographers have a strong track record of examining the direct and indirect impacts of the sector on the physical environment. The relationships between tourism and the physical environment are complex and symbiotic in many respects. On one hand, the natural environment is a critical tourism resource, whether climate- or landscape-based, that creates widespread demand
for destinations. In many cases, the development of tourism naturally leads to the protection of a destination’s natural resources, so that they remain viable in the long term (e.g., national parks and protected areas). On the other hand, the natural and cultural resources that need to be protected are the same attractions tourism utilizes most. Frequently these resources are fragile or located in ecologically sensitive areas and as increasing numbers of visitors interact with them the environment can be literally “loved to death.” Loss or deterioration of such sites is a real danger in both built and natural environments. Geographers have also examined other negative results of tourism on the environment, including changes in biodiversity, water use and quality problems, waste generation, site erosion, reduced landscape aesthetics, and reduced air quality, and how these issues affect the destination residents’ quality of life. Research by geographers shows that these impacts go beyond pure ecology to include economic implications when environmental damage decreases the competitiveness of tourist destinations, particularly those that are most reliant on environmental resources for their tourism development. While many impact studies are undertaken at site- or destination-specific scales, geographers are now highlighting global trends related to the planetary impacts of tourism development. In particular, they are now investigating the impacts of travel on global climate change, which in the future is predicted to alter not only the physical locations of tourism but also the types of markets and demand for destinations and their products, such as those located on islands and coastlines that are especially vulnerable to climate change and rising oceans.

Sustainability is one of the most important considerations in the long-term viability of tourism. Geographers have been key players in discussions about sustainable tourism development and management, particularly in the contexts of protected natural areas and various other ecosystems (e.g., marine environments, coasts, mountains). Although most discussions surrounding sustainability and tourism have focused on natural settings, geographers have been instrumental in broadening the debate into social and economic realms as well. Social and economic carrying capacities are now viewed alongside ecological capacities as vital elements of sustainable development and limits of acceptable change. Geographers also investigate various philosophical, indigenous, and religious views of the natural environment, and have been active in developing environmental ethics and codes of conduct in tourism’s use of natural and cultural resources. These efforts have assisted in improving corporate social responsibility and the establishment of eco-certifications for tourists, guides, tour operators, transportation providers, and lodging establishments.

Critical geographies of tourism

In recent years there have been calls to move beyond traditional views of tourism as a structurally and spatially circular economic practice and the statistical inclination of tourism studies to apply more critical and deconstructed analyses of the moral, cultural, and social dimensions of tourism within wider global trends, including increases in technological, political, and trans-local cultural exchanges. The critical turn in tourism studies coincides with the “cultural turn” in the social sciences, in that scholars have begun to reexamine tourism as a cultural phenomenon in terms of social representation and identity formation. Additionally, critical geographic views of tourism emphasize the ways
in which tourism reinforces dominant power structures and relationships at different scales.

As part of this critical approach, geographers have used postcolonial views of development to argue that tourism is neo-colonialist, because it creates dependency relationships between countries in the Global South where travelers holiday and the wealthier countries of the Global North where they live. From this perspective, neocolonialism suggests that low-income countries act as “pleasure peripheries” for tourists from high-income countries. In so doing, tourism is seen to increase economic, social, and racial divisions between tourists and destination residents – with tourists/tourism being the oppressor and the local community the oppressed – by marginalizing tourism workers from tourists in terms of access to capital and local resources necessary to improve livelihoods, leading in many cases to observed acculturation processes in the Global South (Gibson 2008).

The work of geographers has also noted that tourism marketers and promoters act as cultural brokers and tend to construct idealized images of both tourist spaces and cultural groups that cater to the whims of tourists, resulting in inaccurate representations of culture through the process of commoditization. Commodified, packaged, and staged resident–tourist encounters focus on affirming outsiders’ misconceptions of a particular culture rather than focusing on “authentic” cultural objects and ways of life. Geographers have also noted the performative nature of both tourist and tourist worker behavior in tourism spaces, and how governments have appropriated religious and indigenous cultural heritage to represent their regimes to tourists in a way that legitimizes their authority. Such practices have led some geographers to examine tourism ethics in the context of appropriate cultural and social encounters between tourists and local residents.

Tourists, rather than inherently searching for “staged authenticity” through the act of travel that objectifies cultures and places and utilizes tourism as a means of escape from their everyday lives, are increasingly viewed as modern reflexive subjects that negotiate their identities through the embodied consumption of places, experiences, and encounters with the Other. Geographers therefore have begun to analyze ways in which tourists interact with the signs, icons, and souvenirs created by tourism, as well as the multisensuous, multisensory, and embodied practices in which tourists engage as they try to make sense of what they experience in touristified spaces. At the same time, geographers acknowledge that tourism spaces are social constructs and have examined how tourists, not just tourism marketers and promoters, act as place-making subjects in the (re)construction of tourism spaces.

Future directions

There is virtually no area of the Earth’s surface that remains untouched in some way by the influence of tourism. With the number of people traveling expected to increase in the long term, tourism is poised to have an increasing vital impact on the economies, environments, and societies of the world. Geographers will continue to play a key role in the aforementioned fields as well as in understanding the importance and impacts of virtual travel on embodied tourism experiences; the continued use and importance of GIS and remote sensing in tourism development decision-making; the increased tension between competitiveness and sustainability; the spatialities of changing and mobile tourist and cultural identities; the development of extra-terrestrial tourism (e.g., space tourism, deep ocean exploration); safety and security in the contemporary world of terrorism.
and other threats to travel; migration, diasporas and displaced identities; and the mapping and examination of new patterns of travel from formerly low-income countries (e.g., China, Russia) where larger population cohorts now engage in international tourism. Tourism geographers will also continue to be active in the new mobilities focus in human geography, in which tourism is seen as part of people’s everyday mobility patterns and where tourism is only one manifestation of a multiplicity of diverse travel mobilities.

Trade and regional development

John S.L. McCombie
University of Cambridge, UK

Regions show a great deal of heterogeneity in terms of their production structure. This derives from differences in natural resources or in relative factor endowments, namely the abundance of capital (both private and public) relative to the workforce. A corollary of this geographical specialization of production is the importance of trade, as without trade there could be little or no specialization. Much of the early work on regional development and trade treated regions as equivalent to nations, but within a common currency area, and drew on the pure theory of international trade.

The theory of comparative advantage, first put forward by David Ricardo in 1817, still remains an influential explanation of trade. Suppose that there are two regions, the East and the West, each with two industries. Labor is the only input, and the East has greater productivity in both industries. Labor is the only input, and the East has greater productivity in both industries. The remarkable result of the theory is that trade will benefit both regions, although there is nothing that ensures equality of the gains from trade. The East will specialize in the production of that good where its relative (comparative) advantage in terms of productivity is greater and the West will produce the other good. However, the theory is best seen as a static theory of resource allocation and assumes full employment. It does not explain why the productivity levels differ between regions and assumes constant returns to scale. As such it says little about regional growth except that if there is labor mobility, then there will be migration of workers to the East which will end up producing both commodities, with the West neither. With a common wage rate in both regions, the East, with the higher level of productivity, will have lower unit costs and, hence, lower prices than the West. Even if the West has an offsetting lower wage rate so that prices do not differ, labor will still migrate to the East because of the higher wages there.

The next development in trade theory was the factor endowments (Heckscher–Ohlin) theory. This introduced capital as a factor of production and assumed that each region has the same technology and the production functions once again exhibit constant returns to scale. The theory predicts that regions that have a high capital to labor ratio will export goods that require more capital relative to labor, and vice versa. The rationale is that regions with a relative abundance of capital will have lower profit rates and hence should export those goods that use a lot of capital and where the regions have a cost advantage. Early tests in the 1950s found a paradox in that the United States, a relatively capital-rich country, tended to export relatively labor-intensive goods. A number of explanations were put forward to explain this, including the fact that the United States had a highly skilled labor force and an allowance should be made for its human capital. Tests of the Heckscher–Ohlin theorem are fraught with data problems (especially concerning estimates of regional capital stocks and lack of statistics for interregional trade flows). Generally speaking, the results indicated that factor endowments explain some, but not
much, of the pattern of interregional trade. Even without factor migration, under certain assumptions, the two-country model predicts factor price equalization, but for which there is little empirical evidence. The three-country case has more ambiguous results.

There are a number of serious shortcomings of the theory. The first is that much of trade is now intraintustry, or intrafirm, which the Heckscher–Ohlin theory cannot account for. For example, intraintustry trade in the mid-2000s accounted for between 27 and 44% of world trade, depending upon the level of statistical disaggregation. The degree of intraintustry trade has steadily increased since the 1960s, suggesting a greater internationalization of supply chains with globalization and outsourcing, and this is likely to be reflected at the regional level. Second, the theory does not explain why, in the first place, some regions are relatively capital rich and others poor, especially when factor mobility is taken into account. And finally, and most importantly, there is much evidence that regional production is subject to increasing returns, especially agglomeration economies. Indeed the very existence of cities bears testament to this, because if there were constant returns to scale, there should be a much more uniform spatial distribution of production to minimize transport costs.

A major recent development in the analysis of trade and geography is the use of mainstream economic tools to analyze the causes of the location of spatial activity. The approach of the “new economic geography” (NEG), or “geographical economics,” is based on what is seen as rigorous economic microfoundations. It adopts the “representative agent” approach where the optimizing decisions of single agents (both firms and consumers) are modeled. These models are then taken to apply directly to the macroeconomy (and aggregation problems are ignored).

The pioneer in this field was Krugman (1991, 2009), whose approach was based on the observation that economic activity is highly spatially concentrated. Moreover, areas of manufacturing, such as the northeastern manufacturing belt of the United States, have maintained their dominance long after the importance of any geographical advantages, such as a location on rivers or seaboards or the presence of raw materials, have disappeared. Furthermore, industries also tended to be highly clustered, and this is as true of many older industries as it is of the new hi-tech industries. The reason for this is the presence of increasing returns which includes agglomeration economies, namely the external benefits arising from firms locating next to each other. (For a survey of the evidence see Rosenthal and Strange 2004). This leads to the spatial concentration of industry, while transport costs lead to a dispersion.

The NEG approach was based on the development of techniques that enabled increasing returns to scale and product differentiation to be formally modeled using the monopolistic or imperfect competition model developed in the 1930s by Joan Robinson and Edward Chamberlin. The approach is based on the existence of product differentiation, which explains intraintustry trade. While traditional trade theory could explain specialization of production, intraintustry trade until recently presented problems. Intraintustry trade could be largely explained by this “love of variety.” Because of increasing returns, it is more efficient for each region, or country, to specialize in one, or a few, of the various different products of an industry and to trade them, rather than to produce the whole spectrum. Intraintustry trade can also be explained by globalization and the greater spatial division of labor both between regions and between countries. In the latter
case, the routine assembly is often outsourced to low-cost countries.

The NEG models are often mathematically complicated. However, the fundamentals of the approach have been illustrated in a simple numerical example by Krugman (1991) using aggregate output (rather than a variety of different products) and transport costs. He assumes that there are two regions, namely, East and West. On the one hand, there is an immobile agricultural labor force that is divided equally between the two regions. The manufacturing labor force, on the other hand, is mobile and its distribution depends on the location choices of the firms. Production is subject to increasing returns that result from fixed costs and there are transport costs of shipping goods between the regions. The position is analyzed from the viewpoint of a single firm deciding where to locate. If transport costs are high relative to fixed costs then the other firms will have established plants in both regions and the labor force will be equally split between the regions. Hence, the firm will likewise find it most profitable to set up two plants, one in each region. The extra fixed costs arising from having two plants will be less than the total transport costs of shipping goods from a single plant located in one of the regions.

However, with low transport costs, then it will pay all the firms to locate in one region (to minimize their fixed costs) and pay the costs of shipping to those agricultural workers in the other region. The firm under consideration will similarly find it most profitable to follow suit. Thus, over time, as transport costs fall relative to the fixed costs, so firms will agglomerate in one region, through a process similar to Myrdal’s cumulative causation, but which region they choose may be due to small initial advantage or chance factors. In this sense, history matters. The approach is generalized to analyze other centripetal forces, beyond those caused by fixed costs, such as knowledge spillovers, thick labor markets, and the spatial concentration of suppliers. These cause firms to concentrate whereas such factors as increasing land rents and congestion costs lead to centrifugal forces and dispersion (Fujita, Krugman, and Venables 1999). Krugman and Venables (1995) have extended this model considering the path of wage rates. When transport costs are high, the regional structure of production and the wage rates are similar. But as transport costs fall, one region will gain an advantage because of proximity effects and deindustrialization will occur in the other region. The result is a wage disparity. But with a further fall in transport costs and globalization, wage rates will converge.

Trade, in this approach, is incorporated into the analysis through transport costs, and provides an explanation of why production becomes concentrated in terms of equilibrium (albeit multiple possible) outcomes. As such, it explains the specialization of production, but does not say much about regional growth, or development, per se. Neoclassical endogenous growth models based on the aggregate production function have been extended to allow the interaction through trade between, usually, two regions. The standard Solow growth model treats technological change as occurring exogenously and as a pure public good. Endogenous growth theory, as its name suggests, attempts explicitly to model technical change, either the result of learning-by-doing and a function of capital accumulation (the $AK$ model) or through an R&D (research and development) sector. Trade is, however, rather tangential in the spatial adaption of these models which emphasize, for example, the distance of a region from the technology frontier, and technological spillovers. Donaghy (2009) provides a survey of this literature.

It is somewhat ironical that Krugman (2009) has himself questioned the relevance of the NEG
model to regional economies in the developed countries, noting that the degree of specialization in industry the United States reached its zenith in the 1930s and since then has been steadily declining (Kim 1998). The same pattern is reflected in the increasing globalization of international trade with falling transport costs. Trade is growing between the low- and high-income countries, reflecting comparative advantage and differences in labor costs. There is also the outsourcing of some stages of production from the developed to developing countries. It seems that the NEG now has greater relevance for regions in the new industrializing countries, such as the regions on China’s seaboard which are enjoying rapid growth, reflecting their greater access to overseas markets.

A number of theories have emphasized the role of exports as an important factor in determining the growth of a region or city. The approach was developed, most notably, by Kaldor (1970) and his discursive argument was formalized in the canonical model of Dixon and Thirlwall (1975). The Kaldorian approach concentrates on the factors determining the growth of the demand for a region’s exports, which in turn drives output growth. A faster growth of demand will lead to a faster growth of supply, and the additional resources will be met, inter alia, by the net in-migration of labor and increased capital accumulation. There will also be a faster rate of induced technical change through, for example, learning-by-doing. Hence, it is a Keynesian theory of long-run growth, but where the focus is on the structure of exports and whether they are products for which world (including other regions’) demand is rapidly growing. It thus stands in contrast to the supply-oriented NEG models, where the role of demand does not explicitly feature.

Kaldor also stressed that production is subject to increasing returns (defined broadly to include static and dynamic increasing returns to scale, agglomeration economies, and induced technical change) as evidenced by the Verdoorn law. This is a macroeconomic production relationship and, in its simplest form, is given as \( p = \alpha + \nu q \), where \( p \) is productivity growth and \( q \) is output growth. In the equation, \( \alpha \) is the exogenous growth of productivity and \( \nu \) is the Verdoorn coefficient, which most empirical studies find takes a value of about one half. (These regression studies often use regional data for the states of the United States, China’s provinces, or the European Union (EU) NUTS (nomenclature of territorial units for statistics) regions.) This means that a one percentage point increase in output growth causes an extra growth of productivity of half a percentage point and an increase in employment growth of a similar magnitude. If there were constant returns to scale, then the rate of increase in employment would be the same as output and the Verdoorn coefficient would take a value of zero. The results provide confirmation at the aggregate level of the microeconomic studies that find agglomeration economies important.

Recent estimates of the Verdoorn law extend this approach, most notably explicitly including the growth of the capital stock. For example, Angeriz, McCombie, and Roberts (2009) tested the law for the EU regions over the period 1986–2001, within a more general spatial econometric framework and including other regressors to capture spatial spillovers. They find that the Verdoorn coefficient of 0.67 gives a substantial estimate of “encompassing returns to scale” (i.e., including induced technical progress and the effects of learning-by-doing) of just over 3. The spatial spillovers are also statistically significant.

The cumulative nature of regional economic growth takes the following form. A faster growth of regional output leads to a faster growth of productivity, through the Verdoorn law. A more rapid growth of productivity, in turn, leads to
improving regional price competitiveness. This, in turn, results in a faster growth of exports. Prices are determined by a markup pricing model, and the growth of nominal wages is assumed to be constant across the regions, determined by national bargaining and comparability norms. This implies that the faster the growth of productivity, the more slowly a region's prices will grow, compared with other regions. Export growth is determined by an export demand function and is a function of the rate of change of relative prices and the growth of the region's export markets, often proxied by the growth of the latter's income. The faster growth of exports leads to a further increase in the growth of regional output through the dynamic Harrod foreign trade multiplier.

Whether the regional growth in the model converges to a steady state, or follows an explosive path, depends on the values of the various parameters of the model, including the size of the Verdoorn coefficient and the values of the price elasticity of exports and the elasticity of output growth with respect to export growth. Dixon and Thirlwall (1975) considered that these values are such that there will be a convergence, whereas Kaldor disagreed. As regional growth rates clearly cannot accelerate indefinitely, in the latter case, supply-side factors come into play to restrict the rate of growth. These include the lack of a sufficient degree of labor mobility with resulting labor shortages bidding up regional wages and reducing the region's price competitiveness. Other growth-restricting factors include greater congestion costs and increasing urban land rents. Nevertheless, the outcome of trade flows is a core-periphery situation with relatively high- and low-productivity regions and greater open, and disguised, unemployment in the latter.

A shortcoming of this approach is that it is possible for, say, the growth of regional imports to permanently diverge from that of exports. But no country (or region) can run an increasing deficit on the current account indefinitely. In the case of a country, the net overseas debt to gross domestic product (GDP) ratio will eventually become so large that international borrowing to finance the deficit will dry up. (This is roughly when the ratio of net overseas debt to GDP ratio reaches 60%.) Consequently, a country is constrained to grow in the long run at a rate where the current account is roughly in balance. Likewise, regions have a balance of payments with other regions and countries. While these payments are not recorded in the official accounts, the economic consequences arising from a region's performance in its external markets are just as real for a region as for a country. “Regional problems are ‘balance-of-payments problems,’” as Thirlwall (1980) puts it. The regional balance of payments is similar to those in the national accounts with the exception that there is no category of a change in foreign reserves. Moreover, interregional fiscal transfers can be important.

The importance of this financial constraint has been often overlooked and this is due to the fact that a national banking system may obscure the problems faced by unbalanced trade. Moreover, there cannot be a (regional) currency crisis. The fact that with a national banking system, regional branch bank loans do not have to be matched by deposits may give the erroneous impression that financial flows induced by a current account deficit are automatically accommodated indefinitely. But as the case of the post-2008 eurozone crisis shows, countries cannot borrow indefinitely from other countries, even when they are all in a common currency area.

Suppose that there is a collapse in regional export earnings. It is likely that there will be initially an attempt by consumers and firms to maintain expenditure by borrowing from other regions. However, a reevaluation of the prospects of the region by the banks and the decrease in
the region’s collateral as its assets progressively become mortgaged or sold will lead to a rising regional risk premium. Eventually, there may be credit rationing. There is, consequently, only a limited scope for a region to offset a decline in the performance of its export sector by borrowing from other regions. The only exception to this is through the automatic stabilizing transfers such as unemployment benefits and other fiscal transfers, but these are likely to be relatively small. (See Dow 1986.)

The cumulative causation model can be extended to take into account the regional balance-of-payments constraint. It is now assumed that prices of exports are set in national markets and hence price competition is limited. (In an international context there is evidence that the price elasticities are low and the Marshall–Lerner conditions are only just satisfied, and/or that the terms of trade do not greatly alter in the long run because of oligopolistic pricing policies.)

Under these circumstances, the balance-of-payments-constrained growth of a region \(y_B\) is given by the simple rule known as Thirlwall’s law (see Thirlwall 2012 for a survey). This is

\[
y_B = \frac{x}{\pi} = \varepsilon \frac{z}{\pi},
\]

where \(x\) is the growth of the region’s exports, and \(z\) is the growth of the region’s exports markets. The parameters \(\varepsilon\) and \(\pi\) are the world income elasticity of demand for the region’s exports and the region’s income elasticity of demand for imports. Differences in the values of these admittedly highly aggregated parameters between regions reflect all aspects of the nonprice competitiveness of the region. These include the structure of production, for example whether the region specializes in, say, the production of goods and services, such as hi-tech products or financial services, for which “world” demand is rapidly growing, or alternatively heavy industry for which world demand is falling. If the ratio \(\varepsilon / \pi\) is, say, 3, then this means that if the region’s export markets are growing at 3% per annum, the growth of the region will be 9% when the balance of payments is in equilibrium. Alternatively, if the region is specializing in a declining industry and the ratio is one half, then the growth of the region will be about half that of its export markets. Thus, this approach, although highly aggregated, emphasizes the disparities in the structure of output and the drivers of productivity as key elements of regional development. The cumulative nature of growth is now generated by a faster growth leading to increased nonprice competitiveness, through increasing the income elasticity of demand for the region’s exports and reducing its demand for imports, although this may be a slow process. This is a change in emphasis from the cumulative causation model discussed above, where changes in relative prices are important. Hausmann, Hwang, and Rodrik (2007), in their study of “what you export matters,” have shown that an index of the sophistication of exports (a concept closely related to the income elasticity of demand for exports) in an international context is closely related to the growth of exports and output.

If the growth of exports increases, *ceteris paribus*, the region will initially experience a growing trade surplus. However, with multiplier effects and favorable entrepreneurial expectations, this will induce a faster growth of investment, construction, and services. This will continue until the faster growth of imports that this induces brings the balance of payments back into equilibrium, although at a faster rate of growth of regional output. These are the workings of the Hicks super-multiplier, of which the Harrod foreign trade multiplier is a component.

There is an essential difference in this approach compared with that of the NEG. While the latter also emphasizes the diversity of production and increasing returns to scale, regions can sell as much as they can produce. While the model
explains the concentration of production and its change, it is not designed to explain fully, say, the steady decline of Detroit since the late 1970s, due to the collapse of its major export earnings, the automobile, and the failure of the city to diversify.

Because of data problems, including the absence of interregional trade flow data, most of the tests of this approach have used national and international data. There is now substantial evidence that confirms the importance of export growth and the balance-of-payments constraint. See, for example, the articles summarized in Thirlwall (2012, 343–344, table 2). Data for the US states have been used to estimate export demand functions and hence confirm the importance of demand, although not explicitly within a balance-of-payments-constrained growth framework (e.g., Cronovich and Gazel 1998). D’Acunto, Destefanis, and Musella (2004) test a version of the model for 20 Italian regions using a two-stage approach. First, they find a statistically significant relationship from the growth of exports to that of manufacturing for the North and Central regions, but generally not for the South (the Mezzogiorno). The second stage shows that the differences in these export growth rates could be explained by the constraining effect of supply-side factors.

Rowthorn (2010) uses the export-base framework and finds that a substantial cumulative decline in the North’s export base accounts for much of the UK North–South divide. Moreover, he shows that increased migration from the North to the South is likely to be of limited help in closing the gap.

Porter’s work on “competitive advantage” and clusters presents a detailed empirical examination of the role of spatial specialization in growth. Porter’s notion of a cluster is an attempt to operationalize the spatial nature of production and externalities broadly defined. Porter (2003, 562) defines a cluster as “a geographically proximate group of interconnected companies, suppliers, service providers and associated institutions in a particular field, linked by externalities of various types.” His concept has been subject to a number of criticisms, such as the wide variation in the spatial extent of different clusters and the fact that they are similar to much earlier geographical empirical work on “industrial districts” and related concepts. While Porter does not explicitly set out a theory of regional growth, it is clear he implicitly adopts a form of export-led growth theory (see Porter 2003, 572, n. 13, where he cites a number of studies of this theory). Using data for the 172 US Economic Areas, Porter (2003) finds that wages in the traded sectors are about two-thirds higher than in the local sector and he argues that the causation runs from the wages in the traded sector to the local sector. The implication is that any regional economic development policies need to be particularly focused on traded clusters, because these not only support higher wages but also drive local employment and local wages. This approach provides the foundations for the Kaldorian approach.

Trade unions

David Jordhus-Lier
University of Oslo, Norway

Trade unions have drawn interest from geographers for decades, and the discipline has helped explain their spread through history and their recent decline in Western countries. While many geographers have studied trade unions, very few have offered a definition of the concept. This might seem like a paradox, given that labor geography (see Labor geography), which has emerged as a distinct subdiscipline since the early 1990s, has attempted to redefine trade unionism through its empirical and conceptual contributions. A trade union is an organization of, and for, workers. Trade unions mobilize for worker rights and conditions, often through collective bargaining. Importantly, all trade unions are worker organizations but not all worker organizations are trade unions. While strikes (work stoppages) pre-date the establishment of formal trade unions, they have been associated with trade union organization since the start of the industrial era. The strike threat remains one of the most effective weapons of organized labor, particularly when coupled with negotiations where workers can present their demands. This entry will first briefly introduce trade unionism as a phenomenon of our contemporary world, and then discuss it as a subject of study within the geography discipline. Geographers have studied trade unionism in a variety of ways. Here, the focus is on four dimensions of trade union geographies: the spatial distribution of organized labor since industrialization; the ways in which trade unionism has been embedded in identities, places, and societies; the concept of scale as a lens through which to understand trade unions’ successes and challenges; and, finally, the organic relationship between geographers and trade unionists, and how this tie has shaped political analysis.

Trade unions across the globe

Reports on the global state of trade unionism vary according to different interpretative frames and range from pessimistic readings of universal decline to proclamations of global revival. Even the most basic facts and figures are difficult to obtain and remain subject to interpretation. The International Labour Organization (ILO) found that, 20 years ago, 164 million workers of a globally estimated 1.3 billion-strong workforce were members of a trade union. Since then, the proportion of paid workers with a trade union membership (union density) in Organisation for Economic Co-operation and Development (OECD) countries has dropped from 20.8% in 1999 to 17.0% in 2012. However, this picture is geographically very uneven. The world’s largest national union federation, the All-China Federation of Trade Unions, saw a sharp increase in membership, which was reported at 239 million in 2010. Outside China, in comparison, the International Trade Union Confederation (ITUC) and the World Federation of Trade Unions (WFTU), the two main worldwide trade union confederations, reported a membership on their websites totaling nearly 260 million members. The highest union density in the OECD region can be found in Iceland and...
TRADE UNIONS

Finland, where more than 70% of the workforce belong to a trade union. Nordic countries were also near the top of the chart measuring workdays lost to industrial action in the 2000s, joined by countries such as France, Belgium, Canada, and Spain. Such statistics do, however, undergo dramatic annual variation. While Canada lost an annual average of 186 workdays per 1000 employees in the period 1997–2006, the South African Department of Labour reported that the country had lost as many as 1593 workdays per 1000 employees during the turbulent strike year of 2010.

However, neither trade union membership, nor union density, nor strike action equals trade union influence. While the Chinese trade union movement is impressive in numbers, and is arguably undergoing liberalization, it is still dominated by a one-party state and has “not been able to assert itself as a legitimate outlet for the new kinds of grievances that are surfacing today, particularly among young workers” (Zhu, Warner, and Feng 2011, 141). The human rights nongovernmental organization Freedom House still characterizes the Chinese labor regime as repressive. In fact, in a 2010 review, this organization listed 40 out of 165 countries reviewed as “repressive” or “very repressive” in relation to worker rights. In these countries, few independent unions exist, they are not allowed to mobilize politically, and labor law is either repressive or neglected. Middle Eastern and Northern African countries are, together with countries in the former Soviet Union region, over-represented in the lowest categories. At the other end of the spectrum, 41 countries are listed as “free.” Western Europe is the region with the highest degree of freedom for workers, where all countries get the highest rating (all Western European countries receive status 4 on a scale of 0–4 in the Freedom House report, with the exception of Turkey, which does not belong to the Western European region). Progressive labor laws, independent unions, and authentic collective bargaining agreements characterize these countries. Still, influential trade unionists in these countries have voiced concerns over falling membership and union density rates. The anti-union agenda of conservative administrations in the United States and the United Kingdom in the 1980s, and the subsequent wave of reform-minded governments across Europe in the 1990s, contributed to a weakened trade union movement in the part of the world that hitherto had been the bastion of organized labor. Conversely, several emerging economies in the Global South underwent political transitions which enabled their suppressed labor movements to consolidate their position in the workplace and legitimately seek political power. The growth of the South African, Brazilian, and South Korean labor movements thus provided a counter-narrative to the experiences of European and American unions, and has encouraged unionists and scholars alike.

Union landscapes: the spatial diffusion and retreat of trade unionism

While labor history is by now a well-established discipline whose hall of fame includes prominent names such as E.P. Thompson, there is also an interesting literature within and beyond human geography that has attempted to spatialize the history of labor movements. In Southall’s (1988) study of the early beginnings of unionism, he found that the spread of the labor movement pre-1850 was facilitated by traveling artisans across the United Kingdom, in turn stimulating the establishment of national trade unions in certain sectors. In other sectors, such as cotton and coal, however, the pattern was instead a development of strong localized union cultures.
In other words, the history of labor has simultaneously contained the strategy of crossing space and developing place attachment since its inception. Southall argues that the evolution of early trade unionism was closely linked to the so-called friendly societies in the nineteenth century. Links between trade unions and other civil society organizations are also found in sociologist Hedström’s (1994) study of the Swedish trade union movement of the early twentieth century. In particular, certain free churches and temperance organizations facilitated the spread of Swedish trade unions. These close ties between trade unions and civil society organizations would later attract the attention of geographers studying the contemporary era.

As Marxist geography became dominant in Anglo-American geography departments, scholars attempted to use their analytical tools to understand and explain how class struggle, epitomized by trade unions, shaped the postwar economic map. The shift of production from Northern US states to greenfield sites in Southern states was also given a geographical treatment by Peet (1983). He argued that the concentration of working-class populations in Northern cities had given birth to a strong trade union movement in key manufacturing industries, which then spread to other sectors in the prewar period. Before this process was allowed to spread south, the 1947 Taft–Hartley Act placed strict limitations on organizing, making the American union landscape “more or less set by the time of capital to worker militancy in the late 1940s and early 1950s” (Peet 1983, 124). This paved the way for wage differentials which later, when the United States faced economic crisis and competition from East Asian export economies, would trigger an increase of manufacturing jobs in Southern states, at the expense of stagnation and decline in the North. More nuances were added to this mapping exercise by Clark and Johnson (1987), who argued that in addition to national legislative reforms and foreign competition, the geography of unionism has been shaped by local factors such as union representation elections and the strategy of union locals.

In the United Kingdom, a similar exchange took place in the 1980s, with Marxist geographers wanting to understand how the shift from Fordism to post-Fordism, as postulated by the regulation school, had influenced the geography of trade unionism. In a 1984 article in *Marxism Today*, Massey and Miles argued that deindustrialization (see Deindustrialization), organizational changes in the economy, and the relocation of production had, together with a sharp public sector growth, created a new trade union geography. The old industrial districts of trade unionism had experienced decline, due to the “massive changes in the sectoral composition, technology and geographical organisation” of key industries (Massey and Miles 1984, 20). In short, economic restructuring had dispersed trade unions and shifted their stronghold away from their traditional heartlands. Martin, Sunley, and Wills (1993) added a new chapter to this spatio–historical narrative by showing how this trend was reversed during the Conservative Thatcher government’s attack on the trade unions in the 1980s. While the “spatial dispersal” thesis might describe economic restructuring and decentralization in the 1970s, subsequent union decline created a different pattern. Throughout the 1980s, the union heartlands had – despite an absolute decline in both jobs and union members – kept their union density, in contrast to the union experiences of other areas, where new economic sectors had emerged (Martin, Sunley, and Wills 1993). These accounts of union diffusion and retreat shared a fine-grained understanding of trade unionism as simultaneously local, through activism with strong attachments to particular places, and translocal, as actors and
TRADE UNIONS

ideas traveled between workplaces and towns. The notion of union dispersal across social and material landscapes brought regional science together with Marxist analysis of class struggle. Still, certain dynamics seemed to problematize the assumption that proximity and spatial dispersal were the key ingredients of union geographies. First, international labor migration has challenged the trade union movement. Union landscapes being transformed by migrants were not a new phenomenon. In fact, Mitchell, in his seminal book *The Lie of the Land* (1996) chose as his subject of study migrant agricultural workers in California in the 1930s. These workers were instrumental in building an organized resistance against exploitation on the industrial farms across California in this stage of US agricultural development, and the response from employers and lawmakers was consequently to construct a localized discourse vilifying “outsiders,” in an attempt to secure labor control in this critical stage of the agricultural value chain. Labor migration complicated assumptions of union dispersal through close ties and geographical proximity, because migrants often had close ties to people far away while experiencing social and cultural distance with fellow workers nearby. Trade unions in Western cities have throughout history often failed to organize migrants, who in turn have chosen to rely on other networks for their security and representation.

Second, a globalizing world economy was being pulled together in what Harvey labeled the time–space compression, which affected some places and certain sectors more than others. Trade unions organizing workers in ports and logistics, for instance, have created networks mirroring the stretched nature of their industry, tying workers in one country to others working in a port on the other side of the planet (Castree 2000).

Third, around the turn of the millennium, the impact of communication technologies on trade unions started to draw the attention of activists and social scientists (e.g., Diamond and Freeman 2002). Instant connections across the globe opened up new possibilities for campaigning, illustrated by the fact that the online news and campaigning service LabourStart now claim to coordinate more than 700 trade union websites in 27 languages across the world. But as social media become part of our lives, more deep-seated changes are also likely to take place. Geographers have been late in responding to these virtual union landscapes. Still, it seems clear that in an age when we find friends on the Internet, and when solidarity can be built through Facebook groups, trade unions will again undergo spatial transformation.

Embedded unionism: geographies of difference and union renewal

In the late 1980s and early 1990s new orientations made their mark in the geography discipline – sometimes referred to by the related, but not synonymous, labels of poststructuralism, critical geography, and “the cultural turn.” With them, studies of trade union geographies also changed their focus. Rather than exploring their spatial extent, or their effects on capitalist space, scholars started asking critical questions about who they represented and how they related to other suppressed subjects. Encouraged by feminist and radical theory, categories of class were seen in relation to those of gender, ethnicity, and sexuality. While some critical geographers chose to let other working-class subjects receive the focus of their attention, others did study trade unions, but through a critical lens. With these discussions already underway in parts of the trade union movement, there were inspirational case studies to learn from. What is here labeled “embedded unionism” refers both to actual
changes in the trade union movement, that is, union renewal, and to the broadened scope adopted by scholars who study it.

The trade union has historically been seen as a society of working men, but this is a gross oversimplification. Female unionism has a history that stretches back at least to the Lowell Female Labor Reform Association (LFLRA), established in Massachusetts in 1840s to protect single women working in the textile mills (Dublin 1975). In a seminal study of US waitresses in the early twentieth century, Cobble (1991) portrays progressive single-gender unions in the hospitality industry. By pursuing what she terms “occupational unionism,” waitress unions protected female waitresses from unemployment. However, they did little to protect them from losing their jobs. Instead, they could offer them new employment opportunities in the sector in their capacity as union hiring halls. Thus they managed to secure the consent of the hospitality workforce while serving the flexibility requirements of employers.

These early and encouraging examples notwithstanding, there is little doubt that the trade union movement has remained patriarchal until the present. Interestingly, the historical organization of working women challenges the mainstream narrative of the labor movement, as pointed out by Reimer (1999). She argues that if we focus on the experiences of male labor in late Fordism, one might argue that the flexibilization and deregulation of employment since the 1970s represent a gradual shift towards risk exposure and deregulation. Tracing the trends for female labor, on the other hand, reveals a much less linear pattern. Multiple job-holding, part-time work, and casual contracts were nothing new to women, and Fordism had done little to change that (Reimer 1999). On the other hand, this period of union decline in male-dominated manufacturing coincided with a period of growth in public sector employment, meaning new opportunities for waged work for many women and a concomitant rise in unionization (Standing 1999).

Munro (1999) argues that certain sociospatial conditions have made the unionization of women particularly difficult in the private sector. For instance, while female workplaces in the public sector were larger, reminiscent of the conditions enabling the successful organizing of male industrial workers during Fordism, women in the private sector were often working part-time, in isolation, and in smaller units.

Turning her focus away from the workplace and towards the union itself, Jepson (2005) has studied how female farm workers have been represented by the United Farm Workers in South Texas. Her account found that women tended to become active in the more socially oriented parts of the trade union organization, the educational center of the union known as the campesino. However, once women became actively involved, these spaces were increasingly domesticized and detached from the politics of the trade union. By repoliticizing the campesino in the late 1970s, women were able to create a “‘differential space’ that challenged both the class-based structure of larger South Texas society and the masculinist practices within the movement” (Jepson 2005, 698).

The challenge of labor migration mentioned earlier is not something which simply stretches the social networks of workers. It also creates more heterogeneous working-class populations, particularly in big cities, which presents social actors with new challenges in overcoming difference. Trade unions might accommodate strongly localized identities, and even racist attitudes, which inhibit them from becoming representative worker organizations in a multicultural society. Ethnic divisions in labor markets historically have often been entrenched and
reproduced by trade unionism. One of the most infamous cases took place in Johannesburg in the 1920s, when white mine owners wanted to reform their racially discriminatory labor regime from a “job color bar” to a “wage color bar”: in other words, black workers were allowed to fill labor shortages in higher positions but would still not enjoy the wages of white workers, in order to maintain profit margins. The white trade unions chose to respond in an equally reactionary fashion, by fighting to keep the job color bar to fend off competition from black workers (Johnstone 1971). Fifty years later, black trade unions would form an integral part of the anti-apartheid movement leading the country towards political transition.

Recently, geographers have studied innovative attempts by socially oriented trade unionism (see Unionism, community) to overcome ethnic difference through their mobilization. In a 2001 article, Pastor explores community mobilization in one of the world’s most culturally diverse cities, Los Angeles. The Labor/Community Strategy Center attempted to organize around an issue which affected the mobility of working-class people in need of access to their regional labor market. By focusing on improved bus services, they united the interests of low-income, mainly minority-based, neighborhoods across Los Angeles. What became known as the Los Angeles Bus Riders’ Union also challenged institutional racism and fought for spatial justice. Pastor is not alone in suggesting that there is an embryonic, but significant, reorientation within the Anglo-American trade union movement signaling a more inclusive approach to diversity. Perhaps as acts of necessity, trade unions challenged by conservative policies and neoliberal reforms have chosen to abandon business-oriented models of unionism in favor of social mobilization.

At one level, community-oriented unionism can simply be understood as a way for unions to reach out to the local communities of workers, and to civil society organizations beyond the trade union movement. But it can also be thought of as a more fundamental shift from a politics of production to embracing a politics of consumption. This also has an explicit spatial dimension, as global production networks bring producers in one country into relationships with consumers in faraway places. Hartwick (2000) explores these politics, and how consumers are alienated from the producers of the goods they consume. Johns and Vural (2000, 1210) explore how consumers and trade unions can rebuild solidarity with exploited producers despite “geographic and social disjunctures.” In other areas of life, such as public services and health, consumption and production often take place in a shared physical location, giving trade unions organizing workers the ability to build strong community alliances. Through empirical examples and theoretical work, geographers have attempted to show how trade unions can (re)gain legitimacy among new worker subjects, and in new cultural and socioeconomic contexts. Thus, geography has not simply given us a better understanding of the state of trade unionism, but also contributed to redefining its political agenda.

Scalar union strategies: from local to national to glocal

The historical development of trade union movements in countries across the world has taught us important lessons about how economic and political spaces are ordered. In the human geography discipline, this has nurtured an ongoing debate about the concept of Scale (see also Scale and anti-scale). In its simplest definition, the scale of trade unionism refers to how trade
unions are articulated from the local to the global level. Scale also refers to how agreements, contracts, and jurisdictions are socially constructed. Herod made the point that different scales tend to be produced in relation to each other. For example, when the localized union cultures of early industrial Britain evolved into national union federations, there were particular strategies of local organizations and actors that shaped the mandate of the national union federations. Over time, this influence can work in the opposite direction.

The trade union councils (Landsorganisationene, LO) of the Scandinavian countries are emblematic of the way the trade union movement in many parts of the world evolved into bureaucratic and hierarchical institutions with a strong reliance on the national scale. Typically, LO-Denmark, LO-Sweden, and LO-Norway will have workplace union representatives reporting to district and regional offices, and finally to a national leadership. The national offices of Scandinavian trade unions are very influential in shaping the political direction of the trade union movement. Like other civil society associations and nongovernmental organizations, they tend to mirror the scalar organization of the state apparatus, which forms the key territorial organization of space. In other countries and industries, the development of trade unions has created other scalar configurations, such as the United Auto Workers union, which from the 1930s until an organizational split in 1985 organized US, Canadian, and Puerto Rican workers in the same union (Holmes and Rusonik 1991).

For organized labor in the Nordic countries, strong national federations have facilitated workers’ leverage in collective bargaining, not least due to a high unionization rate and a well-organized employer side. This institutional power has also given the trade union movement significant influence over political decision-making, made possible by their historically close links to national union federations and labor parties. While this model has proven effective in these economies over a sustained period of time, attempts to export a tripartite system of industrial relations have not led to similar successes in contexts where national organizations lack the backing of strong social movements.

As globalization has increased competition between labor markets, driven by the dominance of multinational corporations, national union federations have been put on the defensive. Consequently, activists and scholars alike have been eager to call for a rescaling of union strategies towards the global. Labor internationalism is not a new phenomenon. In addition to the two worldwide union confederations mentioned in the introduction, there is an established organizational infrastructure which includes several industry-specific global union federations, as well as the Council of Global Unions established in 2007. Even though these umbrella organizations have seen some recent success in developing global campaigns and in attempting to secure international framework agreements with multinational companies, their potential impact on the global economy remains unfulfilled (Fairbrother and Hammer 2005).

Nonetheless, union activism at a global scale goes far beyond these formal organizations. Some scholars argue that a “new labor internationalism” can be discerned which distances itself from the hierarchical, bureaucratic, and Eurocentric “old labor internationalism” represented by the institutions above (Webster, Lambert, and Bezuidenhout 2008). One such example is the World Social Forum, which since 2001 has gathered civil society organizations and progressive trade unions annually to discuss global challenges. A more limited and strategic initiative is the Southern Initiative on Globalization and Trade Union Rights (SIGTUR), which is
anchored in particular national trade unions in South Korea, Australia, South Africa, Brazil, India, and other emerging economies in the Global South. According to Webster, Lambert, and Bezuidenhout (2008), this initiative, while still in its infancy, represents an alternative to the European model of internationalism anchored in social compromise and corporate dialogue. International solidarity was also the subject of an insightful study by Johns (1998), who critically examined the intentions and motivations of US unions initiating transnational campaigns. She showed labor internationalism can be motivated by protectionist policies: is, fighting to raise wages in labor markets competing with US workers. This strategy is what Johns labels “accommodationist solidarity,” which she characterizes as regressive in class terms. Alternatively, workers can be motivated by so-called transformative solidarity that transcends place-based interests “in favor of their wider class interests in the international economy” (Johns 1998, 270).

Parallel to debating labor internationalisms, geographers have been exploring new configurations of union power and worker mobilization at subnational and local scales. The importance of communities and neighborhoods has been highlighted by many case studies in labor geography. However, Brecher and Costello (1990) make an important point when they state that, rather than a historical innovation, community unionism should be seen as a return to the early days of trade unionism in the nineteenth century. Beyond the immediate surroundings of the workplace and the home, urban regions are arguably becoming more important as mobilizing arenas for organized labor. For instance, living wage campaigns are based on a distinct rationale that the wages should be able to carry “the costs of social reproduction and care in a particular place” (Wills and Linneker 2014, emphasis added). As costs vary between places, and between rural and urban areas, both strategic and moral reasons can be used to legitimate urban living wage campaigns. By organizing all workplaces across an urban labor market, living wage campaigns can “take wages out of competition” (Walsh 2000). In a ground-breaking study of the living wage campaign in Baltimore, Walsh argues that low-wage workers, whose main threat might not be interregional spatial competition and the threat of relocation, might find this a particularly useful strategy.

As geographers have developed the concept of scale since the 1990s, and debated its relevance, labor geographers have moved away from attempting to locate the ideal political scale in favor of more relational and multiscale approaches. In other words, there is no “right scale,” and political actors need to be attentive towards how different scales are related. Hence, the Liverpool dock workers’ strike in 1995–1998 showcased fundraising with nonunion organizations across the United Kingdom as well as solidarity actions by dock workers around the world. Castree (2000) stressed that this would not have been possible without pre-existing organizational infrastructure at the local and national scale. In a similar fashion, Tufts (2007) suggested that a “spatial circuit of union renewal” was emerging in the hotel sector in Toronto, where support for organizing efforts at the workplace level was bolstered by city-level community action, national coordination, and, finally, international support campaigns. In short, unions do pursue explicitly scalar strategies to secure decent income and working conditions, but these strategies should not be reduced to a quest of scale-jumping.

Union–geographer exchanges

Of course, the salient role of trade unions in geographical research is not simply a result of
analytical curiosity. On the contrary: since the
discipline was radicalized through Marxist, fem-
inist, and postcolonial geographies in the 1980s,
geographers have established close links to their
research subjects, in part motivated by polit-
ical sympathies. The long-term collaboration
between UK geographer Jane Wills and the Lon-
don Citizen campaign, and the research involve-
ment of Canadian geographer Steven Tufts in a
Toronto local of the trade union UNITE HERE
represent only two of many examples.

A question worth asking is whether such
close-knit relationships allow geographers to
maintain academic rigor. The potentials and
challenges of combining academic and activist
subjectivities have been continuously discussed
in seminars and in written form. Such exchanges
of experiences and understanding are part of
a broader critical geography agenda, where
political sympathies are openly announced
while methodological and analytical procedures
are documented and criticized. This balance
between relevance and rigor has arguably given
us accounts of working-class mobilization of
a depth and richness that would be difficult
to attain through a more distanced research
approach. Academic involvement in union
activism combines peer-reviewed publications
with forms of engagement directly relevant
to the labor movement – often directly chal-
lenging their agenda. The journal Antipode has
become an important outlet for geographical
research on working-class mobilization, not
simply because geographers have been able
to publish committed, activist research, but
because unionists themselves have been actively
involved as authors of labor geography. In this
way, union–geographer exchanges share the
ambition of the People’s Geography Project of
US geographer Don Mitchell: “[to] make crit-
ical, radical geography useful to people in their
everyday lives and a resource for those engaged
in the struggle for social and economic justice”
(People’s Geography Project 2016).

TRADE UNIONS

Trade, FDI, and industrial development

Godfrey Yeung
National University of Singapore

International trade is the exchange of goods and services, with currency (normally in terms of US dollars, but also in euros and Japanese yen) as the medium of exchange, across national borders (although it could be conducted in forms of barter exchange: the exchange of goods and services with the same perceived value by two partners). Foreign direct investment (FDI) is the direct investment into production or services by a company across national sovereignty for the purposes of entering into the host country’s market and/or expanding or relocating their existing business from the host country.

International trade and FDI influence the direction and value of commodity flows, services, and financial and human capital, both in their countries of origin and at their destinations. The balance between outward (FDI outflows) and inward (FDI inflows) FDI has an impact on the balance of the capital account and the volatility of exchange rates (especially between US dollars, the currency for international trade, and other countries’ currencies). FDI inflows could bring in capital and expertise in manufacturing technologies and management know-how but could also crowd out domestic investment and cause an appreciation of the exchange rate in host countries’ currency. FDI outflows could lead to a repatriation of income generated from foreign investment and the depreciation of the currency exchange rate, which affects the balance of trade (depending on the price elasticity of demand for domestic versus imported commodities) in home countries. The stock and flow of international trade and FDI are thus regarded as the catalysts or sledgehammers for industrial and regional development, and their relationship has long been a bone of contention for academics and policymakers.

The general trends in FDI and international trade are presented in the next section before a review on mainstream theories on international trade and FDI, followed by a brief overview of the contributions of social scientists and economic geographers on the relationship between trade, FDI, and industrial development. An overview of state policies on FDI and international trade and the responses of transnational corporations (TNCs) on such policies concludes this entry.

The general trends in FDI and international trade

The recent global financial crisis has had a significant impact on the trajectory of FDI and trade. FDI inflow into developed countries had declined by 32%, from US$820 billion in 2011 to US$561 billion in 2012, a level that was reached a decade ago (Table 1). The European Union (EU) accounted for two-thirds of the global decline in FDI. However, developing countries played an important role and accounted for more than half (52%) of the US$1.35 trillion global FDI inflows for the first time in 2012. Notably, China and Hong Kong became the second and third most popular destinations of FDI in 2012, directly behind the United States. Brazil and the Russian

Federation were ranked fourth and ninth, respectively, which was vastly different from 1990 when European or North American countries dominated the top 10 countries for FDI inflows (UNCTAD 2013a).

Developing countries played an increasingly important role and accounted for about one-third of global FDI outflows in 2012 (Table 2). With the outward FDI increased from only 1% of the global flow (US$7 billion) in 2000 to 10% (US$145 billion) in 2012, the BRICS (Brazil, Russian Federation, India, China, and South Africa) countries have become important recipients and origins of FDI. The EU had, however, only recorded US$323 billion of FDI outflows in 2012, which was about 40% of the value reached in 2000. Although only about two-thirds of the income from global FDI was repatriated back to the home countries, developing countries retained the highest proportion of their FDI income (40%) (UNCTAD 2013a).

The significant rise in FDI also contributes to the increasingly fragmented and dispersed production processes where intermediate goods and services are traded across sovereign boundaries. This leads to the double counting of value in international trade, for example, 28% of US$19 trillion global gross exports in 2010 was counted twice. It is estimated that the value of international trade (after adjustment for double counting) was about 30% of developing countries’ gross domestic product (GDP), on average. The corresponding rate for developed countries’ GDP is 18% (UNCTAD 2013a).

International trade had been increasing rapidly until the outbreak of financial crisis in 2008–2009 (Tables 3 and 4). Although the

The significant increase of exports from developing countries also altered the pattern of economic outputs in the global economy. The share of developing countries in global GDP had more than doubled, from 17% in 1990 to 36% in 2012, while the corresponding share of developed economies had decreased simultaneously, from 79 to 60% (UNCTAD 2013b).

Source: Compiled from UNCTAD, UNCTADstat (http://unctadstat.unctad.org/).
The concept of comparative advantage was first introduced by Adam Smith in 1776 and elaborated by David Ricardo in 1817. Instead of focusing on the cost ratios or absolute cost advantages between two trading partners, Ricardo argued that the cost ratios of producing commodities within each country needed to be considered. Comparative advantage is defined as the capacity of a region/country to produce a specific commodity at a lower opportunity cost (the value that one has to forgo) than that of another region/country. Rather than each country trying to produce all the commodities they need, Ricardo argued that countries can gain from trade if they produce commodities for which they have the comparative advantage and then trade them for commodities from other countries.

The canonical neoclassical Heckscher–Ohlin–Samuelson (H–O–S) model of international trade was developed by Eli Heckscher and Bertil Ohlin from the Ricardian conceptualization of comparative advantage and later enhanced by Paul Samuelson. To address concerns about the restrictive assumptions of Ricardian comparative advantage, Ohlin (1967/1933) relaxed the single-factor assumption in the two-country, two-commodity, and two-factor (labor and capital) model and argued that comparative advantage, geographical specialization, and trade are driven by regional factor endowments in Interregional and International Trade. According to the Heckscher–Ohlin theorem (H–O theorem), countries export products that make intensive use of their production factors (labor and capital) and natural resources that are relatively abundant and relatively inexpensive. In other words, a capital-abundant country exports capital-intensive goods to labor-abundant countries while importing labor-intensive commodities in return.

Neoclassical economists argue that the international division of labor (the specialization of production on a national basis) is a natural consequence of the spatial differentiation of labor productivity (Ricardian comparative advantage) and (Heckscher–Ohlin) factor endowment. As the production factors (labor and capital) are mobile within countries but not between countries (as stipulated in the H–O theorem), and markets are perfectly competitive, factor prices will equalized across countries as a result of international trade, according to Samuelson’s factor price equalization theorem. Therefore, the neoclassical theory of international trade hypothesizes that incomes across countries will converge and development will be even. In other words, free trade promotes economic growth and reduces regional disparities across space.

However, the H–O–S model is unable to reconcile the uneven economic growth observed between developed and developing countries since World War II. The H–O–S model still suffers from a set of unrealistic assumptions: that the production function has constant returns to scale (not accounting for technological advancement), production factors are immobile across space (countries), and markets are perfectly competitive.

To address the lack of solid empirical evidence for the convergence of income across countries hypothesized by the H–O–S theorem, international trade economists, notably Paul Krugman, relax the constant returns to scale assumption and argue that the divergence of income between developed and developing countries is due to the increasing returns to scale of investment among the former in the new trade theory. Paul Romer and Robert Lucas also incorporated increasing
returns to capital arising from the accumulation of knowledge in new (endogenous) growth models.

The H–O–S theorem, augmented by the new trade theory and new growth models, laid the foundation for the neoliberal type of trade and capital account liberalization proposed in the Washington Consensus, which international institutes, especially the International Monetary Fund (IMF), until very recently, insisted that developing countries adopt before receiving financial assistance.

**FDI and industrial development**

The eclectic international production paradigm of FDI (the ownership-location-internalization or OLI paradigm) developed by John Dunning is a synthesis of five relevant economic theories: macroeconomic theory, industrial organization theory, location theory, product life-cycle theory, and internalization theory (see Yeung 2001 for detailed explanations). The OLI paradigm postulates that ownership-specific, locational, and internalization advantages are the dominant factors affecting the pattern of FDI.

The rationales of TNCs for investing in host countries directly through FDI rather than through contractual resource transfers or exportation are presented in Table 5. The ownership-specific advantages (O) are prerequisites for contractual resource transfers, exportation, or FDI by TNCs in their home countries, that is, the exclusive production and technical know-how and managerial and marketing skills possessed by TNCs in their home country are superior to those of rival firms in the host country. Through exporting to or investing directly in the host country, TNCs in their home country can reduce their transaction costs and internalize the externalities in factor or product markets. These internalization advantages (I) are larger than the benefits from licensing production know-how to foreign firms. Moreover, TNCs can relocate from their country of origin due to the pull factors of locational endowments (L), such as when the low labor costs and preferential investment incentives available from the host country are stronger than those in the home country. In other words, TNCs select FDI because it can reap the locational advantages enjoyed by local industry in the host country, where direct exportation and licensing cannot be obtained (see Yeung 2001).

Moreover, Dunning argues that the change in net capital inflow or outflow of a country is determined by its changing economic structure in terms of industry and firm-specific OLI compared with other countries. In fact, he suggests that countries tend to pass through five different stages of development according to their propensity to net inward or outward investment. This propensity is determined by

the extent and pattern of the ownership-specific advantages of each country’s indigenous firms, its location-specific advantages, and the internalization advantages relative to the OLI endowments of other countries.

There have been some important additions to the OLI paradigm in response to the significant changes in the global economy during the last two decades. In addition to nonequity alliances or contractual relationships (including outsourcing), Dunning and his associates have highlighted the importance of social relational capital – such as lack of crime and corruption – as institutionally related location advantages for TNCs. Dunning and Lundan (2008) eventually incorporated Douglass North’s (1990) seminal work on the institutional environment – the formal rules (such as laws and regulations) and informal constraints (such as behavioral norms) that govern the OLI advantages – into the eclectic paradigm to allow it to explain the dynamics of FDI flows and home and host countries’ institutional environment effectively.

**Controversies of conventional theories**

The flows of capital and commodities across space could have negative impacts for developed and developing countries. The outflow of FDI, especially the relocation of manufacturing to lower-cost developing countries in East Asia, led to the deindustrialization (“hollowing-out”) and the subsequent massive redundancies in the textiles and clothing, iron and steel, and ship-building industries in the Midlands and the North of England, and the Rust Belt in the Northeast and the East North Central states in the United States in the 1970s and 1980s. The need for developed countries to import their previously locally manufactured goods to sustain the consumption also created persistent trade deficits with East Asian countries (see the previous section).

For developing countries, the significant inflows of FDI and the subsequent boom in international trade also have their costs. The inflow of FDI could crowd out local entrepreneurs who do not have access to the same level of incentive policies implemented by their own countries. These policies could also develop the dependency on foreign capital for economic development in developing countries.

The dominance of TNCs based in developed countries in the economies of developing countries fuels further debates about the effects of inward investments and uneven trade relationships between developed and developing countries. In *Kicking Away the Ladder*, Ha-Joon Chang (2002) highlighted the historical paradox that advanced economies (like the United States and the United Kingdom) used interventionist and protectionist economic policies to accumulate capital during their own early stages of economic development yet bar developing countries from following similar pathways today. He further pointed out that the imposition of a common institutional standard on developing countries with different social norms, cultural values, and conditions is the implementation of a “one-size-fits-all” institutional transplantation with only a 5–10-year transition period. Joseph Stiglitz also joined the debate, arguing that international institutions, such as the IMF, should not force trade and capital liberalization on developing countries without taking local institutions into consideration.

Neo-Marxist social scientists go further, highlighting the exploitative nature of free trade and the subsequent dependency relationship between developed and (newly independent, especially former colonies) developing countries. Rather than focusing on a lack of integration into international trade, as argued by neoliberal
trade economists, dependency theorists, notably Andre Gunder Frank, argue that developing countries are perpetually locked into a world system of core–periphery dependency where the core (developed) countries dominate the advanced technologies and global political and economic institutions while the developing countries are locked into unfavorable terms of trade and remain exploited.

Rather, as a result of FDI and free trade, Neo-Marxist geographers have typically highlighted the relocation of manufacturing sectors from developed to developing countries and the subsequent unequal exchange and the accumulation of capital in core countries. In other words, there is no development for developing countries as TNCs are extracting the surplus value of labor from developing countries through FDI and international trade. Other economic geographers and social scientists examine the increasing importance of international trade and FDI for industrial development from two main perspectives: the agglomeration of economic activities and their development, including the role of knowledge transfer; and the linkages between different economic actors in host and home countries for industrial upgrading.

**Agglomeration, knowledge transfer, and industrial upgrading through trade and FDI**

Industrial agglomeration, the concentration of similar and complementary industrial sectors in a specific area, has long been the focal point of research into trade and FDI flows. Following Marshall’s seminal work on agglomeration, it is generally argued that firms in similar and related sectors benefit from positive externalities of co-location, the external economies of scale, such as cost saving (from shared infrastructures, etc.), knowledge spillover, inter-firm linkages, and the availability of skilled labor due to spatial proximity. International trade and FDI have a great impact on how and where economic activities have tended to cluster in the increasingly globalizing world since the 1980s. Researchers have examined this phenomenon from different perspectives and scales, from the inequality of industrial and economic development in the postcolonial world to industrial districts, knowledge transfer, and the governance of value chains, and so on. Economic geographers, such as Allen Scott, along with business scholar and economist Michael Porter, and Paul Krugman have pointed out the important role the spatial agglomeration of industries has on the globalizing economy.

The ease of overseas procurement through international trade has shaped the characteristics of regional economic activities and their performance. Manufacturers in developed countries are no longer able to compete on cost alone as generic products are readily available from developing economies at much lower costs. The move away from the mass production of Fordism to a flexible form of organization of production was a direct response to the change in consumer demand for differentiated and trendy products in the increasingly globalized world. Regional suppliers are crucial for the “just-in-time” delivery system under the flexible specialization whereby specialized and quality parts and components have to be delivered in frequent, small-volume batches to the assembly plant (Dicken 2011), and this subsequently promotes the development of logistic sectors and the intraregional trade, in addition to the importation of parts and components and the exportation of finished products from and to developed countries.

Constantly upgrading technological capacity is crucial to maintaining the competitiveness of an industry in the knowledge-based economy. The study of how trade and FDI impact on
knowledge transfer and industrial upgrading normally involves examining the institutional factors that play an important role in facilitating various channels of learning and innovation, from the diffusion of tacit knowledge through face-to-face communication and knowledge spillover derived from the economies of agglomeration, to the localization of learning activities. Economic agents have to absorb newly acquired knowledge either through internalizing codified knowledge with the help of tacit knowledge acquired earlier, or through socialization involving the exchange of tacit knowledge (Storper 1995; Dicken 2011).

By referring to various case studies, researchers argue that both Marshallian and Jacobsian externalities are crucial for the development of localized or urbanized economies and the corresponding state policies on FDI and international trade (see Beaudry and Schifferauerova 2009). The specialization of specific industries within industrial districts could be due to Marshallian externalities where potential benefits are generated through intra-industrial knowledge spillovers. The potential benefits of Jacobsian externalities are generated through the co-location of different industries in cities and subsequent inter-industrial knowledge spillovers which stimulate innovation through the interaction of ideas from diverse industrial sectors. As cities are sources of innovation and diverse industrial fabric in close proximity to each other, this fosters opportunities to imitate, share, and recombine ideas and practices across industries. Industrial diversification rather than specialization is crucial for Jacobsian externalities and this could have significant implications for the preferential policies on FDI and international trade (see below).

The importance of highly tacit and idiosyncratic know-how actually creates specific issues of property rights for firms. This is especially the case when the know-how is embedded in the firm’s human capital and thus property rights are difficult to establish, that is, whether the firm or a certain individual working in the firm has ownership of the knowledge. It is therefore in the interests of the firm to convert the knowledge into a codified and transferable form that can be patented, trademarked, or copyrighted. This explains why the regime of intellectual property rights is important for the transfer of codified knowledge, and the importance of the Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) under the World Trade Organization (WTO) on international trade, especially the unbalanced terms of trade between developed and developing countries where the former normally have the technological/knowledge advantages.

To reconcile the asymmetrical relationships between TNCs in developed countries and their suppliers (local firms) in developing countries, economic sociologists Gereffi, Humphrey, and Sturgeon (2005) introduced five specific types of governance for global value chains (GVCs) to unpack the relationship between actors and industries across space in the 1990s. They argued that the type of product and how and where they are produced is determined by the capabilities of suppliers, the extent of efficient codification, and the transmission of complex information and knowledge. To highlight the nexus of the interconnected functions and operations of firms and nonfirm institutions where goods and services are produced and distributed globally, Coe et al. (2004) proposed the concept of global production networks (GPNs) to highlight the asymmetry of the value capture processes associated with various industrial activities across space as manufacturing activities, core knowledge, and technologies are still ultimately controlled by various TNCs and their first-tied subcontractors. This explains the continuous divergence
of growth between developed and developing countries despite the massive relocation of labor-intensive manufacturing industries to developing countries since the 1970s.

State policies and TNC strategies for FDI and international trade

State policies can impact the flows of FDI and trade. The state policies on FDI and international trade include unilateral incentives, from taxation holidays (i.e., a waiver and/or a discount of profits tax) to direct and indirect subsidiaries (e.g., financial supports for investment in certain high-technology sectors and the provision of physical infrastructures). Another commonly adopted policy is the establishment of special economic zones (SEZs), especially for (high-technology) industrial clusters, normally anchored by foreign-invested companies and supported by locally financed enterprises. The aim for these policies is to encourage the inflow of FDI, and the affiliated expertise on manufacturing and management, and promote export-led growth. Furthermore, central banks could buy US treasury to depress the value of its own currencies against the international trade currency to enjoy more competitive production costs in terms of US dollars (but this strategy could only be effective when other countries are not implementing the same strategy, otherwise there could be a race to the bottom with competitive devaluation of currencies).

To facilitate the export-oriented industrialization, especially the development of infant (new) industries, both developed and developing countries have adopted a number of bilateral and/or multilateral agreements, notably the trade blocs formed by the EU, the North American Free Trade Agreement (NAFTA), and the Association of Southeast Asian Nations (ASEAN). Some countries also adopted unilateral policies to regulate trade through the adoption of tariffs (import tax) and export subsidiaries (normally in the form of a refund of value-added/sales taxes).

Despite the adoption of WTO free trade treaties by most countries, there is a frequent deployment of nontariff barriers to trade (NTBs), notably the antidumping and countervailing measures by various trade partners under the WTO’s provision of protecting local markets for importation of commodities with predatory (below cost) pricing. Moreover, developed countries are increasingly adopting other technical barriers of trade, especially in the form of regulations of health and safety and intellectual property rights, against imports from developing countries. One such regulation is the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) adopted by the EU in 2006, which includes specific regulations on the production and use of chemical substances with regard to their potential impacts on both human health and the environment.

In response to state policies on the regulation of flow of capital and commodities, TNCs relocate or expand their manufacturing sites from their home countries into host countries to enjoy the lower production costs and/or conduct intra-TNC trade, including the use of transfer pricing to exploit the spatial differentiation of taxation regimes. Another common strategy adopted by TNCs is to channel the capital through offshore financial centers (i.e., tax heavens), and this partially explains why the tiny British Virgin Islands, with an area of 153 km² and a population of around 28,000, recorded US$64 billion of FDI inflows (ranked fifth in the world, above the United Kingdom, Australia, the Russian Federation, and Canada) and US$42 billion of FDI outflows in 2012 (UNCTAD 2013a).
The flows of capital and commodities across spaces lead to conflicts between trading partners. This is illustrated by the processing and assembling trade where the high value-added economic activities are conducted and retained in home (developed) countries while the lower value-added economic activities are conducted by subcontractors in host (developing) countries. For instance, less than 10% of the typical high-end mobile phone retail price is created in China but its export value is included in the Chinese export statistics. Chinese suppliers are generally facing an uphill battle for upgrade as they have to rely on the importation of higher value-added parts and components for the assembly of finished products for exportation. Moreover, there are significant discrepancies between China’s trade data and world declared trade data, partly due to the methods of how trade data are recorded (export data are recorded on a freight on board (f.o.b.) basis whereas import data are recorded on a cost, insurance, and freight (c.i.f.) basis) and partly due to the inflated value of re-exports of Chinese merchandise by trading companies in the Hong Kong Special Administrative Region (SAR) of China; for example, more than 95% of export value from Hong Kong in 2012 was subsequently re-exported to other destinations.

Traffic sensors

Yang Yue
Shenzhen University, China

Traffic sensors are those devices that indicate the presence or passage of vehicles and provide vehicle volume, vehicle speed, and other data that support traffic management, such as signal control, freeway mainline control, ramp metering, and electronic toll collection (Klein, Mills, and Gibson 2006). Traffic sensors can be generally classified as either fixed sensors or mobile sensors. Most traffic sensors are fixed, either embedded in the pavement, such as inductive loops, or hung overhead, such as cameras. Examples of mobile traffic sensors are probe vehicles that record vehicle location and speed by GPS. Since fixed sensors often have limited coverage, mobile sensors are used to complement fixed traffic sensors.

Fixed sensors

In-roadway sensors

In–roadway sensors are those that require installation on, are embedded in, or require installation below the road surface. The two most widely used in–roadway sensors are inductive loop detectors and magnetic sensors.

Inductive-loop detectors are saw-cut into the pavement and can detect vehicles passing or arriving at a certain point, for instance, approaching a traffic light. Since its introduction in the early 1960s, the inductive-loop detector has become the most utilized sensor in a traffic management system because of its relatively low cost. An inductive-loop detector uses a moving magnet to induce an electrical current in a nearby wire to detect the passage or presence of a vehicle (Figure 1). When a vehicle passes over the loop or stops within the loop, the vehicle induces eddy currents in the wire loops, which decrease their inductance. The decreased inductance actuates the electronics unit output relay or solid-state optically isolated output, which sends a pulse to the traffic signal controller signifying the passage or presence of a vehicle.

By sensing vehicle passage and presence, inductive loops can be used for queue detection, vehicle counting, speed measurement, and, thus, traffic signal control. Other basic traffic flow parameters, such as volume, occupancy, headway, and gap, can also be inferred from algorithms. In general, this technique provides one of the best accuracies for count data compared with other commonly used techniques, and is a common standard for obtaining accurate occupancy measurements (Gordon and Tighe 2005). However, since inductive-loop detectors are saw-cut into the pavement, the analysis of a malfunctioning inductive-loop detector can be difficult. They are easily affected by pavement failure and damage caused by construction activities, rain, and snow.

Magnetic sensors are an alternative to inductive-loop detectors. They are usually placed underneath a paved roadway or bridge structure. A magnetic sensor is a passive device that detects the presence and passage of a vehicle by measuring the perturbation in the Earth’s quiescent magnetic field caused by ferrous metal objects (Figure 2). Two types of magnetic field sensor are used for traffic flow parameter measurement. The two–axis fluxgate magnetometer
detects stopped and moving vehicles, and the induction or search coil magnetometer typically detects moving vehicles.

Two-axis fluxgate magnetometers detect changes in magnetic field anomaly produced by a ferrous metal vehicle. Their outputs are connected to an electronic unit that measures the output voltage, that is, the magnetic signature of a vehicle. When the voltage exceeds a predetermined threshold within the detection zone, the presence or stopping of a vehicle is detected (Klein 2001).

Induction or search coil magnetometers generate a voltage when a moving ferromagnetic object perturbs the Earth’s magnetic field. Therefore, induction magnetometers only detect moving vehicles and cannot detect stopped vehicles. However, multiple units of some magnetic detectors can be installed and utilized with specialized signal processing software to generate vehicle presence data.

**Overhead sensors**

Overhead sensors are mounted above the surface of the roadway, or alongside the roadway, a certain distance from the target traffic lanes; these may be, for example, video image processors (VIPs), microwave radar, ultrasonic, passive infrared, and laser radar sensors. In some wide-area surveillance systems, overhead sensors are mounted on tall buildings, radio towers, and even aerial platforms.
Video detectors are based on real-time video image processor systems to report vehicle presence, vehicle type, volume, lane occupancy, and speed for each class and lane (Romero et al. 2011). Video detector systems normally perform two main tasks: (i) the inference of road geometries and (ii) vehicle and obstacle recognition. Even without its association with VIPs, closed-circuit television (CCTV) has become an important component for traffic management. High-definition and megapixel cameras have been used in CCTV.

The core uses of VIPs for traffic surveillance are vehicle detection, classification, and tracking algorithms. Traffic flow parameters are calculated by analyzing successive video frames. Vehicle speed can be estimated by identifying vehicle travel times within the detection zones. Vehicle tracking can potentially provide a link between travel time and origin–destination pair information. VIPs that track vehicles may also have the capability to register turning movements and lane changes (Klein 2001). The effectiveness of VIP algorithms can be affected by weather conditions, shadows, and daytime or nighttime artifacts (JPL 1997). An effective VIP should meet the following requirements (Kastrinaki, Zervakis, and Kalaitzakis 2003):

- automatic segmentation of each vehicle background and other vehicles, so that all vehicles are detected;
- able to detect correctly all types of road vehicles, motorcycles, cars, buses, construction equipment, trucks, and so on;
- function in a wide range of traffic conditions: lights, congestion, varying speeds, different lines;
- function under a wide variety of lighting conditions: sunny, cloudy, sunset, night, rain, and so on.

Microwave radar sensors: radar was originally an acronym for “RAdio Detection And Ranging.” Most roadside microwave radar sensors utilize the X-band frequency of 10.525 GHz. The effective area, that is, beam width, of a radar sensor is controlled by the size and the distribution of energy across the aperture of its antenna. Higher frequencies illuminate smaller ground areas with a greater spatial resolution given the size of antenna. When a vehicle passes through the antenna beam, a portion of the transmitted energy is reflected back towards the antenna. The energy then enters a receiver that calculates traffic volume, speed, and vehicle length. Thus, microwave radar sensors are usually used to detect vehicle speed, or in electronic toll collection and automated truck weighing applications that need vehicle length information. Two types of microwave radar sensor are used in roadside applications: those transmitting continuous wave (CW) Doppler waveforms and those transmitting frequency modulated continuous waves (FMCW).

CW Doppler radars measure vehicle speed using the Doppler principle by transmitting a stable frequency signal with respect to time. The frequency of received signal increases when a vehicle moves toward the radar and decreases when a vehicle moves away from the radar. Thus, CW Doppler radars can detect vehicle passage and measure vehicle count and speed, but cannot detect stopped vehicles, that is, vehicle presence.

FMCW radars detect vehicle passage as well as vehicle presence. The transmitted frequency of the sensor is constantly changing with respect to time. They can detect stopped vehicles and provide measurements of lane occupancy, vehicle count, speed, and vehicle length. FMCW radars can also use Doppler to calculate the speed of moving vehicles (Edde 1993).

Infrared sensors emit and/or detect infrared radiation to measure the heat of vehicles or
TRAFFIC SENSORS

passengers. Most infrared sensors only measure infrared radiation, rather than emitting it, and thus are known as passive infrared (PIR) sensors; IR sensors that emit and detect are known as active infrared (AIR) sensors.

AIR sensors illuminate detection zones with low-power infrared energy in the near infrared region of the electromagnetic spectrum at 0.85 mm. PIR sensors do not generate or radiate any energy for detection purposes. Instead, they work entirely by detecting the energy given off by other objects, such as vehicles and road surfaces. PIR sensors with a single detection zone measure volume and lane occupancy by sensing vehicle passage and presence. Those with multiple detection zones can also measure vehicle speed and length. Real-time signal processing is needed to analyze the signals for the presence of a vehicle. In traffic management applications, passive sensors may encounter performance degradation due to (i) glint from sunlight, (ii) inclement weather, and (iii) atmospheric particulates.

Acoustic/ultrasonic sensors can be used for vehicle detection and in driver-assisting systems. Similar to radar, the sensors produce a beam of sound and evaluate the echo that is received back by the sensor. Ultrasonic sensors generate high-frequency sound waves (between 25 and 50 kHz), which are above the human audible range. Sensors calculate the time interval between sending the signal and receiving the echo to determine the distance to an object (Ni 2013).

Most ultrasonic sensors operate with pulse waveforms and provide vehicle count, presence, and occupancy information. Pulse-shape waveforms measure distances to the road surface and vehicle surface by detecting the portion of the transmitted energy. When a distance other than that to the background road surface is measured, the sensor interprets that measurement as the presence of a vehicle. Acoustic/ultrasonic sensors cover only a short range and have slow response times. Accuracy is limited by the surface of the objects. Temperature change and extreme air turbulence may also affect the performance of ultrasonic sensors.

LiDAR (Light Detection and Ranging) uses ultraviolet, visible, or near-infrared light in the form of a pulsed laser to measure ranges (variable distances) and image objects. A basic LiDAR system consists of an emitter, mirror, and receiver (Figure 3). The emitter sends out a laser beam that bounces off a mirror that rotates along with the cylindrical housing at a certain speed. After bouncing off objects, the laser beam returns to the mirror and is bounced back towards the receiver, where it can be interpreted into data.

LiDAR has been used extensively to make high-resolution maps in geomatics, archaeology, geography, geology, forestry, remote sensing, atmospheric physics, airborne laser swath mapping, laser altimetry, and contour mapping. Thus, it is often mounted on top of a driverless car in order to generate an accurate map of the car’s surroundings. It is the heart of object detection and obstacle avoidance. In transportation applications, LiDAR sensors produce 2-D and 3-D imagery of vehicles to identify vehicle width, speed, and height, and thus, for example, can be used on toll roads for vehicle classification. They can also provide vehicle presence, volume, speed, length assessment, queue measurement, and classification at traffic signals.

In summary, sensors using different detector technologies are useful in various transportation applications to provide a wide variety of detection parameters and classification information from a single location. The inductive-loop detector is, by far, the most widely used sensor in traffic control systems. Meanwhile, overhead sensors have provided an alternative to in-roadway sensors. The traffic flow parameters measured with overhead sensors
satisfy the accuracy requirements of many freeway and surface street applications. However, a requirement for in-roadway sensors continues, though the installation and maintenance of in-roadway sensors can disrupt traffic and pose a safety risk to the installers. Besides axle counting and weigh-in-motion applications requiring sensors under or on the road surface, cost and safety issues associated with mounting overhead sensors are reasons for choosing or installing in-roadway sensors. Aesthetic consideration is another consideration. Thus, sensor type, mounting height and location, vehicle mix, road configuration, and sensor viewing angles must be analyzed with respect to the intended application (Klein, Mills, and Gibson 2006).

**Mobile sensors**

In contrast to fixed sensors, which collect traffic parameters from a single location, mobile sensors allow for continuous data collection, such as probe vehicle and cellular phone positioning data. They make large-scale data collection possible, including those where data were previously unavailable.

**Probe vehicle**

The probe vehicle is also known as floating car. It is primarily designed for vehicle dispatch, travel time collection, and route guidance applications. The probe vehicles can
be personal or public transit, or commercial vehicles (such as taxis). Probe vehicles may be equipped with several different types of electronic transponders or receivers. For example, a signpost-based system that relies on transponders attached to roadside signposts can be used for tracking bus locations. Electronic tags, such as RFID tags, are used for automatic vehicle identification for those vehicles equipped with tags. These tags communicate with roadside transceivers to identify unique vehicles and collect travel times between transceivers (Turner et al. 1998). Nowadays, GPS has become the most widely used device. The vehicle’s location, speed, and heading are obtained by GPS and transmitted to a control center in real-time.

Cellular phone

An emerging potential source of traffic flow data is from cellular telephone companies who monitor the transmitting status of telephones that are engaged in conversations in support of wireless-enhanced all-automatic location identification. The location of these telephones can potentially be made available to traffic management agencies to anonymously track vehicles on a noncooperative basis. The travel speed or travel time of cellular telephone users can be determined by time-difference-of-arrival techniques. This information can also assist in estimating congestion and travel time over wide areas, while protecting the identity of the telephone subscriber (Turner et al. 1998, Klein, Mills, and Gibson 2006). However, privacy issues become a concern, and coordination is often necessary between the agency responsible for the system’s operation and the agency that would like to utilize the system for travel time data collection.

Other sensor platforms

One emerging source of traffic monitoring data is from satellite, aircraft, and unmanned aerial vehicles. Information gathered from these platforms can be used to estimate arterial and freeway traffic characteristics either in real-time or over long time scales and large geographic areas, especially in those situations that cannot be easily accessed by humans and vehicles, such as estimating road damage caused by an earthquake.

Another source of traffic monitoring data is vehicle-based sensors, for example, event data recorder and on-board diagnostics. These sensors are not regarded as typical traffic sensors, but they may become important sources for collecting traffic data in the future with the continued evolution in the self-driving car, connected vehicle, and cooperative vehicle-infrastructure system.

Trajectories: analysis

Noam Shoval
The Hebrew University of Jerusalem, Israel

Data about movements of objects are often collected as trajectories in space and time, that is, the movement of each object is recorded as a series of geographic locations with respective time stamps, when the object moves in the basic three-dimensional (3-D) framework of our physical world, defined by geographic space and time.

Trajectories in the geographic context usually refer to the space–time paths of people or cars and are mostly related to the conceptual framework of time geography proposed by Torsten Hägerstrand (1970) that integrates time, as a limited resource, into the thought on spatial behavior.

Qualitative analysis of trajectories

One of Hägerstrand’s most profound professional and disciplinary achievements was the ability to represent space and time in a single diagram, unlike an ordinary map, but rather like a snapshot, that reproduces a moment frozen in time. The result was his, now famous, time-geographical diagrams: notational (representational) systems, which formed the basis of much of the subsequent work in the field of time geography, particularly in the realm of analysis and interpretation. The diagrams (Figure 1) consist, as a rule, of two axes: a time-axis and a space-axis, thus making it possible to trace in graphic terms individual time budgets. The effective range of each person is described by a prism, or a series of prisms, whose shape is dependent upon the aforementioned capability constraints. Hence, every pause, regardless of the activity involved, will cause the prism’s (or subprism’s) range to shrink in direct proportion to the time spent at said stop. But there are also other wider structural features, specific to the social systems within which individuals operate, which, as has long been recognized, help shape people’s time budgets and activity patterns (Neutens, Schwanen, and Witlox 2011).

The new computation abilities that have become available within the past two decades have opened new possibilities in the ability to plot space–time data. Kwan (2000) was among the first to produce a “space–time aquarium” within a 3-D geographic information system (GIS) environment using individual activity travel diary data. These images have improved the capability to reveal the characteristics of space–time patterns belonging to different population subgroups, and they have also assisted in improving the ability to identify common patterns.

However, one basic problem in trajectories analysis is the limited ability to aggregate space–time paths in order to create generalized types of trajectories composed of varied activities in order to create patterns fashioned on a quantitative basis while taking into account the sequential element (Andrienko and Andrienko 2010). Previous attempts with quantitative pattern aggregation methods, mainly by transport researchers, did not manage to tackle the issue of the sequential element. Understanding the sequence of activities in space and time allows one to understand an additional integral dimension of activity and to recognize patterns that exist within this dimension.

Geography, like many other research and application fields, has moved in recent decades from being a data-poor field to being a data-rich field. This transition happened with the development of fields such as GIS and remote sensing, and today public and private sector agencies are creating larger and larger datasets. This change made it imperative to develop new data mining tools to extract and construct knowledge from the huge databases that otherwise will remain undeciphered. The introduction of location devices, such as cellular phones, has created databases of human activities in space–time in great detail, but due to their large size there is need for new techniques in order to be able to extract patterns of behavior from within those large databases.

**Quantitative analysis of trajectories**

Attempts to aggregate behaviors into patterns and to analyze behaviors have mostly been descriptive; only a handful of studies introduced analytic methods to tackle the new type of high-resolution data available. The realm of trajectory pattern analysis offers many tools that can contribute to the analysis of spatial behavior. Research in this field grows out of the increasing availability of spatiotemporal data and the lack of techniques to analyze it (D’Urso and Massari 2013). The basic entities in this line of research are moving objects’ trajectories that have a defined beginning and end time, and are divided into movement segments by stops–pauses in movement, identified in accordance with the scale of analysis. Yet, when considering semantic trajectories, one must consider background geographic information in order to understand and model trajectory patterns.

Trajectory pattern analysis attempts to resolve three major issues: how to measure similarities between trajectories, how to recognize clusters of similar trajectories, and how to treat the sequential element of a trajectory (Grinberger et al. 2014). Many measures have been developed to identify the similarity of trajectories—distance-based measures, dynamic time wrapping, and longest common subsequence being some of the most frequently used (Chen, Özs, and Oria 2005). A variety of clustering methods are also used in pattern analysis, following the methods used for clustering of static data: direct methods that create clusters according to a central value or entity ($k$-means, $k$-medoids, fuzzy $c$ means); agglomerative methods, which use a hierarchical tree to cluster trajectories together until a certain threshold is reached.
(hierarchical clustering); divisive methods, which work in a top-down manner, dividing an entire database into a number of clusters; density-based methods, which extend the cluster’s reach until a certain threshold number of objects is crossed; and so on. In order to deal with the elements of time and sequence, three approaches are available (Liao 2005): a raw-data based approach requiring substitution of standard similarity measures with ones that take time into account; the feature-based approach, in which raw data are converted into a feature vector, upon which standard clustering methods can operate; the model-based approach, which likewise converts raw data into prespecified model parameters.

The analysis of trajectories and pattern mining has proven to be useful in many areas aside geography. The fields of travel research and transport planning may be the most relevant fields, with some examples being aggregation of trajectories into trajectory patterns, based on regions of interest (predefined or discovered from data), and the sequence and duration of movement between them (Giannotti et al. 2007); identification of mobility profiles – the routine routes of an individual based on data-defined stops and the sequence between them (Trasarti et al. 2011); and the work done by Renso et al. (2013), which combines a predefined mobility behavior ontology and movement patterns aggregated from trajectories (measured, synthetic, or semantic) in order to classify patterns into behavior classes. Lately, this form of analysis has proven useful when implemented within the framework of time geography, as is done by the Activity Pattern Analyst, developed by Chen et al. (2011).

Sequence alignment methods

Based on the principle of comparing sequences (strings), sequence analysis was developed during the 1980s for use in the natural sciences and was utilized primarily by biochemists to, among other things, analyze DNA sequences. It was adapted for use in the social sciences sometime toward the end of the 1990s (Wilson 1998). Unlike conventional quantitative methods, sequence analysis, as its name suggests, tackles the problem of sequences directly. Sequence analysis could, if applied properly, complement the methods used to collect, present, and analyze temporal and spatial data, particularly the data amassed in the course of empirically based time geography research.

Traditional quantitative methods band similar objects together on the basis of specific shared characteristics, but they cannot expose the hidden patterns buried within sequences (Wilson 1998). Unlike the more generally accepted methods of sequence comparison in which the distance between two sequences of activities is calculated by means of Euclidian-based geometry, such as Euclidean distance, city-block distance, or Hamming distance (the number of positions in which corresponding elements are different), sequence analysis computes the distance between the two on a “biological” basis (Bargeman, Joh, and Timmermans 2002).

The algorithm used in sequence alignment to measure the degree of similarity between two sequences utilizes three elementary operations: insertion, deletion (two operations, which are, on occasion, referred to singly as an “indel”), and substitution (switching the places of two characters). By applying these three processes to one of the sequences, one string is made identical to the other. The more operations needed to make the sequences identical, the longer the distance between the sequences. Hence, the longer the distance between groups, the smaller the similarity. Thus, sequence alignment methods measure the degree of difference between two sequences in terms of their element composition and sequence.
Humanspatial behavior is the sum of three parallel dimensions: the “what,” the “when,” and the “where.” The “what” describes the activity taking place, the “when” the temporal dimension of said activity, and the “where” its spatial aspects. Geographical analysis combines these three dimensions to reproduce and understand part of the complex reality of human behavior. Those social scientists who have used sequence analysis to date have tended to focus on the relationship between the “what” (activity) and the “when” (time). In their work, the temporal dimension forms the basis of the sequences analyzed, with each unit (character or word) representing an activity carried out within a specific time frame. Incorporating information such as the frequency, duration, and timing of an activity, the temporal dimension is as a rule analyzed by traditional quantitative methods (Bargeman, Joh, and Timmermans 2002). The location component “where” can be approached in two different ways. The first is “categorized” locations, descriptions of the functionality of the location, such as home, work, and store. Although these words describe locations, they describe the functionality of the location and not the geographical location. These locations are also not unique. Many different homes exist in different locations, and their geographical location cannot be derived from this kind of location description. (For examples of research applying this approach, see Bargeman, Joh, and Timmermans 2002; Stovel and Bolan 2004; Shoval and Isaacs 2007; Shoval et al. 2015.) The second way to approach the location component of activity is by using geographic locations. This approach creates locations that are unique in the sense that each set of geographic coordinates symbolizes a specific location in space.

The method offers an effective means to extract sequence patterns from trajectories of human activities and by doing so may also present new ways of analyzing such data. It is equally worth noting that the relatively new and more accurate digital methods of collecting spatial data (i.e., GPS) produce databases that are characterized by extremely high temporal and spatial resolutions. This reinforces the observations to the effect that recent developments in the field of location aware technologies (LAT) and location-based services (LBS) could trigger an even wider resurgence in time-geographic studies (Miller 2005; Wilson 2008).

References

Transaction costs are costs associated with effecting an economic transaction, either through market exchange between two or more legally distinct economic actors, or internally within a single organization (firm, or, more generally, “hierarchy”).

Costs for market-mediated transactions might include:

- the cost of gathering information concerning the availability, price, quality, and so on, of particular commodities (goods or services);
- the costs associated with identifying potential customers;
- the costs associated with estimating the reliability and credit of suppliers and buyers;
- the costs associated with negotiating the terms of an exchange, including price, delivery date, and terms of payment (and of setting these out in the form of an agreed contract);
- the cost of completing a transaction (marking or collecting payment); and
- the costs accompanying nonmarket transactions within an economic actor (like a single firm). These are mainly the costs of organizing and coordinating complex, multistep production processes in-house.

The idea of transaction costs was proposed by Ronald Coase (Nobel Laureate in economics) in 1937. In his paper *The Nature of the Firm*, he defines transaction costs as the most obvious costs of organizing production through a price mechanism. It’s the cost of finding all relative prices. In other words, transaction costs are the expense of the negotiating and signing of every transaction that has happened in the market, and other costs associated with using the price mechanism (Coase 1937). Market and firm are two kinds of organizing forms of economic activity, and the cost of market-mediated transactions provides a need for the existence of the firm. Firms can reduce market transaction costs through strengthening vertical integration (Matthews 1994), which will increase management costs at the same time. So the boundary of the firm is determined by the market transaction costs and firm organization costs.

Based on Coase, Oliver Williamson, the 2009 Nobel Laureate in economics, analyzed and investigated the determinants of transaction costs, enriching and perfecting transaction cost theory. Because of his valued contribution, transaction cost economics was established and transaction costs have been widely used in the economic analysis paradigm. *The Economic Institutions of Capitalism* (Williamson 1985), his writing on transaction costs, has become an economic classic, and he has become the master of transaction cost theory.

Williamson divided transaction costs into costs before and after contract business (Williamson 1985). The former includes the costs associated with drafting a contract, negotiating the contract, and guaranteeing the contract can be performed. The latter includes maladjustment costs, bargaining costs, constructing costs, performing costs, and guaranteeing costs.
As to why transaction costs exist, there are subjective reasons and objective reasons. Subjective reasons include bounded rationality and opportunism. Bounded rationality means that people participating in trading activities will be subject to physical, intellectual, emotional, and other types of restriction, which will limit the benefit maximization. Opportunism refers to people involved in the transactions consciously acting with the purpose of seeking self-interest, which increases mistrust and suspicion. Objective reasons include asset specificity, uncertainty, and frequency of transaction. Asset specificity means that the investment asset of the exchange does not have market liquidity. In other words, the cost of investing in the asset is difficult to recycle or convert to another use once the contract is terminated. The uncertainty means that the transaction process is very complex, which will generate a lot of uncertainty and risk. As to frequency, the higher the frequency of transactions, the higher the corporate management and bargaining costs.

However, the definition of transaction costs among academics is not completely consistent, and neither is the scope that transaction costs cover. The term “transaction costs” was first and clearly proposed by Kenneth Arrow in 1969. He argued that uncertainty and negative externalities exist in people’s communicative behavior. As a result, the social system emerges. The costs of using the system are transaction costs (Arrow 1969). Yoram Barzel argues that transaction costs are the costs of defining and maintaining property rights (Barzel 1997), while the broadest definition of transaction costs is made by Steven Cheung, who argues that transaction costs are all kinds of costs that can’t exist in a Robinson Crusoe economy, namely “the system cost” (Cheung 1987). Not surprisingly, there are also many other scholars who have created their own definitions of transaction costs. Although there are differences between these definitions, they are the same in essence.

Though derived from economics, transaction costs have also been widely used in economic geography. In the mid-1980s, Allen Scott, the American economic geographer, introduced transaction cost theory in urban and regional study to analyze industry clusters, forming the new industrial location theory which had a far-reaching influence. He argued that projects with low unit transaction costs would organize production in places with a cheap labor force in the form of enterprise branches (Scott 1983, 1986). By contrast, those projects with high unit transactions costs would locate in big cities or economic centers in the form of market transactions. That is to say, different kinds of firms have different location patterns. Some will agglomerate in big cities while others choose to stay in smaller cities, which will directly influence the urban and regional form.

Transaction cost theory can be applied to understand the microfoundation, structure, essence, and evolution of industry clusters (Iammarino and McCann 2006). In order to cope with sharp fluctuations in the external environment, firms should manage input–output relations with other firms. This will generate transaction costs and create pressure for agglomeration (Storper and Venables 2004). Besides, when an industry cluster forms, it can significantly reduce transaction costs in many ways.

First, geographical factors will influence transaction costs (Scott 1988). After firms agglomerate within a district, the space transaction costs will decrease accordingly (McCann 1995). Second, firms in an industry cluster can share common service providers and suppliers. Being geographically close to each other can help suppliers reduce transaction costs, which will also help firms in the cluster reduce the cost of finding potential suppliers and customers (Bathelt, Malmberg,
and Maskell 2004). In addition, it’s easy for firms to cooperate frequently when they agglomerate within a district. This will increase trust between them and promote information-sharing to enable nonroutine transactions (Harrison 1992; Storper 1997; Nooteboom 2006). Furthermore, the local culture that results from firms’ interactions will bring intangible restrictions to the trading activities between enterprises, which will also reduce transaction costs.

Transcripts: coding and analysis

Meghan Cope
University of Vermont, USA

Transcribing

The term “transcripts” refers to the product of transcribing, which is the process of researchers (or specialists they have hired) creating a textual version from an audio or video recording of some kind of interaction, media report, or research event. Transcribing is commonly used in qualitative research projects when researchers want a written version of their interactions with participants, or from other audio sources such as radio reports, advertising, speeches, or television shows, for the purposes of analysis. Common qualitative research interactions that lend themselves to recording and transcription include focus groups, interviews, oral histories, participatory mapping sessions, photovoice, and any other technique which involves audio content that might be recorded and turned into text. Another form of transcripts that should also be acknowledged here is the transcription that is typically employed in archival work, when, for instance, a researcher creates a typed, digital copy of historical documents written by hand, such as letters, diaries, or other manuscripts. While the process of transcribing may be somewhat different – straining to read faded or archaic handwriting rather than straining to hear a mumbled word – the resulting document is in essentially the same format and can be analyzed in similar ways to transcripts made from audio material. Because there are fewer technical and decision-making points to concern the researcher working with historical manuscripts, many of the comments in this entry focus on contemporary work involving audio recordings, but the analysis principles remain largely the same between various data sources.

The technical aspects of audio recording have become simplified with the development of digital audio technology. Most cellphones can now be used as audio recorders, though for higher quality recordings special equipment may be desired, such as multidirectional microphones placed in the middle of a table during a group exercise. Although researchers will still be faced with the challenges of managing audio files (saving them, organizing them, keeping metadata on them, and insuring their security), digital files are still an improvement over the flimsy, heat-sensitive, and cumbersome audio tapes that were in use until quite recently (and, perhaps, still are in some places). Digital files should be backed up on alternate drives, the “cloud,” or other secure locations, so as not to mistakenly delete hundreds of hours of interviews with the swipe of one cup of tea spilled on the researcher’s laptop. As with all data that may be personal, politically sensitive, or whose violation could potentially endanger the researcher or her/his informants, security measures should be taken seriously. A final note on technology: while there are various software programs and applications that can at least partially automate transcription, they are (as of 2016) still limited to being essentially dictation transcribers – that is, they need to be “trained” by the speaker and, thus, are really only useful for things like transcribing.
audio-recorded field notes, or other instances when only one person (usually the researcher her/himself) is talking. Of course, the field of digital technologies is changing very quickly and it may well be possible to completely automate transcription with sufficiently high levels of accuracy in the coming years.

The practice of transcribing, therefore, involves creating, as accurately as possible, a fair written version of the verbalizations generated in a research encounter with participants, or gleaned from other sources of talk, such as media reports. Transcription typically also involves researchers paying attention to other, nonword audible expressions, such as pauses, laughter, scoffing, sighs, emphasis, and talking over one another. These can be very important for interpreting the meanings of the text and, thus, should not be ignored. At another level, researchers often need to account for movements, facial expressions, directions of the gaze, and other “body language” performed by participants; this can be done either from video recordings or based on written notes taken by the researcher or an assistant during the audio-recorded interview/focus group. There is a system of commonly used markings to indicate these nonverbal expressions, which is reprinted in the appendices of many methods texts (see Silverman 2011, 465–466 for some notation conventions of transcription).

A quick review of the many methodology discussion boards and online forums (Listserves) reveals that there are numerous approaches, many potential pitfalls, and countless spirited debates about various strategies of transcribing, the full extent of which is beyond the scope of this entry, but included here are a few cautionary findings. First, there are professional transcription services that can be hired at varying costs and – undoubtedly – with varying levels of skill. Second, there is a lot of discussion and debate on the topic of (abovementioned) digital transcribers, from phone apps to full software packages, which again have varying costs and levels of accuracy. Third, the biggest downfall for both professional (human) transcription and automated digital transcription is the misinterpretation of sounds and verbalizations because the transcriber is not familiar with the local place names, acronyms, technical terms, or other specialty references that are typically sprinkled throughout interviews and research sessions, and may not adequately represent nonverbal elements that can greatly impact the meanings of the words. This leads to a final observation: through all the online debates about the merits of various outsourced and automated transcribing approaches, the gold standard seems to be that the researcher does her/his own transcribing, or at least performs a careful check on each transcription. There are two reasons most frequently cited for this: (i) the researcher is going to have the best knowledge of those place names, acronyms, and special terms that are inevitably uttered in interacting with research participants, and will be able to discern more of the implied meanings of pauses, laughter, and so on; and (ii) by doing their own transcribing (or careful review of the text while listening to the recording), researchers get closer to their results than is possible just by reading someone else’s transcription and – indeed – they will likely even get a start on the process of sorting, organizing, and analyzing data by noticing patterns and themes just through the transcribing process.

Of course, transcribing can be tedious and is certainly time-consuming. Transcribing one’s research recordings is even, in some circles, a bit of a rite of passage for new scholars, generating the requisite “survival” stories to be shared and sympathized with afterward. These are all points to consider when approaching such a task. Most books on qualitative research methods, in geography as well as other disciplines, have
sections on the joys and sorrows of transcribing, as well as helpful hints on techniques (Kitchin and Tate 1999).

**Putting transcripts to use: making sense of texts**

Diaries, notes and letters, policy statements, newsletters, open-ended survey questions, even photos, performances, and art installations are rich sources of insight that have been creatively employed by human geographers and other social/cultural researchers. However, as the diversity of qualitative research methods has increased over the past two decades, particularly with the inclusion of more participatory methods and the expansion of digital forms of representation, researchers are increasingly in situations where even this broad array of sources is expanded. The digital age is generating new sources of qualitative data, such as tweets, social media posts, sketch maps, images, blogs, video, and so on; these are increasingly spatially referenced, allowing new dimensions of contextual understanding. Thus, the remainder of this entry focuses on methods of coding and analysis that can be used for transcripts, but acknowledges that the organization and analysis functions can be applied to a much wider set of diverse data forms.

While transcribing itself presents some technical challenges, the value of investing time and energy into producing good quality transcripts comes through once the researcher begins trying to make sense of the data. There are many ways to analyze and understand transcriptions, and more or less systematic ways of organizing and understanding the raw material. One common approach to making sense of transcripts, which will be the main focus here, is to construct a system of *codes* as a way to comprehend data. Codes are comprised of *categories* of data and *themes* that the researcher is interested in. For categorization, data are examined and grouped based on similarities (e.g., all mentions of “part-time work” or all experiences related to migration), and each category is assigned a code. For thematic coding, the data are assigned codes based on instances related to themes that are important to the research project (e.g., themes of employment or transnational identities). Beyond just thinking of codes as “categories” or “themes,” there are many other ways to structure a coding system, such as distinguishing between descriptive and analytic codes, “latent” and “manifest” codes, and considerations about how codes relate to each other (are they hierarchical, networked, or parallel?). Many excellent sourcebooks cover the issue of creating coding structures more thoroughly than is possible in this space (Corbin and Strauss 2007; Dey 1993; Miles, Huberman, and Saldana 2014; Saldana 2013; and, in geography, Cope 2009, 2016; Kitchin and Tate 1999). Many of these authors reiterate what Coffey and Atkinson identify as the strengths of coding, which go well beyond mere organization and search functions:

> Coding need not be viewed simply as reducing data to some general, common denominators. Rather, it can be used to expand, transform, and reconceptualize data, opening up more diverse analytical possibilities… The general analytic approach here is not to simplify the data but to open them up in order to interrogate them further, to try to identify and speculate about further features … it is intended to expand the conceptual frameworks and dimensions for analysis. *Coding here is actually about going beyond the data, thinking creatively with the data, asking the data questions, and generating theories and frameworks.* (Coffey and Atkinson 1996, 29–30; emphasis added)

However, a few guidelines and suggestions on coding can provide some starting points.
TRANSCRIPTS: CODING AND ANALYSIS

First, consider the purposes of coding. At its most basic, coding is about breaking data into smaller pieces and then recombining those pieces in order to identify and explore relationships and discover new connections. Imagine how tedious and long a paper would be if you included the full transcripts of, say, twenty interviews or eight focus groups and expected your readers to hold all those accounts in their heads as you made your conceptual argument! Instead, coding allows us to break down those transcripts, distill raw data down to the most pertinent findings by splitting them into constituent parts, and make clear connections between our empirical and theoretical discoveries. Watson and Till phrase it as: “An iterative analytic practice, coding allows the ethnographer to break apart, relate, and recombine the materials generated in the research process” (Watson and Till 2010, 128, emphasis added).

More specifically, coding helps researchers to: organize their data in more digestible forms, perform searches and find key phrases, pull all the instances of one code together for comparison, analyze the copresence of real-world events with certain settings or characteristics, clarify patterns and the relationships between patterns and the underlying processes that create them, and – ultimately – generate new knowledge about the social world. At a different level, coding represents a systematic and rigorous attempt to do justice to the research participants and the time and effort invested by all the various players in the research experience. For all of these reasons, coding is increasingly recognized to be an important component of analysis, with inherent and significant elements of critical reflection, well beyond data organization and processing.

The second guideline is a cautionary note: do not assume that you know all the best codes to use right from the start. While some codes will have their roots in the original research design and the intent of the researcher(s), others will emerge and be developed in varied ways. Indeed, codes sometimes spring directly from the data (referred to as in vivo codes), often from phrases used by research participants. As an example, in a project with low-income women during the 1990s retrenchment of welfare benefits, the phrase “struggling constantly alone” was used as a code, which had come from one of the women participating in one of our focus groups. Although it was somewhat lengthy for a code, “struggling constantly alone” succinctly represented many of the women’s sentiments and experiences, and fostered a way of embedding the participants’ words into the analysis. This is an example of a thematic, emerge from the data. For example, in a project on teenagers’ everyday spaces and mobility, my research partner and I knew from related literature that teens’ communication with family and friends (to coordinate get-togethers, find a ride, or just check in) would be important, but we also discovered from our open-ended surveys and focus groups with teens that there is a hierarchy of the modes of communication: phone and e-mail were used for communicating with adults (parents, teachers, coaches), while texting, “chat,” and instant messaging were preferred for communicating with peers (Cope and Lee 2016). Thus, in examining and coding our data, we started to pay attention not merely to the method of communication (which served as one code) but also where it fit in the hierarchy of technological intimacy (a separate code). Being open to the emergence of new or unexpected patterns need not disprove one’s initial sense of what is important but, rather (as in our case), can enhance one’s understanding of social phenomena.

The third guideline follows on the flexibility mentioned above: do not assume that you know all the best codes to use right from the start.

While some codes will have their roots in the original research design and the intent of the researcher(s), others will emerge and be developed in varied ways. Indeed, codes sometimes spring directly from the data (referred to as in vivo codes), often from phrases used by research participants. As an example, in a project with low-income women during the 1990s retrenchment of welfare benefits, the phrase “struggling constantly alone” was used as a code, which had come from one of the women participating in one of our focus groups. Although it was somewhat lengthy for a code, “struggling constantly alone” succinctly represented many of the women’s sentiments and experiences, and fostered a way of embedding the participants’ words into the analysis. This is an example of a thematic,
analytic code; it is fairly abstract and required a certain amount of interpretation and judgment on the part of the researcher. Thus, it was quite different from more categorical codes such as, for example, whether or not someone has children under 18 in their household or their employment status. However, when going back to review all the segments and statements for the women participants that had been coded “struggling constantly alone,” it provided a rich entry point into the data and allowed patterns and relationships to be seen between that analytic code and the more categorical information collected about the women (Cope 2001). Indeed, the women with multiple children under 18 who were single parents and marginally employed were revealed to be “struggling constantly alone” in diverse contextual settings, but with the commonality of having few social or economic resources and many demands on their time and energy.

There are many strategies and methods available to begin coding but, beyond the basic conventions, researchers tend to develop their own practices. Some people code “by hand,” meaning using note cards, colored pencils, or highlighting markers, lists of codes and relationships, whiteboard diagrams, “sort and pile” techniques, and other tangible means of analysis. Other researchers use computer-aided qualitative data analysis software programs (CAQDAS, such as Atlas.ti, HyperRESEARCH, NVivo, etc.), which operate on the same basic principles but allow the digital storage, organization, coding, memoing, and analysis of data. In a comparison of coding manually and electronically, Basit (2003, 143) found that “the choice will be dependent on the size of the project, the funds and time available, and the inclination and expertise of the researcher.” So, a small project involving a limited amount of data and one researcher might lend itself to notecards and colored pencils for the purpose of expediency, while a multiyear project with many types of data and multiple research partners and students might lend itself to the use of a CAQDAS. However, what Basit calls the “inclination” of the researcher matters regardless of the size of the project. For example, Watson and Till’s (2010) chapter on ethnography and participant observation includes an interesting review of why each of them adopts their method of coding (Watson uses Atlas.ti while Till employs a hard-copy strategy), as well as some interesting step-by-step accounts of how they actually perform their coding.

Finally, employing transcription and coding can generate a more rigorous research practice overall by introducing a systematic approach to the data. This does not mean the analysis should be mechanical or unresponsive to the unexpected; rather, a faithful reproduction of audio files to the written record and the subsequent construction and employment of a rigorous coding system generates insights that are both innovative and defensible. Having a systematic method of coding and analyzing data has the following advantages: (i) it allows researchers to incorporate a broader variety of data sources (text, photos, sketches, tweets, etc.) into the analysis; (ii) it fosters the success of projects involving multiple researchers (Weston et al. 2001); and (iii) it works with a wide range of types of projects from small, exploratory pilot studies by one person to large-scale, multiyear, multi-investigator projects.

Of course, coding transcripts is not the only way to make sense of data. Other methods of analysis include critical discourse analysis, narrative analysis, content analysis (a quantitative approach), and hermeneutics. Transcripts are useful in all of these. As an example, consider Dixon’s employment of critical discourse analysis (Dixon 2010), where her aim is identifying the ways society is “enmeshed” in structures, mechanisms, and events, all of which are conveyed...
and learned through discourse (communication, manner of dress, economic exchange, daily routines, laws/regulations, etc.). While the mechanics of interpretation and meaning may differ, in the end, what social researchers are seeking is the rigorous interpretation of data and the production of knowledge.

Connecting to the conceptual

Transcribing and coding oral and textual data was, even as recently as the turn of the millennium, a pioneering method for human geographers. With the expansion and deepening of qualitative investigations, and a turn toward more critical theoretical approaches, these techniques have, perhaps, become more common. Latham argued there was still much to be done, though, in cultural geography:

Over the last couple of decades we have seen something of a revolution in ways we frame what it is that geography is concerned with. We have seen that it is as much about discourses as about “actual” events; that things that seem small and everyday can be as interesting and complex as phenomena that appear much larger and more general; that our own ways of writing the world are bound up with that world’s constitution. But we do not seem to have made much progress in rethinking what this should mean to us as researchers. (Latham 2003, 1993–1994)

However, it might be suggested that in the decade or more since Latham wrote these words that we have indeed made a great deal of progress on this very question, both in terms of who we are as researchers and in terms of how our research is conducted and its place in the world. Feminist and other critical perspectives have inspired more reflexive epistemologies, the legitimation of broader ranges of topics (including the “mundane,” everyday ones), as well as the methods of investigation and researcher positionality as respectful participation with people who are experts in their own lives. With the cultural turn in human geography, the broader focus on everyday life and mundane social/cultural production of space(s), and the increased attention paid to historically marginalized populations, transcription and coding have become important tools for exploring the lives and spaces of those who do not appear in historical or contemporary records in the same forms as the elite. Overall, then, transcribing and coding are useful methods of data management and analysis for projects at varying levels of abstraction and diverse scales: is the research question about how a national leader frames her/his state’s geopolitical position in official speeches or is it about how children navigate school lunch-time politics? In either instance, careful attention to, recording of, and analysis of actions, verbalizations, expressions, and material props can lead to better insights and the practices of transcription and coding play an important role in both projects.

Transnational environmental governance

Frank Biermann
*Utrecht University, Netherlands*

Environmental governance is the collective steering of societal processes by public and private actors in order to prevent, mitigate, and adapt to environmental change. Transnational environmental governance describes such steering processes that involve two or more countries.

There are a variety of additional or alternative terms used in the literature that emphasize different aspects: *global environmental governance* denotes environmental policymaking that addresses concerns of all countries or that involves all countries. Examples are current negotiations on climate change, biodiversity depletion, overfishing, and the pollution of the oceans. *Intergovernmental environmental governance* describes such processes if they involve only governments. *Earth system governance* is a new paradigm that has emerged in recent years, emphasizing as policy goal the protection of the entire Earth system from transformations brought about by human activities. Climate change is a prime example of Earth system governance, given the global interconnectivity and interdependence of the climate system.

Transnational environmental governance is part of the broader domain of governance studies and governance theory. Importantly, the notion of governance is different from traditional concepts of government. Governance, as opposed to government, is not confined to states and governments as sole actors, but involves myriad public and private nonstate actors at all levels of decision-making, ranging from networks of experts, environmentalists, and multinational corporations to intergovernmental bureaucracies. Governance also often implies notions of self-regulation by societal actors, of private–public cooperation in the solving of societal problems, and of new forms of multilevel policy (Jordan 2008; Adger and Jordan 2009).

As a research field, transnational environmental governance is inherently interdisciplinary. It transcends traditional concepts of environmental policy, given that the current human-made perturbation of the entire Earth system encompasses new problems that range from global changes in biogeochemical systems to the loss of biological diversity. Transnational environmental governance must also address the entire system of multilevel governance, from local to global levels. As a consequence, a complete understanding of transnational environmental governance requires the involvement of the full range of social science disciplines, from the study of local decision-making to international relations.

**Actors of transnational environmental governance**

Transnational environmental governance is marked by a high degree of complexity that involves a large array of institutions and actors. The most important actors are still national governments. National governments are key agents to sign up to international environmental treaties, and to subsequently employ the required means at their disposal to implement these commitments. However, the power and influence of
national governments differ fundamentally. For example, China’s population alone is greater than the combined populations of the 159 least populous countries. While China and India together account for roughly 37% of humankind, the 100 least populous countries represent only 3.9% of the world population and 6.4% of the global gross domestic product. The current system of multilateral decision-making, however, does not sufficiently take into account such vast differences in the size and relevance of countries, leading to recent calls to introduce new types of decision-making in transnational environmental governance, for example, by majority decisions that would weigh the votes of governments by population size or the financial contributions that they represent.

In addition to national governments, transnational environmental governance is characterized by the increased participation of nonstate actors (Dellas, Pattberg, and Betsill 2011). Environmentalist groups have managed to alter the foreign policy of powerful states, to initiate new global rules, or to influence global negotiations. Networks of scientists have assumed a new role in providing complex technical information that is indispensable for policymaking on issues marked by analytic and normative uncertainty. One example is global science assessment programs, notably the Intergovernmental Panel on Climate Change, which involves thousands of scientists from all over the world (Gupta et al. 2012). Business actors have taken a more prominent direct role in transnational environmental governance as well. Many corporations have assumed a direct influence as immediate partners of governments, for example in the framework of the United Nations and of the Global Compact on corporate social responsibility that major corporations have concluded with the UN.

Also important are the many intergovernmental organizations that are active in transnational environmental governance. Many international organizations have developed some activities and programs on environmental governance, including, for example, the Food and Agriculture Organization of the United Nations (FAO), the United Nations Industrial Development Organization (UNIDO), the International Maritime Organization (IMO), and the United Nations Educational, Scientific and Cultural Organization (UNESCO). In addition, most international environmental treaties have set up a secretariat to assist in implementing the agreement, with some of these bodies having evolved into sizable international organizations, such as the secretariats to the United Nations Framework Convention on Climate Change (UNFCCC) and the Convention on Biological Diversity (CBD). To coordinate all these activities, in 1972 governments established the United Nations Environment Programme (UNEP) as part of the general United Nations organization. The effectiveness of this relatively small program, however, has been repeatedly put into doubt in recent years, with many observers arguing that the program should be replaced by a much larger and more powerful independent international organization, such as a world environment organization. The creation of such a new organization is currently supported by numerous countries, including all member states of the European Union and of the African Union. However, other countries, including powerful actors such as the United States, still argue against a new UN agency.

### Transnational institutions

Key instruments of transnational environmental governance are transnational institutions that set standards for participating states and other actors. At present, about 1100 environmental treaties concluded by governments are in force.
Many studies since the 1980s have investigated the emergence, maintenance, and effectiveness of such multilateral agreements, for example the United Nations Framework Convention on Climate Change or the Montreal Protocol on Substances that Deplete the Ozone Layer. Key questions are the conditions that allow for the quick and effective negotiations of transnational institutions, and the primary factors that can explain high levels of implementation, or the failure, of such agreements.

Given the large number of transnational environmental institutions, the interlinkages between different institutions have become a major focus of attention and given rise to concerns about an increasing “fragmentation” of transnational environmental governance. While some studies have argued in favor of a diversity of approaches and a positive evaluation of this growing fragmentation, many others are critical and call for political measures to strengthen the consistency and coherence of the overall system of transnational environmental governance. Important new research has also addressed possible political responses to problems of governance fragmentation and ways forward in “interplay management.”

In addition, transnational environmental governance remains inconceivable without continuous policymaking at national and subnational levels. Transnational standards need to be implemented at the local level, and the global norm-setting requires local decision-making to put into place the frames for global decisions. This results in the coexistence of policymaking at the subnational, national, regional, and global levels in most areas of transnational environmental governance, with the potential of both conflicts and synergies between different levels of regulatory activity. As for the general fragmentation of transnational environmental governance, the emergence of multilevel environmental governance from local to global levels has also given rise to much recent research on optimizing governance effectiveness and on resolving potential problems and conflicts.

In addition to institutions set up by governments, nonstate actors are also becoming part of norm-setting and norm-implementing institutions and mechanisms in transnational environmental governance. Examples are the Forest Stewardship Council (FSC) and the Marine Stewardship Council (MSC), two standard-setting bodies that have been created by major corporations and environmental advocacy groups without the direct involvement of governments. It sometimes seems that traditional intergovernmental policymaking through diplomatic conferences is being replaced by such networks of nonstate actors, which are regarded by some as more efficient and transparent. On the other hand, the distribution of such networks is often linked to the particular interests of private actors who have to respond to their particular constituencies, and serious questions about the legitimacy of private standard-setting remain. For example, policymaking by private organizations such as corporations and environmentalists cannot relate back to democratic elections or other forms of direct representation, and is often perceived as being biased in favor of the interests and concerns of the rich countries in the North.

Public–private partnerships have received much attention since the 2002 Johannesburg World Summit on Sustainable Development (Pattberg et al. 2012). Some observers see transnational public policy networks as an innovative form of governance that addresses the deficits of interstate politics by bringing together key actors of civil society, governments, and business. In this perspective, transnational public policy networks are important new mechanisms to help resolve a variety of current governance
deficits. Others, however, view the new emphasis on such partnerships as problematic, since voluntary arrangements could privilege more powerful actors (in particular industrialized countries and major corporations), would consolidate the privatization of governance and dominant neoliberal modes of globalization, and also lack accountability and legitimacy.

**Equity in transnational environmental governance**

Transnational environmental governance has to operate in a nation-state system that is marked by substantial differences in wealth and power. The richest 20% of humanity account for 76.6% of total private consumption, while the poorest 20% consume merely 1.5%; 842 million people lack sufficient food. The poorest 25% of humanity have no access to electricity. One billion people lack sufficient access to water, and 2.6 billion have no basic sanitation. This global inequality has further increased over the last decades. In 1960, the richest 20% of humanity were 30 times wealthier than the poorest 20%, but this ratio had increased to 74 times by 1997. Transnational environmental governance has to address this context of vast inequalities between people and countries.

One consequence of this global inequality has been that in many institutions of transnational environmental governance, developing countries have insisted on various exemptions. A general rule of transnational environmental governance widely accepted today is the principle of “common but differentiated responsibilities and capabilities,” which was agreed on by governments at the 1992 United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro. This principle is operationalized, for example, in a provision of the Montreal Protocol on Substances that Deplete the Ozone Layer which allows developing countries to delay implementation of the phasing out of such substances by 10 years. Industrialized countries also agreed to compensate the full agreed incremental costs that developing countries would incur in complying with this treaty. In the UN Framework Convention on Climate Change, industrialized countries agreed to take the lead in addressing global warming, and quantified obligations to reduce emissions of greenhouse gases apply at present only to industrialized countries. Since the mid-1990s, a variety of international funding mechanisms have been set up to support poorer countries in their efforts to support transnational environmental governance. One major example is the Global Environment Facility, which is jointly operated by the World Bank, the UN Development Programme, and the UN Environment Programme and which has, since the mid-1990s, allocated US$9.2 billion to developing countries, along with over US$40 billion in cofinancing. In the area of climate policy, developing countries can rely on financial support by an Adaptation Fund, a Special Climate Change Fund, a Least Developed Countries Fund, and, since 2010, a Green Climate Fund.

However, the funding levels to which industrialized countries are committed are not sufficient to cover all the additional costs that developing countries will incur. In addition, the normative principles applicable to global environmental issues are still contested between North and South. Developing countries argue, for example, that industrialized countries should accept a historical responsibility for past greenhouse gas emissions, and should strive to reduce their emissions to levels that equal the much lower emissions of developing countries on a per capita basis, before developing countries have to accept any quantified targets. Industrialized countries, on the other hand, argue that all
countries should implement some environmental policies, and that all efforts by industrialized countries would be pointless if the larger developing countries such as China or India were to continue increasing their emissions through the rapid development of their fossil fuel-based industries and consumption patterns. Overall, these different perceptions of the responsibilities that states have in transnational environmental governance, combined with the vast differences in wealth and welfare, continue to result in substantial deadlocks in negotiations on issues as diverse as climate change, deforestation, and chemicals, with no easy compromises in sight.

The future of transnational environmental governance

In sum, transnational environmental governance is today one of the most important domains of international relations. Its overall effectiveness, however, remains insufficient. A number of key indicators show that planetary systems are moving outside the range that has been known for the last 800,000 years, with potentially disastrous consequences for humankind (Rockström et al. 2009). This calls for renewed efforts by decision-makers in both public and private agencies to strengthen the overall system of transnational environmental governance in order to maintain stable conditions on our planet that allow for a sustainable coevolution of human and natural systems. A number of concrete proposals have been published in recent years, drawing on broader assessments of the social science research in this field (e.g., Biermann et al. 2012). Yet the implementation of reforms is lagging behind. According to recent calculations by the World Bank, all current commitments by governments are likely to lead to a global warming of more than 4 °C by 2100, with a 20% likelihood of more than 4 °C. If current political commitments are not followed through, a warming of 4 °C could occur as early as the 2060s. This is clearly an unacceptable scenario. More political will and efforts in this policy domain are thus urgently needed.

In this sense, effective transnational environmental governance is likely to be transformative. Business as usual will hardly prevent critical transitions in the Earth system. Technological revolutions and efficiency gains might, in theory, provide a solution within the current systems of distribution and consumption, but this is not likely. Instead, to be effective, transnational environmental governance will need to directly address the key concerns of social change. Notably, in a highly divided world, transnational environmental governance poses fundamental questions of equity and allocation within and between nations. Transnational environmental governance also raises important questions about the legitimacy and accountability of public action. The entire system of global governance and world politics is likely to be affected by the changes that are required in transnational environmental governance or, as it is increasingly referred to, earth-system governance. In times of progressing climate change, the accelerating depletion of biological diversity, and growing levels of persistent organic pollutants all over the world, the current system of independent decision-making by 190 nation-states seems increasingly outdated. The success of transnational environmental governance is thus inherently interlinked with the evolution of the overall architecture of world politics. More political engagement and progress toward a “constitutional moment” in international politics (Biermann et al. 2012) seems to be the need of the hour.

Transnationalism

Katharyne Mitchell  
University of Washington, USA

The Latin root trans means across, and transnationalism literally refers to that which takes place across national boundaries. The term is most often used to describe the material ties, networks, and sustained relations that operate in an ongoing fashion between actors across national borders; however, it can also function to describe the cross-border symbols and ideas that flow between people and institutions to create multidimensional transnational spaces.

As a general term, “transnationalism” is often linked with globalization. The similarities are many, as both terms can be used to describe processes that are centuries old which also display attributes particular to the post-World War II period. These include the global production and increasingly rapid movement of commodities and information across national borders, and the transmission of cultural practices and ideas in an ever widening gyre. Contemporary globalization and transnationalism are enabled by innovations in transportation such as airplanes and container shipping, as well as advances in computing, telecommunications, and the Internet.

Globalization refers to the widespread interconnections of people, places, and things and, as such, it is a process that can be traced back to the twelfth century, if not earlier. But contemporary globalization manifests these interdependencies in a denser, tighter, and more accelerated framework—what some have termed time–space compression. It is also characterized by a rhetoric of necessity and inevitability, in which the term itself serves to propagate its own functional workings vis-à-vis the accelerating circulation of finance and commodities and the declining regulatory role of the neoliberal state (Sparke 2013).

In this regard transnationalism can be seen as an idea that overlaps significantly with contemporary globalization, but which also contains its own modalities and trajectories. One of the key areas in which transnationalism displays these differences is when it is applied to migration. Scholarly theory linking transnationalism with migration developed in the early 1990s as a new way of thinking about migrant movement, integration, and attachment. Among the early adopters were Basch, Glick Schiller, and Szanton Blanc (1994), who used fresh terminology to describe what they were observing in their research. Rather than taking a dichotomous view of assimilation versus non-acculturation, these scholars noted the ways in which contemporary migrants seemed to be variably integrated in both sending and receiving societies. The migrants forged ties and allegiances across borders with more than one national community and sustained “multi-stranded social relations [linking] together their societies of origin and settlement” (Basch, Glick Schiller, and Szanton Blanc 1994, 6).

As a result of this particular theoretical framing, beginning in the late 1980s, the term began to connote the practices and experiences of nonstate actors and institutions that extend across national borders. At this time it referred primarily to a kind of highly networked, spatially stretched experience where lives were lived simultaneously in more than one place. In contradistinction to the processes associated with economic globalization, however,
these transnational activities often occurred in a highly regulated and sometimes antagonistic relationship to the state. While the neoliberal state’s regulatory role has greatly diminished vis-à-vis the processes of economic globalization, it still retains the authority and legitimacy to police the transnational flows of human actors and social institutions in the name of national security. And today, while most states have facilitated the free flow of commodities and money, they have simultaneously restrained or otherwise controlled the movement of laboring bodies.

These insights help to create new ways of thinking about transnationalism as a plural, multidimensional process, yet one that is still intricately involved with neoliberal governance, especially involving the nation-state. States remain active in policing borders and membership, and retain great social and political power vis-à-vis cross-border migrants and institutions. Nevertheless, boundaries are inevitably leaky, and their diffuse and variable permeability lends the possibility of subversion to the rules and norms of containment in a number of different registers.

The subversive potential of transnationalism as a concept and set of practices has resonated with recent historical investigations of pan-regional events and cross-border relationships such as the Haitian Revolution and the Black Atlantic. Critical scholarship on these transnational moments in space and time has upended universal history and normative assumptions about nation, race, and revolution (Gilroy 1995). The term has also been implemented in more recent critical scholarship examining the expanding alliances forged through feminist, indigenous, and pan-African movements worldwide. It now broadly signifies an opposition to methodological nationalism and a reconfiguration of the national imaginary – opening up the potential to evaluate new political, economic, and cultural forms, alliances, and systems of governance that exist across and beyond the nation-state.

**Transnational migration, institutions, and communities**

In migration studies, where the term “transnationalism” has been employed most frequently and consistently, the concept has propelled greater interest in the multidirectional processes that simultaneously embed people, places, and things in two or more societies. It has enabled research into the geographies of transnational social fields, which produce spaces and topographies in novel configurations. And it has spurred novel ways of thinking about community and the uneven impacts of global remittances.

A remittance is the transmission of money across national borders by a worker to his or her home community. It generally involves money transferred by transnational migrants from the wealthier nations, where they are working, to the less developed countries from where they originated and where they still have strong family ties. Remittances have become an important source of revenue for individuals and also for countries. In 2012 remittances exceeded $500 billion, with over $400 billion of that going to developing countries. This figure has increased rapidly since the mid-2000s.

The importance of remittances cannot be overestimated, as they account for the largest source of foreign currency in numerous countries and often exceed international aid, as well as official sources of capital inflow. While there has historically always been a flow of money from migrants to their extended families and communities back home, the scale of contemporary remittances indicates changes that reflect both the extent of current transnationalism and also the economic shifts occasioned by neoliberal globalization.
Some of the negative effects of neoliberal free trade agreements such as NAFTA (North American Free Trade Agreement) include widening economic gaps between many rich and poor nations and also the socioeconomic dispossessions and dislocations of certain populations, such as Mexican farmers. As a result, numerous individuals have been forced to move from less developed countries to find work in wealthier ones. At the same time, new kinds of technologies have enabled the simultaneous embedding of lives in more than one national locale. This multilocality has led to family strategies involving splitting productive and reproductive labor; work outside the home is conducted abroad by one family member, while those who remain behind raise children and care for the elderly. This strategy produces a strong incentive to invest in both communities, with money sent home in the form of remittances literally providing for the reproductive care of the household, and often for the larger community as well.

Scholars interested in transnational migration have investigated the impact of remittances on individuals, communities, neighborhoods (including the physical forms of buildings and general aesthetics), gender relations, culture, and the rise of new associations and nongovernmental organizations. They have also looked at the implications of remittances on politics, including the reactions of both sending and receiving states to these major financial flows. Often remittances are used to fund businesses as well as to support family, and governments have responded with various efforts to promote the continued inflow of remittance currency. These include establishing social and economic institutions that provide needed services to the migrants themselves, as well as offering matching funds to encourage continued investment.

In addition to state institutions offering aid and the various forms of regulatory control, numerous intermediary organizations have also emerged alongside the development of transnational actors and practices. Levitt (2001) has examined the rise of religious, political, and civic organizations that span national borders, facilitating transnational life and belonging. In her study of the cross-border lives of people inhabiting the social space between Miraflores, a town in the Dominican Republic, and Jamaica Plain, a neighborhood in Boston, Levitt identified both the legal and extra-legal businesses and informal organizations that arose to aid the transnational villagers. These entities helped the migrants work with or around the law, adapt to unfamiliar cultural mores, negotiate the educational system, and deal with racism, among other things. As with many similar studies, the research indicated a transformation of both family and work life in both venues, and the emergence of shifting ideas around gender and race.

While much of the early work on transnationalism emphasized laboring migrants working in the global North and sending remittances home to the global South, significant attention has also been paid to the movements of the wealthy. For the transnational elite, cross-border movements occur in many directions and take many forms, but the relative lack of friction at the border distinguishes their mobility from the movements of the less skilled. The transnational business class, in particular, is highly mobile, often possessing more than one passport and with cultural and educational capital that is transportable from one nation-state to another.

It is critical to study the movements of these parachuting transnationals for a number of reasons. This elite group often has a disproportionate impact on the communities in which they locate their work or residences because of their wealth and savoir faire. They might simultaneously oversee factory production in southern China, research and design in Singapore, and be involved
(by mobile phone or Skype) with their children’s education in Canada. Moreover, their views on politics, culture, or education may carry undue weight in all three settings. In a study of Hong Kong migrants in Vancouver, British Columbia, for example, Mitchell (2004) showed how their presumed tastes in homes influenced the types of house styles and gardens built by developers hoping to make money from this wealthy and highly kinetic population.

In this sense, both the economic practices and the cultural tastes and attributes of transnational entrepreneurs and hi-tech professionals are implicated in the transnational social spaces that they help to create through their global movements. In addition to political and cultural influences, their activities and experiences can shape the ways in which commodity chains are organized, ethnic entrepreneurship functions over time and space, and even how ethnic communities are integrated into both local and global economic networks.

Expanding research on transnational social spaces now goes beyond a primary focus on migrants and their communities to encompass social formations and other nonstate organizations forming sustained ties across national borders. Rather than just looking at transnational relations involving market-based interdependencies, however, this work also emphasizes the emergence of a global civil society (Faist and Ozveren 2004). These dense and lasting cross-border formations are often institutionalized through systems of law, regulatory agreements, or through forms of status or policy. But sometimes they remain informal, institutionalized via performance and repetition rather than through formal structures and conventions. In each case, however, the relationship between these institutions and practices is generally multidimensional, involving differing levels of governance – including local, regional, national, and supranational scales.

Transnational governance, civil society, and culture

Transnational governance is a critical feature of contemporary society, as it involves policy coordination across national borders, primarily by nonstate actors and nongovernmental organizations (NGOs). This form of transnationalism is distinct from supranational governance (such as the International Criminal Court) because it does not subsume national institutions but, rather, operates more informally to address specific problems impacting more than one area of jurisdiction. It has become particularly important to study transnational governance in an era of global climate change and other profound cross-border problems, as new actors and networks have emerged alongside more traditional national, international, and intergovernmental organizations.

Environmental studies often provide a good lens through which to study this type of political transformation as they give a glimpse into the new geographical spaces and conflicts being negotiated with transnational governance networks. One recent example involves the struggles over the Arctic in the context of melting ice and unclear territorial control. As different nations attempt to assert their sovereign rights to this territory and its resources, other transnational actors have also arisen to mediate the disputes and/or call attention to the region and its issues. These competing, cross-border, and multiscaled networks of actors came into direct confrontation on September 19, 2013, when Russian security forces took over the Greenpeace ship _Arctic Sunrise_ by force, and charged the international 30-person crew with piracy. (Greenpeace had been attempting to highlight the critical nature of the Arctic region and the harm being caused by overfishing and the production of dirty fossil fuels.) In this case, the nonstate actor
was perceived as a direct threat to the sovereign might and right of Russia to govern the territory and was harshly punished as a result.

The Greenpeace debacle indicates both the high stakes involved in these types of conflicts, and also the proliferation and complexity of issues involving transnational jurisdiction in the contemporary era. In addition to environmental problems, these include the movements and rights of migrants who may now have differently scaled forms of citizenship depending on their legal rights and sense of belonging to local, national, and/or supranational levels of governance. Since the mid-1990s numerous scholars have explored the meanings and transformations of citizenship in the context of transnational migration and transnational governance, where rights and responsibilities have become increasingly complex. For example, a person may enjoy the right to vote in a local election or may participate in a discussion about the provision of local services but be denied formal national citizenship; in other cases, an individual may be awarded *jus soli* citizenship (citizenship awarded on the basis of birth in a country) in some member nations of the European Union (EU) but not others.

Transnationalism is intimately connected to the rise of these kinds of differential regimes of citizenship, and also to the changing relationship of the state to its most mobile citizens and denizens. How can the state control the finances and maintain the allegiance of its citizens who may be living *across* one or more national borders? Some states have offered the prospect of dual citizenship, while others rely on more punitive sanctions and regulations, particularly around property ownership and inheritance laws. However, in almost all cases, none of these laws or policies is set in stone but they are, rather, characterized by expedient transitions from one form of citizenship formation to another, depending on the larger political and economic context.

Similarly, transnationalism calls into question some of the long-standing assumptions about the relationship of sovereign states to their territorial borders. Given the expansion of activities across national boundaries, are there presumed limits to a state’s right to survey, monitor, and otherwise spy on its own citizens living elsewhere? This issue has become a critical one in the context of recent media leaks indicating massive US-based spying overseas by the National Security Agency (NSA). The lack of definitive territorial borders to the contemporary nation-state’s sovereign power is related to questions surrounding state interventions in the “internal” affairs of other sovereign states. What is the spatial extent of sovereignty? This issue was especially germane subsequent to the United States’ invasion of Iraq in 2003 (see Elden 2009).

One of the responses to the latter question is drawn from the discourse on terror and security that burgeoned after the al-Qaeda attacks in the United States in 2001 and the London bombings in 2005. The discourse centers on the risk and danger to national security of so-called failed states. Failed states are those with chaotic, poorly governed populations and corrupt or inefficient state institutions—a situation, it is presumed, that enables the internal chaos to flow out and across national borders in ways that adversely affect other nation-states. In the discourse of many powerful states, failed states relinquish their right to territorial sovereignty because they pose a danger to other states, serving as a potential channel of risky and unacceptable cross-border flows of drugs, weapons, and/or terrorists.

Nongovernmental organizations have arisen to both aid and resist state actions on cross-border flows and on the more general issues and problems associated with transnationalism. Together they form what has been termed a kind of
transnational civil society. The organizations range from the types of institutionalized global resisters such as Greenpeace, to globally active but less “activist” entities such as Médecins sans Frontières (Doctors without Borders), to transnational feminist networks such as the Sangtin Writers Collective (Swarr and Nagar 2010).

Transnational civil society also embraces less formal relationships and practices. These can be formed on the basis of ties such as diaspora connections, or social justice movements, or both. One example involves the African diaspora and social movements against racial injustice. Marable (2008) argues that multiple, diffuse pan-African circuits and information highways enabled the development of “transnational blackness” as a social site for resistance and change. Historically these circuits included the movements and relationships of black activist-intellectuals in the countries of Africa, the Caribbean, and the Americas in particular, but they are also linked to broader contemporary struggles against racial injustice worldwide.

In Marable’s (2008) analytical framework the manifold paths of cultural, political, and intellectual exchange in the African diaspora are linked together in a transnational network through their convergence on the highway to racial justice. This type of theorizing exemplifies much of the current scholarship on transnationalism. “Transnationalism” is a term that is often employed to challenge norms of containment and fixity, and to highlight movement, resistance, and boundary transgression.

Human geographers have engaged with these and similar ideas, often emphasizing the spatial component involved in transnational flows. Some have focused on the cultural spaces formed through cross-border commodity chains; others have investigated how transnational migrants and transnational spaces are mutually constitutive. A consistent thread of the scholarship is the importance of engaging the complex dynamics of transnationalism as both a process-based and spatially oriented way of thinking, and an ongoing phenomenon related to the circulation of people, goods, ideas, and exchanges across national borders.

Transport and development

Jean-Paul Rodrigue
Hofstra University, USA

The importance of transportation for development

Because of its intensive use of infrastructures, the transport sector is an important component of the economy, impacting on the development and welfare of populations. A relationship between the quantity and quality of transport infrastructure and the level of economic development is apparent. When transport systems are efficient, they provide economic and social opportunities and benefits that result in positive multiplier effects such as better accessibility to markets, employment, and additional investments. When transport systems are deficient in terms of capacity or reliability, they can have an economic cost such as reduced or missed opportunities and lower quality of life.

At the aggregate level, efficient transportation reduces costs in many economic sectors, while inefficient transportation increases these costs. In addition, the impacts of transportation are not always intended and can have unforeseen or unintended consequences. For instance, congestion is often an unintended consequence of the provision of free or low-cost transport infrastructure to users. Transport also carries an important social and environmental load, which cannot be neglected. Assessing the economic importance of transportation requires a categorization of the types of impacts it conveys. These involve core (the physical characteristics of transportation), operational, and geographical dimensions.

- **Core.** The most fundamental impacts of transportation relate to the physical capacity to convey passengers and goods and the associated costs of supporting this mobility. This involves the setting of routes enabling new or existing interactions between economic entities.

- **Operational.** This dimension involves improvement in the time performance, notably in terms of reliability, as well as reduced loss or damage, which implies a better utilization level of existing transportation assets benefiting its users as passengers and freight are conveyed more rapidly and with fewer delays.

- **Geographical.** This involves access to a wider market base, where economies of scale in production, distribution, and consumption can be improved, and increases in productivity from access to a larger and more diverse base of inputs (raw materials, parts, energy, or labor) and broader markets for diverse outputs (intermediate and finished goods). Another important geographical impact concerns the influence of transport on the location of activities.

The added value and employment effects of transport services usually extend beyond employment and added value generated by that activity; indirect effects are salient. For instance, transportation companies purchase a part of their inputs (fuel, supplies, maintenance) from local suppliers. The production of these inputs generates additional added value and employment
in the local economy. The suppliers in turn purchase goods and services from other local firms. There are further rounds of local re-spending which generate additional added value and employment. Similarly, households that receive income from employment in transport activities spend some of their income on local goods and services. These purchases result in additional local jobs and added value. Some of the household income from these additional jobs is in turn spent on local goods and services, thereby creating further jobs and income for local households. As a result of these successive rounds of re-spending in the framework of local purchases, the overall impact on the economy exceeds the initial round of output, income, and employment generated by passenger and freight transport activities. Thus, from a general standpoint the socioeconomic impacts of transportation can be direct, indirect, and induced.

- **Direct impacts.** The direct benefits are mostly related to capacity and efficiency improvements that impact users and operators, particularly in terms of time and cost savings. Corporations involved in the provision of transport services earn an income and are paying wages to their employees.

- **Indirect impacts.** The indirect benefits are mostly related to accessibility gains and better economies of scale. While employers and the retail sector (as well as other activities such as institutions) gain better access to labor or customers, the customers of freight transport services (distribution centers, manufacturing, retailers) derive some productivity gains that are the outcome of better transport services. The owners of land and activities also usually derive higher rents from the increasing intensity of passenger and freight traffic taking place in the vicinity. Both passenger and freight traffic also convey additional demands for goods and services (e.g., fuel, maintenance, repairs, insurance). Freight-related activities also benefit from a wider range of suppliers for its inputs and markets for its outputs.

- **Induced impacts.** The induced benefits are mostly related to economic multipliers and increased opportunities. A society benefits from increased mobility since individuals have a wider range of options for their activities and the associated social opportunities (education, leisure). An economy usually becomes more competitive, attracts new and expanded economic activities, and has more complex distribution networks.

Transportation links together the factors of production in a complex web of relationships between producers and consumers. The outcome is commonly a more efficient division of production by an exploitation of geographical comparative advantages, as well as the means to develop economies of scale and scope. The productivity of space, capital, and labor is thus enhanced with the efficiency of distribution and personal mobility. Economic growth is increasingly linked with transport developments, namely infrastructures, but also with managerial expertise, which is crucial for logistics. Thus, although transportation is an infrastructure-intensive activity, hard assets must be supported by an array of soft assets, namely management and information systems. Decisions have to be made about how to use and operate transportation systems in a manner that optimizes benefits and minimizes costs and inconvenience.

**Transportation and economic opportunities**

Transportation developments that have taken place since the beginning of the Industrial
Revolution have been linked to growing economic opportunities. At each stage of human societal development, a particular transport technology has been developed or adapted with an array of impacts (Figure 1). Five major waves of economic development can be suggested where a specific transport technology created new economic, market, and social opportunities (Figure 2).

- **Seaports.** These are linked with the early stages of European expansion from the sixteenth to the eighteenth century, commonly known as the age of exploration. They supported the early development of international trade through colonial empires, but were constrained by limited inland access.

- **Rivers and canals.** The first stage of the Industrial Revolution in the late eighteenth and early nineteenth centuries was linked to the development of canal systems in Western Europe and North America, mainly to transport heavy goods. This permitted the development of rudimentary and constrained inland distribution systems.

- **Railways.** The second stage of Industrial Revolution in the nineteenth century was linked to the development and implementation of rail systems enabling more flexible and high-capacity inland transportation systems. This opened up substantial economic and social opportunities through the extraction of resources, the settlement of regions, and the growing mobility of freight and passengers.

- **Roads.** The twentieth century saw the rapid development of road transportation systems, such as national highway systems, and of automobile manufacturing as a major economic sector. Individual transportation became widely available to mid-income social classes, particularly after World War II.

**Figure 1** Socioeconomic benefits of transportation.

Increased competitiveness.
This was associated with significant economic opportunities to service industrial and commercial markets with reliable door-to-door deliveries. The automobile also permitted new forms of social opportunities, particularly with suburbanization.

- Airways and information technologies. The second half of the twentieth century saw the development of global air and telecommunication networks in conjunction with economic globalization. New organizational and managerial forms became possible, especially in the rapidly developing realm of logistics and supply chain management. Although maritime transportation is the physical lynchpin of globalization, air transportation and IT support the accelerated mobility of passengers, specialized cargoes, and their associated information flows.

Prior to the Industrial Revolution, economic opportunities were limited by the low capacity to move commodities over long distances, and most activities were much localized in scale and scope. The Industrial Revolution unleashed greater economic opportunities, initially with the development of inland canal systems, steamship services, and then railway systems. Passenger and freight transportation expanded as well as production and consumption, while new markets and resources became available. In many instances, the development of a transportation mode built on the opportunities developed by another, such as maritime and canal shipping. In other situations, the growth of a new mode of transportation precipitated the decline of others, such as the collapse of many inland canal networks in the late nineteenth century because of competition from railways.

The development of the mass production system at the beginning of the twentieth century increasingly relied on the commercial opportunities introduced by road transportation, particularly the automobile. Later in the twentieth century, globalization benefited from the synergy of maritime shipping, roadways, railways, air, and telecommunications, all of which supported
integrated transport systems and supply chain management. Economic opportunities became global in scale and scope, particularly because of the capacity to maintain an intricate network of trade and transactions through transport systems. More recently, new opportunities have arisen with the convergence of telecommunications and information technologies, supporting a higher level of management of production, consumption, and distribution, as well as a more efficient mobility of passengers. This process, building upon the advantages conferred by other transportation modes, will account for a significant share of economic opportunities of the first half of the twenty-first century.

No single transport mode has been solely responsible for economic growth. Instead, modes have been linked with the economic functions they support and the geography in which growth was taking place. The first trade routes established a rudimentary system of distribution and transactions that would eventually be expanded by long distance maritime shipping networks and the setting of the first multinational corporations managing these flows. Major flows of international migration that occurred after the eighteenth century were linked with the expansion of international and continental transport systems that radically shaped emerging economies such as in North America and Australia. Transport played a catalytic role in these migrations, transforming the economic and social geography of many nations.

Transportation has been a tool of territorial control and exploitation, particularly during the colonial era, when resource-based transport systems supported the extraction of commodities in the developing world and forwarded them to the industrializing nations of the time. The goal to capture resource and market opportunities was a strong impetus in the setting and structure of transport networks. More recently, port development, particularly of container ports, has been of strategic interest as a tool of integration to the global economy, as the case of China illustrates. There is commonly a direct relationship between foreign trade and container port volumes, so container port development is commonly seen as a tool to capture the opportunities brought by globalization.

Due to demographic pressures and increasing urbanization, developing economies are characterized by a mismatch between limited supply and growing demand for transport infrastructure. While some regions benefit from the development of transport systems, others are often marginalized by a set of conditions in which inadequate transportation plays a role. Transport by itself is not a sufficient condition for development. However, the lack of transport infrastructures can be seen as a constraining factor on development. In developing economies, the lack of transportation infrastructures and regulatory impediments are jointly impacting economic development by conferring higher transport costs, but also by causing delays rendering supply chain management unreliable. A poor transport service level can negatively affect the competitiveness of regions and corporations and thus have a negative impact on regional added value and employment. In 2007, the World Bank published its first ever report to rank nations according to their logistics performance based on the Logistics Performance Index. Investment in transport infrastructures is thus seen as a tool of regional development, particularly in developing countries.

The standard assumption is that transportation investments tend to be more wealth-producing investments, as opposed to wealth-consuming investments such as services. Still, several transportation investments can be wealth consuming if they merely provide convenience, such as parking and sidewalks, or service a market
size well below any possible economic return, with for instance projects labeled “bridges to nowhere.” In such a context, transport investment projects can be counterproductive by draining the resources of an economy instead of creating wealth and additional opportunities. Efficient and sustainable transport markets and systems play a key role in regional development, although the causality between transport and wealth generation is not always clear.

Transport investments also tend to have declining marginal returns. While initial infrastructure investments tend to have a high return since they provide an entirely new range of mobility options, the more the system is developed, the more likely additional investment would result in lower returns. At some point, the marginal returns can be close to zero or even negative, implying a shift of transport investments from wealth producing to wealth consuming. A common fallacy assumes that additional transport investments will have a similar multiplying effect to that enjoyed by the initial investments, which can lead to capital misallocation.

**Types of transportation impacts**

The relationship between transportation and economic development is difficult to formally establish and has been debated for many years. In some circumstances transport investments appear to be a catalyst for economic growth, while in others economic growth puts pressures on existing transport infrastructures and incites additional investments. In a number of regions around the world, transport markets and related transport infrastructure networks are seen as key drivers in the promotion of a more balanced and sustainable development, particularly by improving accessibility and the opportunities of less developed regions or disadvantaged social groups. To begin with, there are different impacts on the transport providers (transport companies) and the transport users. There are several layers of activity that transportation can valorize, from a suitable location that experiences the development of its accessibility through infrastructure investment to a better usage of existing transport assets through more efficient management. This is further nuanced by the nature, scale, and scope of possible impacts.

- Timing of the development varies as the impacts of transportation can precede (lead), occur during (concomitantly), or take place after (lag) economic development. The lag, concomitant, and lead impacts make it difficult to separate the specific contributions of transport to development. Each case appears to be specific to a set of timing circumstances that are difficult to replicate elsewhere.
- Types of impacts vary considerably as the spectrum ranges from the positive to the negative. In some rarer cases transportation impacts can promote economic development while in others they may hinder a region by draining its resources in unproductive transportation projects.

There is no straightforward relationship between transport and economic development as the level of impact and its time sequence can vary based on a location and its socio-economic characteristics. This leads to five potential relationships (Figure 3).

1 Weak relationship. Although transportation supports economic and social activities, no specific causality can be expressed. This is particularly the case for infrastructures that have been implemented a while ago and have become embedded in the regional economy. Their lead role can no longer
be asserted but it does not mean that transportation is not important as it is still a fundamental component supporting interactions within the economy.

2 Positive/lead impacts. This represents the best case scenario where investments and the presence of infrastructures convey economic growth for a region, namely the expansion of production and consumption. This process commonly takes place when new infrastructures are built to access resources or new markets, which then triggers a wave of investments.

3 Lag and positive impacts. The development of the transport system follows economic development. A good example would be fast paced development, as seen in Pacific Asia (notably China), where investments in transport infrastructure do not keep up with the substantial growth of the traffic generated by rising mobility and new globally linked manufacturing functions. Such a situation could eventually impair future growth prospects as the existing infrastructure is no longer able to satisfy the demand.

4 Lead and negative impacts. This commonly involves infrastructure investments made with the expectation of triggering development, but failing to meet those expectations. Many negative outcomes of such strategies have been observed. For instance, infrastructure can be built at great cost while failing to generate significant additional traffic, leaving the community with a substantial debt that cannot be recovered and that will drain regional wealth. On the other hand, transportation could generate traffic, but the new accessibility benefits external economies with improved access to the regional market. Local resources, either physical (commodities) or human (emigration), can also be “drained” away by transport improvements.

5 Lag and negative effect. This represents the worst case scenario where, in addition to the negative consequences of transportation investments on the economy (drain on resources), these investments are occurring after the downward spiral began and may even accelerate the process.

Cycles of economic development provide a revealing conceptual perspective about how transport systems evolve in time and space as they include the timing and the nature of the transport impact on economic development. This perspective underlines that after a phase of introduction and growth, a transport system will eventually reach a phase of maturity through geographical and market saturation. There is also the risk of overinvestment when economic growth is credit driven, which can lead to significant misallocations of capital, including in the transportation sector. The outcome is a surplus capacity in infrastructures and modes, creating deflationary pressures that undermine profitability. In periods of recession that commonly
TRANSPORT AND DEVELOPMENT

follow periods of expansion, transportation activities may experience a setback, namely in terms of lower demand and a scarcity of capital investment. Since transport infrastructures are capital-intensive fixed assets, they are particularly vulnerable to misallocations and malinvestments.

Transport, as a technology, typically follows a path of experimentation, introduction, adoption, diffusion, and, finally, obsolescence, each of which stages has an impact on the rate of economic development. The most significant benefits and productivity gains are realized in the early to mid-diffusion phases, while later phases face diminishing returns. Containerization is a relevant example of such a diffusion behavior as its productivity benefits were mostly derived in the 1990s and 2000s when economic globalization was accelerating. Many technologies go through what can be called a “hype phase,” with unrealistic expectations about their potential and benefits, and many are eventually abandoned as the technology proves ineffective at addressing market or operational requirements, or is simply too expensive for the benefits it conveys. Since transportation is capital intensive, operators tend to be cautious before committing to new technologies and the significant sunk cost they require. In addition, transport modes and infrastructures are depreciating assets that constantly require maintenance and upgrades. At some point, their useful life span is exceeded and the vehicle must be retired or the infrastructure rebuilt. Thus, the amortization of transport investments must consider the life span of the concerned mode or infrastructure.

Transportation as an economic factor

Contemporary trends have underlined that economic development has become less dependent on relations with the environment (resources) and more dependent on relations across space. While resources remain the foundation of economic activities, the commodification of the economy has been linked with higher levels of material flows of all kinds. Concomitantly, resources, capital, and even labor have shown increasing levels of mobility. This is particularly the case for multinational firms that can benefit from transport improvements in two significant markets.

- **Commodity market.** Improvement in the efficiency with which firms have access to raw materials and parts as well as to their respective customers. Thus, transportation expands opportunities to acquire and sell a variety of commodities necessary for industrial and manufacturing systems.
- **Labor market.** Improvement in access to labor and a reduction in access costs, mainly by improved commuting (local scale) or the use of lower-cost labor (global scale).

Transportation provides market accessibility by linking producers and consumers so that transactions can take place. A common error in assessing the importance and impact of transportation on the economy is to focus only on transportation costs, which tend to be relatively low, in the range of 5–10% of the value of a good. Transportation is an economic factor of production of goods and services, implying that it is fundamental in the generation of goods and services, even if it accounts for a small share of the input cost. This means that, irrespective of the cost, an activity cannot take place without the transportation factor. Thus, relatively small changes in transport cost, capacity, and performance can have substantial impacts on costs, locations, and performance of economic activities. An efficient transport system with modern infrastructures favors many economic
changes, most of them positive. The major impacts of transport on economic processes can be categorized as follows:

- **Geographic specialization.** Improvements in transportation and communication favor a process of geographical specialization that increases productivity and spatial interactions. An economic entity tends to produce goods and services with the most appropriate combination of capital, labor, and raw materials. A region will thus tend to specialize in the production of goods and services for which it has the greatest advantages (or the fewest disadvantages) compared to other regions as long as appropriate transport is available for trade. Through geographic specialization supported by efficient transportation, economic productivity is promoted. This process is known in economic theory as comparative advantage.

- **Large-scale production.** An efficient transport system offering cost, time, and reliability advantages enables goods to be transported over longer distances. This facilitates mass production through economies of scale because larger markets can be accessed. The concept of “just-in-time” has further expanded the efficacy of production and distribution with benefits such as lower inventory levels and better responses to shifting market conditions. Thus, the more efficient transportation becomes, the larger the markets that can be serviced and the larger the scale of production. This results in lower unit costs.

- **Increased competition.** When transport is efficient, the potential market for a given product (or service) increases, and so does competition. A wider array of goods and services becomes available to consumers through competition, which tends to reduce costs and promote quality and innovation. Globalization has clearly been associated with a competitive environment that spans the world and enables consumers to have access to a wider range of goods and services.

- **Increased land value.** Land that is adjacent to or serviced by good transport services generally has greater value due to the utility it confers to many activities. Consumers can have access to a wider range of services and retail goods while residents can have better accessibility to employment, services, and social networks, all of which translates to higher land value. In some cases, transportation activities can lower land value, particularly for residential activities. Land located near noise and pollution sources such as airports and highways will thus be impacted by corresponding diminishing land value.

Transport also contributes to economic development through job creation and its derived economic activities. Accordingly, a large number of direct (freighters, managers, shippers) and indirect (insurance, finance, packaging, handling, travel agencies, transit operators) areas of employment are associated with transport. Producers and consumers take economic decisions on products, markets, costs, location, and prices which are themselves based on transport services, their availability, costs, and capacity.

TRANSPORT AND DEVELOPMENT

The principles of transport geography

The unique purpose of transportation is to overcome space, which is shaped by a variety of human and physical constraints such as distance, time, administrative divisions, and topography. Jointly, they confer a friction on any movement, commonly known as the friction of distance, or friction of space. These constraints and the friction they create can only be partially circumscribed. The extent to which this is done has a cost that varies greatly according to factors such as the distance involved, the capacity of the modes, and the infrastructures supporting the flows and the nature of what is being transported.

A few core principles of transport geography can be brought forward.

Transportation is the spatial linking of a derived demand

Transport takes place as a result of other economic activities, and links the spatial components of this demand. For instance, commuting is the spatial linking of labor flows resulting from the demand for labor at some locations (e.g., commercial districts) and its supply from others (e.g., residential districts). What is different about transport is that it cannot exist alone, and a movement cannot be stored. An unsold product can remain on the shelf of a store until bought, but an unsold seat on a flight or unused cargo capacity on the same flight remain unsold and cannot be brought back as additional capacity later. In this case, an opportunity has been missed because the amount of transport being offered has exceeded the demand for it. The derived demand of transportation is often very difficult to reconcile with an equivalent supply. This principle underlines that a market economy could not function without the capacity of transportation to link supply and demand.

Distance is a relative concept involving space, time, and effort

How distance is perceived is a function of the amount of effort made to overcome it. These efforts can be assessed in terms of spatial distance, time distance, or other effort measures such as cost or energy spent to overcome distance. Distance can take the form of a simple Euclidean distance considered as a straight line between two locations, but it can also include more complex measures such as transport and logistical distances (Figure 1). Transport distance accounts for the existing structure of the transport network. In a simple form involving only one mode, it is a routing exercise considering the shortest path between two points. In a more complex form, it concerns the set of physical activities related to transportation, such as loading, unloading, and trans-shipment, are considered. The logistical distance encompasses all the tasks required so that a movement between two locations can take place. It thus includes physical flows, but also a set of activities necessary for the management of these flows. To use an air travel example again, a ticket would first need to be purchased,
commonly several weeks in advance. Other common time and cost tasks relate to checking in, security checks, boarding and disembarking, and picking up luggage. Thus, a three-hour flight may in reality be a movement that is planned several weeks in advance, and its full realization can take twice as much time if all the related logistical activities are considered.

Space is a support and a constraint for mobility

Space is the formal context in which mobility takes place, so it can be a support for mobility as it will shape the nature and structure of the transport network. This includes topography, hydrography, and climate. How space acts as a constraint for transport is often relative and paradoxical. For instance, a river acts as a constraint for land transport systems such as roads and railways, but represents the physical support for fluvial transportation (if the river is navigable). At the same time as the atmosphere is the physical support for air transport operations, the weather can be a constraining factor under specific circumstances (e.g., snowstorms, thunderstorms, hurricanes). Since the Earth is a sphere, this fundamental characteristic also impacts transportation, particularly long-distance maritime and air transport.

The relation between space and time can converge or diverge

Every form of transport involves the consumption of a unit of time in exchange for a given amount of space. Over time this process has mostly converged, implying that a greater
amount of space can be reached in the same amount of time (or the same amount of space can be reached in a lesser amount of time). This is jointly the outcome of technological improvements as well as a better capacity and extent of transport infrastructures. Convergence is, however, a spatially and socially uneven process because it impacts the accessibility of locations differently. For instance, transport infrastructure is not laid up uniformly because of economic and political imperatives, and segments of the population will experience a greater improvement in mobility because of their socioeconomic status. The relation between space and time can also diverge when congestion starts to be significant and each additional unit of movement results in additional delays. For instance, traffic in congested urban areas currently moves at the same speed that it did 100 years ago by horse carriage. Air transportation, despite having dramatically contributed to the space–time convergence is also experiencing growing delays. Flight times are getting longer between many destinations, mainly because of takeoff, landing, and gate access delays. Airlines are simply posting longer scheduled flight times to factor in congestion.

Circumnavigation is a good proxy for assessing space–time convergence (Figure 2). Prior to the introduction of the steamship in the mid-nineteenth century, circumnavigating the globe took about one sailing year, a journey greatly delayed by rounding the Cape of Good Hope and the Strait of Magellan. The late nineteenth and early twentieth centuries saw a series of innovations that would greatly improve circumnavigation, notably the construction of the Suez (1869) and Panama (1914) canals, as

![Figure 2](image-url)
TRANSPORT GEOGRAPHY

well as steam propulsion. Circumnavigation was reduced to about 100 days at the beginning of the twentieth century and to 60 days by 1925 with fast liner services. The introduction of the jet plane in the second half of the twentieth century reduced circumnavigation to about 30 hours if two (or three) direct and connecting long-range flights can be booked.

A location can be a central or an intermediate element of mobility

Locations are said to be central when they act as generators (origins) or attractors (destinations) of movements. Locations are labeled as intermediate when movements are passing (transiting) through them on their way to other locations. Ports and airports are often intermediate locations because they act as gateways or hubs within a complex transport network. While a hub is a central location in a transport system, with many inbound and outbound connections of the same mode, a gateway commonly implies a shift from one mode to the other, such as a shift from maritime to land transport. A gateway performs an intermodal function (between modes) while a hub is mostly transmodal (within a mode).

To overcome geography, transportation must consume space

Transportation infrastructures are important consumers of space, which includes the pathways (e.g., roads and rail lines), their rights-of-way, as well as the terminals. The more extensive a transport system, and the higher the level of mobility, the more extensive its consumption of space. For instance, in highly motorized cities, roads, and parking spaces can consume up to 50% of the land. Globalization has been linked to the setting up of massive terminal facilities such as container ports and airports. While the space consumed by road infrastructure is mostly linked to local and regional activities, the space consumed by rail, port, and airport terminals is linked to activities taking place at a higher scale.

Transportation seeks massification but is constrained by atomization

Transport systems are most effective when they develop economies of scale, particularly in terms of the loads (passengers or freight) they carry. Massification involves conveyances with higher capacity and supported by larger terminals. However, more often than not, the first and last segments of a transport sequence require atomization, which implies that loads must be consolidated and deconsolidated. For transport modes, atomization represents the smallest load unit that can be effectively transported. The person is obviously the smallest load unit for passenger transportation, while a parcel or a component are the smallest load units for freight transportation. So, the higher the level of massification the more complex atomization becomes. Individuals and customers tend to prefer the convenience of atomization while carriers favor massification and the economies of scale it confers.

Velocity is a modal, intermodal, and managerial effort

Velocity does not necessarily mean speed, but the time it takes for a passenger or a unit of freight to move across a complete transport sequence. For instance, the speed advantage of air transportation is undermined if a passenger spends several hours between connecting flights. Therefore, the velocity of passengers or freight is a joint consideration of the effectiveness of the respective modes involved, as well as that of the intermodal operations connecting the modes. In addition,
the complexity of transport systems requires an effective management of operations, such as scheduling. All of these jointly contribute to improving the velocity of flows carried by transport systems. Many transportation modes, particularly maritime and rail, have not shown any significant speed improvements in recent decades, with the exception of high-speed rail services.

The principles of transport geography underline that there would be no transportation without geography and there would be no geography without transportation. The fundamental purpose of transportation is geographic in nature because it facilitates movements between different locations. The goal of transportation is thus to transform the geographical attributes of freight, people, or information from an origin to a destination, in the process conferring on them an added value.

The spatial relevance of transportation

Transport plays a role in the structure and organization of space and territories. In the nineteenth century, the purpose of the emerging modern forms of transportation, mainly railways and maritime shipping, was to expand spatial coverage with the creation, expansion, and consolidation of national markets. In the twentieth century, the objective shifted to selecting itineraries, prioritizing transport modes, increasing the capacity of existing networks, and responding to the mobility needs — and at a scale that was increasingly global. In the twenty-first century, transportation must cope with a globally oriented economic system in a timely and cost-effective way, but also with several local problems such as congestion and capacity constraints.

Transport is an indispensable component of the economy and plays a major role in supporting spatial relations between locations. Transport creates valuable links between regions and economic activities, between people and the rest of the world. The relevance of transportation derives from the interactions of its core components, which are the modes, infrastructures, networks, and flows.

- **Modes** represent the conveyances, mostly in the form of vehicles that are used to support the mobility of passengers or freight. Some modes are designed to carry only passengers or only freight, while others carry both.
- **Infrastructures** are the physical support of transport modes, where routes (e.g., rail tracks, canals, or highways) and terminals (e.g., ports or airports) are the most significant components.
- **Networks** are systems of linked locations that are used to represent the functional and spatial organization of transportation. These systems indicate which locations are connected and how they are serviced. Within a network some locations are more accessible (have more connections) than others (which have fewer connections).
- **Flows** are the movements of people, freight, and information over their respective networks. Flows have origins, intermediary locations, and destinations.

These components are fundamental for transportation to take place, but they also underline that geography, in spite of significant technological, social, and economic changes, remain a salient force shaping transportation. Transportation as a multidisciplinary endeavor can be approached through several fields of inquiry, some of which are at the core of transport geography, such as transport demand, nodes, and networks, while others are more peripheral, such as natural resources, political geography,
TRANSPORT GEOGRAPHY

and regional geography. Yet, they all contribute to the understanding of transport activities and their impacts on the economy, society, and the environment. These impacts are historical, social, political, economic, and environmental.

Historically, transport modes have played a role in the rise of civilizations, in the establishment of trade and commercial relations, in the development of societies, and also in national defense. Roman roads and Chinese canals are salient examples. Transportation offers a valuable perspective to understanding the history of a region or nation. Socially, transport modes facilitate access to health care, welfare, and cultural events, thus performing a social service. They shape social interactions by favoring or inhibiting the mobility of people. Transportation thus supports and may even shape social structures. Politically, governments play a critical role in transport as sources of transport investment and as regulators of transport operations. The political role of transportation is undeniable as governments often subsidize the mobility of their populations (highways, public transit, etc.). While most transport demand relates to economic imperatives, many transportation infrastructures have been constructed for political reasons, such as national accessibility or job creation. Transport thus has an impact on nation-building and national unity, but it is also a tool-shaping policy.

Economically, the evolution of transport has been linked to new opportunities and economic development. It is an industry in its own right. The transport sector is also an economic factor in the production of goods and services. It contributes to the value added of economic activities, facilitates economies of scale, and influences land value and the specialization of regions. Transport is both a factor that shapes economic activities, and that is also shaped by them. Environmentally, despite the manifest advantages of transportation, its environmental consequences are also significant. These include negative impacts on air and water quality, noise level, and public health. All decisions relating to transport need to be evaluated by taking into account the corresponding environmental costs and how they can be mitigated. Transport is therefore a dominant factor in contemporary environmental issues, including climate change.

Substantial empirical evidence indicates that the importance of transportation is growing. The years following World War II have seen a considerable growth of transport demand from individual (passengers) as well as for freight mobility. This growth is the result of the larger number of passengers and amount of freight being moved, but also of the longer distances over which they are carried. Recent trends underline an ongoing process of mobility growth, which has led to the multiplication of the number of journeys involving a wide variety of modes that service transport demands. Even if several transportation modes are very expensive to own and operate (ships and planes, for instance), costs per unit transported have dropped significantly over the past few decades. This has made it possible to overcome larger distances to further exploit the comparative advantages of space. Despite the lower costs, the share of transport activities in the economy has remained relatively constant over time. Therefore, the demand for transport infrastructures has expanded for both their quantity and quality. Roads, harbors, airports, telecommunication facilities, and pipelines have expanded considerably to service new areas and add capacity to existing networks.

Consequently, transportation has an important role to play in the conditions that affect global, national, and regional economic entities. Transport is a strategic infrastructure that is so embedded in the socioeconomic life of individuals, institutions, and corporations that it is often invisible to the consumer, but it is
always part of all economic and social functions. This is paradoxical, since the perceived invisibility of transportation derives from its efficiency. If transport is disrupted or ceases to operate, the consequences can be dramatic, such as workers unable to reach their workplace or parts not being delivered to factories, or, worse, inadequate food distribution.

Transportation in geography

Geography seeks to understand the spatial order of things as well as their interactions, particularly when the spatial order is less evident. Transportation is one element of this spatial order which is influenced by geography at the same time as it has an influence on it. For instance, the path followed by a road is influenced by regional economic and physical attributes, but once constructed the same road will shape future regional developments, including urbanization. Transportation is of relevance to geography for two main reasons. First, transport infrastructures, terminals, modes, and networks occupy an important place in space and constitute the basis of a complex spatial system. Second, since geography seeks to explain spatial relationships, transport networks are of specific interest because they are the main physical support of these interactions.

Transport geography, as a discipline, emerged as a branch of economic geography in the second half of the twentieth century. In earlier considerations, particularly in commercial geography (late nineteenth and early twentieth centuries), transportation was an important factor behind the economic representations of the geographic space, namely in terms of the location of economic activities and the monetary costs of distance. These cost considerations, which could be logically articulated, became the foundation of several geographical theories such as central place theory and location theory. The growing mobility of passengers and freight justified the emergence of transport geography as a specialized field of investigation.

In the 1960s transport costs were formalized as key factors in location theories, and transport geography began to rely increasingly on quantitative methods, particularly in network and spatial interactions analysis (Taaffe, Gauthier, and O’Kelly 1996). However, from the 1970s technical, political, and economic changes challenged the centrality of transportation in many geographical and regional development investigations. The strong spatial anchoring effect of high transportation costs receded and decentralization was a dominant paradigm that was observed within cities (suburbanization), but also within regions (Tolley and Turton 1995). The spatial theory foundations of transport geography, particularly the friction of distance, became less relevant, or less evident, in explaining socioeconomic processes. As a result, transportation became underrepresented in economic geography in the 1970s and 1980s, even if the mobility of people and freight and low transport costs were considered as important factors behind the globalization of trade and production (Keeling 2007).

Since the 1990s transport geography has received renewed attention, with new realms of investigation. The issues of mobility, production, and distribution became interrelated in a complex geographical setting where the local, regional, and global became increasingly blurred through the development of new passenger and freight transport systems (Hoyle and Knowles 1998). For instance, suburbanization resulted in an array of challenges related to congestion and automobile dependency. Rapid urbanization in developing economies underlined the challenges of transport infrastructure investment for private as well as collective uses. Globalization
supported the development of complex air and maritime transportation networks, many of which underpin global supply chains and trade relations across long distances. The role of information and communication technologies was also being felt, often as a support or as an alternative to mobility. All of these developments were linked to new and expanded mobilities of passengers, freight, and information (Knowles, Shaw, and Docherty 2008).

This “new transport geography” (Keeling 2007) is based on the premise that transportation is a system supporting complex relationships between its core components: nodes, networks, and demand (Figure 3). Transportation primarily links locations, often characterized as transportation nodes. They serve as access points to a distribution system or as trans-shipment or intermediary locations within a transport network. This function is mainly serviced by transport terminals where flows originate, end, or are trans-shipped from one mode to the other. Transport geography must consider its places of convergence and trans-shipment. Transportation networks consider the spatial structure and organization of transport infrastructures and terminals. Transportation geography must include in its investigation the structures (routes and infrastructures) that support and shape movements. Transportation demand considers the demand for transport services as well as the modes used to support movements. Once this demand is realized, it becomes an interaction which flows through a transport network. Transport geography must evaluate the factors affecting its derived demand function.

Analysis of these concepts within transport geography relies on methodologies often developed by other disciplines such as economics,
mathematics, planning, and demography. For instance, the spatial structure of transportation networks can be analyzed with graph theory, which was initially developed for mathematics. Further, many models developed for the analysis of movements, such as the gravity model, were borrowed from the physical sciences. Multi-disciplinarity is consequently an important attribute of transport geography, as in geography in general.

New, expanded, or receding spatial relations are produced by transport systems. A better understanding of these spatial relations is essential in enabling private and public actors involved to mitigate key transport constraints, such as capacity, transferability, reliability, and the general integration of transport systems through intermodalism.

As all activities are located somewhere, each location has its own characteristics which potentially generate a supply and/or a demand for resources, products, services, or labor. A location will determine the nature, the origin, the destination, the distance, and even the possibility of a movement to be realized. For instance, in addition to consuming resources, a city provides employment in various sectors of activity. Locations require the exchange goods, people, or information, which creates a complementarity. This implies that some locations have a surplus while others have a deficit. The only way to reach an equilibrium is by movements between locations that have surpluses and locations that have demands. For instance, there is a complementarity between a store (which has a surplus of goods) and its customers (which demand goods). Movements generated by complementarity occur at different scales, depending the nature of the activity. Scale illustrates how transportation systems are established over local, regional, and global geographies. For instance, home-to-work journeys generally take place at a local or regional scale, while the distribution network of a multinational corporation is most likely to cover several regions of the world.

Consequently, transport systems consume land and support the relationships between locations at a scale that is increasingly global. Transport geography provides a multidisciplinary perspective to understanding the complexity of transportation and how spaces support and hinder mobility.

Transport networks may be defined as sets of connected nodes and links allowing for the circulation of individuals and/or commodities. Traditionally, transport networks correspond to physical infrastructure such as roads, railways, canals and rivers, streets, and subway lines, while the concept also includes airline and maritime networks in which nodes are (sea)ports and airports, as well as telecommunications networks transmitting information and knowledge flows, such as telephone lines, the Internet, and similar technologies (e.g., telegraph, mobile phones). In fact, the definition of transport networks can be extended to anything that supports circulation, as natural scientists analyze, for instance, termite mounds and fungal networks just as geographers and engineers study road networks. Tero et al. (2010) have particularly demonstrated that biological networks such as those built by slime molds have “comparable efficiency, fault tolerance, and cost to those of real-world infrastructure networks – in this case, the Tokyo rail system.” While the nature of nodes may vary from one network to the other, those are often crossings, stations, terminals, cities, or countries, and so on, while links can be of a totally different nature, from physically grounded tracks to more ephemeral flows. In all cases, transport networks belong to the category of “spatial networks” that comprises many other networks such as so-called technical networks (e.g., power grids) and any network being physically (and often geographically) grounded in space (see Barthélémy 2010). Like any other network, and according to the language used by graph theory, a branch of mathematics describing the topological properties of networks, a transport network may be planar or nonplanar (i.e., with or without crossings between links or “edges”), directed or undirected, and weighted (i.e., where links carry a certain quantity, e.g., of traffic, distance, or time) or not. A multimodal transport network may be understood as a “multigraph” where two given nodes are connected via at least two links of different nature. However, the concept of transport networks does not entirely belong to graph theory; it includes other approaches, such as transport history, spatial analysis, economics, or engineering, where nodes, links, and flows are considered by means of other methods, such as discourses, policies, actors, governance, planning, and dedicated geographical information systems for transport (GIS-T).

Traditionally in geography, transport networks have been the focus of scholars willing to apply quantitative methods to geographical research. Transport networks and flows received foremost attention in the 1960s by US geographers. They particularly developed the idea of ideal-typical sequences of transport network development and applied several graph-theoretical methods to road and railway networks (Taaffe and Gauthier 1973). The most renowned model describes six successive phases inspired by the evolution of transport networks in West Africa (see Rodrigue 2014 for a useful online illustration). In a first phase (scattered ports), a set of ports along a coastline is characterized by homogeneity in...
traffic volumes and connection levels based on local resources. The second phase (penetration lines and port concentration) witnesses an expansion of the hinterland benefiting only a minority of such ports through new transport lines such as rail or canal. The subsequent phases reinforce a path-dependent process by which initially favored ports continue to grow in proportion to the importance of their inland accessibility as the corridor emerges gradually through economies of scale. Although this model has been updated to take into account overseas linkages among ports and more recent trends of deconcentration, there have been many critiques of it, given the linear dimension of the successive phases which ultimately always lead to concentration in the core and decline in the periphery. Similar criticism emerged from (trans)port specialists about early urban models, such as the central place theory, due to its inability to incorporate deviations caused by specific transport configurations (sea-land, intermodal), as in the works of British geographer James Bird. In the early days, however, limited computational power largely explained the reliance upon small, planar networks easily extracted from city and country maps, while detailed – and often more voluminous – data about transport flows remained hardly accessible.

Two central and recurrent themes are the topology of transport networks and the accessibility and centrality of their nodes. The topology may refer to the differences between the actual layout of a given transport network and its simplified representation as a graph, that is, straight lines (or edges) between nodes (or vertices). The graph itself is often understood as a matrix, sometimes called an origin-destination (O-D) matrix, where links either exist or do not between nodes ordered in lines and columns (Figure 1). Several measures express a variety of topological features based on such a graph or matrix (Kansky 1963), such as the size of the network (number of nodes and links), its density (number of links per node), completeness (proportion of existing links in the maximum possible number of links), cliquishness (number of cycles), transitivity (as measured by the average proportion of connected adjacent neighbors in the maximum possible number of connected neighbors), and so on. Using the graph or matrix to calculate network indices makes it possible to apply any graph-theoretical measure, such as those found in social network analysis (SNA) and complex systems, despite fundamental differences in the nature of the studied networks. Some measures may not be interpreted in the same way, depending on whether people, firms, terminals, or neurons are concerned. Nevertheless, transport networks are common objects of an emerging “science of networks,” notably since physics and computer science started to analyze such networks with renewed tools and concepts in the late 1990s (Newman 2010). Other aspects of transport networks have thus been explored, such as their scale-free and/or small-world dimensions, the probability for nodes to connect with other nodes of comparable size (assortativity), the average shortest path length, the “rich-club” coefficient, and so on. While the degree distribution follows a power-law function in scale-free networks, small-world networks are characterized by the existence of dense communities (or subgroups of nodes). The rich-club dimension refers to networks in which nodes with many links connect primarily with each other. Great care must be taken, however, in comparing different networks via such methods, because network indices are often biased by network size. Such measures better apply to the evolution of a single network over time, or to the comparison between actual and optimal configurations. For instance, a given (planar) transport network, if weighted by cost or another metric, is best understood when its two
possible extreme situations are confronted, that is, when all possible links are built (cf. greedy triangulation) or when only the optimal links are retained (cf. minimum cost spanning tree). Novel evidence could have been proposed based on such methods when comparing cities of the world through the configuration of their streets, in terms of planning models, urban architecture, and overall circulation efficiency (see Barthélémy and Flammini 2009).

At the node level, measures are similar and may look at the immediate environment of nodes by the number of adjacent neighbors (degree centrality), which correspond to the number of connected airports, for instance. In a road or railway network, cities or stations can be compared according to their distance from (or eccentricity to) other nodes, their occurrence on shortest paths, and so on. In a weighted network, it is also interesting to look at the proportion of traffic depending on the biggest link; in the case of maritime transport, it revealed the extent to which certain ports heavily depended on a close competitor despite their high traffic volume (e.g., Shenzhen vs. Hong Kong). Questions might concern whether larger nodes are more central in the transport network and what the respective roles are of local and global centralities. Certain findings could have pointed at interesting functions of some nodes: in an air

Figure 1  Graph representations of networks and matrices.
TRANSPORT NETWORKS

Transport network some nodes, despite having few links, can still be highly accessible due to their bridging role between large regions, while larger and more connected nodes often connect across farther topological and kilometric distances. In turn, the existence of such “regions” in a transport network is revealed by means of various techniques of clustering nodes based on certain attributes of connectivity. Other areas of inquiry might include whether best connected airports or seaports are geographically close, or how commuting flows can help in delineating functional urban areas and/or urban regions. Clustering algorithms applied to transport networks, such as modularity, have, among other results, verified the underlying regional patterns of global airline and maritime flows. Single linkage analysis, for instance, was applied to telecommunication flows as early as the 1960s by US geographers in order to delineate so-called nodal regions in a given urban system.

Complementary methods of network coupling based on the concept of multigraphs have explored how different transport networks share similarities but also vulnerabilities. This is where the network analysis of transport meets more practical problems of disruptions, rerouting, and congestion, but also optimization. Questions include where a new node or link should be placed in order to make the transport network(s) more robust to all kinds of failures and targeted attacks, and how two or more transport networks should be connected so as to limit such shocks. Such questions are particularly relevant in the case of networks being largely dependent upon a few large, critical nodes (e.g., Suez and Panama Canals for sea transport). Other aspects to be explored via coupled networks include the study of potential intermodal shifts, the co-evolution of transport networks, and the multimodal accessibility of cities, among others. Geographers have been particularly keen to analyze transport network dynamics in various contexts, such as the impact of deregulation on airline networks, of railway development on urban accessibility, and so on. Notably, Bogart (2009) is a good example of a study combining a dynamical and a multimodal approach when looking at the evolution of canals, roads, and ports during the English Industrial Revolution. This work notably demonstrated the positive effect of road development on canal development, but a less significant role of ports, probably due to their earlier existence. It also suggested that investing in a canal would be less profitable when nearby road improvements were initiated due to higher uncertainties about potential profits from canal tolls.

Overall, graph-theoretical approaches to transport networks attracted a lot of criticism from more applied research due to their inability to include more complex aspects of transport, such as cost, time, strategies, and scenarios, but also graphical aspects. Indeed, a recurrent problem of transport networks is their visualization and cartography. Recent advances in graph visualization algorithms have provided certain solutions to represent, for instance, airline networks as planar networks using so-called edge-bundling tools, in order to limit the fuzziness of mappings caused by the intermingling of numerous, space-constrained links and nodes in a large transport network (Lambert, Bourqui, and Auber 2013). In turn, exploring the multifaceted dimensions of transport networks, such as their territorial embedding, had mobilized methodologies other than graph theory alone. One good example is the raster-based analysis of global urban accessibility taking into account no less than 10 different layers in a GIS understood as “friction surface components” (Nelson 2008). Despite its fundamental graph-theoretical essence, a work on the road accessibility of European seaports integrated several qualitative approaches.
aspects such as national regulations in terms of speed limits and resting times for truckers, the presence and cost of highway tolls, the types and capacities of main road arteries, and the potential delays of loading/unloading at intermodal junctions (Chapelon 2006). In the case of urban streets, more qualitative aspects were introduced by “space syntax,” which proposed to define links based on the continuity of avenues and boulevards from a cognitive point of view, rather than alignments of arbitrarily separated segments (Hillier and Hanson 1984). Such an approach could, by transforming lines into nodes and nodes into lines, reveal a hidden dimension of the network, the hierarchy of streets, which was not visible via the more traditional, planar perspective. Many measures did not provide extraordinary new results, since in general the traffic volume of transport nodes, which is known from classic sources, is highly equivalent to any centrality measure: large seaports or airports have many links and vice versa. Rare studies, however, have truly investigated the spatial determinants of the centrality of transport nodes. These include statistical evidence about the role of urban and regional socioeconomic characteristics, mostly in the realm of airline networks, where cities are nodes and aircraft trips are links. Main results point to noticeable interdependencies between centrality and the wellbeing of localities, for instance in Europe based on airline data and urban indicators, often concluding a circular causation between urban and transport development. The spatial dimension was also included, perhaps more by physicists than by geographers, so as to demonstrate rather trivial, albeit fundamental, properties of transport networks whereby larger nodes connect more distant nodes on average. Such works shared some affinities with the regional science perspective on transport hubs where cost and time are central parameters.

Given such limitations, and despite the improvements brought by GIS-T and natural sciences, geography and other social sciences have increasingly defined transport networks as elements of wider structures. The shift from quantitative/structural to more behavioral approaches is one main explanation (Waters 2006), but another is the fact that network analysis mostly considers transport networks as simplified and self-sufficient entities developed in abstract spaces. New concepts that emerged in the late 1990s, such as global production networks and value and commodity chains, have in common a disregard of pure physical flows, and are more concerned by the “flesh” than the “bones” when dealing with actors, mobility, governance, and territorial issues at various scales. A transport network can thus be approached via more complex and related configurations, planned or not planned, such as corridors and gateways, although the two latter concepts are often subcomponents of the transport network itself.

Another way to place transport networks into a wider analytical perspective has been proposed by urban geographers, in implicit or explicit ways. Early urban models, such as central place theory and up to the point of the new economic geography (NEG), approached transport networks in a rather abstract fashion while conferring on them vital importance in the emergence of cities and hubs within and between regions. Nevertheless, most NEG studies keep considering cities and regions as equally spaced, thus somewhat excluding the friction exerted by transport networks on mobility. Studies of urban systems and systems of cities were more keen on analyzing urban development through the more concrete configuration of transport networks, such as railway networks. From such a perspective, the transport network is used as a proxy for – and a material illustration of – wider
interurban interactions and dynamics in terms of spatial expansion, functional diversification, hierarchical transformations, and innovation cycles. Simulation methods are used to extract meaningful properties about both transport and urban dynamics and to compare estimates with real population data across many decades or centuries. Yet, there are very rare attempts to integrate urban or regional attributes into transport network analysis and/or modeling, such as that by Schintler et al. (2007) analyzing the vulnerability of road and railway networks in Florida through a mixture of various methods and approaches. More efforts are thus needed to push this integration further in order to better meet current challenges in transport and society.

Transport and mobility are essential to human existence. As modes of transport have become more numerous and technologically sophisticated, the complexity of transport provision has increased dramatically in recent years. While contemporary transport systems convey numerous benefits, they also come with considerable costs, including economic, environmental, and social externalities. Making informed decisions about the provision of transport is guided by the development of policy from both the public and private sectors.

The policy context

In general, policy can be defined as a definite course or method of action or inaction selected (by a government, institution, group, or individual) from among alternatives to guide and usually determine present and future decisions. Policy, especially in the governmental sphere, is often expressed in legislation or regulation, or in the form of policy declarations (white papers, executive orders, etc.). Policy is often, but not always, closely linked to planning, which involves efforts to define a problem and to develop potential solutions in a systematic fashion to improve the quality of decision-making. Policy sets the goals and objectives to address an issue or problem and then specifies the rules and principles by which decisions are to be made, while planning is more concerned with the assessment of policy options and the measures needed to reach particular goals and to resolve specific problems.

Accordingly, in the transport realm, transport policy can be defined as a set of constructs and propositions established to achieve objectives related to the functioning and performance of a transport system (Rodrigue 2013). The provision of transport can be the domain of either public agencies or private companies (or both), depending on the institutional frameworks of the countries involved and the historical development of particular transport modes. Countries such as the United States have a history of private sector transport provision, especially in the railroad, maritime, automobile, and airline industries, while state control of transport has been more typical of countries such as France, Japan, China, and Russia. In almost all countries, though, the reality is a mix of public and private ownership and operation. While private companies may provide many transport services, they often rely on public provision of physical infrastructure, traffic control, regulation, and safety. So, while transport policy receives inputs and generates outputs from both the public and private sectors, it is typically governments (at all levels) that establish and coordinate transport policies for their jurisdictions.

As transport systems have increased in scale, speed, and technological complexity, the challenge of creating and maintaining effective transport policies has grown over time. Governments and private companies have limited resources to invest in transport provision, and,
given the considerable investment in infrastructure and operations needed to deliver modern mobility, the stakes for establishing strategic transport policies are high. The time and effort required to create effective transport policies can be considerable, but the cost of inadequate or obsolete policies would be even greater. Since the cost of policy shortcomings usually manifest over time while the costs of creating and improving policy are immediate, there is a perverse incentive for organizations to underinvest in policy development when resources are scarce.

The transport policy agenda

Transport is vital in supporting societal and economic development by providing access to needed goods and services. Because of the significant burden on society that can arise from monopolistic tendencies across several transport modes, which encourage mobility providers to raise prices and lower productivity, transport policy needs to ensure that the general public interest is protected by promoting access to and the availability and affordability of transport services. Transport also has a significant national security dimension since it supports the movement of people and goods into and out of nationally controlled territories and spaces.

The increasing speed and volume of contemporary transport operations has driven an increase in the number of transport fatalities and accidents over time; thus, the promotion of safety in transport operations is a critical concern that requires policy attention. The adoption of new technologies in areas such as autonomous vehicles and systems invites new policies. Negative environmental externalities – burdens that are not borne directly by the user – from transport operations include local air pollution, global greenhouse gas emissions, water pollution, noise, land take, and wildlife habitat encroachment. Governments need to coordinate transport with environmental and energy policies to mitigate these and other negative effects. Societal equity concerns also require thoughtful transport policies to ensure that minimal levels of access are available to all members of society, regardless of socioeconomic status or class, and that the burdens of negative impacts are not concentrated on marginalized and vulnerable populations within a society (e.g., low-income and minority communities adjacent to highways, airports, seaports, or railroad yards).

Deregulation, liberalization, and privatization

Beginning in the late 1970s, public regulatory and administrative structures behind transportation policy, and in some cases the direct management and operation of transportation services that had been created over the past 100 years, began to be transformed to meet a new hierarchy of policy goals. Economic assessments of the transport sector showed mounting evidence of inefficiency and stagnating productivity that were attributed to the effects of regulation. Claims were made that, over time, special interests, usually connected to producers but also including labor organizations, had succeeded in “regulatory capture” to displace the public interest with their own concentrated benefits.

The prescription offered by economists to make transportation perform better was less government intervention, and conservative political leaders from President Ronald Reagan in the United States to Prime Minister Margaret Thatcher in the United Kingdom became enthusiastic supporters of deregulation and privatization in transportation and other policy
domains. Policy redesign to prioritize market forces over government planning was accelerated by a broader liberalization of international trade and finance in the late twentieth century that accelerated the demand for moving people and goods across the globe. The end of the Cold War also served to decrease concerns about national security, which had often been used to justify greater government oversight of transportation ownership and operation.

From the deregulation of air transport, rail, and trucking in the United States and the privatization of national airlines across Europe and Asia, to the sale of publicly owned railway systems that crisscrossed Australia, Canada, Mexico, the United Kingdom, and other countries, the role of government in the business of transportation has declined since the 1980s. And, with reduced economic regulation, the productivity of railroads and airlines has increased considerably during these years, along with an increase in the number of mergers, bankruptcies, and strategic alliances. Profitability has been more erratic as many firms have struggled to stay afloat while trying to maximize revenues and reduce costs. With a shrinking level of engagement and expertise in government, transportation policymaking has become more reactive, responding to crises in transportation after extreme events such as the terrorist attacks of September 11, 2001 (“9/11”), which led to an increase in government intervention in the provision of transportation security.

The implementation of deregulation and privatization policies has resulted thus far in several general outcomes, though there is some variation across industries and countries. Overall, these policies have encouraged more companies to enter the transport industry, but there has also been greater turnover as most of the new entrants have been unable to stay in business. After one or more periods of new firm entry in deregulated markets, there has been a tendency toward increased consolidation through mergers and alliances. Increased competition from new service opportunities for existing operators, as well as new entrants, has resulted in generally lower prices for shippers and consumers, at least until consolidation creates more concentrated markets that provide more pricing power for carriers.

The spatial outcomes of liberalization policies have seen increased geographic concentration in the large cities and key hubs of transport networks, and a reduction in the level and quality of service in many peripheral communities. The most notable spatial manifestation of airline deregulation has been the rise of hub-and-spoke networks, which provide airlines with the ability to create many one-stop connections through their principal hubs. Most large full-service carriers, including many former national flag carriers, have adopted hub-and-spoke networks which have allowed them to concentrate passenger flows at key hubs for both domestic and international feed traffic. Many of these full-service carriers, such as American Airlines, Delta Air Lines, United Airlines, Lufthansa, and Air France–KLM, are now members of global alliances (such as Star Alliance, Oneworld, and SkyTeam) with other airlines from countries throughout the world. In contrast, low-cost air carriers have focused on shorter-haul point-to-point networks, favoring direct services between larger cities and tourist destinations. In the maritime and railroad industries, liberalization policies and technological improvements have allowed carriers to tap inherent economies of scale, resulting in larger ships, double-stack trains, and more efficient intermodal operations. Increased geographic concentration at large port facilities, which can accommodate the much larger cargo ships, typify the contemporary movement of freight. Deregulation has facilitated the entry of
numerous trucking companies into the industry, which handle the movement of freight from the major consolidation terminals to the customer’s final destination.

Privatization initiatives have been extended to infrastructure provision, including airports, seaports, highways, and transit systems. With declining levels of government funding for transport infrastructure, private firms have become more heavily involved in infrastructure design, construction, financing, operation, and maintenance in the form of public–private partnerships. User payments, facilitated by electronic systems of fee collection, have become important sources of funding to supplement gasoline and other more traditional tax revenues.

The changes in the roles and responsibilities of public sector participation in the transportation sector have created a growing asymmetry of information and capacity for policy development between governments and firms. Relative to the private sector, public agencies and decision-makers know less about transportation system performance now than they did in the twentieth century. For example, financial data on carrier costs, revenues, and profits which used to be disclosed to regulatory bodies or reported by state-owned firms has become less available, since private operators and infrastructure owners shield such data under the doctrine of commercial confidentiality. Third-party logistics providers and supply chain managers also sign confidential contracts with carriers and terminal operators, further limiting public knowledge about the movement of goods.

This compartmentalization of knowledge about overall transportation system performance affects private firms as well as government actors. Private firms have almost as few incentives to share commercial information with one another as they do with government. This knowledge gap can inhibit long-range planning efforts in both the public and the private sectors.

Sustainability

Developing sustainable transportation policy poses a contemporary challenge that reveals how the constraints of piecemeal information can inhibit shared understanding of potential solutions to serious risks. The risks of extreme weather events, and the role of transportation in contributing to anthropogenic climate change, are becoming increasingly evident, though no less politically contested. What cannot be denied is that transportation lags behind other major sources of greenhouse gas emissions in reducing these atmospheric outputs. Manufacturing, housing, and power generation have found more ways to reduce the carbon intensity of their activities than the transportation sector has. If these trends continue, transportation will eventually be impacted by climate risks, triggering some form of crisis and response.

The failure to address climate change and the concurrent vulnerability of carbon-based energy supplies, particularly oil which powers over 90% of global mobility, could lead to significant disruption in the growing demand for mobility that was associated with previous shifts toward market-led policy. Success in reconciling mobility with sustainability could inaugurate new policy instruments and organizational structures that evolve to shift the policy paradigm beyond its free-market priority to a greater role for government to contribute to future policy development.

In the realm of urban transportation, policies concerned with sustainability have favored more investment in public transit, bicycling, walking, telecommuting, and reduced travel overall, while being less supportive of automobile-oriented highway systems. Combined with land-use policies that seek to limit urban sprawl and
encourage higher-density mixed-use activity centers, sustainable transport policies are intended to reduce vehicle-kilometers traveled, petroleum consumption, and atmospheric emissions that contribute to both global warming and local air quality concerns.

Safety and security

Increasing transport activity, especially road transport, has had a dramatic effect on transport safety worldwide. While transport-related fatalities and accidents have been decreasing over the last several decades across more developed countries, they have been increasing for many developing countries, mainly as a result of increased levels of motorization and inadequate attention to safety concerns. Transport policies that have been enacted to improve safety include the establishment and enforcement of speed limits, improved transport equipment standards such as seat belts and other accident controls, improved transport infrastructure design, enforcement of laws that prohibit the operation of transport vehicles while under the influence of alcohol and other drugs, and limiting the hours of work for commercial transport operators.

The events of 9/11 and subsequent incidents have refocused attention on the need for greater transportation security. In the United States, the Transportation Security Administration was created after 9/11 and policies such as the screening of passengers and increased inspection of freight were enacted to reduce risks from potential terrorist attacks using transport systems. Coordination between domestic transport security agencies as well as international organizations such as the International Civil Aviation Organization (ICAO) and the International Maritime Organization (IMO) have been a prominent feature of transport policies throughout the world.

Conclusion

While much of the transport policy agenda in the 1980s and 1990s focused on economic opportunities such as deregulation and privatization, increased attention on environmental sustainability and security risks have dominated the twenty-first century agenda thus far. It is likely that these concerns, as well as those of new technologies, will continue to be major issues in transport policy. Petroleum consumption, greenhouse gas emissions, and climate change will continue to be major challenges especially for the transport sector. Government policy must play an important role in coordinating and incentivizing private firms and public agencies to develop transport vehicles and systems that use nonpolluting renewable fuels in a safe and efficient manner. Security concerns are also unlikely to diminish over time, especially the continuing threat of international terrorism targeting transport operations, as well as disputes regarding territorial control and access to air space, land, and water.

Developing the technology of mobility: three dimensions of accomplishment

Moving beyond one’s immediate surroundings to access new territories, resources, and markets has been a primeval source of inspiration for humankind’s efforts to create and improve transport technology. While the means used to enhance mobility have evolved considerably over millennia, the goal of moving people and goods further, faster, and more easily continues to motivate advances in transport technology. These development efforts can be more clearly understood through examining three dimensions of technology that support the movement of people and goods: (i) propulsion, (ii) vehicles, and (iii) infrastructure.

Achieving propulsion advances

Without propulsion, mobility options are quite limited. Thus, humans have regularly sought to harness bigger and better means of propulsion for moving themselves and their goods. Propulsion technology encompasses the range of mechanisms used to convert energy into motion. The original and oldest means of human locomotion comes from moving about under our own power.

Since human migrations out of the African savannah that began sometime between 100,000 and 300,000 years ago, our ancestors have reached all the continents except Antarctica on foot.

Self-powered propulsion was supplemented by animal power once dogs were domesticated 12,000 to 14,000 years ago, with horses and oxen adding considerable power to animal propulsion options around 4000 years ago. Evidence of sails being used to harness the wind and propel boats dates back 4000 to 6000 years (Block 2003). Thus, long before the first motor was primed to power mobility, humans have been eagerly seeking alternative sources of mechanical energy to substitute for their own efforts at locomotion.

Propulsion technology reached a new stage of obtaining inanimate power in the early nineteenth century when the steam engine successfully converted the heat from combustion, another technology discovered by ancient humans, into mechanical energy. These external combustion engines, in which boilers piped steam into large cylinders, propelled a considerable increase in mobility by rail and water during the nineteenth century, particularly in Europe and North America. But their size and weight proved challenging, necessitating the use of tracks to guide land-based vehicles powered by steam. By the late nineteenth century, the internal combustion engine (ICE), which was much lighter and more efficient in its conversion of fuel into mechanical energy, enabled vehicles to operate on the open road, ushering in the era of automobility. Electric motors were also introduced around the same time as ICEs. To date, they have played a more limited role in powering transport, filling specialized niches propelling ships, submarines, and railroad trains.
Recently, concerns about energy efficiency and environmental impacts have led to the adoption of electric motors in automobiles, as both hybrids and battery electric vehicles.

The Wright brothers were first to apply the ICE to rotating a propeller that could lift an aircraft off the ground in 1903. And while piston engine propeller aircraft continue to operate today, jet engines introduced during World War II rapidly became the preferred propulsion source for both commercial and military aviation. Also appearing during World War II were rocket motors that could lift missiles into the upper atmosphere (Anderson 1985). During the “space race” of the 1950s and 1960s, engineers in the United States and Soviet Union developed rockets capable of powering orbital and interplanetary space travel. More recent design efforts have sought to reduce the cost of rocket propulsion to enable commercially viable travel into space.

Improvements in carriage technology proceeded incrementally over centuries. In fifteenth-century Europe, suspension systems of leather straps and iron chains offered a major advance in vehicle stability and capacity. In the eighteenth century, steering mechanisms were added to vehicles’ design. And in the nineteenth century, automotive and bicycle pioneers advanced versions of the horseless carriage as extensions of the same design that had evolved incrementally from the Egyptian chariot.

No evidence of wheeled vehicles has been uncovered from the ancient civilizations of North or South America. Although Mexican archeological excavations have yielded ancient wheels, they were not used on vehicles, but were instead attached to small objects that could have been toys or objects of worship. Before European contact, the vehicles used for transportation in the Americas were quite rudimentary. When French explorers reached the Great Plains of North America in the early eighteenth century, they found first nations people moving freight over land by means of an A-frame litter which they named a travois. These freight-bearing
litters were sometimes pulled by dogs, and later by horses.

Moving over (and under) water has been greatly aided by vehicle designs. Boat building has been dated back to 8000 BCE, with dugout canoes carved out of tree trunks found in Africa and Europe. Lighter boats made with tree bark hulls may have been used even earlier, but they were not as sturdy and thus would not leave an archaeological record. A boat constructed 7000 years ago from reeds and tar has been unearthed in modern-day Kuwait. By 3000 BCE, Egyptians had built larger boats that carried people and goods along the Nile, and by 1500 BCE Egyptian ships were sailing the Mediterranean and Red Seas.

The Phoenicians pioneered trade routes around the Mediterranean between 1200 and 800 BCE by deploying square rigged sailing ships for freight transport and a longer and narrower vessel with a sharpened bow that could be used to ram other vessels during maritime battles (Basch 1969). These ships were slowly scaled upward in size and capacity across Europe over two millennia, while the Chinese built even larger ocean going junks with up to four masts during the twelfth through fifteenth centuries BCE (Levathes 1996).

Traveling underwater, particularly during military combat, had inspired elementary diving equipment as early 413 BCE, when The Peloponnesian Wars described divers taking part in the siege of Syracuse. In 1620, Cornelius van Drebbel invented the first submarine while working for King James I of England. It successfully traveled 6 m (20 ft) below the surface of the Thames River, but was not adopted by the Royal Navy. Submarine design evolved incrementally during the eighteenth and nineteenth centuries, becoming a mainstay of naval fleets only after the self-propelled torpedo was invented in 1866.

The first marine vessel made entirely of metal was an iron barge built by England’s John Wilkinson in 1787. During the 1830s, the Laird shipyard in Birkenhead constructed the first all-metal paddlewheel steamboats, combining innovations in propulsion and vehicle technologies. Today’s steel-hulled ships have been incrementally adapted from the Laird’s design and production.

Vehicles used in air travel predate motorized aviation by 120 years. In 1783, a balloon with gondola designed by the Montgolfier brothers carried two men over Paris in the first documented episode of untethered human flight. Airships were the first vehicles to make use of motorized propulsion in the skies when a propeller-engine-equipped balloon designed by Jules Henri Giffard flew 27 km from Paris to Trappes in 1852. By 1891, Otto Lilienthal had flown a glider in Germany that marked the beginning of the use of craft that were heavier than air. Less than a decade after the Wright brothers’ first flight, in 1912 the Avro Type F monoplane provided the first enclosed cockpit to shelter its occupant from the elements. Pressurized cabins extended the heights that aircraft could reach, beginning with the Boeing 307 Stratoliner, which entered service in 1938. By the 1950s, the technology to protect occupants traveling in the skies had been extended to spacecraft that could maintain a livable atmosphere in the harshness of outer space.

By expanding the capability to shelter people when in motion along, above, or below the Earth’s surface, transportation vehicle technology has proven capable of extending the range of human mobility to reach increasingly inhospitable frontiers. While the dream of interplanetary and even interstellar mobility would certainly benefit from advances in propulsion and communication technology, the vehicles that could reach such extreme destinations are
TRANSPORT TECHNOLOGY

no less plausible than the aircraft and spacecraft in use today would have appeared to people in the preindustrial past. Designing and building vehicles reveals considerable skills that humans have developed in extending the comfort and security of their immediate environment.

Building effective infrastructure

A third dimension of transportation technology development is revealed by the infrastructure that has been developed to facilitate mobility. Infrastructure construction reveals not only the technical capability of various stages of human development, but also the dimensions and dynamics of human community since these creations are shared by many users. The paths that people make when moving from one place to another reveal some of the earliest evidence of ancestral human behavior that created transportation infrastructure. In Tanzania, the Laetoli footprints excavated by Mary Leakey show bipedal hominins from 3.8 million years ago following in one another’s footsteps. While the jumbled fossilized footprints proved challenging for paleontologists to interpret when seeking to understand the evidence from humans’ first bipedal ancestor, they clearly reveal those ancestors were creating pathways that eased the journey of those who took the same route. The oldest footprints that can be definitely attributed to humans dated from around 117,000 years ago and were preserved in Langebaan, in South Africa.

Ancient walking tracks have been discovered across Africa and Europe, but when goods began to be dragged over the ground with sleds and travois, improving the geometry of these routes required additional planning and skill. Ridge-ways were trails that followed high ground to avoid swamps and water crossings. Reaching these heights required creating gradients to access the ridge, and evidence of such graded trails dates to 3000 BCE in England and Germany (Lay 1992). England’s Ridgeway National Trail preserves one such route to this day. Another driver of improved infrastructure was urban settlement, where the density of travel by people and vehicles called for more durable surfaces. Evidence of paved streets can be found dating from 3000 to 4000 BCE in excavations of the cities of Harappa and Mohenjo-Daro in the Indus Valley of Pakistan as well as the Mesopotamian city of Ur in modern-day Iraq.

Extending these roads beyond cities enabled consolidated control of large territories. The First Persian Empire created the Western world’s earliest intercity expressway around 500 BCE, featuring a 2699 km Royal Road commissioned by King Darius I that linked Susa in modern-day Turkey to Sardis, near the head of the Persian Gulf. The Greek historian Herodotus wrote that messengers could traverse the length of this road in 90 days, delivering goods and communications across the Persian Empire at a speed and scale unprecedented for the time. Persia’s Royal Road was subsequently incorporated into the Roman Empire’s more extensive road network, which displayed considerable advances in both engineering and pavement technology along with the legal framework to plan and build highways across Europe, the Middle East, and North Africa (French 1998).

Roman civil engineering introduced standardized dimensions and geometry to road infrastructure, along with the use of consistent and durable pavement materials, including concrete. Romans also advanced the use of bridges and tunnels in road infrastructure and formalized the design of sidewalks as a regular component of street design (Van Tilburg 2007). The Roman legal code offers the oldest documentation to date of principles and regulations on road building and maintenance. The Romans built many long and straight roads and established towns...
TRANSPORT TECHNOLOGY

at regular intervals along the roads. Evidence of these Roman roads and town origins can be found today throughout Italy and other parts of Europe. Roman achievements produced an advanced infrastructure that was not surpassed until the eighteenth century in Europe, with the exception of tar pavement, a breakthrough that was made in Iraq around 800 CE and applied to the roads of Baghdad.

France led Europe into the modern era of road building by rediscovering and improving the engineering and legal techniques that the Romans had created. In 1716, France launched its “Grand Corps des Ponts et Chausées” which was the Western world’s first professional road-and-bridge-building bureaucracy. The Corps was responsible for designing and constructing France’s national road network and continues to play that role along with other engineering responsibilities today. During the eighteenth and nineteenth centuries, England created decentralized administrative units to plan, build, and maintain intercity roads. These turnpike trusts borrowed funds to build infrastructure and then collect tolls to repay the debts. The British turnpike trustee who left the greatest technical legacy was John Loudon MacAdam who improved upon the Roman technique of creating a gravel subgrade between the ground and the exposed pavement. He also invented the mix of crushed stones and tar to produce a durable road surface that has made his name synonymous with pavement the world over.

Railroad infrastructure grew out of the early road technology where carts were guided along ruts that became progressively worn into the ground by the passage of wheels. An early example of such a tracked roadway was the Diolkos, a 6–8.5 km paved trackway across the Isthmus of Corinth (Werner 1997). Built sometime between 700 and 600 BCE and used regularly through the first century CE, this trackway enabled both ships and cargos to be rolled across the isthmus between the Gulf of Corinth and the Saronic Gulf, avoiding the long and rough sail around the Peloponnese. Tracks were used to roll heavy loads out of mines from the sixteenth–eighteenth centuries in Europe, and by the end of the eighteenth century English horse-drawn railways were moving coal from mine heads to canal docks several miles away. The first three decades of the nineteenth century saw a rapid evolution of railroad infrastructure, with England leading the world in developing the first recognizably modern railroad operation, the Liverpool and Manchester Railway, which opened in 1830. Today, rail infrastructure serves a considerable diversity of mobility, supporting the fastest movement of commercial transport vehicles on the Earth’s surface through high-speed rail systems in Asia and Europe as well as moving the heaviest loads of freight on land along the railroads of North America.

Port infrastructure dates back to at least 2550 BCE. Archeologists have excavated a 6 km² wharf complex on the Gulf of Suez at Wadi el-Jarf in Egypt from this era (Tallet and Marouard 2014). Building piers, docks, and warehouses to store arriving and departing cargo has increased in scale up to today’s busiest port infrastructure in Shanghai. Canals appear to have first been dug for irrigation in Mesopotamia and the Indus Valley, but they were being used as a transport corridor to enable boats to bypass rapids and waterfalls along the Nile River by around 2300 BCE. The advantages of water transport in the era of non-motorized transport inspired ongoing efforts to build such infrastructure in the ancient world. For example, the Chinese built their Grand Canal between Beijing and Hangzhou, a distance of 1794 km, by connecting shorter canal stages between around 300 BCE and 609 CE (Davidson and Brooke 2006). China’s Grand Canal is still used today and remains the
TRANSPORT TECHNOLOGY

world's longest. But the highest volume of ship traffic to use such infrastructure passes through the 193.3 km Suez Canal, which was completed in 1869 and allows Asian traffic to reach Europe without sailing around the Cape of Good Hope in South Africa, and the 77.1 km Panama Canal, completed in 1914, which allows ships to transit directly from the Atlantic to the Pacific oceans bypassing the long journey around Cape Horn in Argentina and Chile. A third Panama Canal channel is being built to expand the capacity of this waterway.

Unlike ports, airport infrastructure does not predate motorized mobility. The oldest airport still in use dates from 1909 and is located in College Park, Maryland. At this airfield, Wilbur Wright offered the first training flights to US military personnel. As with ports, the width and length of the runway have expanded, along with terminal and support buildings and ground transport access, but the basic principles of aerodrome design have not changed. The first spaceports were built during the Cold War to launch missiles and later manned spacecraft. To date, there are only four spaceports that regularly launch vehicles into outer space: the Baikonur Cosmodrome in Kazakhstan, the Cape Canaveral Air Force Station (now known as the Kennedy Space Center) in Florida, USA, the Guiana Space Centre in Kourou, French Guyana, and the Jiuquan Satellite Launch Center, in the Gobi Desert, Inner Mongolia, China.

Our infrastructure legacy reveals a great deal about our evolving society and its approach to meeting mobility needs. From paths that were informally carved out of the wilderness and shared by our nomadic ancestors to paved roads that have been designed and administered by ancient empires and modern states, infrastructure design and development reflect the ideas that our predecessors held about pooling their skills and resources to make travel easier, not just for themselves but also for others. As the scale of that challenge mounted, with growing technical complexity and economic cost needed to produce increasingly sophisticated infrastructure, the mechanisms for sharing those burdens were created. From the compulsory labor of slaves in the ancient world to the public finance of expressways, ports, airports, and spaceports today, infrastructure building demonstrates how society has pooled its talents and resources to create shared spaces that enable mobility to be more productive and effective.

Contemporary technologies

Transport has benefited from numerous technology innovations in recent years. In freight transport, the practice of intermodalism, that is, the ability to move goods seamlessly from one mode to another in order to optimize the strengths of individual modes, has been facilitated by several technological innovations. The introduction of the standard container, based on the twenty-foot equivalent unit (TEU), has revolutionized freight transport by facilitating the loading, unloading, and transferring of goods from one mode to another. Together with the mechanized gantry crane, the time it takes to unload a large cargo ship is now measured in hours rather than days. These technologies have contributed to the increasing size of container ships well beyond the limits imposed by the length of the locks in the Panama Canal, resulting in a new generation of “post-Panamax” ships.

The current expansion of the Panama Canal will allow larger ships to be able to use the canal, which is expected to lead to container ships from Asia bypassing US west coast ports in favor of US east coast and gulf coast ports. At the ports, containers can be moved directly from a ship to a rail car or a truck where they can be transported
to inland terminals and eventual destinations. The innovation of double-stacking of containers on rail flat cars has greatly increased rail freight capacity, contributing to the recent resurgence of the freight railroad industry. Intermodal connectivity has been facilitated by improved information technology, such as electronic data interchange (EDI) which has permitted more seamless coordination of freight movements.

The growth and sophistication of information technology infrastructure have had a huge impact on contemporary transportation. Major investments in intelligent transportation system (ITS) development have led to smarter vehicles and infrastructure systems that have automated many elements of the transport process. The operation of automobiles and other motor vehicles has been facilitated by technologies such as cruise control, automated safety systems, and global positioning systems. A considerable amount of progress has been made recently in developing driverless vehicles, led by Google’s pioneering efforts, and aircraft technology has improved greatly so that many of the pilot’s tasks have been automated. A long-term goal of ITS is the development of integrated vehicle/infrastructure systems that will allow smart vehicles to operate in automatic fashion on smart infrastructure, thus improving efficiency and safety greatly. Information on traffic conditions is now routinely collected and disseminated to improve the flow of traffic, so that vehicle operators or traffic controllers can make better decisions about specific routes to take to avoid congestion. Automated ticketing on air, rail, bus, and other passenger transport systems has facilitated the use of these modes, and automated tolling on highways has made the collection of user fees much easier.

The use of technology has been extended to improving the sustainability of transport systems. Development of alternative fuel vehicles, such as electric or hybrid automobiles, has contributed to greater fuel efficiency and allowed transport to utilize more renewable sources of energy rather than continued reliance on fossil fuels. Technological improvements in internal combustion engines have also helped to reduce harmful emissions of local air pollutants and global greenhouse gases. Continued research and development in using alternative fuels, improving fuel efficiency, and reducing emissions from aircraft, motor vehicles, ships, and rail locomotives has the potential to significantly reduce transport’s carbon footprint and other negative externalities.

Transportation and land use

Selima Sultana
University of North Carolina at Greensboro, USA

Transportation serves as a fundamental linking factor between people and for moving goods and information, and has spatiotemporal dimensions. Hence, throughout history transportation investments have had a tremendous impact on land use, yet defining land use is a complex task. In general, land use is the conversion and management of the natural environment for human use. Examples might include the conversion of forests into housing developments with accompanying road networks, or of grasslands into farm land.

The relationship between transportation and land use has been a dynamic process in which the two are interdependent and inseparable. Historically, changes in transportation systems, modes, and speeds have created opportunities to overcome distance, which have been linked to changes in land-use patterns. Similarly, changes in land-use patterns influence travel demand and induce changes in transportation systems. Thus, the interactions between transportation and land use are often referred to as having a “chicken-and-egg” connotation with an essentially inseparable outcome regardless of which change occurred first.

This entry focuses on the nature of these complex processes of interactions between transportation and land use for the twenty-first century. It will first provide an overview of the transport and land-use connection in a historical context. It will then focus on the challenges that have arisen from the dominance of automobile-oriented land-use patterns.

Transportation networks as strategies for spatial interactions of land use

Transportation has always been closely related to land-use developments throughout the world. Preindustrial patterns of compact and dense land use reflected the difficulty of travel and the reliance on slow modes of transportation such as walking. Innovations in transport technologies and their respective transport modes that prevailed at different time periods have had a profound influence on land-use patterns. These relationships can be summarized by reference to specific technological and historic periods.

Before the 1800s, waterways and road networks mostly connected coastal areas and had major influences on early land-use patterns. Transport by waterway was substantially more efficient in terms of time and cost than transport over land, especially because of the limited road capacity that prevailed at that time. As a result, settlement patterns were prevalent along waterways because they were able to maintain economic, political, and cultural activities by creating trade relationships, even over longer distances. As such, the most dominant cities of that time emerged along the waterways in places such as Mumbai, Suzhou, Lisbon, Athens, and Istanbul. Similarly, many early American cities developed along the waterways as they provided access to the interior. Jamestown, Charleston, Savannah, Boston, New York City, and Philadelphia are salient examples.
TRANSPORTATION AND LAND USE

With the development of the steamboat in the 1810s, waterways even became a prevailing force in American settlement patterns. Since steamboats could travel upstream, inland river towns, such as St Louis, New Orleans, Chicago, Milwaukee, and Buffalo, were formed along the major rivers and lakes. They were connected by waterways to the larger port cities of the Atlantic and Gulf coasts.

The development of rail networks made the hinterland more accessible, especially in North America. The setting of new rail connections between 1830 and 1920 resulted in significant land-use changes in the American hinterland with the establishment of rail-based cities such as Kansas City. Unlike waterways, which could only connect locations along navigable rivers or canals, railroads could create their own pathways and were also more efficient than waterways because of their speed and reliability. As a result, rail transportation emerged as a new factor for developing lands between waterways and the hinterland by facilitating better access and connectivity to the existing waterway networks. Since it was easier and cheaper to ship crops and livestock to markets from farms close to a rail station, public lands were given to railroads to capitalize construction and create markets along the lines of railroad constructions. Once railroad spurs were built, land agents were hired by the railroads to recruit settlers as quickly as possible by underlining the benefits of the agricultural land adjacent to the newly constructed railways. To recruit new settlers, railroads carried buyers on a special land-seeking train, with the train ticket price included in the price of the land. Marketing of land using railroads was so popular that by the 1870s railways had become the principal mode of transport for passengers and freight in the United States. Not only did railroads lead to changes in land-use patterns nationwide, they also shaped the development of land use at the local level. For instance, the railroad station became the nexus of many urban cores, resulting in the decline of waterways and many small river towns.

The mass production of the automobile from the early 1920s changed the land-use dynamic around the world and to a greater extent in the United States. Automobiles allowed people to travel faster and wherever roads could be built, hence allowing the development of land in areas that were previously isolated, underserved or underserved by the railroads. The “Autostrade” network, the world’s first intercity motorway, was built in Italy in the early 1920s and eventually linked all regions of Italy with over 6000 km of highways. The “Autobahn” is another example, the first highway system in the world, built in Germany during 1913–1921. This highway system was later used to expand and build the country’s economic growth and financial corridor allowing for transportation of goods from all areas of Germany and beyond. After World War II there was a great deal of interest in launching major highway construction projects in the United States. By the 1950s, the federal government underlined that infrastructure based on roads and interstate highways would be in the strategic interests of the country, particularly to improve the connectivity of its major cities. This led to passage of the Federal Highway Act of 1956 that allowed substantial federal funding to build the Interstate Highway System (IHS). The effects of the IHS were dramatic. The interstate highway network offered tremendous flexibility to individual businesses to deliver goods by truck and resulted in a significant decline in rail transportation. By 1970, it was apparent that interstates carried more vehicles than anyone had anticipated. The IHS and increased automobile use had significant impacts on land use in urban areas across the United States.
Urban modes of transportation and land use

Transportation serves as a fundamental linking factor between a person’s residence and his or her everyday activities within urban areas. Where an individual chooses to live can be decided based on the availability and cost of transportation and the distance to work or to other activities. The innovation of new transportation technologies over the centuries promoted changes in the spatial organization of land uses within and in the vicinity of urban areas as new modes of transport came into use. It is common to categorize the influence of transportation modes on land-use characteristics by different eras (Adams 1970).

Walking and horse car era (before 1890)

The urban land use of this early era was very compact and dense (75–100 people per acre), with most destinations within a 30-minute walk, or within 2 miles, as people were only able to walk or ride horse cars to move within a city. The separation between home and workplace was unnoticeable as factory owners often built their homes next to their factories; artisans and storekeepers lived above or behind their workshop or store. Even though in the mid-1800s railroads were available, they were principally developed for transportation between cities, not within cities, and that led to intense competition for land around railroad stations. Factories, warehouses, and shops were able to pay higher rents for the most accessible areas within cities and they were located in close proximity to railroad stations.

Electric streetcar era (1890–1920)

By the late nineteenth century, cities were very crowded and that increased demand for more transportation. Alternative means of propulsion began to be experimented with, using cables (cable cars) and then electricity (electric streetcars or trolleys). Horse cars (and most cable cars) were eventually converted to electric streetcars, and many new streetcar lines were built in almost every city and in large towns. These systems had very dense grid networks with sidewalks, much like bus routes today. They ran on most major streets, and sometimes on every street in downtown areas. In this era, the land uses in most cities were still compact, but the residential fabric of cities changed radically by expanding along new outlying trolley corridors for the increase in accessibility these areas offered. There were some signs of change in housing styles as well from multifamily to single-family and two-family housing types of land use, but they were built on narrow lots on a grid pattern with sidewalks connected to the main street, and land values decreased away from streetcar lines.

Early auto era to freeway era (since 1920s)

Over the last 100 years automobiles have dominated transportation systems in developed countries, especially in the United States, pushing the urban and suburban boundaries into the surrounding rural areas from the city cores of the nineteenth century. Low-density housing development started outside the city with wider housing lots for driveways and garages as automobiles gained popularity in the 1930s. One notable consequence of this spatial structuring of land use was the increasing separation between workplace and residence, but railroads were expanded to these communities for commuting to city jobs.

The construction of post-World War II freeways accelerated access to plentiful and inexpensive land in rural areas and led to the
TRANSPORTATION AND LAND USE

construction of more roads and low-density residential areas in suburban and exurban areas. This came to be called “suburban sprawl,” with wide lots on various types of curvilinear road networks with differing land uses located far from each other leading to the growing use of automobiles for every trip. Due to the decline of automobile costs coupled with affordable housing options, many workers were amenable to living further from their place of employment, sometimes more than 30 miles from work. This distance necessitated long commute times, and automobiles became by far the most commonly used mode of transportation for commuting to work, which led to the decline of public transportation. Indeed, many systems, especially regional transit, have in many cases seen large decreases in funding because of a perceived lack of need leading to limited investments being made in maintenance and expansion of public transit.

Beginning in the 1950s, geographical expansion of suburban growth was uncontrollable, which led to significant changes in land-use patterns and the distribution of population accompanied by a dramatic increase in automobile numbers. By the end of the 1970s, the uncontrolled outward suburban growth reached a point where more Americans lived in suburbs than in core areas of cities (Table 1). This trend still continues today even though many core areas of cities saw some population gains in the past two decades. Today the average American commutes for a little less than 26 minutes and 16 miles each way. Some 10.8 million (8.1%) US workers commute for more than 60 minutes, and another 600,000 (0.8%), labeled “mega-commuters,” travel for 90 minutes or more and at least 50 miles each way for work (AASHTO 2013).

developed uses of land have expanded by more than 1 million acres annually since 1982 (Alig and Ahearn 2006). It is estimated that there were 73 million acres of urban and built-up land in 1982, and this grew to 111 million acres in 2007, a 56% increase. One may argue that this expansion of urban land uses results from an increase in population, mainly from immigrants, and an increase in wealth combined with certain lifestyle choices. However, population and income pressure are not consistent with the ratio of urban land consumption, which expanded at a faster rate than population growth until the 1990s (Figure 1). Urban boundary expansions reached the point where rural communities started seeing these urban expansions as a negative change in their communities, raising concerns over unchecked growth. Eventually, many rural communities adopted land-use controls designed to make suburbanization difficult and costly. Many rural land-use regulations allow by right (without regulatory approval) uses that support a main use, such as agricultural districts that typically allow a number of uses that would need special permission in urban areas. During this time, regulation on lot sizes also tended to be greatest in urban areas. Land-use controls
that mandated large minimum lot sizes had immediate effects on urban land-use expansion, reflected in Figure 1.

Concurrently, since the 1970s, commercial land uses, such as mass concentrations of office parks adjacent to retail-based industries and skyscraper buildings along the intersections of major highways, have emerged as a distinctive urban-like phenomenon in America’s suburban landscapes. Commercial suburbanization was so rapid that, by the 1980s, job growth (about 150%) in suburbs outpaced population growth in the United States. Today, typically there are more jobs located in suburban locations than within the core urban areas (CTPP 2011). In general, these are areas of lower building densities than downtowns, with large buildings widely separated from others by grass and parking lots with an excessive use of land area. For example, the Cumberland-Galleria and Perimeter commercial areas in the Atlanta metropolitan area have a larger land area than downtown while also having lower population and worker densities. Roadways in these areas often lack sidewalks, which, combined with the low densities, often make it obligatory for workers to drive between
adjacent buildings. These areas typically have limited public transportation services (if any) due to the lack of density and because their locations along expressway and freeway corridors allow for easy access by automobile. This trend continues today, but even farther out in exurban locations where low-density, scattered, and small-scale commercial development such as retail and wholesale is also visible.

Transportation and classical urban land-use models

Classical urban land-use models are the starting point for conceptualizing the continuum of land use in relation to transportation. Burgess’s concentric zone land-use theory (CZLUT; 1925), Hoyt’s radial sector or wedge land-use theory (SWLUT; 1937), and Harris and Ullman’s multiple nuclei land-use theory (MNLUT; 1945) are among the best known. Burgess’s CZLUT viewed the city as a dynamic place evolving from a center point of greatest accessibility of transportation to a series of concentric zones, or rings, like a two-dimensional bull’s-eye with the center zone containing the central business district (CBD) as well as the transportation, social, and cultural hub of the city (Figure 2). According to the model, urban land use is based on distance from this hub in relation to transportation costs and has six rings: CBD, a factory zone, the zone of transition, the working-class residential zone, a
middle-class residential zone, and the commuter zone (usually wealthy single family homes).

In CZLUT, land uses are in competition for space based on their ability to pay for higher valued locations near the center of the city, with the CBD having the highest value, due to its having the highest transportation accessibility, and therefore occupying the most valuable position. Outside the CBD, the secondary ring was a transitional land-use area with mixed uses, including some manufacturing and low-income or slum housing for greater access to transportation. Residential density continues to fall as the rings move outward, with an inverse relationship between residential categories and income. The poorest residents of the city live nearest the CBD to reduce the transportation cost and the wealthiest reside at the furthest edge of the city while incurring higher costs in transportation.

Burgess envisioned an expanding CBD exerting land-use conversion pressure on the surrounding district; this in turn pushed outward on the other districts. In this and later monocentric models, changes in transport costs determine changes in the relative value, and therefore use, of land at specific distances. The concentric zone model therefore follows bid rent curves. Bid rent curves illustrate how the most expensive land is at the central point of a city (e.g., the CBD) and that land value goes down as distance from the CBD increases. While this logic fit the constraints of the first half of the twentieth century, CZLUT focuses almost entirely on the CBD, residential, and factory land uses with no real consideration of the nuances of institutional uses, wholesale and retail sales uses, or office uses, or even ownership characteristics of land, as Burgess essentially envisioned all of these uses to be contained within the CBD.

Two other classical models are SWLUT and MNLUT (Figure 3). These theories are more representative of actual spatial development in urban land use, and both of these theories take the same classifications and land uses of CZLUT and apply them to wedges or sectors radiating out from the central business district, but MNLUT recognizes that an urban area may have multiple hubs of activity outside the central business district. Hoyt’s SWLUT aligns land-use zones along major transportation routes such as highways, rail lines, or ports, but also takes into account geographic realities such as water bodies and the landscape (Figure 3a). SWLUT proposed several major organizing principles of land use. Relative location shapes how the urban form develops in a city. Corridors of industry and warehousing tend to be surrounded on both sides by sectors of working-class housing. Middle-class housing acts as a buffer between industrial/working-class areas and the main sector of elite neighborhoods. Affluent households and transportation have a large impact on city structure. Once the CBD is established and the corridors of industrial development are laid out, affluent households develop adjacent to the most desirable sites. High-status areas then expand along transportation lines.

In this theory, sectorial development occurs with generational shifts. Each new generation of affluent households buys or builds at the current urban “edge” of the city, far from the poorer sectors. These new affluent generations sell off their old family homes, most likely to families of slightly lower status. In this way, sectors are banded into residential zones of different ages, styles, and conditions, moving outward from the oldest areas in the city center to newest areas at the city edge. Over time, high-rent sectors tend to grow outward along major transportation routes. Affluent areas also grow along ridges of high ground, away from the risk of floods and where the best views are located. Hoyt also recognized that neighborhoods go through changes
over time through filtering and vacancy chains. The chain of residential moves initiated by the construction of new homes for the affluent leads to the filtering of households up the housing scale and the consequent filtering of houses down the social scale. This process creates a vacancy chain in which higher-income families move out and lower-income groups fill in houses and areas left behind. The vacancy chain keeps going until it stops at an old house no one wants to move into. This has been the case in the inner city for a long time and the same pattern is taking place in the inner-ring suburbs, the areas immediately outside of central cities. Unlike CZLUT, SWLUT does not address commuter zones.

MNLUT is a schematic representation of the same major categories of land use with several economic centers, based on the decentralization of commercial and industrial nodes beyond the CBD (Figure 3b). MNLUT argues that automobile-based suburban nodes of commercial and industrial activity are not arranged in any predictable fashion, except in relation to surrounding land uses. These nodes may develop around transit stops or highway intersections. If they were office and retailing centers, they would attract middle-income residential development, whereas if they were industrial centers, these nodes would attract working-class residential development. If the node was an airport, it would most likely attract shippers such as

---

**Figure 3** (a) Hoyt’s sector model; (b) Harris and Ullman’s nuclei model. Rodrigue 1998–2016. (Reproduced by permission of Dr Jean-Paul Rodrigue.)
FedEx, hotels, and working-class residents. The mutual attractiveness and mobility allowed by the potential income of each node drives what develops there. The CBD may be separated from the transportation, education, or cultural hubs, thereby creating a scattered land-use development effect. Heavy industrial uses in this model are located on the periphery of the city. The result is an irregularly shaped patchwork of land uses across the urban landscape, which is remarkably present in today’s cities with polycentric and dispersed patterns. American classical models are all essentially center-oriented and do not attempt full descriptions of all land usage. Moreover, these earlier models did not consider the impact of newer technologies such as information and communication technology (ICT) on land uses.

**ICT and land use**

As a rule of geography, if distance between people increases, social interactions decrease as the cost of transportation increases, and this explains why compact land uses were necessary in early cities. Automobiles and freeways have reduced the cost of travel and allowed for greatly expanded cities. Communication costs have fallen and the ability to transmit information (bandwidth) has greatly increased. Some scholars suggest that the Internet and new telecommunication technologies can be a viable option for communication and, therefore, substitute for physical transport. Many tasks that once required personal travel, such as going to the bank, arranging insurance, filing tax forms, searching for library books, and even taking classes or working, can now be done electronically at home. Technologically deterministic futurists have made predictions based on these ICT trends that transportation will not matter for locational decisions of households and firms as people can access anything from anywhere at any time. Commuting distance will no longer be a consideration for residential and firm location, so people will be able to live anywhere or even nowhere near their workplace, therefore travel will be substituted for. This may essentially lead to a weakening link between transportation and land uses.

There appears to be no evidence so far that ICT has much of an influence on land use nor on travel behavior. There is some evidence, however, that back office activities such as routine, repetitive data processing work that follows standardized procedures does not necessarily need to take place in cities or nearby suburbs and can be performed anywhere around the world. Front office activities – highly skilled and specialized occupations – still require face-to-face contact as innovation and creativity thrive in areas with daily intellectual contacts between workers, and still require a center location in the cities. Whether communications could substitute travel or transportation is also questionable as evidence shows that the emergence of e-commerce has actually triggered a surge in goods shipments from businesses to consumers, which is far from substituting transportation or reducing travel. Certainly, ICT complicates the straightforward linkage between land use and transportation and this effect should be integrated to better understand transportation and land-use modeling in future research.

**Challenges for transportation and land use in the twenty-first century**

During the past several decades there have been growing concerns over climate change issues to which automobile-dependent transportation systems with associated low-density land uses are
TRANSPORTATION AND LAND USE

a contributing factor. This has resulted in a general consensus on the need to reduce greenhouse gas (GHG) emissions from transportation – the second largest contributor (about 30%) of total GHG emissions worldwide. These concerns have made the relationship between transportation and land-use even more complex. A recent emphasis has been on encouraging land-use planning policies in ways that will alter the possible relationship between urban form or built environment and travel behavior. Hence, the smart growth and new urbanism concepts emerged in the early 1990s as an explicit alternative to sprawl-oriented development, aimed to integrate urban land use and transportation development in a way that limits outward expansion of cities by preserving open space and promoting density, diversity, variety of transportation options, and job–housing balance – much like historic European cities (Congress for the New Urbanism 2001). Therefore the consensus currently favors promoting compact land-use patterns with high-density, pedestrian, and transit-oriented cities where every trip does not have to be initiated by automobile.

Since then considerable attention has been devoted to understanding how the neighborhood built environment, including density and land use, impacts mode choices, especially on nonmotorized modes of transportation. There is clearly an agreement in the literature that residential environments with a mix of land-use types (such as residential, parks, and small shopping centers), higher population densities with accessible transit, a well-connected street network with short distances between intersections, and a pleasant walking environment (with good sidewalks, shade, and nice views) as well as a lack of parking spaces in commercial areas are associated with higher levels of nonmotorized mode choices (walking and cycling). Residents of these neighborhoods own and use automobiles less and have a reduced carbon footprint.

Today, thousands of new urbanism communities are being developed throughout the country and many downtowns are now being rejuvenated by utilizing this concept. To a certain extent new urbanism has succeeded. New urbanist community residents are far more likely to walk to where they shop relative to their counterparts in traditional suburban neighborhoods, and more likely to use transit if available, but they still use cars for commuting. This has raised ongoing debates among academics and policymakers as to whether it is possible to change car use by creating compact land-use patterns. In reality, American cities are not well served by transit networks. In addition, despite the unequivocal goal of income diversity for new urbanism, many critics have pointed out that most new urbanist communities are artificial, exclusive, and expensive. The nature of the style is affordable only by those in the upper middle income to upper economic classes. As a result, two of the most significant challenges that new urbanism communities face today are to create socially diverse (in terms of mixed income) neighborhoods and to provide transit connection outside these developments to the rest of the areas in the cities. So far there has been no easy fix.

Moreover, it is indisputable that the majority of American urban growth is driven by low-density suburban and exurban expansions, and their existence cannot be just ignored. It is also clear that the opportunity to completely wipe out the suburbs and build new cities and towns with a compact philosophy is impractical. Historically, density tended to increase by locating housing and commercial businesses near transit stops and stations. For that reason transit–oriented development (TOD) has become a possibility to utilize most effectively these existing suburban land-use patterns by creating higher density
regional employment and residential centers connected by transit. The diameter of these types of developments is usually one-half mile, with stations spaced one-half to one mile apart. Residents of this community can rely on rail, and are able to walk or cycle between the stations and their homes. Despite decades of strong resistance to increasing density in suburban areas, there seems to be already some evidence of cultural shift in suburbanized areas, as reflected by a growing urgency in the implementation of smart growth and new urbanism development concepts in land-use planning. If this trend continues, it is expected that TOD could be more favorable to many suburbanites in coming years.

Transportation refers to the means of transporting people, freight, and information from one place to another. In addition, transportation history also focuses on the factors that influenced the setting of transport routes, the emergence and diffusion of transport technologies, and even the biographies of the key persons responsible for the discovery of trade routes or the invention of key technologies, for example.

Walking obviously marks the first step in transportation history. A reliance only on human legs implies movements taking place at a slow pace of about 5 km per hour, and the distance that can be travelled in a single day would be no more than 40 km on good roads. A more constraining environment could easily reduce this range. That people needed to return to their stable shelters before dusk would also have restricted their travel distance by half or more. Therefore, in the past the range of human activities was highly limited by the distances that could be crossed and the amount that could be carried by foot. The emergence and extension of civilizations was, in the earlier stages, closely related to transportation. Transportation is considered one of the four essentials of human life alongside clothes, residence, and food according to the traditional popular Chinese wisdom of civilization, for example.

Three inventions are indeed key to the initial historical impacts of transportation on human activities before the Industrial Revolution: the understanding and application of the principle of buoyancy and wind power for water transportation; the domestication of animals as a source of power in transportation; and the invention of the wheel, which increased the capacity and efficiency of land transport.

Water transport systems

Exploitation of the buoyancy of wood and other materials, crafted into vessels, represented a crucial development in transportation. Early propulsion systems were rudimentary, for example using pole or a paddle to push a vessel over shallow water. The presence of a native population in Australia as far back as 40 000 to 45 000 years ago is indicative of early forms of simple seafaring vessels that enabled people from Eurasia to travel to that isolated continent. The reed boat is one of the older vessel designs as used for river navigation in Egypt, Mesopotamia, and India around 7000 years ago. Later, the galley was an early example of a seafaring vessel that appeared around the Mediterranean by 800 BCE. Using paddles as the main mode of propulsion, the galley was effective for calm sea as well as river navigation. The large crew required to power it, however, limited its capacity and range, as it was necessary to carry food and water to sustain the rowers. It was good for short trips within the Middle Sea but not a practical means of transportation in the blue water. Rowing was also harsh work, and was often done by convicts or slaves; early naval warfare was waged to capture slaves for galleys. The galley was one of the critical elements that helped the Greeks...
TRANSPORTATION HISTORY

to establish their colonial empires in the eastern Mediterranean, and later the pillar of the Roman navy. In the early modern period, galley navigation also contributed to the reform of the penal system in southern Europe as a poena extraordinaria could replace a death sentence with a galley sentence.

The sail is a convenient means of using wind power for propulsion for prolonged periods of time and is thus suitable for deep sea navigation. In most parts of the world, sails have been made from canvas of linen, hemp, or cotton. However, canvases were subject to wear and tear and to degradation by sunlight and water absorption, and hence needed to be repaired and changed frequently. Vessels in the Far East employed bamboo mat instead of canvas which was more resistant to tearing, waterproof and buoyant, and easier to repair en route.

The square sail, which is more effective in downwind sailing, is one of the two basic types of sailing rigs. It was invented in Mesopotamia around 4500 BCE to 6000 BCE and later independently developed in China and Ecuador. The other type is the triangular fore-and-aft sail invented in the Mediterranean region around 1000 CE. It is set completely aft of a mast and placed parallel to the ship’s keel, enabling it to take wind on either side. The triangular sail performs much better than the square one for upwind and crosswind sailing.

Inadequate wind strength and unpredictable wind direction are major constraints for blue water navigation. From the sixteenth century onward, the use of combined square and triangular sails by the European ships significantly enhanced navigation by allowing ships to be steered in several directions in a prevailing wind. The wide application of the compass and watertight compartments, both invented by the Chinese but soon adopted by the Arabs, Indians, and Europeans in seafaring, also contributed to more accurate navigation and hence survival in the ocean.

Facilitated by these new elements, the Europeans were then able to establish long-distance trade networks that went beyond the limits of the Mediterranean. While Arab and Indian merchant fleets frequently harbored around the Indian Ocean, by the tenth century Chinese merchants were also exploring the South China Sea and reaching as far as the East African coast to establish trade and diplomatic relations. At the peak of China’s maritime dominance in the early fifteenth century, Admiral Zheng He (1371–1433) led a large fleet of 317 vessels manned by 28,000 crewmen on seven major expeditions in these maritime regions, just prior to the rise of the Iberian sea powers. Arab, Indian, and Chinese merchants, each of whom had already established important elements of a world trade system, traded goods and exchanged information and ideas. Later, in the seventeenth century, European powers took over these trade routes, established centuries beforehand, in addition to their own elements and discoveries, and consequently created their global maritime empires.

The domestication of transport animals and the wheel

Unlike waterborne transport developments, which took place in different parts of the world independently, breakthroughs in land transport developed mainly in the Eurasian steppes, which offered large tracks of flat land and native species adapted to travel long distances. The nomadic inhabitants of this region employed ox wagons, horseback riding, and chariots to extend their reach. By exploiting the strength of large mammals they were able to travel much faster and with heavier loads than on foot, and to increase the speed and capacity of transport. Nomads of
the Eurasian steppes became traders, conquerors, and wanderers who imposed great changes on the peoples around them through the course of human history.

The ox, one of the first mammals used for transport, was domesticated from 9000 to 7000 BCE. In addition to providing meat and milk, the animals were employed in agricultural activities because of their muscular strength. When equipment was invented and put to use, the ox also became a means of transportation. The domestication of horses probably took place in the Caspian Sea region around 4800 BCE, well after sheep, goats, pigs, and oxen had been domesticated. Horseback riding was developed well after the horse’s domestication, as it took a long period of time to control this less docile animal effectively. In contrast to the slower pace of oxen, the superior speed of the horse was ideal for faster travel, either for pulling vehicles or for horseback riding. From then on, the horse became the dominant form of land transportation until the Industrial Revolution.
