Humans face many environmental threats to their wellbeing and, in some cases, directly to their survival. These come both from such things as droughts which disrupt the regular agricultural activities of societies and impact food supplies, as well as more immediate hazards from storms or earthquakes which directly imperil lives. Insecurity is a matter both of environmental context and of the social organizations that facilitate certain modes of human life in those particular circumstances. As humanity’s agricultural and subsequently industrial capabilities have expanded, vulnerabilities to natural environments have become increasingly mediated by economic and political factors. Food supplies remain a major concern, as they have been through most of the modern period, but now there are repeated discussions of shortages of many other resources such as recent scares about petroleum and rare Earth metals. While huge inequalities in the human condition persist in what has become a global economy, universal norms that encourage aid to the most vulnerable in conditions of natural hazard or famine have emerged too.

To speak of such things specifically in the language of security, as is frequently done in contemporary policy debates, complicates matters because of the multiple meanings of the term “security” and its interconnection with the provision of particular forms of modern social order. Security is a key term in the contemporary political lexicon. It is politically effective because it simultaneously invokes protection from danger and the perpetuation of existing social arrangements that can supposedly provide safety. In terms of national security, it refers to the protection of state institutions, traditionally from external military threats and internal political subversion. Global security loosely means preventing major wars, with their potential, now, for large-scale destruction caused by nuclear weapons, as well as maintaining the conditions for the perpetuation of the international state system. This is now dependent on a functioning global economy and, as at least some policymakers are slowly realizing, a relatively stable climate system, a functional stratospheric ozone layer, and oceans that are not too acidic for complex marine ecosystems.

There have been many prior discussions of the human predicament, and concerns about both shortages of various resources as threats to social order and the dangers of rapid changes to natural systems caused by humans. Concerns about scarcities of one form or another as a source of social conflict go back a long way in Western thought, although Thomas Malthus’s (1970/1798) famous “Essay on the Principle of Population,” first published at the end of the eighteenth century, is usually cited as the key work that clarified the theme. European imperial policymakers frequently worried about resource shortages, and geopolitical conflict has long been tied to matters of access to key supplies for military and economic activities (Le Billon 2012). In the 1960s environmentalists worried about overcrowding and food
supplies as a source of conflict, and frequently (if vaguely) suggested that scarcities were a cause of twentieth-century wars (Robertson 2012). Richard Falk’s (1971) overview of these matters, and his explicit attempts to link environmental change to geopolitical problems of world order, which Jon Barnett (2001) usefully suggests is a key precursor to the contemporary discussion of environmental security, didn’t actually make an explicit connection to formulations of security.

Environmental security

Discussing these things specifically in terms of security is a relatively recent development, one that has generated a huge policy literature that is only sometimes directly connected to academic research. As the Cold War ended in the late 1980s, growing alarm about environmental change and potential conflicts that might arise over resource shortages generated a complicated policy and academic discussion about what became known as environmental security (Renner 1989). While such themes have been part of discussions of economics, geography, and other disciplines for much longer, the heightened attention to environmental concerns in the aftermath of the Bhopal chemical disaster in India in 1984 and the Chernobyl reactor meltdown in 1986, attempts to deal with stratospheric ozone depletion as well as tropical deforestation, in particular in Brazil in the late 1980s, when linked to matters of security, meant that they became high profile. The World Commission on Environment and Development’s report in 1987 on *Our Common Future* warned of conflict over scarce environmental resources, which briefly related these themes to security, led the way to the major Earth Summit meetings at the United Nations Conference on Environment and Development in 1992.

While alarms over potential conflict were good at getting attention, there was little evidence of causal links between the environment and warfare or large-scale violence. That people were insecure in many ways was clear, but quite how this was to be understood as a matter of either policy or academic research was anything but simple. The discussion about these relationships continues apace with policy and academic studies intertwined in ways that are frequently confusing (Floyd and Matthew 2013), not least because of the contradictory claims made by academic studies and the misleading headlines that appear when studies become a matter of media attention. Most recently all this has become a high-profile discussion once again as fears of climate change have reinvigorated policy discussion, academic investigation, and media coverage.

The early discussion

Arguments about resources shortages and the potential for conflicts over water suggested that, as Cold War confrontation was reduced, new sources of conflict would arise. Hence, as *Our Common Future* had suggested, sustainable development was needed, not just because of the obligation to help poorer societies become more affluent states, but because the failure to anticipate and deal with deleterious environmental changes might have more serious consequences. Implicit in the discussion was the assumption that scarcity might lead to violence, although quite how was frequently not specified. As with earlier environmental advocacy in the 1960s, when population concerns were rather incoherently linked to crowding as a source of social friction, the relationships between resource shortages and conflict was assumed to be obvious. If this were so, the logic frequently went, then it must be
a matter of national security which is at the heart of modern state power (Mathews 1989). But quite how scarcities would lead to conflict, or what the standard institutions of national security, the intelligence agencies, police, and military might do about environmental issues frequently wasn’t clear.

Critics of the argument about the utility of national security means as a way of dealing with environmental difficulties made a number of key points. First, Daniel Deudney (1990), in a widely cited critique, made the simple but important point that military institutions are often serious polluters and, even in training, are very destructive of the environment. Explosives and heavy equipment are directly damaging to environments, while the chemicals used in military operations are frequently toxic. Huge clean-up operations were necessary in the 1990s to deal with the toxic residues from many Cold War vintage bases. Matthias Finger (1991) bluntly argued that the industrial infrastructure that generated the war machines in the first place was a key part of what caused environmental damage.

Nor was it clear in the early discussion exactly how resource scarcities would turn into military conflicts, especially between states. While wars in which oil was a major factor were obviously possible, as the 1990–1991 Gulf War apparently showed, they were not about spreading deserts, disappearing forests, or water supplies. How societies suffering acute shortages might mount military campaigns to rectify the situation wasn’t clear even if small-scale violence over access to such things as grazing land was plausible. Prins and Stamp (1991) posed the problem of pollution as an issue in contrast to high-technology warfare in the pithy title of a television documentary, *Top Guns and Toxic Whales*. The top gun fighter pilots were of little use in either preventing whales from absorbing toxic effluents from sea water or disposing of the hazardous corpses of dead ones that washed up on beaches.

**Academic skepticism**

While the policy discussion continued, academics posed questions about the causal links between environmental changes and conflict. Given the all-encompassing and hard to define nature of the term, Thomas Homer-Dixon (1999), in particular, focused on acute conflict rather than security. Looking at cases in various parts of the world, a series of research initiatives under his direction in the 1990s tried to track the causal pathways from environmental change to direct violence. These studies suggested that, while such connections could be found, the social context and actions (or failure to act) of political elites were an important part of the picture, not least because sometimes the actions of elites in a crisis made access to resources more difficult. Resource capture by elites and the resultant ecological marginalization of vulnerable peoples was often part of the problem. Assumptions that simple relations between scarcity and violence were commonplace were not supported by his empirical investigations. Guenter Baechler (1998) led a broadly similar set of investigations in Europe in the 1990s which concluded that environmental issues were related to violence in circumstances where they were superimposed on discrimination and restrictions of access to resources that followed other social cleavages. Baechler’s research emphasized that environmental matters were sometimes related to violence in situations of what he called mal-development, and that this was likely to take place in marginal lands including mountainous regions where development was causing disruptions to traditional ways of life.
ENVIRONMENTAL (IN)SECURITY

Despite the caveats and cautions in the scholarly work, Robert Kaplan used Homer-Dixon’s early papers to write an essay for the *Atlantic Monthly* in February 1994 that ominously announced “The Coming Anarchy.” In this dystopic account of current conflicts, Kaplan melded discussions of the clash of civilizations with ideas about militias, civil wars, and the changing nature of warfare and concerns about resource shortages, environmental change, and violence into an alarming vision of the near future. It was widely circulated and discussed at the time, and many thought it provided an explanation of the genocide in Rwanda that took place a few months after its publication. This single article galvanized attention to the discussion of environmental security in Washington in particular and influenced policy debates in the Clinton administration. NATO undertook a series of studies into various relationships between the environment and security problems and developed a series of analyses that suggested that environmental matters were related to politics in numerous different patterns, only a few of which syndromes fitted the classic discussions of environmental change causing violence fairly directly (Lietzmann and Vest 1999). Many of the others involved disputes over development projects, pollution, and campaigns to reduce the damage caused by industrial expansion.

Methodological debates

While the discussion of environmental security and its policy ramifications was underway, a number of methodological debates took place among scholars trying to tease out how these relationships might be understood and researched. Three are noteworthy, and all have a bearing on how the subsequent more recent discussion of climate change is playing out.

First is the question of what counts as evidence in the discussion of causal relations between environmental change and violence. While both Baechler and Homer-Dixon looked to field investigations to find cases where these links could be demonstrated, others suggested that large-scale statistical investigations were more appropriate methods for investigating the relationships. If there is a correlation between episodes of violence and documented environmental change, then, so the argument goes, a scientific case can be made for the relationship. Individual field investigations, focusing on particular situations rather than general patterns, cannot effectively demonstrate general causal patterns. Second, without detailed fieldwork, so the counterargument goes, correlations between the two might be entirely spurious because of other factors that are not clear from statistics; only practical investigations on the ground can show what causal mechanisms are in play.

Third, this controversy was aggravated by some geographers’ and anthropologists’ concern that the case study research ignored previous careful ethnographic research into the changing relationships of people to environments in particular places, research that suggested that the relationship of political violence related to environmental change was much more complicated than simple measures of resource scarcity (Peluso and Watts 2001). These critics pointed out that this political ecology literature, and what it had to say about the disruptions caused by processes of development in particular, had been given short shrift by political scientists. Globalization and the rapid expansion of resource extraction, the spread of corporate and commercial agriculture, and related development projects such as dam and road building are, in this scholarship, much more important than the scarcity variables considered in the political science literature.
An additional important argument emerged in the late 1990s from development studies suggesting that violence was more obviously related to resource abundance than to scarcities and shortages (Bannon and Collier 2003). The discussion of the resource curse and related phenomena suggested that, in places where poverty was widespread and few economic development options were available, it might be more sensible on the part of those looking for wealth to use violence to seize control of mines and forestry resources and control the rent streams instead of following the long slow road to economic development. Related to this, the resource curse is also connected to the phenomenon of inflated currency prices due to the effect of commodity exports, the so-called Dutch disease, which also complicates economic development strategies. Conflict resulting from attempts to gain instant wealth from selling resources was, so the argument went, an alternative interpretation to those suggesting that rural resource shortages lead to violence (Le Billon 2012). As with the political ecology studies, the resource abundance argument suggested that interconnections between the global economy and particular places were an important part of the puzzle of how resources were linked to violence.

**Human security**

In addition to the policy debates about environmental scarcities and the academic arguments about the appropriate mode of investigation of these issues, the United Nations’ agenda in the 1990s included a much broader consideration of social matters and human welfare than the Cold War period had permitted. Matters of environment, gender, development, and related matters were the focus of a series of large conferences. This led to various attempts to develop new policy agendas to deal with societal matters and extend human rights and development not just to states and their elites but to peoples, and eventually to a much larger academic discussion of how to rethink these issues in light of environmental change and globalization (Brauch et al. 2008).

Among these initiatives was the high-profile formulation of the idea of human security in the 1994 United Nations Development Report. Instead of focusing on security in the narrow sense of military danger and direct threats to states and social order, the authors of the report suggested a much broader understanding of security related to the wellbeing of people. Focusing on the conditions necessary for development to take place, the report also suggested that insecurity for many people was not the result of direct political threats from other states but of unanticipated and unintended consequences of the huge transformations underway globally as economic growth, urbanization, and globalization caused rapid change across boundaries. Human security was formulated in anticipation of such consequences, with measures being taken to protect people from hurtful disruptions; unlike traditional military security, human security was about preparation rather than violent response after the fact.

While the human security formulation dealt with political, economic, and other changes, it also included environment as a key factor that makes people feel insecure. What it did not offer was an explanation of how this came to be, beyond some obvious concerns about ozone depletion and pollution in particular places. Nonetheless, as a matter that concerned people’s safety, the environment is clearly a factor to be considered in discussion of the necessary prerequisites for development and the expansion of freedom for people, especially in the poorer parts of the planet (O’Brien, Wolf, and Sygna...
Subsequently, some of these discussions have been extended in the debate about the now widely adopted principles of responsibility to protect as governing state legitimacy. While environmental degradation is not listed as one of the key factors that trigger international action to protect people where their state has manifestly failed to do so, there have been discussions as to how these principles may be extended to help in emergency situations caused by environmental factors such as floods, storms, or droughts.

**Climate change**

While matters of environmental security were a low priority in many parts of the world in the early stages of the American “war on terror” in response to the attacks of 9/11, they have since found their way back into discussions of security. While there was great reluctance on the part of the Bush administration to deal with matters of climate change, by 2007 a number of high-profile reports were appearing, which raised the alarm about traditional national security implications of a rapidly changing climate (CNA Corporation 2007; Campbell et al. 2007). This has a number of aspects, not least the very direct one that the American military is concerned that its facilities, and its ability to operate them, might be vulnerable to climate change. Low-lying runways and port facilities are obviously in danger of rising sea levels and hurricanes might directly impact bases in many ways. The military is also usually the first agency called upon to aid in disasters, not least because of their ability to move emergency supplies and operate outside normal civilian supply systems. For all these reasons, many militaries are starting to take climate change seriously as a factor that may affect their operational capabilities and as a threat that they cannot directly control.

One formulation that has appeared repeatedly portrays climate change as a threat or conflict multiplier. The suggestion is that either climate change in general, or immediate disruptions caused by storms, can aggravate social tensions and in turn provide a pretext for insurgency, civil unrest, or terrorist action. If states are unable to cope with climate change, then, according to this argument, political disruptions and violence are likely to be more frequent, some of which may involve military interventions, and all of which will make global security more tenuous. Hence a sensible security policy requires dealing with these situations before they can cause destabilization. The worst case scenario of state failure may require military action to contain terrorist, criminal, or piracy threats that might result.

This discussion has revived the earlier scholarly debate about the relationships between environmental change and insecurity, albeit with a more direct and narrower focus on climate and its specific consequences. But, insofar as climate change affects basic environmental factors such as rainfall, water availability, droughts, and storm damage, it involves a variety of matters similar to those in the earlier discussion. Once again scholars have looked to the empirical record in terms of climate change and social consequences; a formal German advisory council itemized many of the studies in terms of climate change as a security risk (German Advisory Council on Global Change 2008).

At the macroscale the discussion about climate engages with themes of historical crisis and the collapse of civilizations that were unable to cope with resource shortages or changing weather patterns for agriculture (Diamond 2005). The archaeological record is not clear in many cases and, even if climate changes have been exacerbating factors, in the absence of clear historical documentation, how social changes happened,
and where and how these were unsuccessful, simply are not known in most cases.

Historical research into more recent events is beginning to trace connections between many episodes in recorded history and their climatological circumstances. The seventeenth century, in a period sometimes known as the Little Ice Age, is particularly pertinent because there are numerous clearly documented situations from across the globe that allow connections between disruptions in food supplies, in particular, and subsequent political events, including widespread warfare, to be traced. While climate wasn’t the only factor in play in this tumultuous century, political elites made decisions in the context of climate variability which drastically upset traditional agricultural calculations. What is clear, as Geoffrey Parker’s (2013) synthetic study suggests, is that attempts to deal with such problems by going to war were usually counterproductive.

The direct relevance of historical studies to present circumstances, with its very different global economy, a gradually emerging global civil society, and an international food system, is questionable but highly suggestive nonetheless.

Recent social science work on climate change and potential political difficulties has in some ways replicated the discussions of the 1990s. Some researchers have once again looked at large-scale databases on conflict and tried to link these with weather conditions to draw statistical connections between the two. While these are contentious, and some media headlines have drawn alarmist conclusions from the published studies, data from the last few decades has provided few clear indications that climate change has caused conflict. While some statistical correlations may link meteorological factors with civil unrest, many of these studies use national statistics, which are at a level of generalization that doesn’t effectively explain specific political developments in particular places. Attempts to disaggregate data to focus on smaller areas have not definitively proved causal connections between climate and conflict.

Other studies which have investigated particular cases where environmental change might be related to conflict or violence have concentrated on development and, in work loosely consistent with Gunther Baechler’s 1990s studies, suggested that economic structures are more important than environmental matters in explaining how environmental circumstances might be related to conflict. But these too have made it clear that the relationship is complicated and that contextual factors have to be considered in any attempt to connect the two; conflicts over water happen in the context of complicated institutional arrangements and in conditions of structural violence which have to be understood for the dynamics of conflict to be grasped and policies put in place to deal with these difficulties. Clearly, media preoccupations with “water wars” notwithstanding, interstate wars caused directly by water issues simply haven’t happened. Structural inequalities make many people insecure, and access to water is a very important matter for human security, but it does not lead to security problems in terms of overt warfare (Zografos, Goulden, and Kallis 2014).

In the case of the Arab Spring food, prices were in some senses a precipitating factor in the political upheaval, and the rise in food prices was related to climate factors in the global agricultural system. In the civil war in Syria journalists have repeatedly suggested that the drought in the years prior to the outbreak of violence was a significant factor in setting the stage for the subsequent war. While climate change might have been a contributing factor to the drought, which caused people to migrate to the cities, it is clearly not a direct cause of the civil war. Political institutions and their ability or inability to handle rapid environmental and social change are the key
to whether conflict results. Larger geopolitical calculations and support for factions in struggles are also a key part of most conflicts; environmental scarcities are neither the sole cause of conflict nor the cause of other forms of insecurity.

**Earth systems science**

As global change accelerates, the questions facing human security increasingly relate to the artificial circumstances that humans find themselves confronting in what is now frequently called the Anthropocene. The majority of people now live in urban areas in dependence on the surrounding rural areas, and sometimes very distant locations, for supplies of food as well as other necessities of life. Globalization means not only the interconnection of economies and production systems, but also the transformation of environments directly to supply materials and absorb wastes. It also works indirectly through climate change which is raising sea levels and upsetting assumptions about food production in numerous places. Insecurities are, hence, increasingly artificial and, as such, encompass the social provision of the necessities of life (Dalby 2009). While great care has to be taken over extrapolation from the history of elites who failed to take seriously their responsibility to people in their charge and ended up with collapsed societies, this theme needs serious research attention in our interconnected world marked by great inequalities.

This is especially important now as Earth system scientists trace the scale of the transformations that humans have set into motion and emphasize that current changes to the earth system are faster than anything in the geological record. Insecurity is now of our collective making. Human insecurity is now connected to key decisions about the future of energy systems that power the global economy. The environment is not an independent variable that causes human insecurity, but is now partly a human artifact, and as such a matter for political deliberation and decision (O’Brien, Wolf, and Sygna 2013). So far political attention has focused on matters other than the future configuration of the climate system, but this may change in the coming decades as changes multiply and climate adaptation requires more attention. Given that climate change is being caused by human actions, it is no longer appropriate to think of the environment as a residual category that is separate from humanity. Climate change now makes it clear at the macroscale, as it has long been evident in political ecology research at the microscale, that humans are transforming environments and in the process changing who is insecure where.

What research has so far shown is that the failure to think carefully about our ecological context may lead to unwise or counterproductive attempts to mitigate the effects of or to adapt to climate change. The purchase of offsets for the use of carbon fuels have sometimes aggravated land-use conflicts in the Global South, whereby forestry plantations certified as carbon sinks require numerous ecological changes that undercut their ostensible purpose. Land grabs are part of national and corporate strategies to secure future supplies of food, but if they displace local inhabitants or cause disruptions in land markets they may cause conflict in the process. Rather than environmental change causing conflict, it may be that attempts to cope with that change will stimulate upheavals and violence (Dalby 2013). The failure to understand the complex interconnected natural and artificial systems that are now humanity’s context will result in simplistic, counterproductive security policies. If the perils of such misguided policies are to be avoided, considering how economies are remaking environments should form a key
part of current research agendas (Brauch et al. 2008). All of this requires careful analysis of how particular places are connected to the rapidly changing larger ecological contexts of our times.

ENVIRONMENTAL (IN)SECURITY

Environmental assessment techniques

Luuk Fleskens
University of Leeds, UK
Wageningen University, Netherlands

Environmental assessment techniques comprise a range of methods and tools, either applied in isolation or in combination, to qualify or quantify environmental changes and/or the environmental impacts of human interference. Environmental assessment is a systematic process for evaluating and documenting information about natural systems and resources that may be used in planning for sustainable development and environmental decision-making by different actors, for example, governments, companies, and so on (Sadler 1996). Whereas environmental assessment techniques can be deployed autonomously, that is, as a stand-alone tool, they are often used institutionalized within legal frameworks for environmental impact assessment or environmental accounting procedures. When institutionalized, certain standards need to be adopted, a combination of assessment techniques may be required, certain procedures may need to be complied with, and a certain sequence may be prescribed.

There is a distinction between “environmental assessment,” which focuses on the effects and consequences of specific human undertakings, and “environmental monitoring,” which takes the wellbeing of the whole system (ecosystem, land-use system, etc.) as its starting point (Kessler et al. 2002). The wider system provides the context within which decision-making processes operate and is normally more difficult to assess as sources of information are outside the direct sphere of influence of the decision-maker. For example, monitoring the quality of a watershed for water resources development requires information on a range of parameters, many of which (e.g., meteorology, land use, soil types) are not directly collected by a water resources authority. Notwithstanding, monitoring this context is important as it is here where impacts from the decision manifest, and also because changes in the context may interfere with the possibilities to reach objectives.

Reconciling performance monitoring and measuring of environmental change requires selecting appropriate environmental indicators (Kessler et al. 2002) and environmental assessment techniques can essentially start this reconciliation process from either end. This means that environmental assessment can include environmental monitoring although this may not always be feasible or appropriate. Conversely, environmental monitoring could point to effects of management interventions although it is often difficult to attribute change to the effectiveness of measures.

The deployment of environmental assessment techniques should be carefully organized within analytical frameworks. The ecosystem functions and services framework (De Groot et al. 2010) offers such a comprehensive framework that explains how changes in environmental systems affect human wellbeing. This framework has been widely adopted for environmental assessment, including the Millennium Ecosystem Assessment (MA 2005). The focus in the
ENVIRONMENTAL ASSESSMENT TECHNIQUES

ecosystem services assessment framework is on increasing understanding of the linkages between nature and society and raising awareness of the value of the natural environment for society.

The DPSIR (drivers–pressures–states–impacts–responses) framework (European Environmental Agency (EEA) 1999) provides an alternative structure to assess how human undertakings affect the environment and is also frequently used to structure environmental assessments, for example, in the EEA’s State of the Environment Reports. The DPSIR framework allows indicators to be presented in a way to enable feedback to policymakers on environmental quality and the resulting impact of the political choices made or to be made in the future.

Historical evolution

Environmental assessment techniques may go back a long way, for example, meteorological records are available since the 1730s, but their integrated use for environmental assessment is more recent. One of the first methods for environmental assessment was environmental impact assessment (EIA) which was developed in the 1960s (e.g., Leopold et al. 1971). EIA at that time was carried out using a checklist matrix to identify the importance and magnitude of impacts of future projects and plans. Such matrices replaced earlier ad hoc tools that were criticized for being subjective and descriptive and not accounting for spatial and cumulative effects of identified impacts (Munier 2004). Checklist matrices, however, lacked the necessary guidelines for estimating the degree of impacts, which affected the transparency of the EIA process. In response, more elaborate techniques such as the semiquantitative rapid impact assessment matrix technique (Pastakia and Jensen 1998) and environmental risk assessment were developed. Such techniques deepened and broadened the assessment in order to get more comprehensive data for project planning while at the same time being able to demonstrate better the evidence on which the assessment was based to multiple stakeholders.

With increasing attention to long-term trends of global change effects and evolution of computers, model-based scenario analysis was added to the toolbox. New methodologies such as strategic environmental assessment (SEA) emerged that complemented EIA by focusing on the environmental impacts of policies and strategies for which EIA was ill-equipped (Therivel 2004). It was also recognized that the portfolio of assessment techniques required to plan for environmental change needed to be augmented to respond to different information needs at different levels of decision-making and involve the potentially affected stakeholders. This led to the introduction of multistakeholder multiscale assessment techniques (e.g., Reed et al. 2011; see also Figure 1). More and more, use is being made of remote sensing and (web-based) participatory monitoring techniques. In several fields, the integration of several types of information gathered at multiple levels by different actors is currently being advocated to advance environmental assessment. For example, policymakers at national level require information on the future likelihood of extreme events affecting the country in order to develop appropriate policies. District-level authorities require assessments of which adaptation options will be required where. Farmers need seasonal forecasts in order to anticipate adaptation choices. Citizens need early warning signals to respond to threats to their safety not attenuated by the adaptation measures implemented.

For measuring the progress toward long-term environmental goals, systematic accounting techniques have also developed over time. Natural resource accounting has gained prominence
since the early 1980s and evolved into the first system of environmental-economic accounting (SEEA) in 1993. SEEA allows integration of the environment into national accounts, and enables environmentally adjusting macroeconomic indicators such as GDP. Mainstreaming of the ecosystem services concept (MA 2005) gave a further impetus to development of sophisticated environmental accounting techniques for tracking the contribution of the environment to economic activities. Roughly at the same time, Rockström et al.’s (2009) concept of planetary boundaries reiterated the need to closely monitor environmental change to avoid crossing resilience thresholds with potentially severe implications for humanity.

**Techniques**

Environmental assessment techniques constitute a wide range of tools to assess or monitor a variety of environmental conditions and indicators. Among the most prominent of these techniques are expert judgment, checklist matrices, environmental risk assessment, mapping and spatial analysis, impact prediction, impact evaluation, remote sensing, natural resource accounting, participatory techniques, and crowdsourcing.
ENVIRONMENTAL ASSESSMENT TECHNIQUES

Expert judgment

Expert judgment is one of the most frequently used techniques, especially in the context of EIA/SEA applications. This recruits a team of experts covering multiple specialisms and asks them to rank alternative projects or plans, and/or suggest mitigation measures. Procedures include (group) discussions, sometimes in multiple rounds, to generate data, judgments, or suggestions. The main advantages of using expert judgment is that it is quick and cheap, able to consider multiple types of information, can lead to innovative solutions, and contributes to information sharing and education. Its drawbacks are that it is sensitive to biased opinions based on selected experts and is a nonreplicable and unscientific process (Therivel 2004).

Checklist matrices

Checklist matrices are used to qualify the importance and magnitude of environmental impacts expected from future projects and plans and constitute the most commonly used technique applied in EIA. A number of variants have been developed. In the simplest form, checklists matrices present a list of environmental qualities against which to score the importance and magnitude of impacts of future projects and plans. A more sophisticated matrix is the rapid impact assessment matrix (RIAM) proposed by Pastakia and Jensen (1998). RIAM uses a structured matrix to allow for semiquantitative impact judgments, specifying importance of the environmental condition (ranging from no importance to importance to national or international interests) and magnitude of effect (from major disbenefit to major benefit), together with judgments on the permanence, reversibility, and cumulative nature of changes.

Environmental risk assessment

Risk assessment refers to a formal process of evaluating the consequence(s) of a hazard and their likelihoods/probabilities. The process followed resembles an EIA, with components of formulating the problem, carrying out an assessment of the risk, identifying and appraising the management options available, and addressing the risk with the chosen risk management strategy. In the risk assessment phase, however, frequently attempts are made to quantify the consequences and probabilities of risks as qualitative and semiquantitative assessments would remain subjective and inconclusive. Quantitative assessments can, for example, use quantitative exposure assessments, simple deterministic risk estimation, or Monte Carlo simulation techniques.

Mapping and spatial analysis

In environmental assessment, there is often a need to understand spatial patterns of threats, impacts, applicability of mitigation options, and so on. A wide range of practical tools fall into this technique. Overlay maps can be produced for each specific factor of interest and combined (e.g., flood risk and asset value maps) to quickly identify hotspot areas. Geographic information systems (GIS) have generated rapid advancements to mapping and spatial analysis, and are now the tool of choice for analyzing spatial aspects of environmental assessments. Commonly, field data and other assessment data collected outside of the GIS environment are geo-referenced and linked in spatial geodatabases to accommodate mapping and spatial analysis. An example of a spatial analysis in environmental assessment is land-use partitioning analysis which is used to assess the effect of habitat fragmentation resulting from infrastructure projects. It involves the identification, assessment, and recording of landscape fragmentation effects.
Impact prediction

For informed decision-making, environmental impacts frequently need to be anticipated. This can be achieved by impact prediction techniques which compare environmental changes with and without implementing a strategic action. Of interest may be whether a strategic action’s impact is expected to be positive or negative, large or small, short term or long term, reversible or irreversible, and likely or unlikely. While such assessments can be based on expert judgments or checklist matrices, there is often a need for more comprehensive quantitative assessment based on modeling. A huge variety of environmental model types exists, for example, through Bayesian belief networks (BBNs), a probabilistic type of network analysis, it is possible to capture the probabilities about the performance of an outcome indicator (e.g., farm income) based on different state variables (e.g., rainfall and soil quality). BBNs are versatile in that the conditional probability tables used to populate the model can be filled with different types of information (qualitative judgment, measured or modeled data). Life cycle analysis (LCA) is another modeling tool in which environmental impacts of a product are quantified by considering all resources consumed and emissions to the environment during all stages of its life cycle. In the framework of impact prediction, models are generally used for scenario analysis of different strategic options. For example, Basset-Mens and van der Werf (2005) report on a scenario-based assessment of different pig production farming systems in France using LCA.

Impact evaluation

Taking decisions on whether or not to implement strategic actions requires impact evaluation, that is, interpreting the information from impact predictions to know which option is the most preferred. Impact evaluation techniques consider environmental impacts, often along with other (economic, social) criteria, but the way in which this is done varies. In cost–benefit analysis, an attempt is made to value all costs and benefits of implementing a strategic action in monetary terms relative to not implementing the action. An alternative tool is multicriteria analysis, in which strategic options can be compared based on multiple criteria that can remain in different units, for example, considering environmental impact, economic return, employment generation, and health benefits. Impact can also be evaluated based on solely environmental grounds, for example, using tools such as carrying capacity or ecological footprints. Impact evaluations can also be made spatially explicit, for example, Fleskens, Nainggolan, and Stringer (2014) provide a framework for spatially explicit financial cost–benefit analysis of sustainable land management options.

Remote sensing

Given considerable resources required for environmental assessment when based on field data collection, and in response to a need to extend assessments over larger areas and longer time spans, a variety of remote sensing techniques has gained prominence in environmental assessment. Remote sensing applications include satellite-based monitoring of terrestrial and environmental changes (e.g., land cover, vegetation greenness) as well as observation of different characteristics using ground-based methods (e.g., laser to assess micro-topographical changes due to tillage erosion) or, increasingly, drone-based methods (e.g., sensors to detect pollution, video cameras to detect forest fire spread). Satellite-based products such as Landsat and MODIS have already proven invaluable for environmental assessment, whereas development
ENVIRONMENTAL ASSESSMENT TECHNIQUES

of assessment techniques with drones is a hot topic in many environmental science disciplines.

Natural resource accounting

Natural resource accounting is a technique aimed at monitoring stocks of environmental resources and understanding how dependent economic growth is on depletion of such resources. It was introduced in response to demands from policymakers to have systems in place to fulfilling these purposes since the manifestation of environmental crises and in particular the realization of limits to growth in the 1970s. The island state of Nauru is a case in point where natural resource accounting demonstrated high dependency of its GDP on a dwindling natural capital (phosphate). Statistical standards for the assessment of natural resource stocks became common ground with the SEEA environmental accounting system. The existing standards are continuously being improved and extended; for instance, experimental statistics about the flows of ecosystem services are currently being developed and piloted in several countries.

Participatory techniques

Public participation has been advocated since the inception of the EIA process, but is in practice often better qualified as consultation. Arguments in favor of involvement of non-expert participants revolve around normative, substantive, and instrumental rationales (Glucker et al. 2013). Participatory techniques range from focus groups and citizen’s juries to more specific techniques with the purpose of eliciting specific knowledge from stakeholders, including participatory indicator development, participatory scenario development, and participatory technology appraisal (for examples in the context of dryland management, see Reed et al. 2011). One technique which has been used to make the voice of marginalized groups heard (stressing the normative rationale) is participatory mapping, for example, forest resource mapping by indigenous people to contest logging concessions.

Crowdsourcing

In crowdsourcing, sometimes also referred to as citizen science, public participation becomes the driving force of environmental assessment. It refers to (online) collaborative efforts either initiated by scientists or by the public themselves. The aims for crowdsourcing can differ, but it calls upon specific expertise or local knowledge as the only or most cost-effective way to generate or validate large datasets. Increasingly mobile apps are used for this purpose, such as in the EU Horizon project Interactive Soil Quality Assessment for Agricultural Productivity and Environmental Resilience (iSQAPER, www.isqaper-project.eu).

Applications

Environmental assessment techniques are being applied in multiple contexts, such as in EIA/SEA, environmental governance, disaster risk management, adaptation planning, environmental markets and compensation schemes, environmental monitoring, environmental accounting, scientific research, and knowledge management.

EIA/SEA

In the screening and scoping phases of EIA/SEA and other strategic planning decision support tools to assess the environmental impacts of activities, projects, plans, programs, and policies assessments seek to identify the most critical potential environmental effects and to predict
and evaluate which alternatives or options may mitigate such impacts. Environmental assessment in EIA and SEA is characterized by a streamlined application of techniques to fit windows of opportunity for influencing decisions. For example, EIA of large infrastructural development projects, such as dams, are in many countries required by law. The purpose of environmental assessment is to understand how construction of a reservoir might affect water provisioning and regulation downstream in the river basin, under both dry and wet conditions. The environmental assessment should take a broad view and, for example, offset hydropower generation against alternative sources of energy. The assessment could lead to alterations in the design, for example, by identifying a need to prevent sedimentation of the reservoir by afforestation of its catchment area. Ultimately, a profound and well-carried-out assessment could lead to project plans being shelved. Complex large-scale projects may not fail directly on environmental criteria, but can be particularly controversial when it comes to social criteria such as displacement, prospects for development of different social groups, or environmental impacts disproportionately borne by a specific group.

Environmental governance

Environmental assessment techniques directly inform decision-makers about the need to adjust policies or regulations, or enforcement officers about infringements. An example of the first is assessment of water availability for abstraction in catchments in the United Kingdom. Based on climate and hydrological monitoring information, so-called environmental flow indicators are calculated to inform a color-coded system of implications for water licensing. An example of the latter is the Brazilian satellite-based real-time system for detection of deforestation (DETER) which provides fortnightly high-resolution updates of deforestation hotspots, which has greatly facilitated law enforcement officers to act upon illegal logging and has received credit for reducing deforestation rates in the Amazon since the early 2000s.

Disaster risk management

Environmental assessment techniques are increasingly deployed in a range of early warning systems, varying from linked observational–prediction networks for natural hazards (e.g., the Japanese earthquake early warning system which issues warnings along with guidance on how to react in case of observed seismic activity, or more commonly, weather forecasts including severe weather alerts) to multifaceted systems that predict how dynamics in environmental and social systems may culminate in disasters. A much-lauded example of environmental assessment information in predicting disasters is the famine early warning system network (FEWSNET) which combines remotely sensed information on climate (e.g., droughts, vegetation greenness), agriculture production, prices, trade, nutrition, and other factors, together with an understanding of local livelihoods in order to predict areas at risk of food insecurity and famine. Starting in sub-Saharan Africa in the 1980s, the program has recently expanded its monitoring activities to nontraditional regions at risk of food insecurity such as Central America and Central Asia (see Figure 2).

Adaptation planning

Planning for uncertain future conditions such as climate change requires multiple environmental assessment data and a combination of risk assessment, scenario modeling, and mapping techniques to understand patterns of exposure.
and sensitivity in order to increase adaptive capacity. Assessment of exposure requires understanding the severity of threats such as sea level rise, heatwaves, droughts, and floods. At national level, countries are developing national adaptation plans with a view to increase preparedness for future climate change.

**Environmental markets and compensation schemes**

Environmental assessment techniques are used to devise and manage environmental markets where providers and buyers of environmental services need information on the effects of their interactions. Monitoring systems that allow for credible measurement, reporting, and verification (MRV) of activities are essential in underpinning such schemes. For example, new assessment techniques in carbon markets are being developed and need to be approved before they are allowed to enter the marketspace of schemes such as the Clean Development Mechanism or Verified Carbon Standard. Payments for other environmental services, such as watershed services (e.g., Green Water Credits) or enhanced ecological functioning (agri-environmental measures in the EU Common Agricultural Policy) have a similar need for compliance and effectiveness monitoring to prove that they are doing what they claim.

**Environmental monitoring**

Governments have agreed to monitor and report several indicators in the framework of United Nations conventions, either directly linked to commitments or for general monitoring of the state of the environment. Similarly, companies and organizations engage in sustainability
reporting in which the environmental impacts of operations are presented.

Environmental accounting

An arena of application which is rapidly gaining attention is ecosystem accounting, which deals with integrating complex biophysical data, tracking changes in ecosystems, and linking those changes to economic and other human activity (UNSTATS 2014). Starting with techniques such as natural resource accounting and environmentally extended input–output matrices, accounts of environmental flows and changes are being targeted.

Scientific research

For monitoring, environmental change data are often required over large spatial areas and long periods of time. Hence there is a need for long-term multisite data collection using the same or similar environmental assessment techniques. The datasets that are generated by such initiatives are important for scientific research. An example of this is the Long Term Ecological Research Network (LTER, www.lternet.edu) created by the National Science Foundation in 1980. Recognizing that long-term data across sites allows for continental-scale questions to be addressed, the LTER Network makes data collected by all LTER sites broadly accessible to other investigators.

Knowledge management

Increasingly, attention is also paid to the fact that environmental data needs of different stakeholders vary and that knowledge is fragmented across these actors. Knowledge networks need to be created to unlock this knowledge about the environment. Environmental data portals and hubs where users can collaboratively construct, combine, and discuss about data obtained from different assessment techniques can form a useful starting point for this purpose. Specific portals of this kind for environmental assessment include the International Institute of Applied System Analysis-initiated Geo-Wiki site (www.geo/wiki.org) where citizens are invited to contribute to address global land-cover issues, and the World Overview of Conservation Approaches and Technologies (WOCAT, www.wocat.net) dedicated to uniting efforts in knowledge management and decision support for upscaling sustainable land management among all stakeholders.

Challenges and outlook

Environmental assessment is hampered by a number of challenges including lack of data, tempo-spatial variations in environmental qualities, scale effects, and normative aspects. EIA judgments are often claimed to be subjective, based on a limited evidence base, or because they are done too superficially. This could in part be due to a dominance of expert judgment-based or other qualitative methods. However, even quantitative methods require judgments which may be subjective due to spatial variations and uncertainties in risk assessments.

Inherent uncertainties would imply that ideally, environmental assessment should be periodically repeated, at least for complex projects. When new evidence becomes available, this should then feed into the decision-making process to consider readjustments. In fact, SEA offers a framework for such more-embedded assessment procedures. However, this does raise the bar for demands on the systematic recording and reporting of considerations, and also of subjective
judgments, as the people involved in conducting the assessment may change over time.

The role of participation in different assessment procedures and techniques is also a challenging issue that continues to provoke debate. Engaging people in assessments is often easier said than done and the outcomes are not necessarily leading to more sustainable decisions in the long term and may give rise to dominant “not in my backyard” notions. In case of conflicting stakeholder interests, finding middle ground using transparent procedures may be illusive.

Nexus thinking gives rise to increasingly complex issues for which an increasing amount of data is required and, accordingly, an appropriate set of assessment techniques needs to be selected. Good systems knowledge is required to understand the linkages between different environmental processes and welfare outcomes. Roles of different stakeholders may need to be rethought as, for example, nonexperts will probably have an increasing role to play not only in the decision-making, but also in environmental monitoring. Operationalizing indicators for assessing planetary boundaries, and transforming these into national targets, may be one task for environmental assessment techniques and a simultaneous bottom-up process for building and managing knowledge of what approaches and strategies work where and why will be crucial to meet human needs in a changing environment.

Environmental certification and eco-labeling

Tad Mutersbaugh  
University of Kentucky, USA

Certification networks are fundamentally concerned with the management of extrinsic qualities, that is to say, qualities which are not detectable in the final product but whose existence is important to the buyer. To give an example, organic products provide an exemplar of a certified, extrinsic product: although it may be possible for a laboratory to detect trace quantities of synthetic chemicals banned in organic food production, this cannot tell the consumer whether the organic product was produced in fields where the integrity of soil and water were protected and biodiversity nurtured, whether organic seed or rootstock was utilized, or indeed whether any banned chemicals were used since trace chemicals found during testing might be the result of contamination by overspray from a neighboring “conventional” field. Under these conditions of uncertainty, certification offers a package of field, packing-shed, transport, and storage inspections that trace an organic product from point of origin to consumption, providing an “audit trail” of the “chain of custody” that serves to justify the issuance of an organic label that provides a guarantee of product integrity.

Even a brief inspection of the number and types of “green” environmental and ethical certifications will show that this constitutes a rapidly expanding product category. For instance, the eco-label index (www.ecolabelindex.com) provides a listing of 458 certified products that include consumer-oriented consumption items such as bird-friendly® coffee, wildcrafted and organic products from shrimp and timber, carbon (sequestered), and industry-oriented services such as waste management, building codes, mining protocols, product lifecycle assessment, water management, and ecotourism. However, even this extensive “eco-label” product list excludes environmental products such as GIs (geographical indicators, e.g., wine, cheese, and other terroir products), ISO 14000 environmental management processes, and sanitary (e.g., phytosanitary, bioterror) certifications.

Origins and rationales of certification

Although certification has been important for commodities such as agricultural seed since the early twentieth century, the modern certification framework came into being with the establishment of ISO (the International Organization for Standardization) after World War II. This 1940s institutionalization took on initial tasks of governing standards such as the length of a meter and introduced the contemporary relationship between standards, certifications and accreditation. In these early years standards adoption was for the most negotiated and democratic, and featured limited state involvement, voluntary agreements, and few third-party inspections. Since the early 1990s, however, ISO has grown to include 165 member bodies such as US ANSI (US American National Standards Institute), and now takes a rather more activist approach, enforcing standards compliance via the TBT (technical barrier to trade) agreement, which requires...
World Trade Organization (WTO) signatory nations to comply with global standards.

Within this ISO context, one of the most important standards is the 17065 certification standard “Conformity assessment – Requirements for bodies certifying products, processes and services.” By establishing this standard, ISO has become the de facto governing body for global certification practices, since any organization that sells a globally traded, certified product (such as certified organic coffee) is required to undergo a lengthy (and costly) audit to demonstrate that their inspections and accreditation practices comply with ISO norms. Without this ISO audit, an organization is unable to process certified goods for international markets due to the TBT restrictions noted above. These ISO certification practices are rigorous and require the establishment of stable links between certifiers, standards makers, and accreditors as noted in Figure 2.

This rapid expansion, wide purview, and emergent complexity of ISO-inspired certification have prompted a wide range of research focusing on certification’s positive and negative consequences. These practices make the certification process much more transparent and the application of standards more robust from the standpoint of auditors (e.g., the US Department of Agriculture, which audits US-destined organic certifications). However, ISO-based practices also increase certification costs and make it difficult to implement and opaque from a producer standpoint, which results in the exclusion of many poorer producers such as small farmers (Mutersbaugh 2004). Below the entry assesses three aspects of certification research as noted in Figure 1: (1) the global certification economy, (2) the impact of certification on environments and social movements, and (3) the effect of certification on the everyday experiences of certified product producers and inspectors.

Certification forms a global industry

Certification’s global industry is represented in the diagram by the ISO emblem and the combined images – found on ISO World Standard’s Day (WSD) posters – that depict the effects of standards on labor and the environment. These images point toward an understanding of certification as a global network comprised of transnational institutions, certifiers, certified producers, consumers of certified goods, in essence a global industry of certifications, standards-making, standards compliance, and audits that involves – for our particular focus on environmental certifications – hundreds of thousands of “nature workers” that include farmers, foresters, fishers, and craftspeople who labor to comply with “environmental” standards and the tens of thousands of personnel working in a burgeoning global certification service sector involving certification agencies, nongovernmental organizations (NGOs), national regulatory boards, and ISO working groups.

Certification networks are, then, rapidly expanding to form a global network that comprises a set of practices that shape an everyday, lived “certification” experience, which in turn affects people, environments, and economies. Nonetheless, place still matters within this global setting: the processes of the “harmonization,” through which all global standards are rewritten to conform to a single standard, and “routinization,” through which all certification practices must also conform to a single standard, both accompany network expansion. However, as examples in this entry will demonstrate, place matters because local social movements, unions, and governments have played a role in how these norms and standards are enacted and linked to other institutions. In some cases concerned parties have challenged, modified, and resisted...
the application of ISO-style certification standards and practices. In others, ISO certification mechanisms have been replaced by alternative, locally controlled forms of certification (Schewe 2011; Kimura 2012; Gonzalez and Nigh 2005).

As a result of these limits and challenges, the global certification network is uneven, with some places and practices strongly affected and others less so. Current research on global certification networks considers three questions. The first question asks, “what are the parameters of this global certification framework, and what should be excluded and included from analysis?” An article on the “NGO-industrial complex” noted a rapid expansion in those forms of “private governance” in which products were increasingly subject to varying forms of certification (Gereffi 2001).

- First party intra-firm assessments, such as factory quality control or academic teaching evaluations.
- Second party verification arrangements (e.g., Starbucks practices) in which an outside auditor verifies a product’s compliance with firm-specified standards (that is, not set by an independent standards board).

Figure 1 Three research perspectives on certification geographies.
Third party or “Type 1” certification, which is defined as a “tripartite” relationship consisting of three components: an independent standards board, a certifying agency that is legally separate from both producers and the standards board, and an accreditation process to assure that certifiers are qualified to assess quality.

Fourth party governmental regulation of firm practices (e.g., meat-packer audits by the US Department of Agriculture).

Here we are principally concerned with 3rd party certification, which has become the “gold standard” or preferred, most rigorous form of certification (i.e., short of 4th party governmental regulation). Recent research on 3rd party certification has both examined the tripartite relations between aspect of 3rd party certification, such as audits and inspections, and also expanded the focus to examine the wider “metrology” and “audit culture” or set of sociotechnical practices and discursive understandings within which certification is based. These studies have focused also on the certification governance frameworks, for example, multistakeholder initiatives, sustainability networks, or global production networks (Freidberg 2010; Ponte and Cheyns 2013; Loconto and Busch 2010; Baird and Quastel 2011).

The shift to view certification within a governance framework has led scholars to consider an expanded number of “sites” that support certification practices. Figure 2 provides an overview of some of sites that might nominally
be included in an expanded network for certifying a “simple” cup of organic coffee. In this diagram, the tripartite relation is depicted in the center, but the diagram also includes a very large number of financial and labor subsidies from other organizations upon which certification is economically dependent. For example, certification is supported by Mexican government agencies, such as the Conservation and Forestry and the Agricultural Ministries that provide direct governmental subsidies for forest management and export promotion and also manage foreign subsidies such as those linked to REDD+ (reducing emission from deforestation and forest degradation) reforestation, and by national and transnational banks that support a coffee producer credit union, micro-lending, and electronic funds transfers.

Several recent studies have assessed the role of governmental agencies in the “public promotion of private [neoliberal] governance.” In many cases, such as the Mexican case depicted in Figure 2, governmental support has subsidized and supported certified markets; in a few instances, governments have become directly involved in fostering public–private certification initiatives – and the Chinese state has gone so far as to initiate “state-led” NGOs, “capturing” certification institutions to better promote exports (Buckingham and Jepson 2013; Foley and Hebert 2013; Jaffee 2012).

A second question on global certification networks inquires into the origins of globalized certification, asking “does the rapid expansion in certification mechanisms reflect a specific, contemporary conjuncture of global capitalism?” Geographers in particular, have explored the idea that certification reflects a reconfiguration in global production networks, commodity chains, or rent relations within the context of existing neocolonial relations (Baird and Quastel 2011; Loconto and Busch 2010).

A third and related question seeks to ascertain which theoretical perspectives will best explain the social and economic dynamics within globalized certification. Certification scholars have applied a number of theoretical perspectives concerned to understand the “certification and auditing” relations depicted on the lower left of Figure 2, asking how private and public forms of governance operate to shape legitimacy, autonomy, and democracy, how the social and economic relations depicted in Figure 2 are best assessed and understood, how embodied practices such as inspections are experienced, and how engagement rules and audit cultures (Ponte and Cheyns 2013; Buckingham and Jepson 2013; Konefal and Hatanaka 2011).

Certification shapes environments and social movements

The lower right compartment of Figure 1 highlights another arena of certification studies, namely, the role of certification practices in shaping environments and social movements. Recent research into the environmental effects of certification has sought to determine: (i) the specifics of existing environmental standards and certification frameworks, for instance, what agricultural inputs are permitted by organic farming standards, and what practices are required by organic farming inspections; (ii) the geographic distribution of environmental standards – that is to say, the location of the fields, forests, and aquatic environments that are subject to certification; and (iii) whether standards and certification practices have the desired impact on the environmental and production activities that they are designed to regulate.

For example, the Marine Stewardship Council (MSC) was analyzed using a political economy perspective, which found limited evidence that MSC certification brings environmental
benefits, and rather more evidence of geographical unevenness with few “sustainable fisheries” located in the Global South, suggesting that MSC certification produces a “sustainable fish market,” which is to say an opportunity to market fish that are certified as “sustainable” rather than improve the ecological sustainability of fish stocks in the sea (Ponte and Cheyns 2013; Eden and Bear 2010).

In many cases the environmental practices associated with certified environmental products provide uncertain benefits, and in some cases may damage the environment. Reasons for the mismatch between standards and ecological realities may include inadequate or politicized standards, and a centralization of standards-making by boards located in sites – such as the National Organic Program in Washington, DC – that introduces a social distance and complicates communication between standards boards and producers such as farmers or fishers located in other countries. In either case this “environmental distance” may result in detrimental effects: for instance, environmental inspectors may suggest practices, such as the planting of exotic erosion control species, that address the environmental concerns of soil erosion and yet introduce another ecological problem by introducing nonnative species; or farmers themselves may prefer ecologically sound practices that allow for greater productivity yet contradict accepted environmental standards, such as reducing the number of shade trees or applying night soil (Elder, Zerriffi, and Le Billon 2013; Gonzalez and Nigh 2005).

In addition to shaping environments, certification also shapes the character of environmental and social justice movements. As social movement NGOs such as the organic agriculture movement or antisweatshop campaigns have created certified standards in a bid to make these practices legible and consistent, certification practices have, during the same period, become subject to new pressures. Perhaps the most important overall has been changes to ISO certification norms, which has in recent years declared the practice of writing standards to be in conflict with standards certification. As a result, NGOs have had to eliminate standards-making activities or stop certification activities. A second source of pressure has come from states, which have in some cases, such as organic agriculture, carbon sequestration, and sustainable forestry, exerted at least partial state control over NGOs involved in setting standards and certifying these activities. A third source of pressure has come from industries that produce certified products. In some cases industry-sponsored certifications have been created to compete with NGO-sponsored standards, whereas in other cases industry actors have sought to alter certification standards to weaken standards to make them more amenable to industry practices. Taken together, these pressures have had the effect of reducing the ability of social movements to shape standards (Mutersbaugh 2004; Gereffi 2001; Jaffee 2012; Buckingham and Jepson 2013).

Within certified organizations, certification requires changes to the organizational configuration of participating unions, families, and communities. For NGOs involved in making ethical standards, ISO specifications require a separation between standards-making and certification activities, for instance, Fairtrade International was forced to create a new “FLO-CERT” organization to handle certification. For producer organizations such as farmers unions, ISO norms require the hiring of technical staff to supply certification services such as pre-inspections, extension officer training, and farmer training and accreditation exams (each organic farmer must be accredited according to ISO 17061 guidelines).
Within communities, the complexities of certified production (see Figure 2) shape social relations. Negative effects include increased economic and organizational costs that cause poorer certified organic farmers to quit certifying (Méndez et al. 2010). Positive effects include new skilled labor opportunities such as community inspection jobs, stronger unions due to increased income from premiums and higher quality coffee, and procedures that allow women farmers to receive their coffee and subsidies payments via direct deposit to personal bank accounts, thereby bypassing male-dominated unions (Elder, Zerriffi, and Le Billon 2013; Lyon, Bezaury, and Mutersbaugh 2010; Mutersbaugh 2004).

Certification as an everyday experience

The image of a field inspection (Figure 1, panel 3) emphasizes that certification alters the social relations of production in the field by reworking the relations of inspectability and surveillance. This has been described by coffee producers as “ecological neocolonialism” because under certified international standards, the decisions about what standards such as organic, fairtrade, or bird-friendly (to pick a few of many possible examples) mean, what they entail in terms of production norms, are set by multiple tiers of Global Northern institutions including ISO – which sets certification and accreditation norms – and standards bodies such as, respectively for our examples, the USDA National Organic Program, Fairtrade International, or the Smithsonian Migratory Bird Council. Producers in the Global South are required to comply with these standards without having much say in crucial aspects of standards and certification, including, for instance, how standards are formulated, what is required to meet the standards, how certifications are performed and compliance determined, how much certifications cost, how producers and producer organizations are audited, and how accreditation is performed among other aspects. In this sense, then, it is neocolonial in the sense that certification reproduces the pattern whereby Global Southern producers are required to conform to the dictates of Global Northern institutions, and ecological in that these standards shape human practices that in turn affect ecological relations in fields, forests, and fisheries.

Despite strong producer sentiments regarding ecological neocolonialism and the attendant dissatisfaction with the top-down and opaque relations between standards makers, certifying agencies, and producers, the social relationships and experiences of producers in fields, fisheries, and forests are an understudied aspect of global certification. Research that has been undertaken from a producer standpoint paints a picture of adversarial inspections processes in which trained, accredited inspectors in the field, survey in hand, require producers to answer questions regarding their farming practices, even when the inspector already knows the answer. In addition, under ISO certification norms, inspectors are not supposed to inform the inspected parties regarding how to correct errors that they uncover, thereby creating an additional source of frustration that contributes to the sense of frustration and disenfranchisement felt by inspected parties (the producers). However, it is important to note that not all certifications are alike: to take the case of organic agriculture, although the recent history of certification has led to a loss of the peer and participatory character of earlier forms of organic certification, such as those undertaken by the Organic Crop Improvement Association (which was displaced by the USDA National Organic Program), some forms of agricultural certification such as the Demeter
ENVIRONMENTAL CERTIFICATION AND ECO-LABELING

biodynamic approach still offer greater participatory engagement and higher levels of producer satisfaction (Schewe 2011; Mutersbaugh 2004; Gonzalez and Nigh 2005).

This everyday experience of certification as adversarial and imposed is also in part a consequence of the style of environmental certifications in the Global South. In order to defray high certification costs that arise from the expense of visiting very small and remote plots, producers generally undertake “group” certifications rather than certify each farmer individually. The groups that are formed typically undertake “internal” inspections in which persons within the producer union inspect each farm in preparation for “external” inspections, performed by an inspector appointed by the certifying agency, that inspect a randomly selected sample of 10–20% of plots. This leads to significant cost savings, but exposes producers to decertification since the failure of a few group members to comply with certification standards can, in some instances, result in a loss of certification for members who do comply. It also creates a situation in which some group members are subject to peer inspections by “farmer inspectors.” This can introduce significant dissent if a group member is “failed” by the group’s farmer inspector, and can also introduce new forms of identity and social status into groups. In this fashion, the specifics of certification practice, constrained both by ISO dictates and economic realities, can introduce significant tensions that call into question the notion that certification will in each case necessarily introduce greater transparency and accountability (Klooster 2010; Mutersbaugh 2004).

As Figure 2 demonstrates, as certified production networks have grown, they have become increasingly linked to supporting relationships such as financialization, state subsidies, and commercial product differentiation efforts. This linkage of course shapes the experience of certification for producers who find it difficult to determine which requirements and demands come from certifiers and which from other sources including NGOs, inspectors, financiers, state agencies, or companies seeking to commercialize the product in niche markets (Dolan 2010; Wilson and Curnow 2013; Marston 2013).

Conclusion

From the standpoint of those who are likely to read this, the question “what is certification?” might prompt them to hold up a cup of certified organic coffee or bar of fairtrade chocolate. The farmer, however, might just as well point out that she is the consumer of certification and accreditation services, for which she must pay each and every year, a certified product inspector might point to the accreditations for which they must endure training each year, and the coffee roaster or chocolatier might signal the product label (e.g., certified organic, bird-friendly) embossed on the bag or bar. Each, as we have seen, is correct. Although these multiple meanings of consumption and production may seem to confuse any tidy schema, they also signal a key point regarding the broader certification network. Insofar as “final” consumers in cafés and shops, NGOs or governmental agencies seek to use certification as a tool to promote social and environmental goals, each must also be aware of the complex geographies of global certification that contribute to uncertain and often contradictory outcomes. As the global certification network expands to include new products, people, places, and, of course, subsidies and financing, it will also become increasingly integral to state agencies, NGOs, unions, and confederations. Although we do not yet know how these expanded networks will shape our
future understandings of environmental conservation and social action, current research shows notable effects upon environments and society, and the importance of continued research (Guthman 2007; Goodman 2010; Jaffee 2012; Wilson and Curnow 2013; Naylor 2014; Freidberg 2010; Konefal and Hatanaka 2011).

ENVIRONMENTAL CERTIFICATION AND ECO-LABELING

Environmental change results from natural processes such as droughts, floods, and wildfires, and from human activities. Land transformation is the most common form of human-influenced environmental change. Humans have been transforming the Earth’s land surface since ancient times. This started with the use of fire to open up natural savannas and grasslands for hunting and early forms of agriculture. There is evidence that, as early as 8000 BP, human activities began to transform the landscapes of Europe and Asia with settlements and agriculture, albeit on a local scale. From 1500 onward, the European colonization of the New World, Africa, and Australia resulted in the clearing of vast areas of forest and woodlands for timber, cultivation, and livestock pastures. This process accelerated after the Industrial Revolution with the global area of cropland increasing fivefold and the land area used for grazing livestock increasing tenfold over the last three centuries (Klein Goldewijk et al. 2011). Urbanization is a more recent driver of land transformation. While urbanization currently occupies less than 5% of the global land area, the demand of urban areas for food, building material, products, and water has severely impacted on environments elsewhere.

Environmental change also involves the physical and/or chemical change of soils, water, and the atmosphere resulting from human activities. Air and water pollution came to prominence in the Industrial Revolution, with the unregulated burning of coal and the discharge of waste polluting the atmosphere and waterways of Britain and Western Europe. More recently, the pioneering work of Rachel Carson’s Silent Spring (1962) exposed the environmental contamination caused by the pesticide DDT, raising public awareness of the environmental cost of technological progress and the need for regulation, and setting the stage for the modern environmental movement. The rapid rise in anthropogenic greenhouse gases such as carbon dioxide (CO₂) and methane (CH₄) since the Industrial Revolution, and especially since World War II, has resulted in the warming of the atmosphere and oceans, the melting of snow and ice, and a rise in sea levels. Each of the decades since the 1980s has been successively warmer at the Earth’s surface than any preceding decades since 1850. This acceleration in global warming is a pervasive form of environmental change, and represents a major challenge for humanity and our ability to survive on the planet in the long term.

Since the 1960s, scientists and policymakers have struggled to respond to environmental change, relying mostly on solutions designed by technical experts and implemented using top-down control. While these approaches proved appropriate to simple environmental problems (e.g., point-source pollution), environmental change over time has become more complex (e.g., diffuse pollution, climate change),
triggering a paradigm shift in the way environmental management is approached (Holling and Gunderson 2002). It is now recognized that top-down technical solutions are often inadequate and that a social-ecological systems approach, which recognizes the social and institutional dimensions shaping ecosystem processes and dynamics, is required (Folke et al. 2005).

Within this approach, the concept of social learning has gained prominence. Learning can be defined as a change in behavior or attitude due to critical reflection. Social learning is therefore understood as a change in the understanding of individuals that becomes accepted as a wider community understanding through social interactions (Reed et al. 2010). Social learning is a concept that initially emerged from psychology and organizational theory, which emphasized the context-dependent nature of knowledge (Bandura 1977; Argyris and Schön 1978). The concept has gained traction in environmental management since the mid-2000s, with a substantial effort devoted to understanding the way in which social learning builds social-ecological resilience and adaptive capacity.

Social learning (in the environmental management literature) can be defined as the process of learning from and of responding to environmental experience. It is not the domain of a particular group of experts or stakeholders, but of all stakeholders and all institutions at all scales. It involves learning not only about the environmental or natural resource problem at hand, but also about one another in a social or relational sense, based on the premise that knowledge is heavily context-dependent. The involvement of all stakeholders and all types of knowledge thus increases both the efficiency and legitimacy of the solution. Stakeholder collaboration, and the recognition of different types of knowledge (e.g., expert, local, indigenous), are thus the critical prerequisites for social learning to occur. Institutions (legal, organizational, cultural, socioeconomic) that support social learning are also crucial.

Social learning is understood to encompass learning at multiple levels (individual, management, social network, organizational) (Berkhout, Hertin, and Gann 2006). It is an ongoing dynamic process, which may emerge in a locally generated or self-organized form triggered by crisis, or from part of an active adaptive comanagement strategy. It can occur across time scales, whereby instrumental single-loop learning occurs within short to medium time frames, and more radical double-loop learning occurs over longer time scales. Instrumental single-loop learning only informs and changes the most immediate technical operations, while deeper learning may change governance procedures at the organizational level, and even overarching values and norms at the policy level (Argyris 1976).

The conceptual framework of multilevel social learning for natural resource and environmental management is captured in Figure 1 (Pahl-Wostl et al. 2007). Formal and informal multiparty collaboration leads to social learning which is influenced by the socioecological context, and produces outcomes that may lead to changes in that context and thus to a cyclic and iterative process of change. These arenas of collaboration are referred to as “communities of practice.”

Early proponents claimed that facilitating social learning in environmental management would undoubtedly have positive effects on the outcomes. However, experimentation has revealed that social learning also comes with costs, risks, and pitfalls. For example, the high levels of sustained stakeholder participation required for social learning can result in stakeholder fatigue or burnout. In cases where social learning processes have failed to reconcile highly contested
environmental values and worldviews, participants have been left feeling alienated. Social learning will therefore not happen automatically. A number of preconditions need to be met, including an active civil society, receptive and willing participants with a capacity to learn, and available platforms for interaction. It is also important to note that social learning cannot be guaranteed even if these preconditions are met. This is because the factors affecting the transferal of lessons upward in organizational and policy hierarchies are often far beyond the control of those who facilitate social learning. Factors such as broader constitutional rules, governance settings and political ideologies may inhibit the effective upward transfer of important lessons (Adger et al. 2009). Finally, while social learning has been proven to assist in the solution of clear-cut environmental problems, it has yet to solve more intractable problems such as climate adaptation, where there is little agreement on both the causes and the solution.

As a concept, social learning also presents challenges. It has been used vaguely to refer to both individual and group learning, or interchangeably with stakeholder participation. While progress has been made in refining the concept and separating the social learning concept from the stakeholder participation concept, there also remains a lack of parameters to measure social learning. Furthermore, while there has been some important theoretical and single case study work in this domain, there has been very little systematic comparative work on how social learning can effectively respond to increasing inequity, complexity, and change.

Social learning is also slow, whereas environmental change can be both slow and rapid, requiring rapid assessment and implementation of the lessons of new insights. As a consequence, research and practice have scaled up the focus of analysis from the design of learning processes for individuals and groups to multiscale governance regimes that can facilitate social learning, with new insights from the fields of political geography, sociology, public policy, institutional economics, and public administration (Morrison 2014). Further development of systematic work in this domain is focusing on the role and tools of the state, and other “metagovernors,” in organizing both the ecosystem-level conditions for social learning and the higher-level enabling fiscal, administrative, and democratic preconditions.

Environmental citizenship has gained increasing prominence in policy-making processes and academic work over the last two decades, as a means of promoting the goals of sustainability and environmental protection, and integrating environmental concerns into political theory and modes of political engagement. However, there is no clear definition of the term; rather it aggregates the two concepts of “environment” and “citizenship,” both highly contested in their own right. A key element of citizenship is the sense of belonging to a particular community or geographically defined area (such as a city or nation-state), with implications for how citizens understand and perform their own identities. The notion of environmental citizenship in particular raises questions about where the bounds of this community or environment of belonging begin and end, as definitions of the environment multiply, are contested, and challenge assumptions about the appropriate scale of analysis and action.

Citizenship entails a conditional set of rights (freedom of speech, for example) and obligations (to keep abreast of political developments or to protect the freedoms of others, for instance) as part of this community. In the case of environmental citizenship, the primary focus is on regulating and reducing the environmental impacts of individual actions, however defined. Consequently, definitions of environmental citizenship tend to emphasize obligations over rights, challenge the geographical definition of the community to which a citizen belongs, and commonly require the cultivation of particular skills or virtues, such as scientific literacy. Environmental citizenship is an idea associated with both conservative and radical political projects, from behavior change programs which aim to tweak current consumption habits, to experiments in making alternative communities and ways of living. Debates over the proper definition of environmental citizenship and how to inculcate its associated virtues within particular populations have become a significant element in environmental politics and policy, particularly in Western democracies. Furthermore, environmental citizenship has been a key site of struggle and contestation through which broader issues of political engagement and process have played out, and where visions of the future have been co-constructed.
ENVIRONMENTAL CITIZENSHIP

(Mitchell 2009). In the twenty-first century, early developments include: the inception of environmental virtues and responsibilities as a part of citizenship; the emergence of transnational or global forms of citizenship; increasing recognition of the plurality and diversity of citizens; and changes in the categories of who or what might be considered citizens.

Many of the concepts and commitments associated with environmental citizenship have a long history, stretching back to the conservation movements of the late nineteenth century – from George Perkins Marsh to John Muir and the Sierra Club – and finding clear political expression in the environmentalism of the 1960s onwards. Pro-environmental virtues and responsibilities were articulated first by these popular movements and advocates, through treatise writing, through the creation of voluntary associations and charities, through social movements, and through protests and opposition to environmental harms. Such virtues and responsibilities included a general desire to live in harmony with the natural environment, the conservation of “natural” landscapes or endangered species, and concerns about the depletion of natural resources.

The emergence of environmental citizenship as an important concept in environmental policy, politics, and scholarship is closely linked to the discourse of sustainable development. From the early 1980s both concepts were debated at an international level, gradually filtering into national policies as well as the discourse of nongovernmental organizations (NGOs), civil society groups, and businesses. As a consequence, environmental citizenship has become closely allied with the goal of sustainable development to marry the apparently conflicting aims of human development and environmental protection, and has also been central to much academic analysis.

Changing definitions and understandings of environmental citizenship are also linked to changing expectations about citizen participation and engagement, which have been particularly marked in the context of environmental politics and decision-making, in the Global South as well as in the North. Initially governments saw environmental policy-making as a primarily technical business and thus envisaged little role for citizens to play, beyond upholding the principles expected in a representative democracy. However, repeated local planning and land-use conflicts, protests about government inaction on environmental issues like climate change, and knowledge controversies around environmental policies have all been interpreted by governance actors and social scientists as indicators of the need for greater involvement of lay citizens in environmental decision-making.

Methods for achieving this encompass opinion polling, citizen science – typically scientific projects involving lay people in data collection or analysis, for example species counts – and deliberative processes – decision-making processes based on giving participants time to learn about the issues under discussion and the points of view of others in order to reach an informed decision – amongst others. Such methods were typically justified as leading to better decisions through the inclusion of different (local) knowledges and values, helping to improve the legitimacy of policy decisions and processes, and making environmental policy more democratic in an era when science and environment-based decisions regularly have important consequences for citizens’ everyday lives (Fiorino 1990). These methods of citizen engagement have gradually become institutionalized, especially in the West, allowing for their broad use in different policy- and decision-making contexts.
Creating environmental citizens and consumers

Geographers and others have been interested in investigating how environmental citizens might be created. This was an important principle in Tim O’Riordan’s seminal book *Environmentalism* (1976), where he draws his narrative to a close with a hopeful passage about the potential for a better educated and more environmentally aware citizenry, which may put into practice many of the values he describes. More recently such sentiments have been strongly echoed in the science communication and education literatures, which emphasize the need to inform citizens and have increasingly adopted the language of behavior change. With this forming a significant part of government environmental policies, the techniques developed to promote behavior and attitude change have become increasingly sophisticated. Conventional social marketing campaigns have been replaced, for example, by the promotion of community projects, from Transition Town groups to local energy initiatives, as a behavior change and environmental citizenship tool. Likewise the concept of “nudge,” which aims to subtly influence citizens’ decision-making contexts and thus promote certain forms of behavior over others, has gained popularity in policy-making in the United Kingdom, the United States, and beyond.

In debates about the responsibilities of environmental citizens, tensions between so-called deep green and more consumerist or market-oriented models of environmental citizenship are played out, in politics and in academic work. It has been argued by many that mainstream practices of environmental citizenship, as promoted by many governments, NGOs, and businesses, tend to cast citizens in the role of consumers. Such campaigns, policies, and initiatives tend to focus on information giving – to make sure that consumers make informed choices – and price changes to alter consumer behavior in order to reduce environmental harms.

However, it has been strongly argued in many areas of the social sciences that this “rational actor” model of human behavior is flawed, and that there are many other social, emotional, and contextual influences on the consumption choices people make. Furthermore, imagining environmental citizens as consumers is seen as potentially limiting, as it constrains the responsible actions of environmental citizens to activities around their consumption, excluding activities which challenge or operate outside of conventional modes of consumption, such as protests or attempts to build low-consumption communities around housing, energy, or food cooperatives. It has also been suggested that this citizen-consumer model takes for granted the market-based logic of much policy-making and business activity, despite the environmental harms this mentality potentially creates – from negative externalities such as air pollution to the idea that societies may become locked into an economic model dependent on the continual growth of consumption.

The political scientist Andrew Dobson (2003) argues that a model of ecological citizenship is potentially more productive than one of environmental citizenship, which he feels has become too closely associated with market-based mechanisms for pro-environmental behavior change. Dobson sees ecological citizenship as representing a greater ideological challenge to the liberal state, by emphasizing responsibilities and virtues, sometimes in opposition to market logics. The political scientist John Barry (2006) has suggested the notion of sustainability citizenship as a useful alternative to environmental citizenship. For Barry, sustainability citizenship challenges consumption-based definitions of environmental citizenship by requiring an engagement with...
the underlying structures driving environmental degradation and injustice, rather than inculcating pro-environmental behaviors. Like many other academics in this field, both are keen to point out the political economies and infrastructures underlying apparently unsustainable or un-environmentally friendly behaviors. In doing this, they suggest that initiatives which fail to challenge these underlying structures, such as those focused on consumption or market-based mechanisms, will be unsuccessful or even potentially damaging.

Though many civil society groups and NGOs have to an extent bought into market or consumer-oriented models of environmental citizenship, some have also sought to challenge this model. Behavior change policies in particular seek to control citizen behaviors sometimes at the micro-level, for example through surveillance by smart technologies or attempting to more subtly influence attitudes and values. These policies are potentially constraining for the more radically minded civil society actors, such as those opting to live in eco-homes or even alternative communities or those who are part of activist and social movements, for whom marketing campaigns to get them to turn the heating down a few degrees or to take fewer car journeys rather miss the point. Furthermore, the behaviors of these more alternative environmental citizens may actively contradict some of the aims of mainstream behavior change policies, such as getting people to upgrade to more efficient and therefore newer appliances. Or more alternative environmental citizens may be held back by existing infrastructures, for example for public transport provision or the capacity for electricity grids and energy technologies to support personal electricity generation, in their attempts to build more sustainable lifestyles.

In contrast to the rational-actor model of environmental citizenship assumed by most governments, environmental citizenship could also be thought of as an ethic of care, evoking an emotional as well as rationally informed concern for and connectedness to distant others. These attitudes again challenge some of the assumptions underlying mainstream government policies in this area, yet they can potentially encompass a larger spectrum of pro-environmental actions, from mundane everyday practices such as taking shorter showers to more radical experiments in alternative living. Academics too have become increasingly interested in looking at how everyday actions and practices are linked to societal and individual attitudes to environmental protection, often concluding that household technologies and the way people learn to use them are equally as important as pro-environmental beliefs and commitments in the development of more sustainable ways of living (e.g., Shove 2010).

Scales of environmental citizenship

Geographers have long sought to challenge the assumption that the nation-state is the only or primary site relevant to questions of citizenship. As processes of globalization became increasingly apparent through the 1980s and 1990s, the idea that citizens’ rights and obligations need only apply at a country level became increasingly untenable. Individual actions, from our consumption choices to use of resources in the home, and political allegiances unavoidably impact on distant citizens of other countries and continents, and increasingly on environments and environmental processes apparently unconnected to the initial actions. It has been recognized that environmental issues do not respect national boundaries, and are often bound up in broader transnational processes associated with globalization, such as international travel or lengthy supply chains for consumer goods (e.g., Dobson 2003).
This more transnational or global view of citizenship has been characterized as *cosmopolitan citizenship*, because of the implied sense of connectedness to and responsibility for geographically distant others. Furthermore, cosmopolitan citizenship entails the conferral of political authority and administrative capacity away from the nation-state to other scales of governance and organization. On the one hand, environmental policy-making has appeared to increasingly play out on a global or transnational level – with a predefined constituency of global or transnational citizens – with faith placed in international negotiations and standard-setting by international bodies. On the other hand, in response to the apparent failures of international environmental governance, there have also been moves to promote and study what are seen as more pragmatic and manageable forms of environmental governance at continental, regional, city, and community levels, engaging with different communities of citizens. Some scholars have also noted the increasing importance of virtual networks, particularly for environmental activism and protest, which tend to be fluid and cannot be confined to conventional understandings of territory and scale.

Some have suggested that the multiscaled nature of environmental citizenship means that it can no longer be based on the exclusive membership of a particular territorial community but must be based rather on general rules and principles which are applicable to diverse settings (Held 2010). This leaves us in uncharted political and ideological territory, and attempts to formulate a political and academic project of cosmopolitanism have faced robust criticism. Despite occasional successes in international environmental negotiations and in the creation of international institutions such as the IPCC (the Intergovernmental Panel on Climate Change) and more recently the IPBES (the Intergovernmental Panel on Biodiversity and Ecosystem Services), attempts to create a global environmental constitution or bill of rights and responsibilities have thus far been unsuccessful. The challenge is to create a meaningful sense of solidarity and responsibility at multiple scales, which engages with citizens’ actual experiences of their environments and of environmental problems. Whilst the idea of cosmopolitanism brings attention to the multiple scales and networks beyond the nation-state which are important to understanding environmental politics and citizenship, its challenge to the sovereignty of the nation-state might also have the effect of appearing to support so-called *neoliberal* policies and initiatives. Cosmopolitan expressions of citizenship rights and responsibilities have thus been criticized for appearing to tacitly support the deliberate attempt by many governments to shift the burden of responsibility for environmental ills onto individuals, through the behavior change agenda.

It is not only the spatial scales of environmental citizenship that are being challenged through academic work, environmental politics, and emerging environmental problems, but also its temporal scales. The discourse of the Anthropocene, which claims that human impact on the environment has become so marked that it represents a new geologic epoch, also has ramifications for how we understand environmental citizenship. First, the Anthropocene represents a blurring between the categories of the human and the natural, the environmental and the political, which are conventionally assumed to be separate domains in definitions of environmental citizenship. This has the effect of potentially bringing the environment into the political sphere in a more radical way than simply promoting pro-environmental behaviors. By casting human life in the context of geological time, the concept of the Anthropocene also challenges the temporalities usually associated
with environmental citizenship, concerning everyday decisions and practices, electoral time spans, the event horizons of particular protests and movements, or the span of the individual life. The geographer Kathryn Yusoff asserts the need, in the wake of the Anthropocene, to engage not only with the biopolitics or biology of human life but also with the geopolitics or geology of life (Yusoff 2013), from renewed social scientific interest in the formation and effects of fossil fuels and other fossilized minerals, to a consideration of the fossil residues contemporary human societies will leave behind. Following this argument, perhaps it is more appropriate to talk of geologic citizenship rather than environmental citizenship, evoking responsibilities to and the rights of temporally distant others.

Engaging with environmental citizens

Modes of engaging with and including environmental citizens in decision-making are also constantly evolving. Following the institutionalization of deliberative modes of public participation in environmental policy, they have increasingly become the subject of academic critique (Chilvers 2009). Some scholars have been concerned with the increasingly powerful role played by the mediators or facilitators of deliberative processes, who are able to design and control modes of citizen engagement and speak on behalf of citizens in policy-making contexts. Furthermore, it has been argued that the way environmental problems are framed strongly influences the kinds of discussions that are possible during deliberative processes, and even which citizens are permitted to be involved in the first place. For example, if climate change is framed as a purely technical problem of regulating the level of greenhouse gases in the atmosphere to avoid more than 2°C warming at a global level, then only those with technical expertise related to climate and to reducing greenhouse gas emissions can be involved in deliberating over policy solutions. If it is framed as an issue largely requiring dramatic behavior change to reduce heavy emitting behaviors then lay citizens must be involved in deliberations over solutions, but they are only permitted to contribute insights on the drivers of their consumptive behaviors rather than challenging the infrastructures or political systems which may also underlie this behavior. If climate change is framed as primarily an issue of equity which requires societies to work together to ensure that the burdens of mitigating and adapting to climate change are distributed fairly and not only felt by the poorest in society, then all citizens deserve to have a say in decision-making and should be permitted to make normative judgements and draw on all aspects of their own knowledges and experiences of climate change.

Usually only a small number of methods for citizen engagement become institutionalized in governance mechanisms, and these methods then become highly standardized and are promoted across the board regardless of the specific issue under discussion. This can be seen with the popularity of a particular kind of public opinion polling in government where attitudes are elicited through survey methods from a statistically representative sample of the population. Similarly, certain highly standardized forms of deliberative methods of public engagement have been used in policy-making, planning, conflict resolution, and development projects, with subtle variations across different domains and national contexts. In more recent years there has been an increasing turn to internet-based modes of engagement, in formal policy-making as well as in activism. These new practices, including the opening up or crowd-sourcing of large data sets to be analyzed and interpreted by citizen
data scientists or the use of algorithms to analyze citizen sentiments expressed through social media, have the potential both to empower and to exclude and require new skills and understandings of citizens, just as we have seen with other forms of democratic engagement such as deliberation or opinion polling.

Geographers and science and technology studies (STS) scholars have taken a close empirical interest in how ideas about environmental citizenship and environmental citizens themselves are constructed in particular contexts. This strand of scholarship significantly departs from political science approaches to citizenship which aim to identify and define, instead shifting the emphasis to the practices, processes, and performance of (environmental) citizenship. For example, the conventional citizen imagined and therefore summoned by powerful actors around public engagement and participation related to biotechnology has been characterized as the “innocent citizen” (Irwin 2001), an individual assumed to have little subject-specific knowledge or political preferences related to the issue under discussion – and therefore in need of proper information and education – in contrast to the prominent role played by certain vocal activist groups around these issues. Such work highlights how certain kinds of citizens can be excluded from or cast as invisible to environmental policies, but also how certain visions of environmental citizens can be brought to life and reinforced through the performance of deliberative processes around environmental issues. Such accounts have also observed how debates around environmental issues, from nuclear power to climate change or the introduction of genetically modified foods, have played out very differently in different national contexts due to different national modes of engaging with citizens, institutional contexts, and histories of dealing with environmental problems and controversies.

Scholars have also been interested in studying attempts to create environmental citizens through top–down, usually policy-led approaches, from the rolling out of smart home technologies, to practices of public deliberation, behavior change policies, or housing regulations (e.g. Hobson 2013). It is argued that the embedded assumptions about environmental citizenship, and views about what environmental citizens should be and do, can become internalized by citizens themselves when they are the subjects of these top–down policies, such as behavior change. So citizens will use their homes differently when they feel they are under surveillance by the smart meters and other smart technologies which have been installed, or consumer-focused behavior change initiatives may cause citizens to internalize the role and message of sustainable consumption, neglecting the other possible roles they could play. However, it has also been suggested that these top-down policies are not absolute determinants of the performance and practice of environmental citizenship. Rather these top–down impositions can be contested and altered from the bottom up through the practices of environmental citizens, who use their smart home technologies in ways other than those expected by the designers, who subtly undermine or challenge discussions in the context of deliberative public engagement processes, or who find alternative modes of consumption away from the narrow sustainable consumption measures promoted in government behavior change initiatives.

An ongoing challenge for democratic theorists and those interested in public engagement has been how to engage environmental citizens in decision-making justly and in a sustained manner, without citizens’ voices being co-opted or people simply becoming tired of being constantly consulted. Recent scholarship has attempted to take a more systematic or organization-wide view of how participation processes play out and
how they interrelate with and feed into other political processes, for example highlighting the role played by social protest, such as climate camp or protests against the third runway at Heathrow in the United Kingdom, as well as formal deliberative processes in influencing government policy. Another tactic has been to point out how citizens are always already engaged with aspects of environmental politics through their everyday lives and practices, from the consumption decisions they make about buying fairtrade, local, or organic products or through resource use in the home. Citizens also engage heavily with environmental issues through the media, and through diverse forms of protest and dissent, from demonstrations to signing online petitions. This moves the focus away from the sometimes narrow view of how environmental citizens can be engaged with environmental policy and politics, towards an interest in how institutions and decision-makers themselves listen and respond to citizen voices. A further strand to this debate has been the promotion of the view that environmental decision-making is always partial and incomplete, requiring constant debate, development, and monitoring amidst moments of settlement and decisiveness.

Redefining environmental citizens

With the advent of universal suffrage, at least in Western liberal democracies, it would initially appear that the question of who has the right to be considered a citizen has been definitively settled. One exception to this rule is the case of the rights of marginalized indigenous peoples to be considered environmental citizens. Whilst indigenous communities are thought to broadly live in a more harmonious and interdependent relationship with their surrounding environments, official environmental policies can sometimes work to exclude and harm such peoples, for example by preventing access to important food-gathering or hunting areas despite the minimal environmental impacts of such activities.

Political developments have enshrined the rights of nonhuman nature in law in some countries, for example Bolivia which passed the Ley de Derechos de la Madre Tierra (Law of the Rights of Mother Earth) in 2010, which gives Mother Earth certain inherent rights as a subject of public interest. Bolivia has also been instrumental in inserting such perspectives on the rights of Mother Nature into the conceptual framework of the newly created IPBES. In academic work, developments in political philosophy and in animal or more-than-human geographies have further complicated this dimension of environmental citizenship. Such approaches emphasize the capacities of the nonhuman, from individual animals to plants or even bacteria and viruses, to sense and to have political significance and effects, and call for the redistribution of political agency, with implications for the practice of democratic politics and science (e.g., Whatmore 2006). Furthermore, it is not just the citizen-like qualities of individual entities that have been emphasized; there has also been a move to consider the rights and responses of systems or assemblages, for example in the growing importance of the ecosystem (including the concept of ecosystem services) as an object for policy-making and critical inquiry. It has also been claimed that the difficult moral dimensions opened up by environmental policy-making require a reconsideration of the citizenship rights of as yet unborn humans and nonhumans, opening up similar challenges for political engagement and the definition of citizenship rights.

These developments raise serious questions for those concerned with environmental citizenship
ENVIRONMENTAL CITIZENSHIP

around how the eligibility of nonhumans for citizen rights might be defined, and how they can be engaged in political processes. New dimensions for defining the right to citizenship have been suggested, including the ability to sense, the ability to suffer, or the ability to have significant effects on human communities or networks. Several geographers have adopted experimental approaches in attempting to engage with and take seriously these potential citizens. A current UK project funded by the Arts and Humanities Research Council (AHRC) and hosted at the University of Edinburgh (More-than-Human Participatory Research 2014) has experimented with adapting co-design and other participatory procedures in order to have conversations with nonhumans, including trees, dogs, bees, and water. The point of the project is to engage with and reflect on both the practicalities and the politics of attempting to adopt a broader definition of citizenship and democratic rights.

ENVIRONMENTAL CITIZENSHIP

Environmental degradation

Salvatore Engel-Di Mauro
State University of New York at New Paltz, USA

Definition and brief historical overview of the concept

A term frequently used but rarely defined, environmental degradation, in the current scientific and broader institutional mainstream is considered a specifically human-caused negative change in the biophysical (i.e., nonhuman) environment (e.g., UNEP 1997) or a human-induced decline of environmental health. The same concept may also be expressed by different labels, as ecological degradation or as ecological or environmental decline, deterioration, destruction, or disruption. Irrespective of semantic manifestation, the matter is posited as a reduction in the quality of the environment and is imputed to direct or indirect human impact, also referred to as human disturbance. Excluded from definitions of environmental degradation are nonhuman sources of environmental change that is deleterious to people (e.g., natural hazards). This does not mean that those who study environmental degradation bracket or dismiss nonhuman sources (drivers) of environmental change. Such instances are regarded as processes at most impinging on environmental degradation as either part of its effects or exacerbation of existing nonhuman drivers. For instance, accentuation of landslide frequency and magnitude in areas susceptible to such hazards may be traceable to or increased by anthropogenic slope deforestation.

Concerns over the quality of the physical environment and the state of other organisms have been expressed in diverse ways in different places over millennia, whether orally, textually, or pictorially (see e.g., Marks 2012). Such preoccupation has directly involved shifting ideas about nature and attendant diversity in worldviews more broadly, including, among others, questions of value, ethics, and ways of knowing. Describing undesired changes in the nonhuman natural world as environmental degradation appears traceable to the late 1960s, during a time of popular uprisings and of the concurrent rise of mass environmental movements in many parts of the world. As in earlier periods, matters of meaning, normativity, and other social questions have pervaded the use of the concept even while public and private institutions representing a variety of interests have tended to treat the large and expanding number of problems under the banner of environmental degradation in technical terms, requiring the application of expert knowledge certified by governing national and international organs. This latter technocratic approach has emerged some centuries ago and very unevenly with the development and especially expansion of certain national states, largely in Western Europe.

It is still an often Eurocentric technocratic approach that reigns in the framing of research questions, techniques and data gathering and analysis used, and discussions about environmental degradation. For instance, soil erosion is still considered solely in negative terms and a priority in the fight for soil conservation even though it is not a main concern for many farmers and in spite of instances where erosion can be beneficial to downslope ecosystems (Brookfield 2001).
ENVIRONMENTAL DEGRADATION

This does not imply that other perspectives are completely shut out or have been ignored within predominant institutions (such as the UNEP, World Bank, European Union, or environmental or resource-conservation branches of the world’s most powerful governments). Over the past few decades, for example, the importance of “local knowledge” to environmental monitoring and reconstructing past environments has gained considerable ground, thanks in part to scientists working within the same technocratic framework or institutions. To a moderate degree more attentiveness has been given to noninstitutional understandings of environments as well, so that there has been rising documentation and discussion of various resources as they are defined and categorized by nonexperts or, for example, indigenous peoples. This is reflected in the various subfields established with an “ethno-” prefix (e.g., ethnopedology). There are also overlaps among types of knowledge, either, among other factors, because of cross-cutting species-specific needs that to some extent transcend social differences (e.g., food and water needs) or because of increasing sensitivity by institutional actors to more grassroots concerns or because of perspectival convergence resulting from socially wide-reaching education systems, or combinations of all three.

On the main, within current mainstream institutional frameworks, environmental degradation is understood in terms of generic effects on human health and/or economic processes, but it is increasingly extended to other forms of valuation, such as aesthetic appreciation and, potentially, relative cultural framework (perhaps, eventually, even according to different social position, given the greater sensitivity to matters of environmental justice). The concept is thereby also defined by such notions as natural resource availability, productivity, and development, as well as cultural amenities. It is not uncommon to find the depletion of resources, the impairment of biomass or crop production, and implications for various indicators of development among the topics embedded in discussions of environmental degradation. Still, the concept is treated as if it were possible to free it from social specificity.

Measurement and interpretation of environmental phenomena

Environmental degradation encompasses a wide range of processes, including depletion (e.g., deforestation, soil erosion, water withdrawals faster than replenishment rates), disruption of biogeochemical cycles (e.g., alteration of atmospheric and oceanic chemical composition, soil acidification), species extinctions, and pollution (e.g., overloading of environment with trace elements or synthetic compounds). Observations and measurements of environmental degradation involve many different kinds of methods and data, in line with the great diversity of processes studied. There are direct and proxy sources of data that can be assessed qualitatively and/or quantitatively and gathered through a variety of techniques. Direct sources are those entailing measurements (e.g., rainfall gauges, field and lab soil pH analyses) or documented observations (e.g., interviews, archives, diaries, landscape paintings). Proxy or indirect sources require inference about past environments from nonhuman material remains (e.g., fossils and subfossils, buried soils, ice cores) or artifacts whose meanings are unknown to analysts (e.g., cave pictographs, sculptures, reliefs) or whose likely uses, composition, or attached residues aid paleoenvironmental interpretation (e.g., sherds, stone tools, pieces of worked metal, construction ruins). The enormous diversity in the types and sources of environmental data is reflected in the variety of quantitative and
qualitative techniques that can be employed, ranging from, for example, remotely sensed data through satellite imagery and magnetometry to more direct data acquisition through interviews and textual analyses.

Once acquired, data can be compiled and analyzed to glean changes over time and space so as to detect trends and thereby ascertain whether environmental degradation has occurred or is occurring. For instance, remote sensing instruments (e.g., aerial photography, satellite imagery) are often used to estimate the extent and type of forests over time in different places. Such data can be tested against the results of fieldwork-based inventories. For longer-term considerations, pollen extraction from nearby sediments (often in lake beds) and tree rings of existing trees can be examined to supplement current observations or carry the analysis further back in time. These research activities have been important to identifying deforestation problems and measuring rates of deforestation in different parts of the world.

Indices can and have also been devised and applied to facilitate interpretation of environmental change. The normalized difference vegetation index (NDVI), based on red and infra-red reflectance by vegetation, gives an indication of the amount of photosynthesis in an area and thereby enables interpretations about the state of plant life for a given area. Other indices have been developed that attempt to estimate human impact per se, on the basis of biophysical observations, inferred data, and indices. One recently popularized index is the Ecological Footprint, the total biologically productive land and marine area implied by resource consumption and waste generation by a given human population. Another is the human impact index (I=PAT), measured by multiplying figures for human population, affluence, and consumption rates relative to technologies used.

Involving the study of many different types of data and resulting from multiple inter-related processes, environmental degradation presents a major challenge in merely describing the phenomenon, regardless of time period considered. A common approach to classifying forms of environmental degradation is on the basis of geospheres or sets of interactions, a method that roughly corresponds to the existing division of labor among the biophysical sciences. Thus, one may describe a problem as pertaining to air (atmosphere), water (hydrosphere), land (lithosphere), and/or organisms (biosphere). Sometimes additional areas of research are specified and separated from these four geospheres, such as soils (pedosphere) and ice-covered regions (cryosphere).

There may be advantages to splitting descriptions of degradation relative to geosphere, such as avoiding the complete redrawing of disciplinary boundaries and the overhaul of education systems that would imply, but this conventional splitting can be at the expense of integrating data and analyses to detect mutually altering effects between geospheres. For example, acid precipitation can alter both soil and groundwater quality and thereby affect biodiversity in and geochemical composition of surface waters. Such environmental degradation is clearly described more effectively by combining analyses of atmospheric, soil, hydrological, and biological processes. A multidisciplinary approach is therefore necessary just to reach a basic comprehension of the problem. The Millennium Ecosystem Assessment (Hassan, Scholes, and Ash 2005) provides an example of how multiple sources of environmental monitoring and studies can be integrated to produce a broad understanding of environmental degradation. The exercise involved hundreds of scientists from disparate fields convened to discuss and carry out analyses that could put together findings in

ENVIRONMENTAL DEGRADATION
such a way as to render the results intelligible for the purpose of detecting major planetary trends as well as reaching a wider public.

Grasping the full extent of the consequences of environmental degradation is even more involving than the already challenging process of gathering analytical results from disparate fields (using diverse approaches and methodologies) into a coherent estimation of the status of biophysical environments. There are issues of complexity, cumulative repercussions, thresholds, and distance-related time lags, to cite some of the major aspects. Relationships among different biophysical processes are complex in that a change in one can have multiple and cascading effects upon others. For instance, in regions characterized by acid sulfate soils, the building of dams, and the installation and operation of deep-pumping wells, for instance, can lead to the lowering of water tables and the oxidation of underlying parent material, triggering a rapid acidification process affecting surface water quality and thereby also aquatic life forms. Heavy metals embedded in soils may eventually be released into nearby streams and bioaccumulate to the point of threatening the health of people consuming affected aquatic species. Consequences can also be cumulative and involve time lags and thresholds, such that an environmental degradation process may not be discernible until an irreversible change has occurred, as in the activation of acid sulfate soils. There are, in other words, threshold conditions that may be lurking and may not be clear until after the problem emerges. This is further complicated by the reach of some human impacts at great distances from a source area, as in the case of acid precipitation. Emissions of sulfur and nitrous oxides from coal-burning power plants can lead to acid precipitation hundreds to thousands of kilometers from emission sites. In this case, there is a time lag in that, for example, it takes time for emitted compounds to work their way through atmospheric processes and then precipitate in acid form. There is also a potential cumulative impact as, over time, acid precipitation can change the water chemistry of receiving lakes and more sensitive soils (e.g., those with little acid-buffering capacity).

It can also be no straightforward matter distinguishing anthropogenic from nonhuman sources or drivers of environmental degradation. The fact that multiple concatenations of biophysical processes are typically involved, as in the acid sulfate soils example, already makes it evident that environmental degradation entails more-than-human causation, even if it is evident that such problems are human-induced. This multiplicity of interlinked processes also reduces the possibility of gauging environmental degradation comprehensively, as one impact can have repercussions in many different components of ecosystems, not all of them necessarily negative. Much more difficult to interpret relative to drivers of environmental degradation are instances in the remote past, such as Late Pleistocene megafaunal extinctions, and in cases where changes are initiated unknowingly, such as the multiple introductions of new species that become invasive and, in turn, supplant one another in predominance. Sometimes, human-induced environmental change (degradation) bears results virtually identical in frequency and/or magnitude to that induced by nonhuman forces, as in the case of distinguishing subsidence due to karstic processes from those traceable to over-pumping of groundwater in largely limestone bedrock environments. Biophysical environments involve interdependent processes of which human agency constitutes but one (or possibly several, if one wishes to distinguish among types of societies), so there is an added complexity to pinpointing anthropogenic impact in that one must gather many different kinds of data (not always feasible) to enable the
discernment of human from nonhuman impact in general. Finally, but not exhaustively, there can be lags in time and space between putatively destructive human impact (e.g., reduction of soil cover) and its effects (e.g., sedimentation in streams and lakes) in different ecosystem components.

Data and indices can be plotted and analyzed statistically against values ascribed to a societal variable (often economic figures such as gross domestic product (GDP)) to begin formulating hypotheses regarding the causes of environmental degradation. To some extent, this is the basis for establishing causal relationships, but since there are always multiple human and nonhuman factors involved, it is seldom the case that straightforward cause–effect relationships can be established. Nevertheless, broad explanatory frameworks have been developed that guide much policymaking and enliven academic debate. Major governmental and international institutions and often large environmental organizations subscribe to multifactorial models that posit different social dimensions as influential in shaping human impact, such as demography, economy or wealth (measured according to specifically capitalist frameworks), formal politics, religious beliefs or cultural values, and technological characteristics. Some academics, activists, and policymakers emphasize one or another of these dimensions and it is often the case that population growth or poverty looms large in such arguments as a primary driver of environmental degradation. Problems also tend to be framed as a matter of maintaining resources (presumed the same for all societies) or “natural capital” within the strictures of some predetermined “stocks and flows” or “carrying capacity” (e.g., Ecological Footprint analyses) or as a set of “ecosystem services” where policy choices amount to tradeoffs among such services to a generic humanity.

Critical appraisals of environmental degradation

Yet even within such a narrow scope of institutional viewpoints, the concept remains vague and its definition, as mentioned at the outset, rarely formulated. Moreover, there has even been institutional inconsistency over the meaning of environment. Early on, by the early 1970s, the term was beginning to encompass issues such as housing and sanitation within an overall attempt at reconciling development with humans’ interdependence with ecosystems (Ambio 1979). By the late 1980s, with the popularization of the Brundtland Report, it appears that environment took on (again) the meaning of nonhuman nature in contrast to what is human-made, as in more widely accepted notions. The predominant view continues to be of environment as external nature and therefore of environmental degradation as the ruination of biophysical environments as if separable from human-constructed ones, like cities.

To complicate matters further, the term degradation is even more intrinsically malleable because the referent is an unspecified set of criteria that supposedly constitute a coherent basis to rank environments as improving or declining in quality. This is made evident in the application of the concept in more specific instances of environmental degradation, namely land and soil degradation, which have received much greater attentiveness regarding their definition. Attempts to define such processes have evinced both overlaps and substantive divergence in the content and objectives of such formulations. This is due to the inherent contingency of any such definition on the perspective of those establishing it. For instance, soil salinization is disastrous to most people involved in food procurement, but could be a boon to salt miners if salt accumulation is sufficiently extensive. The introduction of
an invasive grass species can be problematic for one community where efforts are dedicated to preserving a native grassland ecosystem, but the change may be instead welcomed in another community where there is reliance on herding and the invasive species improves on existing pastures. Or, to apply the same principle to a process more commonly regarded as worrisome, deforestation is a form of degradation to those concerned with, for instance, global warming and habitat preservation, or to those relying primarily on forests for, say, their livelihood or political prestige, but it is arguably an environmental improvement to those whose livelihood is largely dependent on growing shade-intolerant crops. Different criteria may apply relative to which purpose or need one deems a priority. The issue of social context-dependence or specific human objectives or needs becomes more knotted if one considers different species and their widely divergent survival requirements (e.g., between aerobic and anaerobic organisms), as what is degradation for one species may be beneficial for another. In any case, it seems that by and large it is a single species (some might say a single type of society) that serves as the main if not the only (often tacit) referent in defining degradation.

This is not to suggest that there are no generalizable cases of degradation whose impacts cross species and/or social needs or purposes. There are overlaps in what is covered by the term, regardless of criteria, and in how environmental degradation is more broadly understood across and beyond institutions. After all, we are all organisms enmeshed in ecosystems and there are certain basic physical processes that serve to enable all life forms, even if organisms are differently positioned within and differentially affected by ecosystem dynamics. Still, degradation implies a ranking system that points to valuation criteria. Since people have differing perspectives (and members of other species or physical forces are not involved in any discussions on the topic in any direct manner), it cannot be presupposed that ranking criteria will be the same for everyone or in every instance. The concept of degradation implies the application of a value system involving people’s varied understandings and, to go further analytically, their social position. The general use of the term may presently refer exclusively to destructive human impact (disturbance), often regarded as “artificial” or “nonnatural,” yet what qualifies as destructive remains contingent on one’s point of view and on the social relations that favor the emergence of such a perspective. Hence, environmental degradation should be understood as change that is perceived as negative or undesirable. This has been a conclusion reached, at least by some, even within the environmental sciences (Johnson et al. 1997), but without an ostensible awareness of the social processes and contextualization involved and analytically necessary to consider.

This more socially contextualizing understanding has yet to reach most academic and wider institutional circles. Environmental degradation continues to be discussed as if relative perspective has no impact on policy formation and application or on the development of research questions and the analysis and interpretation of environmental data. It is assumed that, for example, human-induced deforestation is necessarily a form of degradation even if there are cases of biodiverse forms of farming replaced by tree monocultures. Likewise, soil erosion is considered as harmful regardless of context, as if there were no instances where human-induced erosion contributes to raising soil nutrient status downslope (e.g., Brookfield 2001, 165–166). Arguably, the majority of instances of deforestation are problematic relative to loss of species, regional climate, and other deleterious effects (the case of soil erosion is rather murkier; see,
for example, Stocking 2006). However, lack of contextualization may lead to overestimations of a problem and the misidentification of areas requiring policy attention.

Geographers, especially environmental and human geographers, have been particularly attentive to this problem and have developed ways of including a critical appraisal of the variable meaning of environmental degradation, examining the social dynamics involved as well as perceptual aspects, without denying its occurrence. To some extent, concern over environmental degradation has deep roots in geography, traceable to the field’s very beginnings in the 1860s as an institutionally recognized field of knowledge (Goudie 2006, 3–11). Geographical work on the topic has also shaped the study of human impacts, as in the influential 1955 meeting and derivative volume titled “Man’s Role in Changing the Face of the Earth.” The project involved human geographers as main organizers and it was inspired by the writings of geographer George Perkins Marsh (1801–1882). It was among the first international and interdisciplinary meetings aimed at a comprehensive assessment of human impact and environmental degradation.

Nevertheless, studies or entire research agendas focused on expressly social explanations of environmental degradation are of more recent vintage. One can find precedents in approaches such as cultural landscapes and cultural ecology a century ago, which largely addressed human shaping, not degrading of environments. There are even earlier, prescient contributions, mostly of a speculative and prescriptive character, in late nineteenth-century anarchist geographers’ writings, as well as a few other precursors, but these were largely ignored (Robbins 2012). Sustained, critical analyses and explanations linking social relations of power to environmental degradation and to its socially uneven effects did not come about until the 1970s, when earlier marginalized anarchist geographical approaches were recovered and newer Marxist and feminist, and eventually antiracist and various poststructuralist perspectives emerged, influenced by intellectual currents and social movements outside geography and the academic setting more generally (e.g., works on environmental racism). Some of these reside at the margins of academia and exert greater influence in wider social movements, such as in the case of indigenous environmentalisms, environmental justice/racism, ecofeminism, and eco-Marxism/socialism. The ferment of the latter half of the twentieth century emerged as several strands of thought, from within as well as beyond geography, coalescing about a paradigm that came to be known as political ecology by the late 1980s. This paradigm, especially influenced by Marxist theories (including world-systems perspectives) in its early phase, was infused with and enriched by the aforementioned perspectives (not so much anarchism, though). There have also been separate, parallel Marxist dialectical currents in human geography that intertwine with parts of political ecology, aside from similar and copious social science scholarship emerging especially in the fields of anthropology and sociology. There have also been critical empirically focused interventions from physical geography, though more recently and rarely (see, e.g., Kiage 2013).

These varied but mostly complementary approaches have contributed fundamental correctives to the explanatory frameworks briefly described above and that dominate policymaking and mainstream environmental activism. Featured among the major contributions are demonstrations of the importance of multiscale analysis, the corollary consideration of interlinkages among places, a focus on social differentiation, and attentiveness to the dangers of common-sense ideological constructs (e.g.,
environmental narratives, received wisdom). Multiple-scaled and interlinkage analyses, for example, show how environmental degradation in one place cannot be explained and hence cannot be resolved by pretending that it is due solely or even largely to local human impacts. This understanding can be translated even to studies solely concerned with biophysical phenomena. Perspectives and conclusions about the occurrence and severity of environmental degradation may vary according to an analyst’s scale of analysis and the manner in which data are spatially bounded (e.g., how data are aggregated, pixel resolution). Studies centered around social differentiation underline the fact that social processes cannot be treated as independent entities in explaining what motivates human actions leading to environmental degradation. They also uncover major explanatory weaknesses in conventional explanations that treat humans as homogeneous (as if we all have the same political leverage, for example) and that fail to grasp the inherently inter-related character of social processes (e.g., economic growth is never divorced from political decisions over what counts as economic growth and how it is distributed socially). Therefore, such conventional explanations cannot account for the large social unevenness in both the causes and effects of environmental degradation and for the multiple social processes that combine to promote different kinds and magnitudes of human impact. Finally, taking apart common-sense views can be crucial in devising constructive policies. For instance, political ecologists have demonstrated how often received notions about past environments have been constructed as part of legitimizing the displacement of communities or in justifying colonial or other sorts of authoritarian interventions. Others have shown how technical terms are infused with ideological commitments to wresting resources from some communities and handing them over to private interests, as in the conflation of commons with open-access resources or the untenable use of “carrying capacity” to people-environment relations (since, for example, long-distance trade obviates its applicability). Still others have pointed to constructs, like “ecosystem services” or “wetland mitigation banking” that buttress attempts to commodify and thereby render alienable resources necessary to human survival.

The outpouring of these studies over the past few decades has yet to inform conventional policies in fundamental ways, but they point to ways forward in making of environmental degradation a context-sensitized and hence more viable concept as well as a means to gauge environmental degradation more accurately. Some of the results of such critical scholarship have found their way to conventional projects and have been shown to provide innovative ways of producing knowledge about environmental degradation that overcome technocratic or decontextualized understandings of environments. An example is the UN-sponsored project titled “People, Land Management, and Environmental Change,” a farmer-centered participatory approach that led to identifying knowledge and technologies that sustain agrobiodiversity and reduce destructive impact. This is one way not only of raising the relevance of environmental degradation to communities otherwise excluded from policy development and implementation, but also developing appropriate interventions addressing instances where they are actually useful and constructive both socially and environmentally.

Environmental discourse

Tom Mels
Uppsala University – Campus Gotland, Sweden

Environmental discourses are frameworks of meanings about the biogeophysical world and its attendant natural and social qualities. Each environmental discourse is part of an exchange of knowledges, imaginations, assumptions, and judgments. In this exchange, the individual and combined notions of environment and discourse themselves remain highly contentious and appear in various political, cultural, and economic contexts, and webs of historical and geographical association. For example, the environment understood as nature or aesthetically pleasing landscapes differs from the environment understood as a scientifically demarcated ecosystem or toxic waste site. And discourse understood in narrow terms of conversation, writing, and language use differs from discourse understood in a wider sense as particular ways in which distinctions between truth and untruth or right and wrong are made, such as through scientific research. These wider, more political and critical, notions of discourse are of central importance to social scientists. They draw attention to the variable degrees to which different environmental discourses are expressions of power and authority, and come to pervade both social ways of seeing and material practices in the landscape, such as choosing which crops to grow where. Control over how and why particular configurations of representations and understandings are constructed and given authority, while others are downplayed, rejected, or excluded, is therefore often a vital feature of environmental discourse analysis within geography and the social sciences.

Work on environmental discourse by geographers was prompted by a wide-ranging surge of critical and notably poststructural theory within the discipline, and of an outpouring of social science literature on environmental issues since the mid-1980s. As in other fields of research, the term “discourse” originally appeared as a critical analytical tool, designed to reveal connections between, on the one hand, bodies of knowledge (rhetorical strategies, vocabulary, background assumptions) and, on the other hand, practices of social power, projects of domination, and systems of control. A cultural and linguistic turn in research insisted on the textuality of objects of geographical knowledge, including images, maps, descriptions, and whole landscapes and environments. Instead of accentuating the material world, this textual approach treated language as a conduit for the expression of social meaning about spaces and environments.

The accepted notion of textuality of the environment therefore contrasts with the intuitive notion of environment as natural and taken for granted. Drawing on Michel Foucault’s highly influential analyses of modernity, discursive practices are often theorized as naturalizing the socially made, normative expression of particular interests. The creation of a modern wilderness park, for example, may be promoted through very partial understandings of the park space as uninhabited and strictly natural, and, while this may be in the interest of the nature tourism business whose customers take this naturalness for granted, it may simultaneously entail a ban against established human practices in the new park, such as husbandry or hunting.
ENVIRONMENTAL DISCOURSE

Such discursive formations encourage particular social patterns of behavior and institutional practices, and establish particular orders of truth in the form of powerful, taken-for-granted ways of understanding. To talk of these orders in Foucauldian terms of discourse does not aim to reveal their falsity or to expose a deliberately designed “dominant ideology,” or hegemonic forms of consent, as in Marxist versions of ideology critique. It aims, rather, to display discourses as human-made constructs, emanating as they do from various practices and sources of sociopolitical life rather than from nature. Congruently, this approach encourages us to understand environmental discourses not as ideological processes expressing the struggle over political economic power, social justice, and class-based ontologies prevailing in capitalist society, but instead as the markers of shifting categories, classifications, and subject positions of regimes of truth about the environment. In this vein, several thinkers of more forthright postmodern inclination emphasize the multivalent and unstable qualities of discourse and the shifting situatedness of individuals in relation to different discourses. For yet others – including Gayatri Chakravorty Spivak, Ernesto Laclau, Chantal Mouffe, and Edward Said – the borders between discourse and ideology critique are more permeable. They emphasize the normative qualities of power and (opposing) discourses, in tandem with developing a keen interest in social justice. There is, for example, a world of difference between categorizing large-scale corporate control over Ethiopian fields as an unjust process of “land grabbing,” resulting in the “dispossession” of local farmers, and categorizing it through a discourse of legal “land acquisition” based on “modern agriculture” and farm labor.

Although Marxist ideology critique and discourse analysis differ in theory and intent, both are fundamentally driven by an impulse to denaturalize, resocialize, and repoliticize what was traditionally, or at least according to conceived stereotype, considered to be products of nature. Both would indeed question the naturalness of the aforementioned “wilderness” park. The introduction of discourse theory into environmental studies thus brought a profoundly social agenda to the critical scrutiny of the production of knowledge. The natural science pursuit of gaining objective knowledge about “the environment” was instead seen as affected by the shifting theories, terms, concepts, conventions, and accepted methods (the structured codes, or epistemes) that organized the scientists’ work and directed their possibilities of gaining knowledge. While environmental science may carry an aura of scientific precision and neutral inquiry, it was increasingly understood as a political rather than an objective field of research. To speak of environmental discourse expressed the recognition of this awareness.

Environmental discourse has subsequently been widely adopted to highlight the social construction of (knowledge about) nature, and to disclose how dominant discourses about the environment are reinforced by existing systems of education, law enforcement, media coverage, scientific research, and other practices. The importance of the concept of discourse was partly influenced by worldly developments such as the realization that uneven geographies of ethnicity, race, gender, and class across the world mapped closely onto environmental health problems. Also, a multiplicity of often conflicting interpretations about the societal causes and consequences of environmental change on all geographical scales have erupted since the 1980s. Global warming, genetically modified foods, threats to biodiversity, toxic waste, air pollution, deforestation, the nuclear disaster in Chernobyl,
Bhopal’s gas tragedy – an endless list of emblematic places and issues of environmental ruin have become vitally important to the politics of sustainable development and a globalizing environmental justice movement. For example, Hurricane Katrina was not just a “natural” cyclone that heavily damaged and polluted particular parts of New Orleans in 2005, but a disaster exacerbated by and deepening already existing social inequalities of race, class, and gender that have been structurally present in the built environment, and that continue to shape the cityscape and its protection. Contested discourses of race, class, and gender were thus of vital importance to understanding the environmental effects of Katrina’s impact and aftermath, during which the environment was profoundly politicized in terms of social inequality, demands of corporate responsibility, the causes and consequences of uneven systems of power, and ever-present struggles over interests.

Environmental discourse in academic research

There are several different (sub)disciplines that have taken up the concept of environmental discourse in the social sciences and humanities. First, within environmental sociology, interventions based on, inter alia, critical realism, social constructivist theory, and visions of reflexive modernization have gained prominence through the work of scholars such as Ulrich Beck, Peter Dickens, Anthony Giddens, John Hannigan, Michael Redclift, John Urry, and Graham Woodgate. These unsettled and subverted the traditionally dominant objectivist or what was seen as naive realist standpoints within sociology, with their reliance on the apparent naturalness of the environment, and emphasized instead sociality and contested claims made about the world.

Second, within environmental ethics, controversies arose about the intrinsic or inherent value of nature and social science notions of the social construction of nature in environmental discourses. Seeing the environment as a more or less natural entity, external to society, was challenged by more discursive approaches to wilderness and the nonhuman world. A much cited case in point was environmental historian William Cronon’s dissection of wilderness as a category of knowledge, resting on sharp but ultimately untenable distinctions between nature and culture. Cronon not only saw the idea of wilderness as a particular human construct, but also questioned the strong orientation toward uninhabited landscapes within environmental discourse, which often failed to recognize nature in inhabited landscapes such as cities. What Cronon and his fellow contributors in the seminal collection *Uncommon Ground* (Cronon 1996) gestured at was a concept of nature as fully implicated in social life.

Third, environmental historians such as Richard H. Grove, Ramachandra Guha, Donald Worster, Carolyn Merchant, and Richard White also examined ecological discourse and environmental change. Among other things, this work contributed much to deeper understandings of the character and profound consequences of colonial and gender relations embedded in past environmental discourses.

Fourth, green varieties of historical materialism also accentuated a normative edge to nature and the environment. Ecological Marxism (developed by Elmar Altvater, Ted Benton, John Bellamy Foster, and James O’Connor, among others) emphasized the social and environmental consequences of capitalism and ontological realism rather than representational practices and histories of ecological thought. Such work did develop an interest in an environmental discourse of sorts, by examining the politico-economic
ENVIRONMENTAL DISCOURSE

assumptions, ideological tactics, and various valorizations within capitalism of nature as resources.

Finally, environmental discourse also emerged as a major concern within political science where, for instance, Maarten Hajer’s work on ecological modernization and discourses of acid rain, and Karen Litfin’s exposure of global cooperation around ozone depletion, made renowned contributions to the politics of environmental discourse during the 1990s. On a meta-level, the political theorist Richard Dryzek (1997) developed a taxonomy of competing interpretive repertoires of environmental concern, identifying several environmental discourses that challenged the no-limits, Promethean discourse of industrialism that dominates mainstream society. All versions of environmental problem-solving, he argued, reject radical change and instead recognize experts, markets, or democratic processes as agents of change. What he calls “discourses of sustainability” (sustainable development and ecological modernization) aim instead at dissolving conflicts between economic development and environment. Finally, versions of green radicalism propose a complete transformation of modern society.

Environmental discourse and geography

Geographers also contributed in distinctive ways to this extensive intellectual and practical politicization of environmental discourse. With an understanding of all sorts of knowledge in terms of discourses, geographers were drawn to highly specific forms of human reasoning, learned ways of seeing, arbitrary political rationalities, and cultural preferences through which the world is made accessible and comprehensible. Mapping how and to what end particular discourses came to possess power in society was an interest shared with other scholars. Yet geographers devoted particular attention to the spatialities of environmental discourse, or the way certain more or less strategic forms of representation on a variety of scales emerged, vanished, and were implicated in the making of specific landscapes and places. For example, the European discourse of wilderness was applied in colonial Africa to make spaces available for the creation of national parks, by supplying a rationale for the exclusion, repression, and eviction of indigenous people from such spaces.

Geography’s engagement with environmental discourse appeared more or less simultaneously in two multidisciplinary fields: environmental justice and political ecology. Environmental justice studies, as developed in the work of scholars like Julian Agyeman, Brendan Gleeson, Nicholas Low, Laura Pulido, Petra Tschantz, and Gordon Walker, have, since the mid-1990s, gone through a fundamental shift from explaining environmental inequalities simply in terms of the distribution toward explaining them in terms of how difference is produced and normalized. This emphasizes both the various material-discursive processes underlying disparities and encourages emancipatory calls for environmental justice as recognition and participation in public life, environmental planning, and policymaking (Walker 2012).

In political ecology since the 1990s, discourse analyses were frequently combined with other qualitative and quantitative methods of inquiry to grasp changes in biogeophysical environments (Peet, Robbins and Watts 2011). Part of this work is discontented with any geographical analysis that tends to separate natural processes from social processes (culture, politics, economy) in environmental change.

Any discourse research, therefore, encouraged a rethinking of the material efficacy and entanglement of discourse: that is, how knowledges
ENVIRONMENTAL DISCOURSE

and modes of representation can transform and reproduce spaces and the biogeophysical world. The problem of discourse is thus at the heart of the matter of nature and related mind/body, self/world, nature/culture, material/mental dualisms. In this context discourse is used to explore a wide variety of research questions, including those concerning the material properties of nature, the cultural predispositions that accompany our concepts of environment, and the role of an array of nonhuman things and processes.

An ongoing conversation about the discursive construction and materiality of nature was inaugurated during the 1990s, involving poststructuralist deconstruction and ecological Marxism (Braun and Castree 1998). This claimed that the environment always appears in socially interpreted guises and shapes, and that, therefore, it is crucial to scrutinize discursive conventions, silences, and affordances (the possibilities of action made available through discourse), and also to trace how those guises influence ongoing environmental change on the ground. However, it has been argued that what is at stake is not just a question of discursive mediation, but of coproduction through practices and performances of nonhuman life. From a relational vantage point, environmental discourses at all times actively constitute embodied and enacted, socially specific modes of existence.

Under the combined influence of Michel Callon, Bruno Latour, and other actor-network theorists, and so-called new materialist perspectives developed by Jane Bennett, William E. Connolly, Manuel DeLanda, Gilles Deleuze, Félix Guattari, Isabelle Stengers, and others, the constructivist focus on thinking and representing human subjects is largely rejected. Geographical interpreters such as Ben Anderson, Nick Bingham, Bruce Braun, Steve Hinchliffe, Hayden Lorimer, Nigel Thrift, and Sarah Whatmore lament what is seen as the privileged position given to humans, their agency, practices of representation, and discourse. Instead, we need to go beyond discourses to look at nondiscursive, tangible, and material things too. A common commitment in this work is thus to shift attention to the constantly changing exchange of things, technologies, and forms of life (Whatmore 2002). Within these combined human–nonhuman processes, new assemblages and unstable hybrids are both steadily vanishing and being made. No entity, concept, or action can be privileged over others, and therefore what are perceived as the increasing abstractions or, in some cases, self-referential tendencies of discourse analysis remain unable to give matter and becoming its due. In that manner, the new materialism calls not so much for the abandonment of environmental discourse and entanglements of power in environmental research, but for a recontextualization of discourse in the ongoing processes of environmental change.

Although many researchers have exposed the limitations of discourse analysis, they remain important to geographical work on the environment. Against what is taken to be the idealist tendencies of discursive construction and the monopoly of agency by humans, Marxian scholars like Karen Bakker, Gavin Bridge, Noel Castree, George Henderson, Becky Mansfield, Thomas Perreault, Scott Prudham, and Erik Swyngedouw have also positioned discourses as one way in which the biogeophysical elements of social and economic life are constituted. Unlike the new materialists who build on a flat ontology of relations, Marxian scholars emphasize the importance of capital in shaping society–nature relations, although across very diverse discourses and contexts (Harvey 1996). In recent years, this take on environmental discourse has been pursued in critical geographies that analyze neoliberalism as an environmental project. The
construction and mobilization of discourses—such as about the compatibility of economic growth, capitalist competition, and environmental care—are seen as feeding neoliberalism’s unhealthy and unjust appetite for new modes of appropriating natural resources (Heynen et al. 2007). The significance and agency of environmental discourses are particularly well recognized in literature on the neoliberalization of nature that focuses on appropriating biophysical phenomena and resources for environmental ends. According to these scholars, discourses about ecosystem services, ecotourism, biofuel production, biodiversity conservation, biocarbon sequestration, and the like alter material access to, and use of, resources, and also invent new forms of value, meaning, and intent. In particular, green discourses of commodification (i.e., discourses that are instrumental to bringing ecologies, aesthetic experience, or CO2 to the market as commodities) remain entangled within the network of capitalist economies and their commercial rationales and discursive values. For example, the producers of biofuel for cars use discourses about the nature-friendliness of biofuel to justify their use of rural spaces and resources that might have been used for food crops instead. Such discursive maneuvers contribute to the commodification of nature and are indispensable to convince customers and to secure market shares in a capitalist economy.

Environmental education

Lindsey Atkinson
University of Hull, UK

Environmental education (EE) can be defined quite broadly as education about, from, and for the environment. Education about the environment seeks to develop knowledge and understanding about the environment and the skills needed to benefit the environment. The environment here includes the living (biotic) and physical (abiotic) environment, both natural and built. Environmental education can also include education from the environment, using the outdoors as a learning resource to enhance learning (Palmer and Neal 1994) (Figure 1). Education for the environment aims to develop a sense of awareness of and responsibility for the environment and thus aims to influence attitudes and behavior.

While environmental science is largely associated with the disciplines of geography and the sciences, environmental education is viewed as interdisciplinary (UNESCO 1978), incorporating social, economic, and political perspectives. Environmental education takes place in both formal and nonformal education settings, through governmental and nongovernmental organizations. Teaching methods place an emphasis on fieldwork to develop awareness and skills, and also on participatory learning to engage learners with the subject matter. Environmental education is carried out at different ages and levels, and is also very much considered as part of lifelong learning.

Topic areas that may typically be covered include materials and resources, in particular energy, climate, water, plants and animals, buildings and industrialization, and people and communities. In early childhood, environmental education is likely to be topic-based and to focus on the development of basic skills such as numeracy, problem-solving, and communication. At this level, outdoor education is often used to enhance all areas of the curriculum. In secondary education most environmental education takes place in geography and the sciences, and some aspects may be covered in history. Cross-curricular opportunities may be more limited at secondary level as a result of timetabling and curriculum constraints, although there is still scope for individual schools or teachers to develop learning opportunities outside of the formal curriculum. In higher education, although most environmental education will still occur in geography and the sciences, some aspects may be covered in many other disciplines, such as law, politics, literature, business, and health studies. Schools, colleges, and universities may also act as environmental role models, demonstrating, for example, recycling, energy conservation, and the promotion of biodiversity. Outside of the education system, informal environmental education may occur through visits to museums, wildlife reserves, and so on and through organizations such as the Field Studies Council in the United Kingdom.

Environmental education has its origins in the study of natural history, followed by the development of the discipline of ecology from the late nineteenth century. Around the same time, Patrick Geddes (1854–1932), a Scottish town planner whose interests spanned biology,
Prior to the 1960s and 1970s environmental education was an activity carried out in a number of different disciplines, including conservation, environmental and urban studies, and outdoor education, but the term itself was not widely used. For instance, at the first meeting of the IUCN at the Conference of Fontainebleau in 1948, the importance of the role of education in conservation was noted as either “conservation education” or education for the “protection of nature.” In the 1960s environmental education began to establish an identity of its own in the literature with the setting up of the Journal of Environmental Education (formerly Environmental Education) in 1969. In the first issue William Stapp and others put forward an early definition of environmental education as “aimed at producing a citizenry that is knowledgeable concerning the biophysical environment and its associated problems, aware of how to help solve these problems and motivated to work toward their solution” (Stapp et al. 1969).

A fuller definition was agreed in 1970 at the IUCN’s International Working Meeting on Environmental Education in the School Curriculum: this definition acknowledged the interrelatedness between people and the environment to a greater extent. Following Recommendation 96 from the United Nations Conference on Human Environment (the Stockholm Conference) held in 1972, the United Nations Educational, Scientific and Cultural Organization (UNESCO) and the United Nations Environment Programme (UNEP) held an International Environmental Education Workshop in Belgrade in 1975, at which the International Environmental Education Programme (IEEP) was launched, with Stapp as its first director. Resulting from this meeting, the Belgrade Charter, “a global framework for environmental education,” put forward a goal and objectives for environmental education.
which noted the need not only for awareness and knowledge but also to develop attitudes and skills.

The first Intergovernmental Conference on Environmental Education was held in October 1977 at Tbilisi (UNESCO 1978). This conference referred back to the sense of urgency about environmental problems expressed at the Stockholm Conference and emphasized the important role that education has to play in addressing these problems. The meeting set out the purposes of environmental education, expanding on the Belgrade Charter with three goals relating to awareness, skills, and attitudes. The declaration from the Tbilisi Conference also built on the guiding principles for environmental education put forward by the Belgrade Charter. According to these principles, environmental education should be for all ages, lifelong, and interdisciplinary, and should cover all scales from local to international. In addition, environmental education should cover a breadth of teaching and learning approaches, focusing on practical problems and with learners participating in planning their own learning. As environmental problems are often complex, there is a need to develop critical thinking and problem-solving skills. The meeting also considered that environmental education should be integrated into the curriculum, rather than being taught as an additional subject. Since Tbilisi the momentum has been maintained with subsequent international conferences (e.g., International Conference on Environmental Education (ICCE); World Environmental Education Conference (WECC)) and the establishment of international journals on the subject: the Australian Journal of Environmental Education was established in 1985, followed by International Research in Geographical and Environmental Education, Environmental Education Research, and the Canadian Journal of Environmental Education in the 1990s.

There has been increasing emphasis on sustainability and sustainable development since the 1980s. Consequently, in the 1990s there was a shift toward environmental education for sustainable development (EEFSD) or environmental education for sustainability (EEFS), and later to education for sustainable development (ESD) or education for sustainability (EfS). ESD incorporates ideas from both environmental education and development education (DE). While there is overlap between environmental education and ESD, the two have different roles: environmental education tends to focus more on the knowledge and values of the individual, whereas ESD looks more at a move to a sustainable society (Tilbury and Cooke 2005).

The importance of education was again emphasized in the Rio Declaration, which resulted from the UN Conference on Environment and Development (UNCED, also known as the Earth Summit, held in Rio de Janeiro, 1992) and the subsequent action plan for advancing sustainability, Agenda 21. However, the extent of progress since Tbilisi continued to be questioned. Recommendations from the UN World Summit on Sustainable Development in 2002 included a call for a Decade of Education for Sustainable Development, which ran from 2005 to 2014 with the aim of promoting the role of education and training in working for a sustainable future.

There are two main areas of criticism of environmental education. First, there may be issues about how it is presented, such that it can be seen as advocacy rather than unbiased presentation of factual information. The use of the preposition “for” in “education for the environment” may in itself be problematic and may appear to be value-laden (Scott and Oulton 1999). Jickling and Spork (1998) view “education for the environment” or “education for sustainable
development” as a slogan and argue that, while slogans may be useful for providing a focus, they can also develop into doctrines. Complex arguments about environmental issues may be simplified, potentially leading to misconceptions, and in some cases the presentation may be alarmist (e.g., on overpopulation, depletion of oil reserves). These alarmist approaches may be counterproductive when the predicted events do not occur, resulting in uncertainty and lack of trust in the sources and deliverers of the information. To counter this, students need to be made aware of the complexity of environmental issues and to develop skills in critical thinking and problem-solving (Palmer and Neal 1994). They will need to consider plural understandings rather than privileging certain viewpoints (Scott and Oulton 1999) and to apply systemic thinking (Sterling 2001).

The second area of criticism, according to some views, is that environmental education has been relatively ineffective and its outcomes uncertain (Scott and Oulton 1999; Sterling 2001). This may have resulted from a top-down approach based largely on knowledge deficit, along with a transmissive model of education, that is, one focused on the one-way delivery of information by experts. Sterling (2001) argues instead for the need of a transformative model of education to effect change. This would take a democratic, bottom-up approach, with a focus on participatory learning. Education may also be seen to play a role in developing environmental citizenship as a route to sustainability.

Despite these criticisms, environmental education has become more established and has broadened in scope since the 1960s. As ideas around sustainability have continued to develop, the concept of resilience has been explored in the context of the relationship between learning, society, and sustainability (Krasny, Lundholm, and Plummer 2010). Thus environmental education may contribute to preparing for and managing complex change, through building resilience from the level of the individual to that of social-ecological systems.

Environmental ethics

Why study environmental ethics?

Toward the end of the twentieth century, environmental ethics emerged to address the mounting environmental problems. The hope was and still is that, through addressing humanity’s responsibilities to care for, protect, and offer adequate stewardship of the nonhuman “natural” world, humanity might learn to change its ideas and practices and thereby tackle environmental problems. Environmental problems are those that arise from human dealings with the natural world and its physical processes. The natural world supports human life, through the production of food and clothing and through providing shelter, water, the air we breathe, and the fuel we consume. This treatment of the nonhuman world for human exploitation to meet humanity’s needs is called an instrumentalist view of nature. The instrumentalist viewpoint treats nature as existing exclusively to meet human ends, and is an attitude that has dominated for centuries. Thus instrumentalism is also an anthropocentric view stemming from the belief that the whole of creation exists for the sake of humanity and that humanity was given dominance, “rightful mastery” over all fellow creatures. However, in the last few centuries there has been a change in the extent and rate at which the natural world is being used as a resource for humanity. Not only are we using nature, but we are also producing “nature” (Smith 1984) in novel forms. As we enter the twenty-first century, the scale, penetration, and domination of humanity’s activities on the planet are radically altering human relations with the environment as a sustainable resource that supports life. Despite the principles of an instrumental relation with “nature” having been established millennia ago, from which the practice of treating the natural world as a resource derives, it is the extent to which “nature” has become a resource under industrial capitalism in the twentieth century that is of urgent concern. Smith (1984) argues that capital produces “nature” itself in material form. Thus, it is widely accepted that not only is human activity affecting the nonhuman natural world, contributing to climate change, the extinction of species, the pollution of water supplies, and the destabilizing of fragile ecosystems, but it is also manipulating life at the genomic level, giving life to un-“natural” beings in animal and plant form. Equally, concerns are raised about how we look after nonhuman life that we control and manage, for example animals produced for human use on farms, in laboratories, and as domestic pets. This range of human activities raises serious questions about the inclusion of the nonhuman “environment” in its diverse forms within politics and how to adequately address humans’ ethical relationship to it.

What is ethics? Ethics is the branch of philosophy concerned with how we should decide what is morally wrong and what is morally right. As humans we are faced with moral decisions about the right thing to do. These may be matters of great concern or, more often, small matters:
ENVIRONMENTAL ETHICS

Should we buy eggs from hens kept in battery cages? How should we travel to reduce the negative impacts to the environment – by bicycle, car, or plane? We may give a lot of thought to some questions and very little or no thought at all to others. Ethics is a specific discipline that probes the reasoning and the practices that engage us in a moral life. It does this by critically examining and analyzing the thinking that is or could be used to justify our moral choices and actions in particular situations. Geography, as the discipline that specializes in studying the relationship between humans and the environment, is particularly engaged with addressing environmental ethics through empirical research and theoretical and methodological innovation.

How should we foster practices that are more in sympathy with sustaining a quality of life for both humans and the rich diversity of nonhuman animals and plants that inhabit this planet? Can these ethical considerations be extended to inanimate natural processes and geologic life, with which humans, animals, and plants have codependent life-supporting relations?

Anthropocentrism

During the Enlightenment period from the mid-seventeenth to the eighteenth century, when the authority of God and monarch was decentered and human individuals were positioned at the center of the social world, the grounds for establishing a moral ethical framework based on the human capacity for reason and agency took hold. The consequence of this shift was to emphasize humans’ exceptionalism as beings capable of reason and agency, and to dismiss the nonhuman world as lacking reason and cast (wrongly) as insensible and inert. The great variety of beings and entities that fell into this category of the nonhuman natural world was not differentiated. Plants, animals, rocks, and rivers were marveled at for being the antithesis to humanity and for the qualities of naturalness that were “untouched” by humans. Human civilization in Europe at the time witnessed increasing numbers of people living in industrial, polluted towns and cities through the eighteenth, nineteenth, and twentieth centuries. Notably, this dualistic representation of the nonhuman world of “nature” on the one hand and the representation of humanity on the other was a further extension of the anthropocentric position. The modern thinking that produced an ontological divide between the world of nature and the world of society continues to have a tenacious grip on the cultural meanings of nature and, therefore, approaches to environmental ethics. Accompanying this thinking was the belief that it was morally appropriate to consider only the interests of humans, thus excluding the nonhuman world from moral judgments. Consequently, the nonhuman world of animals and plants was considered outside the remit of ethical concerns and the scope of human morality in Western society. In summary, the division between society and nature characterized much post-Enlightenment thought. The ecofeminist Val Plumwood (1993) has argued vigorously against this mode of thinking, in which the essence of human nature is located in a masculinist, rational human mind, in opposition to the physical, embodied, and emotional nature of the feminized human.

Despite post-Enlightenment thinking being still very much alive today – for example in how the term “natural” is used to describe an aesthetic that implies the absence of human intervention (e.g., natural birth, natural food, natural landscapes) despite this being far from the case. Take, for example, organically certified milk: despite controls over the use of antibiotics on organic cattle, unnatural practices are still at large in the
industry, where artificial insemination is used to breed the dairy cow. Various events through the last 200 years have heralded changes to the level of concern human society expresses about its relationship to “nature” and the environment. To illustrate, the following are a selection of the historical events that have paved the way for animals to become included within Western society’s circle of ethical reasoning.

Close relations have formed between humans and animals over millennia, and yet it is only in recent centuries, as human society has moved away from an existence based on subsistence farming to be able to focus on more than food production, that concerns about the plight of animals has come to the fore. Jeremy Bentham wrote about animals in his *Introduction to the Principles of Morals and Legislation* in 1789: “But a full-grown horse or dog is incomparably more rational and conversable than an infant of a day, or a week, or even a month old. Even if that were not so, what difference would that make? The question is not, Can they reason? Nor, Can they talk? But, Can they suffer?” (1907/1789, 144).

In the United Kingdom the Royal Society for the Prevention of Cruelty to Animals (RSPCA) was established in 1840. In 1954 Ruth Harrison published *Animal Machines*, which critically examined and exposed the conditions of animals raised in the newly established industrialized large-scale farming systems in post-World War II Britain. Swiftly following Harrison’s pioneering book was the first UK government inquiry into the wellbeing of farmed animals, the Brambell Report, published in 1956. The report outlined recommendations for the living conditions of farmed species. It included the Brambell version of the five freedoms: “freedom of movement to be able without difficulty, to turn around, groom itself, get up, lie down and stretch its limbs” (Brambell 1965, 13). These have since gone on to form a key pillar in applied animal welfare ethics globally, and continue to inform production standards for farmed animals. In the second half of the twentieth century, an ethical literature dedicated to animal rights became more widespread and affected public consciousness. Most notably, Peter Singer in his pivotal 1975 book *Animal Liberation* argued for animals to have rights, claiming that the boundary between human and animal is merely arbitrary. Animals can be intelligent and have reasoning and/or linguistic capacities; like humans, they also have the capacity to feel, most notably to suffer and experience pain (Singer 1975). Since the mid-1980s animal welfare science, a discipline that provides scientific knowledge specifically on the capacity of animals to suffer, to experience pain and positive emotions, has become established. This science has supported moves to change the legal status of animals. In 1997 the European Amsterdam Treaty legally recognized animals as sentient beings, and by 2009 the United Kingdom Farm Animal Welfare Council (FAWC) was looking to a future beyond the five freedoms, where all farm animals would have a life worth living, from the animal’s point of view, and where an increasing proportion of farm animals would have a good life.

These various historic milestones both chart the development of normative challenges to the abstract moral philosophies that had placed human interests central in all ethical concerns, and mark shifts in society’s cultural thinking about animals. Changes to human cultural thought and practice continue to alter the meanings given to the nonhuman entities that make up “the environment.” These changes are guiding the direction of scientific funding to ask different questions about nonhuman entities and ecosystems. Together new knowledges, scientific or otherwise, and the impact of particular events inform the development of environ-
Environmental ethics

mental ethical frameworks that guide environmental policy in its widest sense from the care for farmed animals to the management of ecosystems in coastal waters. Some readers may think the illustration of the development in animal welfare to be something quite different to the ethical work related to thinking of the environment. It is notable that animal-welfarists tend to prioritize the value of the wellbeing of individual animals, whereas environmentalists think holistically about the whole ecosystem – plants, animals, and biophysical environment – and how its collective health can be sustained. This leads to value attributed to continuing the existence of species, and maintaining biodiversity whereby the individual is valued in relation to its contribution to maintaining the whole. Indeed, while both fall under the broad category of environmental ethics, animal welfare and ecological environmental approaches often have quite different orientations and, at times (though this may not always be the case), this has led to different types of ethical reasoning. For example, deontological ethics, which is concerned with rights as advocated by Tom Regan and Peter Singer, is easier to apply to animals than to a river. An animal can be given rights to feed and water, and someone can have a duty to provide that feed and water. But what rights does a river have? Does it have a right to flood annually and to change its course slowly over time without interference from humans? Are those what a river needs to have a life worth living? Instead, it may perhaps be more beneficial to place the river within an ecosystem that is a habitat that supports nonhuman animal and plant life. The “happy” state of the river is then judged by the flourishing of animal and plant life in its waters and on its banks and floodplain. It is these types of questions that are actively discussed.

An alternative approach to environmental ethics is one that puts it in broad alignment with deep ecological perspectives and attempts to address the complexity of ecosystems. These approaches have sometimes been informed by Lovelock’s Gaia hypothesis which dates from 1979. This theory conceives of the Earth as a self-regulating system, maintaining the conditions that support life, and as such it is a “superorganism.” These ecological perspectives share an impulse to extend human consciousness to include recognition of our embeddedness in constitutive relations with the nonhuman world, in the commitment that humans should not be the sole measure of ethical considerations. However Plumwood identifies a humanism at the center of these nonanthropocentric enterprises, which links ecological imperialism with the “master model of self” (1993, 145), because they privilege the self–world relationship and deny difference in terms of gender and race in their conceptualizations of self–world relations. Despite attempts at an intersubjective conception of ethical agency in these deep ecological perspectives, the nonhuman world is still conceived as an extension of the human being rather than as having value that is independent of human life.

Environmental ethics in the Anthropocene

Bill McKibben argued in 1990 that we have reached the end of “nature” as a separate entity untouched by human life (McKibben 1990). More recently, Crutzen and Stoermer (2000) have proposed that we are now living in the Anthropocene – an era in which the biogeochemistry of the planet itself is being altered and the climate is being destabilized, because ultimately humans are influencing coevolution at a planetary level. As a consequence, it no longer seems feasible to continue to place humans at the center of an ethical framework as this
immediately places limits on the capacity for ethicists to properly consider the interests of nonhumans and to recognize their unique and highly differentiated capacities and affects in the anthropogenic environment. It is for these reasons that environmental ethicists have sought to move beyond anthropocentric perspectives on the nonhuman natural world, and rather to meet the demand to engage with anthropocentrism as a material fact in the Anthropocene. This point is made to stress that it is not only about how humans represent and give meaning or values to the nonhuman world that needs to be written into our ethical frameworks but how the environment is materially produced and internally transformed by the activities of humanity.

The challenge to include how humanity has materially transformed the environment has led some environmental ethicists to move away from the historic ontological framework of division between society and nature, human and animal, to adopt frameworks of ontological relations. Debates about ontology are interested in exploring what the nature of being is, and refer loosely to what constitutes the physical stuff in the world. Geographers have made important contributions to the field of a material, relational environmental ethics through developing a number of strands of thinking that work to develop environmental ethical frameworks around an ontology of relations between the heterogeneous entities, beings, and persons in the world, rather than ontologies that divide the world up into categories of different entitlements for ethical consideration. The implications are that ethical frameworks revolve around what ontological choices one makes and the consequences of who or what qualifies for ethical consideration. Does the environment — as a place separate from humans — still exist? And, if it doesn’t, this demands a radical shake-up of what environmental ethics can be. Indeed, the debates within geography and other disciplines about ontology have heralded the advent of nonanthropocentric ethical frameworks for studying environmental problems. But, as various commentators have made clear, the ethical framework needs to be supple, sensitive to contingency and inclusive.

What has influenced this turn toward a relational ontology? Perhaps most influential is feminist environmentalist ethical thought that built on the thinking in Plumwood (1993). Plumwood posed the challenge to contend with a humanism that went beyond engagement with the human characteristics dominated by the white rational male, to include human characteristics of emotional vulnerability and gender and racial differentials. To address this challenge, there has been an important shift toward studying humans as embodied beings that are practically engaged with the world around them to the extent that it is less clear where the human ends and the nonhuman world begins. The term “more than human” has become popular to gesture to this sense of walls coming down between self and other, the other being nonhuman. Sarah Whatmore (2002), the clearest advocate in geography for this form of thinking, argues that we should focus our attention on how materiality connects humans and nonhumans together and do this via mapping out imaginative cartographies of these connections to articulate a material ethics.

Relational material ethics

Whatmore’s influential book *Hybrid Geographies* (2002) puts into practice an ontological politics based on the inseparability of nonhumans from what should constitute the social, and by doing so opens up a different way to explore environmental ethics. Hybrid geographies are mapped to disrupt categories of humans and nonhumans and hence the “purification” of the
world of nature and the world of society. There is a strong sense in this work of the world not staying still. This is a world that is always being caught up in dynamic processes and practices that undermine the stasis of pregiven entities, and therefore looks toward the immanent potential of something very different possibly coming into being. This move is significant for how it reorders our ethical community beyond the universal human subject as through the cartography of networks (or rhizomes), a vast range of “affective actants-in-relation” (Whatmore 2012, 251) perform to make and hold their shape. The shapes they make and hold are precarious achievements whose durability and reach are either threatened or supported by humans. For example, the market for free-range eggs is a sociotechnical achievement made up of hens, charities, supermarkets, science, and compassion, whose precarity is underlined by the fact that its market share has only really become established in UK supermarkets in the first decade of the twenty-first century. There was a time when the free-range egg shelf in a supermarket did not exist and had not been imagined. It has become possible to sell free-range eggs at a higher cost than barn or caged eggs because shoppers feel compassion toward the plight of the battery hen through the campaigns of animal welfare charities raising the profile of hens in the media; the effective use of findings from hen welfare science to give credibility to the claims made, and ultimately the growth of support for criticism of caged hen production systems; and the use of EU legislation, specifically the 2012 caged system ban, which encouraged the egg industry to invest in changes to their production systems.

Crucial to Whatmore’s approach is the attention given to what Michel Serres names as “extra-linguistic forces, bonds and interactions,” acknowledging the impossibility of language being the mode of engagement between humans and nonhumans. It is the ways that humans and nonhumans interact, and affectively bond with or force their presence on each other, that direct her cartographic methodology. Returning to the free-range egg market example, there are emotions and affects that shape its precarious achievement: humans responding with concern about the experiences of hens living indoors or outdoors, in a cage or in a barn; the use of pictures and drawings on egg boxes of imagined rural landscapes with free-range hens happily clucking around. Drawing on Whatmore’s thinking, it could be argued that the ethical connectivity between hens and humans is oversimplified, whether this market were to be understood only in utilitarian ethical terms, or merely as an example of hens being given more rights. Whatmore’s approach enables spatial imaginaries and spatial practices to be witnessed that challenge “myopic parameters of ethical connectivity” (2002, 158) to complicate geographies of intimacy and affect that have, to date, configured conventional understandings of what the worldly responsibilities of humans are and should be. For, to give a different example, when we eat meat in the form of a burger, it can be easy to forget about the animal from whose body the meat came from. Why should we care about the life of the animal that has become meat? Or why care what food the animal from which our meat came from ate? Bovine somatic encephalopathy (BSE), or “mad cow disease,” and the pathological connection with Creutzfeld–Jakob Disease (CJD) – a brain disease in humans – demonstrates the significance of mapping the practices, processes, and events in the life of a nonhuman actant. In this case the prion remains intact through the metabolic pathways between beef fed to cows, which are then fed to humans. Eating prion-infected meat can make people susceptible to the brain disease. Thus cartographic practices of this kind can
emphasize the relevance of exploring new spatial imaginaries and spatial practices as they can make distant, remote practices relevant and ultimately engage ethical responsibilities in new directions.

Relevant to Whatmore’s theorization of hybrid geographies is the need to begin from an embodied and practically engaged human self. Feminist phenomenological thinkers have developed a theory of the flesh and a theory of intercorporeality to indicate more carefully how a material ethic can evolve from this material, bodily engagement with the self. For example, the embodied practice of eating directly places the bodily flesh of human in intimate relation with the bodily flesh of another body, whether human or animal, when eating food. Thus, when we eat foodstuffs with different material provenances, how we engage with the edibility of an egg from different farm production systems – caged, barn, free-range, or organic – and specifically how the material aesthetic plays a part in the practice of eating, are of ethical relevance. The affective response that leads to the quality of an egg from a battery cage system as being not as “tasty” as one from an organic free-range system, illustrates an intercorporeal ethic in operation. Whether or not there is a discernible difference purely in the aesthetic taste or appearance between one egg and another is a different matter. The aesthetic appreciation of the eggs as a result of the ethical connections between egg, hen, and human are evident and are bundled into the eating experience for some consumers.

A second influential theme for Whatmore, which emerges again from feminist ethics, is the praxis of care that is elaborated through the concept of an intersubjective situated self. Recent advances in this element of thought can be found in Haraway’s (2008) concept of “sharing suffering” as an embodied intersubjective ethical position outlined in her book *When Species Meet*. Here she explores possible alternatives to interspecies relations as they are currently known, arguing for a new style of ethical consideration that, instead of drawing on ethical principles to explain and guide decision-making, seeks to understand ethics as practiced in the everyday work of caring. In terms of addressing how we share suffering, Haraway argues that it is through a performative approach – in other words what we do practically, as opposed to abstract reflection – to ethics that we can *respond* to another’s suffering rather than *attend* to it. In this way Haraway’s concept of “response-abilities” is a way to understand “ethics in practice” as more than representational. This approach focuses less on making decisions, showing good judgment, and suppressing gut feelings, and more on the ability to feel and respond, which modern moral frameworks have often sought to drill out of subjects. The hope is that we can better enact the principle of minimizing harm and suffering through learning how to become more responsive to the nonhuman material forms with which we live.

The object of ethical concern therefore affects how we perform ethically, how we establish more care-full and more response-able relations. For example, paying attention to how somatic sensibilities can offer insights into how to respond to the suffering or needs of a mammalian nonhuman animal may face fewer immediate challenges than to the needs of fish, with whom humans share fewer corporeal experiences. And, yet, when it comes to the constituent beings of the environment, it is of course very important not only to be attracted to caring for those most like us, or most charismatic, but to be aware of the need to be open to respond with care in diverse and contradictory circumstances. Thus, the attention to the praxis of care focuses attention on how ethical responses can be aligned with learning how to be affected and how to do the right thing. It is not a straightforward route
to prioritize attending to opportunities to learn how to respond differently, or to make the world different from how we have come to know it. Karen Barad (2007) argues that, depending on the “cuts” we necessarily make into the world to observe any phenomena, the world opens up to us differently or, in other words, what we learn about the world will change, depending on how we make the cut between the subject and the object. Thus the ethical emphasis here, as in Haraway, is on what we do rather than on our capacity to be self-reflective about ethical principles. For example, new understanding about animal lives has led to a legal recognition of animal sentience – that is, that animals have emotional experiences in response to the environment they are in. Interestingly, the experiences of sentience of farm animals does not register only in their living bodies but also affects how their bodies can be used as meat. Meat science now recognizes that the treatment of a farmed animal prior to slaughter directly affects the material quality of the animal’s flesh, now meat, postslaughter. Following Barad’s thinking, what is happening here is an interaction between how the body registers stress responses in pigs, and how the physiology of the pig’s body responds differently if it is stressed at the point when oxygen leaves the living breathing body through the process of dying and becoming dead. However, the effect of this process on the actual flesh of the pig has arguably always occurred, but, in the contemporary age of concern for animal welfare, knowledge and awareness of animal welfare supports the interpretation of the material change in the pig’s flesh in a new way, and in the process articulates another way to make an ethical relation between human and nonhuman.

Looking toward the future and continuing the work to develop nonanthropocentric approaches, there are some notable fields of work that use participatory methodological approaches for working with nonhumans of diverse kinds. Participatory approaches have developed in geography in relation to working with human individuals and communities to achieve social justice. By including nonhumans as constitutive members of the social, following Bruno Latour (1993), how can participatory approaches support social justice for the nonhuman world? In many respects this work is still in its early stages of innovating methodologies and theories appropriate for nonhuman participatory research practices. One participatory approach is to use the human imagination to explore what it is like to be a plant, an animal, or a river through the use of thick descriptions derived from scientific knowledges and lay knowledges and creative thought, to encourage humans to explore becoming cow-ness, or becoming river-ness as an embodied experiment of becoming. An advocate of this approach is Joana Formosinho (2014), who is exploring methodologies for encountering otherness and acquiring knowledge of things in themselves as a route to learning how to see and respond differently. A second approach is to try to engage in “conversation” with nonhumans. Michelle Bastian and colleagues have been pioneering this experimental approach More-than-Human Participatory Research. For example, this might include asking how the nonhuman world can be included within our ethical protocols, thus questions we might ask include: How do you ask or seek consent from a river to change their management plan? How do we invent ethical protocols that encourage asking questions differently to take into account the interests, capacities, and potential disruptive elements of the nonhuman world in environmental governance practices?

Environmental futures

Geographers from Alexander von Humboldt onwards have played leading roles in developing scientific methods of observation, data collection, and deriving and testing hypotheses that have proved effective in increasing understanding of environments past and present. However, key questions preoccupying contemporary society also relate to what our past and current actions might mean for future environments and generations. Explicit attention to environmental futures is therefore becoming an increasingly familiar practice in research and policymaking. Thinking critically about environmental futures is not, however, a recent phenomenon. There is a long and diverse history of literary, artistic, and scientific work that provides the foundation for current thinking about environmental futures. While based on different drivers and motivations, adopting divergent methods and approaches, and culminating in distinct and not necessarily comparable outputs, the broad field of environmental futures research nonetheless encompasses core geographical concerns including matters of scale and place and most fundamentally of nature–society interactions.

Much of the historic literary work in the field of environmental futures is focused on all-encompassing visions or blueprints of sustainable societies, often gathered together under a banner of the “utopian tradition.” The utopian tradition can be traced back to Plato, through the political philosophies of Thomas More (Utopia, 1516), to William Morris (News from Nowhere, 1891) and on to the work of anarchist geographer Peter Kropotkin (The Conquest of Bread, 1892, and Fields, Factories and Workshops, 1904) and planning visionary Ebenezer Howard (Garden Cities of Tomorrow, 1902). At the same time, dystopian visions of future environments have also been prominent features of politico-literary texts, as seen in the work of Aldous Huxley (Brave New World, 1932) and George Orwell (Nineteen Eighty-Four, 1949) and increasingly through contemporary science fiction novels, films, and computer gaming. These visions, both utopian and dystopian, have been widely critiqued and categorized according to the proposed solutions for society’s ills, be that extended state control or anarchy, private or public ownership, and the degree of democracy and equality. Visions explicitly concentrating on environmental futures emphasize matters of resource use and consumption, typically focusing on problems of scarcity and the search for some attainment of “the good life.” Yet solutions remain diverse, some focusing on sufficiency and limiting consumption based on basic needs, others placing great faith in technological progress to enable continued production and consumption of goods and services.

Envisioning environmental futures is not just the preserve of utopian/dystopian literary authors. Quotidian processes of land-use planning, for example, frequently embody the creation of plans for how neighborhoods, cities, regions, and nations might evolve in the future. Yet these plans often depict near-term futures
ENVIRONMENTAL FUTURES

(around ten years in most cases), and are constrained by pragmatic resource limitations and the realpolitik of policymaking. Yet, as Marius de Geus (1999) argues, imaginative visions for future societies as produced by the utopian authors may work usefully together with planning – at local, national, regional, and global scales – as a means to provoke discussion about longer-term developments, providing alternative ideas, perspectives, and questions about decisions to be made and resources to be allocated.

Modeling global environmental futures:
trends, forecasting, and scientization

In April 1968 the Club of Rome, an international think tank, commissioned a team of system scientists from the Massachusetts Institute of Technology (MIT) to model possible future environmental scenarios based on five factors seen as limiting growth: population, agricultural production, natural resources, industrial production, and pollution. The model predicted global economic collapse and ultimately population decline by 2030 if trends in production and consumption were to continue. Other scenarios identified possibilities for economic growth, but only if systems of governance were developed that both regulated resource consumption and invested in technologies to control humanity’s ecological footprint. The research was published in 1972 as “Limits to Growth,” and while heavily critiqued for its assumptions and limited data, it had international impact selling more than 12 million copies in more than 30 languages. It was followed in the same year by “A Blueprint for Survival” by Edward Goldsmith and colleagues (1972). This document set out a manifesto for addressing the challenges identified in “Limits to Growth” and included supporting signatures from 36 experts from biology, chemistry, genetics, natural history, and medicine as well as two British geographers, S.R. (Bob) Eyre from Leeds University and George Melvyn Howe from Strathclyde University. Central to the authors’ vision for a survivable future were radical shifts in the ways society, as experienced within Western industrial countries at the time, would function. The vision was to create stability through decentralized, self-governing, and self-sufficient communities where diversity rather than uniformity could be fostered. While technology was perceived to play a role in this stabilized future it would only do so when the full cost of its development and use was proven to be less than the benefits it provided. Likewise, the Blueprint focused on the recognition of what was termed “real value” rather than economic value, with an emphasis on quality rather than quantity in design, and a reclamation of value for skilled craftsmanship and the arts. However, how such transitions to the stable, survivable society envisaged by Goldsmith and colleagues were to be enacted were not outlined.

Many of the concerns of the Club of Rome regarding an impoverished environmental future, biodiversity loss, environmental pollution, and unsustainable consumption, remain concerns for global environmental governance institutions in the twenty-first century. Indeed, little progress has been made in redirecting the trajectory of trends identified by the MIT scientists back in the late 1960s. There has been significant progress, however, in terms of the computing capability of the program used to model possible environmental futures, the quality and quantity of data to underpin those models, and the transnational collaboration between experts to refine both data and modeling attributes. A frontier activity in this regard is following the global emissions scenarios of the Intergovernmental Panel on Climate Change (IPCC). The IPCC was established to assess scientific, technical,
and socioeconomic information relevant to the understanding of humanly induced climate change, potential impacts of climate change, and options for mitigation and adaptation. In 1992, the IPCC released the first global scenarios to provide estimates for the full suite of greenhouse gases (GHG), but by 1996 an even broader set of emission scenarios were developed. The new scenarios included improved emission baselines and updated information on economic restructuring globally, incorporating rates and trends in technological change and expanding the diversity of the economic-development pathways considered. Modeling these broader parameters indicated that different social, economic, and technological developments strongly influence emissions trends, thereby providing significant insights into the interlinkages between environmental quality and development. Following the rules and procedures of the IPCC, multidisciplinary core writing teams, including geographers, draft reports which are then sent to international experts and member governments of the IPCC. For example, more than 2400 experts were formally invited to review the 2007 IPCC Synthesis Report and reviewers included geographers Thomas Spencer from Cambridge University, UK, and Georg Kaser, Institut für Geographie at the University of Innsbruck, Austria.

During the following decade, other international organizations followed the IPCC in its environmental futures activities. The World Water Commission produced their “World Water Vision,” while agricultural scenarios were developed by the International Assessment of Agricultural Science and Technology for Development, and scenarios of global ecosystems services resulted from the work of the Millennium Ecosystem Assessment. Meanwhile, transectoral environmental scenarios have also been produced by both the Organisation for Economic Co-operation and Development (OECD) and the United Nations Environment Programme (UNEP). The analysis for the OECD Environmental Outlook combines economic and environmental modeling frameworks developed at the OECD and the Netherlands Environmental Assessment Agency (PBL). Specifically, a global dynamic computable general equilibrium model “ENV-Linkages” is used to describe how economic activities are linked between sectors and across regions. It also links economic activity to environmental pressures, specifically to emissions of GHG. These links are then projected several decades into the future, in an attempt to illuminate potential impacts of environmental policies. Outputs from ENV-Linkages are combined with the IMAGE (Integrated Model to Assess the Global Environment) models run by PBL. A dynamic integrated assessment framework to model global change, IMAGE is underpinned by modeling of global land allocation, subject to production of food, feed, timber and water, and projects emissions, mapped onto a grid of the world. IMAGE has been used for other key global environmental assessments such as the Global Environmental Outlook (GEO) by UNEP. In contrast to the OECD approach, GEO aims to be a more consultative, participatory process focused on building capacity for conducting integrated assessments reporting on the state, trends, and outlooks of the environment. Based on integrated assessment and reporting approaches developed by a team of authors, including geographer Jill Jäger, the UNEP GEO approach also aims to make its reports scientifically credible and policy relevant, supporting multi-stakeholder networking and intra- and interregional cooperation to identify and assess key priority environmental issues at the regional levels. To this end a worldwide network of partners has been developed which
allows governments and other stakeholders to nominate experts to the process, advisory groups to provide guidance on scientific and policy issues, and a comprehensive peer review process.

However, while there have been increased efforts to ensure greater interdisciplinary input into models of environmental futures, academics including geographers David Demeritt and Michael Hulme, have demonstrated that they remain predominantly informed by natural rather than the social science research (Hulme and Mahony 2010). As well as marginalizing attention to important social components of global environmental change, this has also meant less critical attention to the philosophical and methodological aspects of prediction and forecasting. That there remains gender and spatial bias in terms of the inputs to many of these models also suggests that the visions of environmental futures portrayed are both narrowly conceived and highly bounded; there are what Richard Powell (2007) calls geographies of science even in the modeling of big data with respect to global environmental change. Equally, as with the Club of Rome, such modeling provides little assistance in terms of imagining how society might develop governing pathways to manage and construct less destructive environmental futures.

**From forecasting to backcasting:**

**the participatory turn in environmental futures research**

Within much standard environmental modeling work, natural phenomena are assumed to behave in the same way, whenever and wherever they occur. This assumption extends also to natural processes that represent a departure from long-term average conditions, and to nonlinear processes, such as a collapse of the thermohaline circulation (Rahmstorf 2000). However, it is argued that this assumption of continuity cannot extend to the social sciences where innovation and discontinuity have been identified as key features in the development of social systems. While many significant social structures, processes, and norms may remain relatively stable for periods of time, it is also the case that they can and do evolve, either suddenly or gradually, as a familiar outcome of economic and social activity. So, in contrast to the forecasting approaches adopted by the IPCC, OECD, and UNEP reports where past trends and current “rules” are iterated into the future, a body of work collectively called backcasting has evolved that explicitly adopts a normative scenario building approach (Dreborg 1996). The process is shaped around the question, “where do we want to go and what actions do we need to take in order to get there?” Essentially, backcasting assumes that futures can be created. This is its relative strength when compared with forecasting approaches although there are also dangers of overstating the capacity of actors to influence the future and clearly not all actors have equal influence in terms of shaping change. In response to these concerns, a third way between forecasting and backcasting has been framed as exploratory scenario building. In this context a range of underlying socioeconomic conditions are used to generate alternative futures as a means of mapping “possibility spaces.” Within this exploratory framing, the future is imagined through the development of multiple alternative states in which social agents can respond according to their own interests albeit with limited control. It is the emphasis on the importance of adaptation that is a defining feature within this arena of environmental futures work.

Of particular importance in many of the backcasting activities are the interlinked features of expanded participation, innovation, and creativity. Including diverse interests and
expertise and explicitly focusing on a future that is far enough away to free participants from the constraints of everyday living, but close enough to imagine themselves or their children inhabiting, is thought to offer more opportunities for combining knowledge, stimulating creative thinking, and developing innovative visions. Such transdisciplinarity in these normative environmental futures exercises is seen as essential to address the complexity of environmental challenges now and into the future. Backcasting scenarios are not theoretically based or empirically validated models, but heuristic tools to enable experts and others to engage in a collective process of deliberation. For example, the generated scenarios are frequently accompanied by a narrative, and sometimes even visualized, storylines elucidating the imagined futures. As such their value is seen to lie predominantly in their capacity to bring together disparate actors and agencies in a common process of envisaging desirable as well as possible futures; creating spaces for sustainability learning (Davies, Doyle, and Pape 2012). The development of scenarios is thus a process through which imagined futures can be revealed, ordered, and analyzed although uneven patterns of power and participation in those visions remain.

Collective visioning experiments have been undertaken by different environmental sectors from energy and city planning, to water resource management and sustainable consumption and at different scales, from the household scale to national planning fora. The Netherlands in particular has adopted backcasting as a feature of its strategic environmental decision making with visioning applied within the main Dutch research organization for agriculture and rural areas. Elsewhere experiments with participatory backcasting for supporting sustainable environmental futures have been undertaken in Sweden, Germany, New Zealand, and Canada.

Environmental futures: themes and roles

It is clear that thinking about environmental futures has a diverse lineage and continues to be practiced in many ways. Environmental futures activities can be constructed by individual visionaries or transdisciplinary collectives and can address different scales, from the modeling of global futures produced by the IPCC to the small-scale utopian ecological communities crafted by Peter Kropotkin. Such imagining occurs both in terms of near environmental futures, the ten year development plan within a local government district for example, as well as in terms of the far futures of science fiction, way beyond the lifespan of current populations. While literary visions of environmental futures have tended to be characterized as utopian or dystopian, the scientization of thinking through environmental futures sought to create positive rather than normative fields of possibility for environmental futures. Yet, even these increasingly sophisticated scenarios based on complex models map only certain dimensions of those futures, for example, predicting weather patterns or rainfall frequency and intensity based on lessons from the past and the present to estimate future patterns. How those altered environmental futures might affect the ways in which people live across the globe and under what governing arrangements is not addressed. Yet, environmental change scenarios involve much more than the scientifically based models that underpin them. Scenarios, whether they are developed by the IPCC or any other organization involve processes of selection and negotiation between different interests and stakeholders. For as Michael Hulme and Suraje Dessai (2008) outline, fundamental choices are made about the types of models used, the ways in which uncertainty is assessed and communicated, and the development pathways and
emissions scenarios on which to focus. So, while there is widespread skepticism of the utopian grand plans of individual visionaries or the singular blueprint of the future proposed by elite groups such as the Club of Rome, even the most scientifically robust vision of environmental futures are constructed following debate and contestation. Recognizing such characteristics does not diminish the usefulness of scenarios, as heuristic, motivational, and informative tools for design, planning, and policy development. Environmental futures experiments of all kinds provide spaces to debate important questions about the kinds of environments we might wish to inhabit in the future. While clearly multidisciplinary endeavors, the fundamental attention to nature–society interactions at the very roots of imagining environmental futures means that geographers (both human and physical) have a key role to play within them.

Scholars have noted an incremental shift over the past few decades in the way that the environment is governed. While originally the preserve of local and then national governments, environmental governance (as distinct from “government”) now encompasses the activities of multiple actors, including states as well as also industry, nongovernmental organizations (NGOs), and the public. Indeed, the term environmental governance has been coined by scholars to denote such patterns of interaction that derive from the strategies of these various actors to govern or “steer” society towards achieving environmentally-related objectives (Adger and Jordan 2009). States and/or governments have traditionally used regulation and the courts to govern the environment in a relatively top-down fashion, but in the last two decades non-state actors, including businesses and communities, have become much more directly involved in governing, necessitating the use of other approaches that rely on market forces and/or networks of local actors.

At first, the literature on governance was rather disjointed, but by the 2000s it had consolidated around three core perspectives: empirical (i.e., describing how society is governed and the changing form and role of the state in contemporary industrialized societies); theoretical (i.e., seeking to explain how it is governed and predict future changes); and normative (i.e., indicating how society should be governed and the different forms of environmental governance required to solve complex, cross-scale and cross-societal issues such as climate change and sustainable development). Normative in this sense refers to how governance should be organized in practice. One of the most well-known formulations is provided by the World Bank, which publishes good governance principles for implementation by developing countries and also a wide array of other public and private bodies. In this context, “good” refers to a set of normative standards against which governance can be benchmarked.

A short history of environmental governance

Environmental problems are as old as humanity, along with societal attempts to address them. One of the earliest recorded environmental laws was a proclamation in 1272 by Edward I of England banning the burning of sea coal in London to prevent smoke pollution. Air quality issues then became progressively more important during the Industrial Revolution. Noxious gases from the production of chemicals in Victorian Britain led to the introduction of the national Alkali Act 1863, along with a government inspectorate to reduce emissions. However, government intervention did nothing to combat chronic air pollution in Britain’s rapidly growing cities, with
abatement measures, mostly regulatory in nature, primarily left to local authorities. This situation was replicated in other countries such as the United States, where cities such as Chicago and New York introduced their own clean air controls in the 1800s. Concerns over polluted drinking water, sanitation, and waste management then became salient public health issues in many other countries during the late nineteenth century. Again, governance was invariably predicated on action being taken at local scales. For example, in the United Kingdom, municipal authorities assumed most responsibilities for the supply of drinking water and sanitation, while catchment drainage and fisheries boards performed related management functions such as land drainage.

Thereafter, a wave of limited centralization spread across the western world, with central governments becoming gradually involved in environmental management in the early twentieth century. Six national parks had already been created by the US Congress before 1900, and a federally funded Soil Conservation Service was then established to reduce agricultural erosion. The creation of the Tennessee Valley Authority by Congress in 1933 became the prototype for integrated water management systems worldwide (Benson, Jordan, and Smith 2013). In the United Kingdom, the centralization of water management started in the 1940s, via the national Rivers Board Act 1948. After a succession of severe smog incidents in London, Parliament introduced the Clean Air Act (1956) that significantly reduced the burning of coal in the city. But most environmental tasks remained the preserve of subnational governments in many countries well into the 1960s. And, crucially for those seeking to understand the changing governance of the environment, legislation and other forms of regulation remained the chief instruments of environmental policy, and very much the responsibility of national governments.

Environmental decision-making in the late 1960s and 1970s became increasingly dominated by central governments. Across the developed world, chronic air and water pollution problems became coupled with mounting threats from toxic waste, species decline, habitat loss, and damage to marine environments. The transboundary nature of many of these problems meant that the local level actors responsible for them found it difficult to govern effectively, thus providing a strong rationale for the centralization of many environmental governance tasks. This process was first visible in the United States, where the inability or unwillingness of state governments to intervene in solving pollution issues, despite some federal clean air and water legislation, led to a shift in the national public consciousness, which then precipitated demands for government intervention (Andrews 2006). Adoption of the landmark National Environmental Policy Act (NEPA) by the US Congress in 1969 for the first time anywhere established environmental protection as an objective of a central government. Other major federal legislation on air pollution, water quality, species protection, and toxic waste clean-up followed quickly afterwards. The federal Environmental Protection Agency (EPA) was also established to implement these measures. Taking a lead from the United States, many national governments worldwide then acted to introduce environmental legislation and implementing institutions. During this era of expanding internationalization, national governments also cooperated multilaterally to adopt several major environmental regimes or international agreements, such as the 1973 Convention for the Prevention of Pollution from Ships (MARPOL) and the 1979 UN Convention on Long-range Transboundary Air Pollution.

The shift towards state-led environmental government was then followed by moves towards forms of governing that were less reliant on the
introduction of new legislation. During the 1980s, a regulatory backlash occurred in the United States, United Kingdom and other countries, reflecting wider ideological and discursive shifts globally towards a more neoliberal political agenda. More decisions were taken after comparing economic costs and benefits, rather than following political demands for legal intervention (Jordan and Turnpenny 2015). This discursive shift promoted government deregulation and a greater role for markets in governing environmental problems. In the United States, for example, the Reagan presidential administration sought to undermine the federal environmental protection structure, primarily through defunding the EPA and attempting to decentralize its powers back to the state level (Andrews 2006).

Governments began to share even more powers with nonstate actors after the emergence of sustainable development as a political discourse, following the United Nations’ Brundtland Report (WCED 1987). Sustainable development recognizes that environmental, social, and economic issues need to be addressed holistically. This notion underpinned the UN 1992 Rio Earth Summit, which implored national governments to introduce wider ranging and nonlegal strategies for environmental governance. Agenda 21, the main implementing agreement of Rio, also envisaged new roles for nonstate actors, such as businesses, local governments, and communities, in governing for sustainability. These principles, to varying degrees, became integrated into environmental decision-making by different governments. In particular, they found a receptive audience in “greener” European countries, such as Germany, Denmark, and the Netherlands, via the discourse of ecological modernization. Premised on the notion that economies can be reformed along more ecologically-friendly lines, this approach involves government intervention (i.e., “steering”) to empower societal actors such as consumers and businesses in promoting environmental protection, often through the creation of new markets and technological innovation. Less regulatory or even nonregulatory ways of environmental protection (such as environmental taxation and emissions trading) were actively promoted by economists. Their views encouraged many states to adopt what came to be known as “new” environmental policy instruments (Wurzel, Zito, and Jordan 2013).

At the same time, many countries, such as the United States, Canada, and Australia, witnessed moves towards more collaborative and/or participatory forms of environmental governance based at the local or ecosystem level, involving state and nonstate actors cooperatively managing resources such as watersheds, forests, and oceans (Benson, Jordan, and Smith 2013). “Co-management,” or community-based environmental management, also found favor in developing countries, through involving localized stakeholders in government-led efforts to protect environmental resources. New policy formulation tools were developed to provide more anticipatory and participatory responses (Jordan and Turnpenny 2015). During the 2000s, the transition from national or central government-led environmental protection towards more governance-based forms continued. Intensifying globalization of socioeconomic processes and ongoing trade liberalization meant that governments were less and less able to deliver sustainable development on their own. Moreover, the increasing complexity and cross-scale characteristics of environmental problems, such as climate change or biodiversity loss, necessitated the involvement of multiple actors at different institutional scales. The follow-up conference to Rio, in Johannesburg in 2002 (the UN Rio +10), was, therefore, dominated by commercial and NGO interests, rather than by states. Public–private
partnerships, the main policy outcome of the conference, reflected the relative disengagement of governments in the sustainability agenda and also the greater emphasis being placed by this point in time on alternative governance forms at the global level.

As a result of these developments, the current situation is perhaps best encapsulated by the concept of multilevel environmental governance, in which governing occurs through many actors. The locus of environmental decision-making has expanded, vertically and horizontally, from local or subnational levels prior to the late 1960s to national and international scales in the early twenty-first century. At the global level, environmental governance now takes the form of multifarious regimes agreed between states – many brokered by the United Nations – that seek to address transnational issues as diverse as marine pollution, ozone depletion, deforestation, biodiversity loss, nuclear threats, and climate change. Regional scale initiatives are also prevalent, most notably in the European Union (EU), which, over several decades, has developed a broad-ranging body of environmental policy that now determines action in some 28 Member States (Jordan and Adelle 2012). Nonetheless, national governments arguably remain the most significant actors in managing the environment globally, although they share responsibilities with supranational bodies, subnational and local governments, businesses, NGOs, civil society, and communities in the pursuit of environmental objectives. One defining feature of this multilevel era is also the expansion of bottom-up, community-based initiatives in many states, often introduced reactively in response to the failure of more top-down and centralized approaches of environmental government of the past. Another characteristic, in the post-2008 “age of austerity,” has been the relative downgrading of the environment as a policy issue in national government policy as economic priorities have taken precedent (Russel and Benson 2014).

The main features of environmental governance

Research into environmental governance reflects this evolution through time, with geographers amongst others detecting changes in the focus, modes, and means of governing. First, scholars employ the term governmentality to denote the way in which power is exercised by the state (Evans 2012). Here, what became widely perceived as localized problems in the Victorian era, soliciting subnational institutional responses, gradually changed over the twentieth century as knowledge about the transboundary and socioeconomic effects of environmental problems increased. Concerted government intervention in the late 1960s and 1970s constituted a new knowledge system, which prioritized greater centralized state powers and regulatory solutions. In the 1980s, the adoption of more neoliberal approaches meant governments relied much less on regulation. Although sustainable development became an important feature of government approaches in the 1990s, by the late 2000s the governmentality of problems altered again, as national economic priorities became more pressing than environmental or developmental ones in the wake of the global recession.

Second, another feature of environmental governance is the increasing interconnection across hierarchies, markets, actor networks, and communities in developing and implementing policy (Evans 2012). As with multilevel governance, this involves the dispersal of powers formerly the preserve of the state in favor of government interaction within a nested hierarchy of multiple institutional levels or scales. For example, the governance of climate change now
ENVIRONMENTAL GOVERNANCE

Involves actors at the international level (the United Nations), regional supranational entities (the EU), national governments, subnational and local governments (Connelly et al. 2012).

Governance also now features many economic actors, with markets emerging as a significant mechanism for achieving environmental objectives, despite economic pressures often being the root cause of many problems. According to this logic, if markets can be harnessed properly they can provide powerful incentives to producers and consumers to behave in environmentally friendly ways. Here, markets can help “internalize” the negative externalities or impacts of economic activities, such as pollution, by placing a value on them. A well-known example is the establishment of emissions trading systems in the European Union and elsewhere that force industrial polluters to purchase permits to emit carbon dioxide, thus encouraging them to reduce emissions in order to save money. One of the features of environmental governance is, therefore, the prevalence of market-based instruments (or MBIs for short), as discussed below.

Third, environmental governance is closely associated with a growth in networks that span horizontal and vertical scales of interaction, and are sometimes composed entirely of nonstate actors. Such networks can operate within nation-state contexts or be transnational in nature, such as an “epistemic community” (Haas 1990), comprised of scientists and technical experts, bound by common belief systems concerning specific issues and often formed for advocacy and initiating policy change. Within environmental governance, examples could include the Union of Concerned Scientists, the Intergovernmental Panel on Climate Change (IPCC), and the Stockholm Environment Institute.

Another type of network operates transnationally (Bulkeley et al. 2012), in a more horizontal form that connects local actors across an international space in order to exchange knowledge and engage in learning about solving environmental problems. Such networks may be “self-organizing” to the extent that they are not necessarily reliant on central government steering or resources for their operation. One widely-known example is ICLEI, a global network of cities, regions, and towns devoted to transferring knowledge on local sustainability best practice. Other networks operate across more vertical scales, linking levels such as the international, national, and local.

As identified already, environmental governance has also involved greater roles for the public in decision-making. Agenda 21 strongly promoted citizen participation in sustainability, as did the UN Aarhus Convention in 1998. Public engagement by governments is thus encouraged via processes such as environmental impact assessment (EIA) in land use planning and strategic environmental assessment (SEA) of policies. Collaborative environmental governance is also a growing feature worldwide, particularly within integrated water resources and coastal zone management.

Finally (and as noted previously), environmental governance is itself associated with and constituted by the emergence of “new modes of governance,” such as taxes, voluntary arrangements, and information provision (Wurzel, Zito, and Jordan 2013). Early government intervention in managing environmental problems during the 1970s and 1980s was characterized by so-called “command and control” regulations, typified by US legislative measures such as the federal Clean Air and Clean Water Acts. Such mechanisms impose specific targets or objectives that societal actors must meet, with implementation often achieved through punishing noncompliance. The European Union has also introduced many regulatory measures as part of its wider environmental policy. These measures can be contrasted with market-based instruments that impose costs on environmentally damaging actions,
but which also establish economic incentives for actors to modify their behavior. Examples include environmental taxation, which levies charges on actors for the right to pollute and also subsidies for encouraging environmentally friendly approaches. In the United Kingdom, each ton of waste sent for disposal in landfill is subject to a tax, with some of the revenues dedicated to supporting local environmental projects. Meanwhile, the United Nations has introduced mechanisms such as the reducing emissions from deforestation and degradation (REDD) program that employs market-based instruments to support forest protection in developing countries.

As an alternative to the market, informational instruments provide information to influence environmentally friendly behavior through extending consumer choice. One well-known example comes from Germany and Austria, where governments have introduced eco-labels for some consumer products that provide details on their environmental performance. Another is the Forest Stewardship Council self-certification approach for labeling sustainably produced timber, in what has been called “nonstate market-driven” governance (Cashore et al. 2007). Environmental management and audit systems also allow businesses to assess the impacts of production cycles and hence reduce them.

Another “new mode” of environmental governance is the increasing use of voluntary agreements between governments and “target” groups such as industry. Agreements can either be self-imposed via declarations of intent by social actors to act in environmentally responsible ways, or they can be negotiated with governments. An example of the latter could include covenants, or formal legal contracts, struck between the Dutch government and business groups in the 1990s. Such “new modes” could additionally include the creation of individual institutions to achieve specific environmental objectives. For example, the global diffusion of integrated water resources management (IWRM) norms has led to the establishment of task-specific governance institutions at the river basin scale, such as the river basin districts introduced to implement the EU Water Framework Directive (Benson, Jordan, and Smith 2013).

**Theorizing environmental governance**

As well as describing the changes outlined so far, scholars have sought to use the term governance in a more theoretical manner, in attempting to explain some of these empirical patterns. For example, scholars have employed theoretical arguments to understand governance by focusing on different networks of actors, both in the European Union and in national contexts (Schout and Jordan 2005). Another example comes from the work of the OECD, which employs a particular network-based mode of “good governance” known as the “OECD technique” (Lehtonen 2007). This technique involves states benchmarking or reporting their implementation of environmental policy against OECD performance reviews and checklists. They then share best practice with other states in order to improve implementation. Other theories draw upon the literature on public participation to explain the collaboration of different actors in the management of resources such as river basins, forests, and coastal zones (Benson, Jordan, and Smith 2013). One argument made for greater collaboration by theorists is that it supports information sharing, trust, and learning amongst actors, which helps environmental governance become more adaptive and resilient in response to rapidly changing threats such as climate change. Finally, some political geographers refer to the ongoing neoliberalization of environmental governance.
to explain the growth in market-based mechanisms and deregulatory processes (Benson, Jordan, and Smith 2013).

Despite many attempts to test different types of theory, there is still no single “theory of environmental governance.” The vast majority of accounts of how the environment and sustainable development has been governed make little or no reference to what currently passes for “governance theory.” Mostly these studies import what theory or theories they need from the broader field of social science research, with a pronounced emphasis on those that feature networks, learning, collaboration, and voluntarism.

Environmental governance as a normative strategy

Environmental governance has undeniably also become somewhat of a normative strategy in itself. Although there are many arguments about how governance should be organized, there are five key areas of debate around: (i) global governance; (ii) market liberalism; (iii) the green economy; (iv) the green state; and (v) localized or decentralized models.

1 **Global governance.** Some authors see global governance as an antidote to the failings of state-led environmental government (Biermann 2006). Since the early 1970s, states have cooperated to form environmental regimes – sets of norms and institutions – aimed at resolving different problems, with varying degrees of success. Evidence from successful environmental regimes, such as the 1987 Montreal Protocol on ozone depletion, would suggest that internationalization can provide solutions to collective-action environmental problems by increasing transparency and trust amongst state actors. Yet this success is rare; more often than not, state self-interest dominates, as demonstrated by the past impasse in the UN Kyoto Protocol process or the inability of the UN Forum on Forests to counter chronic global deforestation. Environmentalists, meanwhile, remain skeptical over whether nonstate actors such as multinational corporations (MNCs) should be included in global environmental governance, seeing them as part of the problem rather than the solution to greater sustainability (Connelly et al. 2012).

2 **Market liberalism.** From this perspective, sustainable development is best achieved through limited government, less regulation, and greater engagement with economic actors. This view places great faith in markets and economic actors to deliver environmental objectives through their ability to value environmental resources. But the combined record of market liberalism and international capitalism in promoting more sustainable forms of global economic development is hardly encouraging, primarily because issues such as environmental justice, equity, and resource limits are often sidelined in market-based approaches. Some environmental resources, such as the Amazon rainforest or the global climate, also remain difficult to value in pure monetary terms, meaning that they can be overexploited. In response, some authors, such as Newell and Paterson (2010), call for reformed market-based approaches to addressing global warming, that is, “climate capitalism,” by suggesting that rather than eschewing business, environmental governance should accommodate it better through new economic growth models.
ENVIRONMENTAL GOVERNANCE

3 **Green economy.** The notion of the green economy (Barbier and Markandya 2013) builds on earlier work that sought a “greening” of economies to make them more sustainable and promotes the use of economic instruments, valuing natural capital and providing more socially equitable solutions via green employment and poverty reduction. Here, governments act as central facilitators in setting economic policy working in conjunction with nonstate actors such as business and communities to achieve collective objectives. While still very much a normative perspective, green economy, green growth, or green capitalism ideas have nonetheless permeated institutional responses at national and international levels, although progress has to date been globally variable (Russel and Benson 2014).

4 **The Green State.** Another normative argument is that the state should itself be reformed to promote more ecologically friendly forms of development that involve different actors. This chimes with the idea (Connelly et al. 2012) that state-centered governments are paradoxical in the way that they simultaneously generate environmental problems (through support for economic growth) and seek to solve them (through environmental policies). Governments are important in this respect, as they alone retain sovereignty to act on environmental issues within their territories, despite also allocating some powers to nonstate actors. Hence, Robyn Eckersley (2004) has argued for a greener state, through more inclusive “ecological democracy” based on greater public participation and integration of environmental and social norms into decision-making.

5 **Localized governance.** Finally, some scholars have gone further still in outlining more localized models of governance, which seek to greatly decentralize existing state powers. Collaborative environmental governance could help reframe government–society interactions through creating new responsibilities for actors, alternative forms of democratic engagement, and innovative mechanisms for managing resources. Green commentators have also called for more consideration of justice in environmental governance by shunning globalization, demanding controls on corporations, and promoting localization (Connelly et al. 2012). This localization of governance, with its rejection of centralized state-led steering, has in places become a partial empirical reality, with community-based economic activity emerging, such as the Transition Towns movement in different countries. More radical approaches still demand the rejection of environmental government entirely, favoring forms of eco-anarchy based on bioregions, rather than geopolitical borders, and exclusive community control.

“Governance” is a vital aspect of all these debates, suggesting that, after 40 years of governing the environment, the eagerness amongst geographers to understand and discuss its empirical, theoretical, and normative dimensions is as great as ever.

Environmental hazards

Ilan Kelman
University College London, UK
Norwegian Institute of International Affairs (NUPI), Norway

Environmental processes and phenomena are everywhere around planet Earth, affecting life and livelihoods, and sometimes leading to death and damage so they are seen as environmental hazards. That does not mean avoiding or preventing the hazards. Instead, society can use knowledge of environmental processes and phenomena to gain advantages from them while avoiding many hazardous aspects.

Definitions

Hazard

The word “hazard” tends to mean some form of potential danger, difficulty, or peril – actual or metaphorical. The word “risk” is often used in English to be synonymous with “hazard,” but in disaster studies the words are subtly different. “Risk” combines hazard and vulnerability into an expectation or probability of harm occurring. “Hazard” is a phenomenon or process with the potential to interact with vulnerability, thereby exposing the vulnerability. It is the vulnerability which causes harm in a disaster. Examples of environmental processes and phenomena with the potential to become hazards are earthquakes, lightning, comets, icebergs, floods, bacteria, and parasites.

Hazards are sometimes described as being foreseeable or unavoidable. Neither descriptor is necessarily correct in the context of disasters. Hazards can be unforeseeable if, within the bounds of knowledge, no attempt was made to examine them or the knowledge was not fully understood. For example, prior to the start of the 1991 cataclysmic eruption, it is unclear whether or not Mount Pinatubo in the Philippines had erupted before settlement of the area, so foreseeability of the 1991 eruption is disputable. In contrast, Soufriere Hills volcano on Montserrat appears not to have erupted since Europeans arrived in the Caribbean, but the volcano was studied with the hazards documented in scientific papers and reports to government. The eruption sequence starting in 1995 and its consequences were largely foreseeable. Regarding unavoidability, theories and realities of influencing environmental hazards are described later in this entry.

Characterizing environmental hazards uses parameters and descriptors including the following.

- A physical process explanation such as through motion, energy, or chemistry. Examples are acceleration (change in velocity, encompassing magnitude and direction) during seismic shaking, velocity (speed and direction) of a landslide followed by forces imparted by the landslide’s material, heat from lava, volumetric flow rate of floodwater, and mass of a meteorite or of locusts in a swarm.
- Magnitude, intensity, and scale values of specific parameters.
ENVIRONMENTAL HAZARDS

- Time characteristics, which could cover the time required for a hazard to emerge and decay, the duration during which the hazard threatens, the frequency with which a hazard manifests, and the time periods during which a hazard might be expected (for instance, specific months of the year for tropical cyclones for different locations).
- Space characteristics, describing the linear extents, areas, and volumes which the hazard affects along with distribution patterns over space.

All the above characteristics can be described in terms of predictability, quality of predictions, and what is known and unknown – all of which are essential parts of trying to understand and respond to environmental hazards.

Environmental

The environment tends to refer to the four “spheres” of nature, none of which is created by humans: the atmosphere (air), the hydrosphere (meaning water – salt, fresh, and frozen – such as oceans, rivers, lakes, glaciers, and ice sheets), the lithosphere (the Earth’s surface, such as soil and rock and everything below the surface, down to the core at the planet’s center), and the biosphere (plants, animals, and ecosystems). The environment outside planet Earth could also be considered to be a sphere of nature. The spheres are rarely distinct, instead having blurry boundaries and extensive overlaps such as tidal zones. Although humanity and society are excluded from this strict definition, it is difficult to delineate a definitive boundary between the environment and society, with environment–society enmeshment being a starting axiom for many scientific disciplines.

As an example, human-induced alteration of the atmosphere’s composition is leading to rapid climate change affecting the planet’s surface, especially manifesting through changing weather and a changing biosphere. Similarly, many human-made chemicals persist in the environment for long periods, with chlorofluorocarbons staying in the stratosphere for decades and affecting natural ozone there. The loss of stratospheric ozone leads to increased natural radiation intensity from the sun reaching the Earth’s surface, potentially harming the biosphere. As such, the environment and society cannot be separated; they are heavily interconnected and continually influence each other.

Nevertheless, many hazards tend to originate in the spheres of nature, such as volcanic eruptions, precipitation, bacteria, and solar flares – even if sometimes affected by society such as climate change altering precipitation or genetic engineering producing bacteria. Other hazards clearly originate from society only, such as chemical releases, the stock market, vehicles, and vehicle drivers. These societal hazards are not considered in this piece.

Some argue that the environment never produces hazards, only processes and phenomena which can become hazardous due to human choices, actions, or inactions. When a ship strikes an iceberg, when a plane crashes after being hit by lightning, or when a petrochemical tank explodes after being struck by a landslide, it is possible to argue that the hazard originated in the environment, in society, or both.

If rain comes through a window ruining the carpet inside because the homeowner did not close the window, then the rain in itself is not necessarily a hazard although it has potential for hazardousness. The human decision made the rain a hazard because the rain damaged a human creation due only to a human decision. If a housing development is approved in a known earthquake zone without earthquake-resistance measures being factored in, then the earthquake itself is not necessarily the hazard although it has
potential for hazardousness. Instead, the human decision made the earthquake a hazard because the earthquake damaged a human creation owing only to a human decision. An environmental phenomenon or process can become a hazard to society because human decisions led to damage of a human creation.

The environmental processes/phenomena and the circumstances leading to manifestation of hazardousness are often distinct. A “chain of hazard emergence” could be postulated in which “environmental” refers to only the phenomenon or process from nature which might be modified by society. Then, it encounters a societal creation – such as a process, structure, person, or network – so that damage to society could result, at which point it becomes an “environmental hazard.”

The importance of the hazard emerging only upon interaction with society is that it is rare that environmental processes or phenomena are deemed to be hazardous to the environment itself. In ecology, a “disturbance” is a phenomenon or process which kills organisms or forces them out of their habitat. The disturbance opens up opportunities for other organisms to colonize the location. Windstorms, ice storms, and wildfires kill trees and knock off branches, sometimes with animal mortality as one consequence. But they are essential ecological processes, being part of the ecosystem and contributing to biospheric life cycles. Many tree species have evolved under the assumption that fires occur periodically, so those disturbances are part of the species’ reproductive cycle (Reice 2001). How would an environmentalist perspective view disaster impacts – and disaster risk reduction efforts to reduce those impacts – when the environmental phenomenon or process becoming a hazard for society is also essential for a healthy ecology?

The “chain of hazard emergence” helps to answer that question by explaining that societal interaction with an environmental process or phenomenon sometimes creates the environmental hazard. That societal interaction might be deliberate modification of the environmental process or phenomenon. Wildfires can be started by a cigarette butt or arson. For several decades in the twentieth century, the United States’ government managed “natural” forests to avoid fires. The policy changed following the realization that natural fires were inevitable, but suppressing fires in the short-term leads to larger and more intense fires in the future which could be outside the parameters within which species evolved. The fire is a “natural” environmental process, but human management transformed the specific parameters into non–natural fires which were an environmental hazard to both society and possibly the ecosystem.

Environmental hazard

An environmental hazard is a phenomenon or process with root origins in the environment which is interpreted by or interacts with society to pose a threat or danger to society. That is, it has the potential to damage or cause harm to society due to society’s actions. This definition gives environmental hazards a negative connotation, but threats and dangers to society can be opportunities, trivialities, or major concerns. The influences depend on the exact environment–society contexts and perspectives in which the environmental phenomenon or process occurs and is viewed.

Russia has been saved at least three times from invading armies by the winter weather contributing to the invaders’ defeat, although that does not diminish the military mistakes made by the invaders and the military strategies of the defenders. Examples of invading
leaders are Charles XII of Sweden from 1708 to 1709, Napoleon Bonaparte at the end of 1812, and Adolf Hitler from 1941 to 1943. The Russian defenders used the winter weather to their advantage by implementing a scorched Earth policy as they retreated. Meanwhile, the victory of the English navy in the Camperdown Campaign in 1797 has been attributed as much to weather as to military tactics (Wheeler 1991) which is the same for the Spanish Armada’s attempted invasion of England in 1588. In all these cases, one side of the battle saw the weather as being an environmental hazard while others saw it as being an environmental boon and opportunity.

On April 14–15, 1912, in the northwest Atlantic Ocean, the ship Titanic struck an iceberg and sank with over 1500 passengers and crew dying. It is suggested that the captain knew that icebergs were in the area but chose to travel at a fast speed, in addition to the ship being constructed of low-quality steel and not having enough lifeboats for everyone on board (Smith 1994). The iceberg’s hazardousness emerged due to only the long “chain of hazard emergence” involving the environmental phenomenon of the iceberg coinciding with human decision-making from design through to operation of the ship, producing iceberg forces on the ship which the ship could not withstand.

Consequently, the labeling of an environmental hazard can be subjective, because (i) the hazardousness can depend on the viewpoint and (ii) the hazardousness might emerge due to human action. While these points do not apply to every case, when analyzing or labeling an environmental hazard, it is important to consider how much these points do apply and what humanity might be able to do in order to reduce the hazardousness to society of an environmental phenomenon or process.

Categories

Environmental hazards have numerous modes and levels of classification (IRDR 2014). Here, four groups are selected: astronomical, biological/ecological, geological, and hydro-meteorological.

Astronomical

Astronomical or extraterrestrial hazards are defined as hazards with origins in space, that is, hazards with extraplanetary or non-Earth origins.

A common form of astronomical hazard is geomagnetic storms, which are high-energy particles, such as flares emanating from the sun, that meet the Earth’s magnetic field. These are most often seen as beauty rather than hazard in the form of the aurora, most visible at high latitudes. They can also be highly disruptive to life on Earth, with geomagnetic storms damaging satellites, interfering with communications networks affecting everything from mobile phones to bank machines, inhibiting power networks leading to blackouts, and forcing airplanes to re-route in order to avoid high radiation levels.

Near-Earth objects are another prominent example of astronomical hazards. They are objects in space such as asteroids and comets which could collide with the Earth. Such collisions occur continually, but most objects burn up in the atmosphere, almost unnoticed. Frequently, we see larger objects burn up as meteors, poetically termed shooting stars or falling stars. When the object is large enough to make it through the atmosphere and hit the ground, wide-scale destruction can occur. Humanity has been fortunate thus far that human injuries and deaths from near-Earth objects are rare. There is speculation but no proof either way that many people were incinerated by the June 30, 1908,
Tunguska explosion in Siberia and by the Kaali meteorite strike on Saaremaa, Estonia, several thousand years ago. In addition, isolated claims appeared through the centuries of people being struck by celestial bodies.

No injuries or deaths from a near-Earth object were confirmed until February 15, 2013, when a meteor burned through the atmosphere over the Chelyabinsk region in Russia. The shockwave shattered glass in thousands of buildings injuring over 1200 people. This event might be behind concerted efforts afterwards to establish a global approach to near-Earth object monitoring, warning, and response, but many scientists had been trying for decades beforehand.

A large near-Earth object strike has the potential to be cataclysmic for the planet, with such strikes identified as likely causal factors in planet-wide mass extinction events including the death of the dinosaurs approximately 65 million years ago. Other potentially cataclysmic astronomical hazards for the planet which could threaten humanity if they occur within several light-years’ vicinity include a supernova – an exploding star – or a gamma ray burst which would release huge amounts of lethal radiation.

**Biological/ecological**

Biological or biospheric hazards are hazards with origins in living organisms, ecosystems, or other levels of the ecological hierarchy. These hazards tend to be listed as only biotic (living) without fully accepting abiotic (nonliving) biospheric hazards, an example of which would be wildfire (also called a forest fire and a bushfire) as an ecosystem process. Here, only biotic biological/ecological hazards are considered. Wildfire is classified as hydrometeorological, since this environmental process usually starts from lightning with dry weather conditions abetting it.

Microbial pathogens and parasites represent the main biological/ecological hazard, encompassing, for example, archaea, bacteria, prions, protists (including protozoa and some algae), rickettsia, and viruses. They provide numerous services to ecosystems, such as breaking down dead plants, and to individuals, such as bacteria in our gut aiding digestion. They also affect people detrimentally through diseases, some examples of which are the prion causing Creutzfeldt-Jakob disease, the bacterium Esherichia coli O157:H7 causing food poisoning, and HIV (Human Immunodeficiency Virus) causing AIDS (Acquired Immunodeficiency Syndrome).

Microbial pathogens and parasites are perhaps the most lethal environmental hazard, not just through epidemics and pandemics but also through regular death rates. More than 600 000 people a year die from malaria (WHO 2013) and up to one-third of that toll die annually from cholera. The black death, being different forms of plague caused by a bacterium carried by fleas which live on rats, killed perhaps 200 million people in the fourteenth century including one- to two-thirds of Europe’s population. Infectious diseases – including cholera, colds, measles, plague, smallpox, tuberculosis, and typhoid – brought by Europeans to the Americas played a major role in destroying indigenous populations and permitting Europeans to settle there, with some indigenous groups experiencing 100% mortality due to microbial pathogens (Alvarez 2014). The most widespread modern epidemic, HIV/AIDS, kills approximately two million people a year with infection rates of 15% in some sub-Saharan countries (Bongaarts, Pelletier, and Gerland 2011).

In addition to microbiological hazards, macrobiological hazards – namely plants and animals – can pose hazards to people and society through mechanisms including poison, crushing when falling on people or buildings, trampling,
ENVIRONMENTAL HAZARDS

constricting, and biting. Swarms of insects, such as locusts, can devastate crops. Some animals which commonly kill many people each year are alligators, ants, bees, dogs, elephants, scorpions, sharks, and snakes. Many more people die when vehicles crash into elk, kangaroos, and moose. Vegetation most commonly causes fatalities when people ingest toxic varieties or when a large plant, such as a tree, falls on people as often occurs during storms.

Geological

Geological or lithospheric hazards are hazards with origins in the Earth or on the Earth’s land surface. Earthquakes and volcanoes tend to be seen as representing geological hazards, but they have a wide scope beyond the stereotypes of the Earth’s surface rupturing in an earthquake and a mountain exploding for a volcano.

Many tremors occur hundreds of kilometers below the surface or along the ocean floor. Shaking can occur in any direction, so infrastructure must withstand combinations of horizontal and vertical shaking. Two distinct sets of earthquake waves strike, with the faster waves generally being weaker than the slower waves. Earthquakes have numerous associated hazards, most prominently tsunamis, which are a series of waves caused by sudden displacement of large amounts of water. An earthquake-generated tsunami can be more lethal than the original shaking. Tsunamis can also be generated by a near-Earth object landing in water, linking tsunamis with astronomical hazards, as well as by mass movements such as landslides. Mass movements have multiple origins (see later in this section) including earthquakes. When El Salvador was struck by two earthquakes on January 13 and February 13, 2001, approximately half the fatalities were attributed to landslides.

Volcanoes present a wide range of hazards across all states of matter and their combinations as well as massless hazards (Figure 1). Here is some terminology is explained.

Fumaroles: openings emitting gases.
Jökulhlaups: in a volcanic context, glacial melt floods when a volcano erupts underneath.
Lahars: mudflows, often from ash deposits.
Pyroclastic density currents: hot, fast flows of gas and ash.
Tephra: solid material ejected into the atmosphere, including rocks and ash.
Vog: fog and smog resulting from volcanic emissions of gases and aerosols.

Large volcanic eruptions sending ash high into the atmosphere can alter weather for several years afterwards. When Tambora, Indonesia, erupted in 1815 it affected weather worldwide, especially leading to a damp and cold summer in the northern hemisphere which allegedly led to Mary Shelley writing *Frankenstein*. The impact of volcanoes on climate is disputed apart from in extreme cases. An example of the latter is basaltic flood eruptions in which one or several fissures release lava and gases over vast areas – with the eruptions sometimes lasting millennia. They have been implicated as potential causal factors in mass extinctions.

Other geological hazards include erosion, ground subsidence, quicksand, sandstorms and dust storms, sinkholes, and slides and mass movements (such as landslides, rockslides, mudslides, and debris flows). Mass movements have different origins, including earthquakes, rainfall (linking them with hydrometeorological hazards), accumulation of too much material, and destabilization by human activity such as cutting a road through a slope.

Ice ages are a global, catastrophic geological hazard which has occurred many times during
ENVIRONMENTAL HAZARDS

Gas hazards:
- fumaroles and other emissions
- high air temperatures

Liquid hazards:
- jökulhlaups
- tsunamis

Solid hazards:
- debris and ejecta, including tephra
- slides

Gas/liquid hazards:
- aerosols
- vog

Liquid/solid hazards:
- lahars
- lava
- wet tephra

Gas/solid hazards:
- aerosols
- pyroclastic density currents

Massless hazards:
- air shocks
- fire
- ground deformation
- lightning

Figure 1 Volcanic hazards.

Massless hazards:
- ground deformation
- tremors

The Earth’s past but not during humanity’s reign. Ice ages can bring glaciers several hundred meters high into the locations of current-day cities such as Toronto and Moscow. The glaciers weigh down the land, pushing countries lower and reshaping topography, yet because so much water is frozen in the ice, ocean levels dip by dozens or hundreds of meters.

Hydrometeorological hazards, including atmospheric and hydrological/hydrospheric hazards, are hazards with origins in the water (hydrological) or air (meteorological), joined into a single category because they are frequently linked. Examples of hydrometeorological hazards are avalanches, droughts, floods, fog, glacial surges, icebergs, lightning, precipitation (with different forms including freezing rain, hail, ice, rain, sleet, and snow), storm surges, temperature extremes or fluctuations (cold and hot), tornadoes (which come in many varieties including waterspouts), tropical cyclones (referring to cyclones, hurricanes, and typhoons but not forgetting cyclonic storms outside of the tropics), waves, and wind.

Weather-related and climate-related hazards are often conflated and many languages do not differentiate between weather and climate. Nonetheless, English does make the distinction, with IPCC (2014, 5) stating “Climate in a narrow sense is usually defined as the average weather, or more rigorously, as the statistical description in terms of the mean and variability of relevant quantities over a period of time ranging from months to thousands or millions of years … Climate in a wider sense is the state, including a statistical description, of the climate system.” IPCC (2014) does not define “weather.” IPCC (2012, 114–115) explicitly treats weather and climate events as being the same, again without defining “weather,” while also stating that time scale differentiates them in that (somewhat circularly) “An extreme weather event is typically associated with changing weather patterns, that is, within time frames of less than a day to a few weeks [and an] extreme climate event happens on longer time scales.” (p. 117).

Converging dictionary definitions assist: weather describes or parameterizes the atmosphere’s state while climate is the usual weather or a statistical description of weather. Since the weather–climate differentiation is a linguistic-cultural construction which does not always make an operational difference in understanding and dealing with hydrometeorological hazards, that latter phrase is used here rather than categorizing the phenomena and processes as either climatological or meteorological. The lack of distinction supports inclusion of environmental processes and phenomena which can fall between the weather time scale of
Environmentally, hazards can last from minutes to weeks and the climate time scale of decades and more—such as droughts.

Droughts are effectively the absence of water, due to lack of precipitation or increased evapotranspiration, but most droughts result more from human decisions than from precipitation variation (Glantz 1976). Examples are extraction of too much water for drinking, hygiene including flush toilets, irrigation, manicured lawns, or watering non-native trees. When lack of precipitation or excessive evapotranspiration does produce a meteorological drought—so it is a true environmental phenomenon with the potential to become an environmental hazard—it can be described by absolute or relative metrics. An absolute drought metric is a specific parameter, such as rainfall over a time period. A relative drought metric is an index indicating the difference or deviation from a predefined “normal,” such as soil moisture availability.

With regards to environmental processes and phenomena involving too much water, storms can be brief and highly localized or, as with tropical and extra-tropical cyclones, can last days and affect thousands of square kilometers. Floods appear in numerous varieties, from rivers slowly rising over days to flash floods through ravines and canyons which can be devastating within minutes of an upstream cloudburst. Large-scale freshwater floods include Pakistan in 2010 during which approximately 20% of the land area flooded with some areas still underwater several months after the initial inundation and China in 1931 with death toll estimates exceeding one million people. Storm surges are low air pressure and winds across a stretch of water raising the sea level and reaching the coastline as a wall of water, the height of which can be exacerbated by coinciding with high astronomical tide. Hundreds of kilometers of coastline can be inundated over several hours.

Hot and cold temperatures can lead to significant numbers of fatalities which are difficult to tally. In Europe, during the summer of 2003, tens of thousands of people died during a heat wave, but no exact compilation of numbers could be completed because it is not always feasible to attribute an individual’s death directly to heat. Calculations are usually conducted by considering excess mortality, examining death rates above the standard rates and correlating that with heat-related measures, involving combinations of air temperature and humidity or associated metrics such as dew point (e.g., humidex). Aside from heat waves, outdoor laborers in the tropics experience heat-related illnesses, leading to high numbers of lost work hours as well as some deaths.

Similar issues emerge with respect to cold as an environmental hazard. Compiling the impacts is fraught with difficulty due to attribution problems, but studying mortality patterns reveals the high rate of excess mortality during cold spells. As with heat, it is not just the cold temperature which contributes to the hazard, but also relative humidity and wind (e.g., the wind chill factor) combining with cold temperatures.

The environmental hazard of temperature has two noteworthy aspects. First, the view of temperature effects as an environmental hazard has a cultural component. People who have grown up in tropical climates feel extremely uncomfortable in temperatures such as 10–15°C which are considered balmy in mid-latitude winters. Meanwhile, 30°C with high relative humidity is standard fare for the tropics, but can be dangerous for people not used to it who overexert themselves.

Second, thresholds in temperature in addition to extremes are important as environmental hazards. One significant threshold is water’s freezing point. Precipitation falling through air around water’s freezing point is far more

hazardous for the unprepared than rain (above freezing) or snow (below freezing) because, around water’s freezing point, it can come down as ice, leading people and cars to slip while accumulating on and breaking trees and power lines. Additionally, water infiltrates into masonry and, if that freezes, it expands causing cracking and damage. The number of times that masonry experiences a freeze/thaw cycle dictates its lifetime more than specific air temperatures.

Cascading and coincident environmental hazards

The abovementioned categories have overlaps and connections (see Table 1) as seen through cascading environmental hazards and coincidental environmental hazards. Cascading environmental hazards occur in sequence, with one triggering the next. Tsunamis are representative because they never occur in isolation. There must be a triggering phenomenon or process such as an underwater volcanic eruption or earthquake, a landslide underwater or into the water, or a meteorite striking water. As an example of a series of cascading hazards, for a volcano near a coast, an explosive eruption would be accompanied by earthquakes which could trigger a landslide into the sea generating a tsunami. In 1980, Mt St Helens in Washington, USA, was ready to erupt with most volcanologists expecting a near-vertical explosion. Magma movement inside the volcano generated an earthquake that caused a large slope failure on one of the volcano’s flanks, relieving enough pressure for the magma to burst out in a lateral (sideways) eruption. A hypothetical sequence of cascading hazards would be a meteorite striking land leading to seismicity and landslides as well as sending tremendous amounts of dust into the stratosphere which influences weather and, potentially, climate.

Biological/ecological hazards can be influenced by the consequences of geological and hydrometeorological hazards through microbiological hazards emerging during or after a disaster. The direct link from disaster to epidemic is rare (Floret et al. 2006) but diseases which are already endemic can manifest further
ENVIRONMENTAL HAZARDS

if disaster response measures are inadequate. Increases in rates of dengue, hepatitis A, leptospirosis, malaria, typhoid, West Nile Fever, and yellow fever occur after poorly managed floods where those diseases were already present. One example where a long-absent disease re-emerged postdisaster was cholera appearing in Haiti for the first time in decades following the January 12, 2010, earthquake in the Port-au-Prince area. The disease was brought in by United Nations troops who were assisting with the recovery, but who came from a country where cholera is endemic and they did not enact proper sanitation and hygiene methods in Haiti.

Coincidental hazards happen at the same time and might or might not be related. In June 1991, Mount Pinatubo in the Philippines exploded in one of the largest volcanic eruptions of the twentieth century. The cataclysmic eruption coincided with the passage through the area of Category 3 Typhoon Yunya. Volcanic ash accumulated on roofs and readily absorbed water from the typhoon’s rain. The weight of wet ash collapsed the roofs and killed dozens of people, including places where people had sheltered because the load calculations had assumed dry ash. Pandemics and droughts can last for months, leading to the possibility of other hazards occurring during that period.

In terms of coincidental hazards which are related, many volcanic eruptions are accompanied by tremors while landslides frequently occur during earthquake-related shaking as well as during rainfall. Poor response to a drought might reduce a population’s nutrition levels making them more susceptible to diarrheal outbreaks which could then become an epidemic coinciding with the drought. Around Taiwan, typhoons have been shown to trigger “slow earthquakes” in which seismic energy is released over hours rather than seconds (Liu, Linde, and Sacks 2009).

Climate change and environmental hazards

Today, one notable influencer of many environmental hazards is the climate changing globally. The climate has always changed, throughout humanity’s and the planet’s history, including long-term trends, shifts in the state and baseline, variabilities, and cycles. Contemporary global climate change is marked by human influence through two main mechanisms. First, the release of greenhouse gases such as methane and carbon dioxide which trap heat and warm the planet’s average temperature. Second, anthropogenic changes to the Earth’s surface which reduce the planet’s ability to absorb the greenhouse gases emitted by human activities. The most prominent of these land-use changes is deforestation, since trees are an excellent source of uptake and storage of carbon dioxide.

Contemporary climate change influenced by human beings has two principal definitions. The main scientific body responsible for assessing and synthesizing climate change science for governmental approval is the Intergovernmental Panel on Climate Change (IPCC). The first IPCC assessment was published in 1990 with the latest one, the fifth assessment, published in 2013–2014. The IPCC’s (2014, 5) definition of climate change is “Climate change refers to a change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties, and that persists for an extended period, typically decades or longer. Climate change may be due to natural internal processes such as modulations of the solar cycles, volcanic eruptions, and persistent anthropogenic changes in the composition of the atmosphere or in land use.” Meanwhile, the main international treaty for addressing climate change is the United Nations Framework Convention on Climate Change (UNFCCC) which defines climate change to be “a change of
climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods” (UNFCCC 1992, art. 1, para. 2). The difference in definitions is that the science examines all climate changes irrespective of the cause of the change while the international policy processes and measures consider climate change from human origins only. Both the IPCC and the UNFCCC agree that the human influence on the climate seems likely to push the planet into a climate regime that humanity has never before experienced.

Contemporary climate change influences many hazards, exacerbating some and diminishing others. Climate change is, in effect, a potential hazard driver or potential hazard diminisher, rather than being a hazard itself. The complexities of the interactions between climate change and specific hazards in specific locations sometimes make attribution and projections challenging. The IPCC (2012) attempted to systematically analyze links between climate change and hydrometeorological hazard trends and extremes. Few strong associations were found, with daily high temperature being the most prominent. It is conceivable that IPCC’s (2012) method might not be robust enough to discover correlations or lack thereof by (i) highlighting climate change perspectives and theories without equal balance from wider disaster and development topics and (ii) aiming to analyze connections that would require centuries of consistent and comparable hydrometeorological data from around the world – data which do not exist. Nonetheless, individual studies provide insight into possible influences of climate change on various environmental processes and phenomena.

For tropical cyclones, it appears as if – particularly for Atlantic hurricanes – climate change could lead to reduced frequency of storm formation but increased intensity once a storm forms (Knutson et al. 2010). There are feedbacks among sea surface temperatures, stratospheric winds, and the lessening temperature differential between the poles and the tropics (because the poles are warming faster than the tropics), in addition to other factors, which make analysis challenging. It is much clearer that storms in the Norwegian Sea termed “polar lows” are expected to decrease in frequency due to climate change because the North Atlantic’s ocean water is projected to warm more slowly than the air above it, leading to more atmospheric stability which discourages polar low formation (Zahn and Von Storch 2010).

Nonetheless, precipitation is expected to become much more intense in many locations around the world due to climate change. Warmer air can hold more moisture meaning that it can rain much more in terms of quantity and intensity. That seems likely to lead to more rainfall-induced flooding overall. Meanwhile, as sea ice around the Arctic diminishes due to climate change, storms can produce more wave energy which exacerbates coastal erosion. Communities such as Newtok, Alaska, are already experiencing this problem and are preparing to resettle inland due to it. Meanwhile, sea levels rising due to climate change are impacting low-lying islands, especially in the tropics, through worsening flood, erosion, and water salinization leading communities such as Takuu, Papua New Guinea to plan resettlement. Again, interactions are complex and climate change is not certain to increase floods in all locations. As a specific example, climate change is expected to decrease winter flood frequency in central Europe’s Elbe and Oder rivers due to fewer ice jams (Mudelsee et al. 2003).

Such complexities impact other hazards. Increased precipitation (and even increased earthquakes) under climate change could
be expected to increase the frequency and magnitude of landslides, but it is not straightforward. For a mass movement to occur there must be material to slide. An initial increase in frequency of mass movements due to climate change has the possibility of using up much of the slidable material, leading to smaller movements in the future because less material can build up before it moves. With avalanches, increased precipitation could lead to more snowfall accumulation and hence more avalanches while air temperature rise could reduce avalanche magnitude if the precipitation falls as rain rather than snow. The effects of climate change on avalanches are expected to be highly localized.

Costello et al. (2009) summarize the impacts of climate change on microbiological hazards by focusing on rodent-borne and vector-borne diseases. As temperatures increase, vectors and parasites tend to breed and mature more quickly. More life cycles are permitted within a given time frame along with an increased rate of biting, each of which supports the spread of vector-borne diseases. In addition to these time factors, vector density over a given area tends to increase with temperature increasing. Meanwhile, vectors are able to survive at higher altitudes and latitudes than before because the climate in the new locations matches what the vectors are used to in the original locations. Populations living at higher altitudes and latitudes often have never before had to deal with these vectors or pathogens, so their immunity and their knowledge of countermeasures is limited.

Costello et al. (2009) particularly highlight mosquito-borne and tick-borne diseases such as malaria, encephalitis, and dengue fever, but their arguments likely apply to many other diseases such as Lyme disease, leptospirosis, and West Nile Fever. The authors, though, indicate some factors inhibiting vector-borne and rodent-borne diseases due to climate change. For instance, where hydrometeorological hazard frequency or intensity increases, or where the environmental hazards change in nature, vector eggs and larvae could be harmed. Heavy rains can wash away vectors at many life cycle stages. Salinization of water due to sea level rise and coastal inundation could inhibit vectors which need fresh water or could force them to move inland or to higher elevations.

Prospects for geological hazards being influenced by climate change are discussed by McGuire (2013) who provides geophysical explanations for how volcanic eruptions, tsunamis, and earthquakes have the potential to be augmented. Simplistically, as sea levels rise and as glaciers melt, a shifting of the weight on the Earth’s crust has the possibility for affecting seismicity and underwater landslides, with subsequent effects on tsunamis. Similar impacts could affect volcanic eruptions. There is much speculation and many uncertainties regarding the interaction between climate change and geological hazards. In contrast, since climate change by definition affects only planet Earth, there seems little scope for impacts on astronomical hazards.

Climate change is an example of a major environmental hazard driver and diminisher, indicating the intricacies and complexities involved in trying to understand the overlaps, connections, and interactions among environmental hazards. Other examples of environmental hazard influencers are cycles such as the El Niño Southern Oscillation and the North Atlantic Oscillation.

**Influencing environmental hazards**

A major portion of human–environment interaction involves attempts to prevent or control environmental hazards. Aside from appealing to deities or nature to actively avoid environmental phenomena or processes which can be hazardous
to humanity, human efforts tend to involve technology which actively changes the environment. Such actions frequently create, augment, or exacerbate an environmental hazard—sometimes even making an environmental process or phenomenon become hazardous, as discussed above.

**Astronomical**

Astronomical processes and phenomena have perhaps been the least affected by human efforts to influence environmental hazards because of the logistical and financial difficulties of space-related operations and the scales involved. Preventing geomagnetic storms or solar flares would involve manipulating the sun, an act which is barely conceivable with current technology. Shielding the Earth from these phenomena is more realistic, but would still be an exceptional undertaking. Instead, the successful efforts shield individual pieces of infrastructure such as satellites or computers, preventing the harmful radiation from reaching damageable components.

Many realistic and achievable plans have been proposed to monitor space for near-Earth objects on a collision course with the planet and to prepare a response plan in case of a threat (Bobrowsky and Rickman 2007). Few have been implemented. The suggested responses are not as dramatic as depicted in Hollywood films portraying the use of nuclear weapons or lasers to destroy the offending object. Instead, small-scale interventions with enough lead-time could deflect an object's trajectory by a tiny fraction of a degree leading to it bypassing the Earth rather than striking it.

**Biological/ecological**

Biological/ecological hazards are influenced inadvertently and deliberately through habitat destruction and species extinction. Sometimes specific ones are targeted. Malaria and similar diseases were eliminated from the southern United States and from the United Kingdom (where it was called ague) by draining swamps and killing the mosquito vector. One microbial pathogen has been deliberately eliminated by humanity: the virus causing smallpox, although a few laboratories retain stockpiles of the virus. Many other microbial pathogens and parasites are currently the target of elimination campaigns, including dracunculiasis (Guinea worm disease) caused by a parasitic worm, measles caused by a virus, and polio also caused by a virus. More common, everyday approaches to influencing biological/ecological hazards are seen in the form of mouse traps, pesticides and insecticides used in buildings or for crops, and vaccines and antibiotics.

Influencing sentient biological hazards, such as keeping polar bears out of Arctic communities and elephants out of communities in India, is attempted, usually by discouraging the animals from entering the area rather than by killing them. That leads to questions about why preventing microbiological hazards by eliminating them is acceptable. Intense moral debates ensue on whether or not laboratory stockpiles of the virus causing smallpox should be destroyed. Vaccines and antibiotics have undoubtedly saved many lives, but their overuse and misuse is problematic, leading to stronger microbial agents. The same occurs for drug-resistant malaria parasites and insecticide-resistant mosquitoes carrying the malaria parasite. In many cases, short-term preventive measures have the potential for making longer-term prevention even harder.

Instead, interventions tackling the root source of biological hazards are often suggested. Separate water and wastewater systems alongside proper treatment and management of drinking water and wastewater provide a cleaner, healthier
ENVIRONMENTAL HAZARDS

environment and help to prevent cholera. Cleaning up the environment by avoiding stagnant water collected by discarded tires and coconut husks can reduce the places where eggs are laid by the mosquito vector of the dengue fever virus. Proper waste management, especially of food, can discourage mice and rats, reducing the chance of flea-borne diseases and of leptospirosis which is a bacterium carried in the urine of many wild animals. Constructing properties with good ventilation reduces dampness and condensation, inhibiting mold formation. Overall, preventing many biological hazards follows creating and maintaining a healthy and clean environment.

Geological

Geological hazards are difficult to influence. Certain earthquakes might be controllable, with case studies of reservoirs, dams, nuclear explosions, groundwater removal, oil extraction, or fracking (using high pressure fluids to break underground rock for releasing fossil fuels) apparently increasing small-scale seismicity (see the review by Ellsworth 2013). So far, no large earthquake has been definitively shown to have been caused or triggered by human actions. That has not stopped conjectures about injecting water or other fluids into fault lines, to induce numerous low-magnitude earthquakes for avoiding a large shock (or even perhaps to create a large, damaging shock). A danger exists of having appeared to have caused a large earthquake whether or not that was indeed the case.

Volcanically induced seismicity could conceivably be controlled by providing an artificial outlet for the volcanic gas or magma which causes earthquakes. Excavating surface material or drilling holes are possible techniques for creating the outlet. The amount of material needed to be moved and the depth of the holes required would often be far beyond that which could be achieved quickly, cheaply, and safely, so success might be limited. There is also the danger of inducing an unwanted volcanic explosion since complete control of the volcanic processes could never be attained.

Lahars (mudflows) and water from jökulhlaups can be directed by hydrological engineering techniques, including dams, levees, and floodways. Lava flows can be diverted with analogous barriers and diversions. Additionally, an advancing lava flow can be doused with water, cooling it and forcing the lava to spread sideways. Even if such techniques do not divert the lava flow, they usually slow it down, providing more time for evacuation and for natural cooling of the lava. All these techniques are controversial with regards to analyzing their success or failure.

Barriers and landscape engineering could be used to affect avalanches, landslides, rockslides, mudslides, and other such mass movements as well as diverting poison gas emissions from volcanic lakes away from settled areas. Some experiments have been completed on degassing volcanic lakes to prevent a sudden, catastrophic gas release. An example of such a gas release killed approximately 1700 people in Cameroon in 1986. The effectiveness of these approaches cannot be entirely assured. Barriers cannot always block hazards completely, since gas pressure can build up behind a barrier while snow, rocks, Earth, mud, and water can pile up behind and then overtop a barrier. Jökulhlaups and other flash floods sometimes occur because water built up behind a barrier which then fails suddenly.

Hydrometeorological

Attempts at weather modification have a long history, from efforts to seed clouds to yield rain to efforts to change the strengths and tracks of storms including hurricanes. The effectiveness of
these measures has always been disputed, especially because it is difficult to prove what might have happened in the absence of cloud seeding. In 1947, the American Army and General Electric Corporation seeded a hurricane which suddenly altered its direction and struck land in Georgia and South Carolina. Damage resulted, so people affected blamed the seeding. Overall, controlling rain, hail, and storms is fraught with difficulties and it is rarely straightforward to attribute cause and effect, although cloud seeding is still commonly carried out around the world from the Philippines to the United Arab Emirates to the United States.

Floods and droughts are easier to influence. Structural measures such as dams, levees, floodways, dredging, and reconstructing the courses of waterways are used for influencing these hazards. Dams such as the Aswan Dam along the Nile River and China’s Three Gorges Dam were built for several reasons, some of which were political, but incorporating statements that they would help agriculture by controlling water flow meaning flood and drought prevention. A floodway was built in 1968 to send overflow waters from the Red River around Winnipeg, Manitoba, rather than having the city center flood regularly. London’s Thames Barrier and Singapore’s Marina Barrage assist in keeping periodic floodwaters out of those cities’ streets.

But every structure has design limits and those limits can be exceeded, leading to a catastrophic flood. The flooding of New Orleans, Louisiana, in 2005 from Hurricane Katrina; along the Saguenay River, Québec, in 1996; and in the town of Morbi, India, in 1979 resulted from failures of the structural measures designed to prevent flood hazards.

In many cases, the efforts to use structures to prevent flood hazards end up creating or exacerbating flood hazards (Etkin 1999). Engineering waterways can cause waters to flow faster. More insidiously, people tend to settle in floodplains which have been dried out due to walls, levees, and barrages, as with New Orleans and London, meaning that extensive infrastructure is built because the area is deemed safe. In addition to more assets being damaged when the design limits of the structural defense are exceeded by a flood, the urban buildup augments run-off, raising the water level and increasing the flood hazard. Consequently, efforts to prevent the flood hazard actually exacerbate the flood hazard and the disaster is much worse than it could have been in the absence of the structural defense.

Living with environmental hazards

So far, environmental hazards have been defined and described along with their influence on, and how they are influenced by, society. To a large degree, the hazardousness is socially constructed, owing to either the viewpoint taken or to human actions which make an environmental phenomenon or process hazardous. An implicit baseline has been present, from the beginning, where the environmental phenomenon or process is neutral, but society can make it negative, that is, a hazard. Society also reaps rewards from environmental phenomena and processes, even when they are hazards.

Advantages of environmental processes and phenomena

The previous section on the influencing of environmental hazards identified significant problems when humanity tries to control environmental hazards. Influencing environmental hazards predictably is not straightforward, with the potential for dangers to emerge from those efforts. That is especially the case when environmental phenomena and processes are important to the
ENVIRONMENTAL HAZARDS

environment, to society, or to both, being part of what nature needs while providing society with opportunities for life and livelihood. This does not support zero interventions, but instead suggests a balance of actions which complement each other, including but not limited to environmental hazard prevention.

For example, orogeny – the process of mountain building – is an environmental process emerging from tectonic forces, illustrating the continual balance of creation and destruction achieved by nature, a balance which cannot and should not be prevented. The island of Surtsey, Iceland was created by a series of volcanic eruptions in 1963 – although this creation process “destroyed” a section of the ocean. The March 27, 1964, earthquake in Alaska changed the elevation of more than 250,000 km² of land, with large portions of land dropping into or rising from the ocean. Seismic zones frequently make groundwater accessible so that urban centers, such as in Iran, grow across or near earthquake faults because of (not despite) the earthquake hazard (Jackson 2001).

Volcanic ash blankets land resulting in a barren landscape – until the nutrients enter the ground and create fertile soil, amply demonstrated in many parts of Indonesia. Volcanoes contribute significantly to biogeochemical cycles of metals, including aluminum, arsenic, cadmium, copper, iron, lead, mercury, and zinc; assist the sulfur, chlorine, and nitrogen cycles through gas emissions; and contribute to the atmosphere’s evolution into its breathable-for-humans state today. Tectonic subduction and spreading processes cycle minerals and elements by eliminating old rock and creating new rock. All these environmental phenomena and processes make the world livable for humanity, so despite the hazards which might result, they are essential and are to be welcomed.

Hydrometeorological processes and phenomena involve the transfer of mass, heat, and linear momentum through the atmosphere and hydrosphere, and so are responsible for air flows, ocean currents, weather, and climate. Winds knock down dead trees permitting the wood to decompose, adding nutrients to the soil, while leaving space for new growth. When humans or their infrastructure sit below that tree, the wind appears hazardous, but it is actually a needed environmental phenomenon which contributes to a healthy ecosystem. Glacial movement has been responsible for the good farming till, along with much of the topography, in places such as southern Ontario and Orkney, Scotland. The water cycle, incorporating precipitation, affects most biogeochemical cycles and makes available fresh water needed for human survival. Some Caribbean islands receive a major proportion of their annual fresh water from storms.

Hydrometeorological processes and phenomena also contribute to ecological and geological processes. Floods scour out stagnant waterways and inundate tracts of land, often causing damage to the land and vegetation, but depositing nutrients so that people settle in floodplains to farm the land – a process which makes life both feasible and hazardous on the island chars of Bangladesh. In the African Sahel, many farmers traditionally use “flood retreat farming.” When the usual annual floodwaters retreat from the floodplain, the farmers plant seeds in the floodplain so that the moisture left behind can be used by the seeds before the moisture evaporates or drains (Matlock and Cockrum 1976).

Biological/ecological processes and phenomena have many advantages, leading to a major concern about the speed and extent of human-induced ecosystem destruction and species extinction. Food production, medicine, recreation, and materials development continually
experience advances from new species discoveries along with new ways of using a species without devastating it or its habitats. In fact, “bioprospecting” – the search for new species products which can be exploited commercially – tends to find its greatest rewards in biodiversity conservation hotspots. Many animals and plants have direct advantages for society, irrespective of their potential hazardousness. Venom from a saw-scaled viper kills people and is used to produce drugs combating heart attacks. The poisonous nightshade is applied to detoxify PCB (polychlorinated biphenyl) chemicals. Plenty of meat and hide can be obtained from large and often dangerous game animals, which could be sustained as long as they are bred and hunted in such a way that does not harm the species or their ecosystems.

Astronomical processes and phenomena have brought major advantages to humanity. Most accessible precious metals are theorized to have arrived due to meteorite strikes (Willbold, Elliott, and Moorbath 2011). The bombardment occurred long before humanity existed, meaning that society can exploit the advantages of the astronomical processes and phenomena without worrying about the associated hazard.

Managing hazardousness

Given these advantages across environmental processes and phenomena – even those which are made to become hazardous – the view should never be about humanity versus nature, with humanity needing protection against terrible environmental hazards and therefore building up protection or defenses. This is not a game during which “nature bats last” or during which each side gets a turn to try to harm the other. Dealing with environmental processes and phenomena and reducing hazardousness is not about surviving despite adversity or countering abnormal, unpredictable, unwelcome extremes (see also Hewitt 1983).

Instead, humanity and society could decide to learn to live with the environment in all its forms. This approach does not mean harmonious living where everyone adores nature and nature returns that love. No one expects a monthly ritual of tree worship or dismantling our homes and settlements to live exposed to the elements, clothed in only leaves. “Living with environmental hazards” means recognizing the intertwined resource and hazard aspects of environmental phenomena and processes and using those as much as feasible to create a society in which damage from the environment is minimized and gains are maximized. Dangers can never be eliminated, nor should they be. Hazardous aspects will and should always remain, in the same way that gravity as an environmental phenomenon is essential for living but is also frequently hazardous, through falling off a cliff or dropping a glass. Nevertheless, it is possible to live in such a way that environmental processes and phenomena, such as gravity and precipitation, are integrated into daily life and livelihoods in such a way that people and society can deal with them without being harmed or causing harm.

That can be difficult when an environmental process or phenomenon has not manifested in living memory or even since humans settled the area. Conversely, we know enough to be able to assess any location and to act on those assessments in order to reduce the potential hazards while exploring and applying the benefits. Rather than “living with environmental hazards” being harm avoidance and nothing else, gaining knowledge and using the opportunities is necessary too, through managing the hazardous aspects. That also means wider reduction of risk and vulnerability in terms of addressing human behavior such as population numbers,
consumption rates, inequality, injustice, and wealth/asset distribution.

Irrespective, living with environmental phenomena and processes by just ignoring the hazard potential, and without any form of separation between humanity and nature, is not possible. Humans need daily shelter from, for example, precipitation and extreme temperatures. Where a volcano continually erupts, such as in Montserrat, or where degassing a volcanic lake cannot be completed with full confidence, which might be the case in Cameroon, then the main option for ensuring that people live with – rather than die from – environmental hazards might be protection. In Montserrat, people and communities have been evacuated out of the main danger zones. In Cameroon, resettlement in consultation with the communities might be the best option as well – or it might be feasible to design a warning system giving enough time to escape when a gas release occurs. All suggestions need to be considered carefully to avoid any potential snags or shortcomings. Often, the key is not to rely on a single approach, but instead to combine elements of avoidance, warning, protection, designing infrastructure, and other suggestions, overall achieving a balance of multiple approaches.

Environmental phenomena and processes – and their potential hazardousness – are based on balances among, interaction between, and cycles throughout the atmosphere (air), the hydrosphere (water), the lithosphere (Earth’s surface and interior), and the biosphere (life) – while not neglecting the environment outside the Earth, namely space and the rest of the universe. Humans must live with and within that environment. Environmental processes and phenomena are unavoidable and are needed components of the Earth, making the planet habitable. Even if it were possible, preventing all potential hazards from the environment would severely impact the resources available to society, particularly over the long term. Environmental processes and phenomena are frequently damaging, but it is the damage to be avoided rather than the environmental processes and phenomena themselves.

Environmental health

Brian King
Pennsylvania State University, USA

Environmental health addresses the quality and sustainability of the natural environment in order to understand the impacts for human health and wellbeing. This requires a historical and spatial approach that is sensitive to the complex interrelationships between human and nonhuman species, and within natural and physical settings. Environmental health is a field within public health that examines the ways in which the natural and physical, or human-constructed, environment shapes human health and wellbeing. These interrelationships can be complex and historically mediated as well as varying across different contexts.

Environmental health studies how different population groups are unequally exposed to pollutants and other conditions that shape wellbeing. Environmental negatives, such as proximity to landfills and polluting facilities, are differentially experienced based on race, socioeconomic class, gender, generational differences, and ethnicity. Similarly, environmental positives are not universally experienced, with some individuals and communities more likely to be located in close proximity to green space for recreation, bike lanes for alternative transportation, and full service grocery stores that offer healthy food and produce. Much of the awareness of these environmental inequities has come from activist and policy communities that use the concept of environmental justice to show how some groups are more vulnerable to health hazards than others.

A standard definition of environmental health is provided by the World Health Organization (n.d.), which emphasizes all the physical, chemical, and biological factors external to a person, and all the related factors impacting behaviours. It encompasses the assessment and control of those environmental factors that can potentially affect health. It is targeted towards preventing disease and creating health-supportive environments. This definition excludes behaviour not related to environment, as well as behaviour related to the social and cultural environment, and genetics.

The World Health Organization notes that millions of deaths can be prevented each year by addressing environmental hazards, such as unsafe drinking water or exposure to air pollution. Within developing countries, the main environmentally caused diseases are diarrheal disease, lower respiratory infections, unintentional injuries and accidents, and malaria. Within wealthier and industrialized countries, cancer, cardiovascular disease, asthma, lower respiratory infections, and traffic injuries are among the primary environmental health hazards (see Figure 1). According to the World Health Organization, 85 out of the 102 categories of diseases and injuries listed in the World Health Report are influenced by environmental factors (Prüss-Üstün and Corvalán 2006). This contributes to the assertion from multiple agencies and policymakers that healthy and sustainable environments are needed to reduce mortality for human populations. These environments also influence human morbidity, which is the incidence or prevalence of disease within a population.

In considering environmental health, it is helpful to distinguish between infectious and noninfectious, or noncommunicable, diseases. Infectious diseases are often the product of social and ecological conditions that facilitate their spread. As one example, *Anopheles* mosquitoes require specific ecological conditions in order to survive and to transmit the malaria parasite (see Figure 2). Recent scientific studies have shown these mosquitoes to be highly dependent on the natural environment, specifically in terms of precipitation and temperature which can alter the environmental conditions that allow for their survival. Recent work has shown that daily fluctuations in temperature affect parasite infection, the rate of parasite development,
and the components of mosquito biology that combine to determine the intensity of malaria transmission.

In addition to the natural environment, the spread of malaria is also facilitated through host organisms, also known as disease vectors, which help transmit the virus. Human populations that reside within malarial zones are placed in direct contact with mosquitoes, but cultural patterns and behavioral practices, such as the adoption of a bed net, can reduce susceptibility to infection. As a result, the spread of an infectious disease, like malaria, should be understood through a diverse mix of social and ecological conditions that combine to produce the necessary conditions for exposure.

**History of environmental health research**

Research that addresses the relationships between human health and the environment has been advanced by a number of disciplines. One influential example was the work of Dr John Snow, a British physician and early leader in the emerging field of epidemiology. Snow was a skeptic of the dominant miasma theory which held that diseases such as cholera or the Black Death were caused by pollution or a noxious form of “bad air.” An outbreak of cholera in the Soho district of London in 1854 allowed Snow to test his belief in germ theory, an alternative that was not widely accepted at the time. Cholera is an infectious disease that causes severe diarrhea,
ENVIRONMENTAL HEALTH

which can lead to dehydration and, in extreme cases, death. It is caused by the consumption of food or drinking water contaminated with a bacterium called *Vibrio cholerae*. Through careful research Snow was able to demonstrate how cholera was spread through the environment. In speaking with those affected by the outbreak, he was able to locate the source of cholera infection as a public water pump on Broad Street. Snow's study helped to establish the field of epidemiology, which addresses how diseases are spread, and to demonstrate how the built environment has a direct bearing on the health and well-being of human populations as well as giving greater credence to germ theory within public health.

Related work on environmental health has come from the field of environmental history. Environmental historians have shown how the management of environmental landscapes to reduce the spread of infectious disease has resulted in distinct infrastructure and development projects. The eradication of malaria in the continental United States was the result of aggressive efforts to remove the environmental conditions that enabled the spread of the *Anopheles* mosquito. In *Inescapable Ecologies*, Linda Nash (2006) provides a compelling examination of changing understandings of environmental health within the United States. At the time of European expansion into California, the dominant understanding of environmental health was based on humoral theory, which asserted that the blood and other bodily fluids, regarded as “humors,” had to remain in proper balance for health to be maintained. Humoral theory depended on a “constant exchange between inside and outside, by fluxes and flows, and by its close dependence on the surrounding environment” (Nash 2006, 12). This led to European settlers being concerned about remaining in balance with the natural environment through the human skin, which was understood as a porous boundary that enabled interactions between the individual and the environment. Nash suggests that the dominance of germ theory in the late nineteenth and early twentieth centuries shifted attitudes so that the skin was seen as a layer of protection from outside threats. This would influence new ways of viewing nature and its impact on human health.

Understanding of the changing relations between humans and the natural world shifted in the twentieth century. A clear example of this was the work of Rachel Carson, who used scientific methods to demonstrate the relationships between human health and the natural environment. Carson was a leading scholar and environmentalist who helped raise public awareness about the hazards of pesticides. The publication of *Silent Spring* in 1962 made the use of pesticides and other chemicals a major concern. Carson argued that chemicals, such as dichlorodiphenyltrichloroethane (DDT) were becoming widely used for controlling disease and pests. Modern agriculture relied on pesticides, as well as on single-crop farming and imported species. The combination of careful scientific analysis and Carson’s compelling writing led to a ban on the use of DDT in the United States, the formation of the Environmental Protection Agency, and the implementation of other environmental acts such as the Federal Insecticide, Fungicide, and Rodenticide Act, which regulates the use of these chemicals.

In the early twenty-first century, increasing industrialization and urbanization within the United States has contributed to a perception that humans have become more disconnected from the natural environment. In *Last Child in the Woods*, Richard Louv (2008) argues that the current generation is experiencing a new relationship with the natural world that
is characterized by five elements: (i) severance of the public and private mind from our food origins; (ii) a disappearing dividing line between machines, humans, and other animals; (iii) an increasingly intellectual understanding of our relationship with other animals; (iv) the invasion of our cities by wild animals (even as urban/suburban designers replace wildness with synthetic nature); and (v) the rise of the suburb as a new form of spatial organization. Louv asserts that these dynamics reduce the direct contact between humans and nature in ways that have profound effects for how people understand their position within the system.

These contributions help advance environmental health by arguing that health and wellbeing can be produced by direct contact with the natural environment; in other words, environmental health is generated through positive encounters with nature that provide therapeutic benefits. This idea has been promoted by landscape architects and health geographers for some time. Landscape architects and urban planners work to create landscapes that have beneficial elements for human health, such as green space or bike lanes to encourage exercise and alternative commuting options. Health geography has worked with the concept of a therapeutic landscape to show that people’s connection with certain places can be beneficial to their health and to their relationship with the external environment.

It is recognized that the disciplines of environmental epidemiology, toxicology, and exposure science contribute significantly to the field of environmental health. Environmental epidemiology studies the relationship between environmental exposures, such as exposure to chemicals, radiation, microbiological agents, and human health. Toxicology studies how these exposures lead to specific health outcomes. Finally, exposure science examines human exposure to environmental contaminants by both identifying and quantifying exposures. In addition to these research fields, scholars and practitioners within social epidemiology, medical anthropology, and public health work to demonstrate the interconnections between human populations and the natural and built environment.

**Causes of environmental health patterns**

The incidence of infectious disease is not equally experienced around the world and different factors are important in different places. Developing countries, such as those in Africa, face distinct challenges in addressing the underlying environmental health conditions that shape the spread of infectious disease or management of noncommunicable disease. More than 90% of the estimated 300 million to 500 million malaria cases worldwide every year occur in Africa, mainly in children under five years of age, but many governments are moving toward better treatment policies (WHO 2006).

The United Nations has emphasized the need to concentrate on noncommunicable human diseases, which were identified as the primary cause of death and disability in the world. Roughly two-thirds of annual deaths are caused by cardiovascular diseases, cancers, chronic respiratory diseases, and diabetes. Because many of these can be prevented, public health experts emphasize the importance of reducing tobacco and alcohol use, improving unhealthy diets, and addressing a lack of exercise. There are also a variety of behavioral and physical environmental factors that make such noncommunicable diseases more common. Obesity and type 2 diabetes are often identified as being caused by the relationships people have with their surrounding environment. Built infrastructure, which encourages
driving rather than walking or cycling, is often blamed for giving rise to poor health outcomes. Employment occupations that require more sedentary lifestyles can contribute to decreased physical exercise. The role of diet and nutrition are also central to current understandings of noncommunicable diseases.

Another factor affecting environmental health is large-scale, industrial agricultural production. In the United States this affects the production and consumption of food, which have consequences for human health. Popular authors such as Michael Pollan (2006) and Eric Schlosser (2001) point to shifts in the diet of Americans toward heavily processed foods, meat products, and fast foods, arguing that these have transformed the social environment and led to dramatic consequences for economic systems, cultural patterns, and nutrition. Pollan and Schlosser assert that the expansion of industrialized food production has led to an overreliance on pesticides and reduced crop diversity which make ecosystems vulnerable. Other authors warn that increasing exposure to pesticides through food production and consumption patterns could damage human and environmental health. These shifts in agricultural production, while notable in the increased production of food per unit area, are also credited with disrupting human and environmental interactions in ways that can reduce human health and environmental quality.

Human health is the product not just of the natural environment. Environmental health is the consequence of policies, planning mechanisms, and political and economic processes that give rise to places and landscapes in which the conditions that contribute to noncommunicable diseases are produced. These same conditions also result in differential vulnerability to infectious diseases within places and populations.

Environmental health futures

Environmental health represents one of the central challenges of the twenty-first century. Anthropogenic climate change is expected to rework and disrupt human and environmental systems, and therefore to affect the spread of infectious disease. Shifts in precipitation and temperature dynamics may facilitate new health challenges for nonhuman species. The Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment Report (Smith et al. 2014) includes a chapter that concentrates on the links between global climate change and human health. The IPCC identifies changes in temperature and precipitation, and the occurrence of heat waves, floods, droughts, and fires, as having direct effects for human populations. It is also anticipated that indirect effects to human health may result from ecological disruptions caused by climate change, such as crop failures or shifts in disease vector patterns. Scientists point to the spread of malaria in parts of Africa and the West Nile virus in the United States as examples of how infectious disease can accompany changing weather patterns, demonstrating that changes to the underlying environment can have repercussions for human wellbeing.

The IPCC report (Smith et al. 2014) also notes that there can be social effects that influence health, such as the displacement of populations due to sustained drought or declines in agricultural productivity. It is believed that, until the middle of the twenty-first century, climate change will largely intensify already existing health problems, with the largest risks to populations that are most directly affected by climate-related diseases. This could occur with shifting disease vectors or the negative health effects from increased food insecurity. The IPCC emphasizes the importance of reducing vulnerability to these changes by ensuring sustainable
public health measures that increase access to clean water and sanitation, health-care services including vaccination and child health services, the reduction of socioeconomic poverty, and improvement in the ability of populations to respond to disasters.

Another factor shaping the possibilities for healthy people and environments is economic development. As evidence of this, the United Nations Millennium Development Goals emphasize health and environment as key challenges for the global population. Goal 6, designed to combat HIV/AIDS, malaria, and other diseases, identifies the need to expand access to treatment for HIV/AIDS while also altering the conditions that facilitate the spread of malaria, which causes the deaths of hundreds of thousands of people each year, largely in the developing world. Goal 7 emphasizes the importance of environmental sustainability. In addition to addressing biodiversity loss and sustainable policymaking, this goal seeks to reduce the proportion of the population living without sustainable access to safe drinking water and sanitation. The urban population residing within informal and slum conditions was also identified as a key environmental health factor. According to the United Nations, 863 million people are estimated to be living in slums in 2012 compared to 650 million in 1990 and 760 million in 2000. However, the proportion of urban slum residents in the developing world declined from 39% in 2000 to 33% in 2012, and more than 200 million of this population gained access to improved water sources, improved sanitation facilities, or durable or less crowded housing, thereby exceeding Millennium Development Goal 7 (United Nations 2013). This demonstrates an earlier point that investments in natural and physical environments can have positive impacts for human health and wellbeing.

The concept of sustainable development is widely acknowledged as being integral to environmental health. This is particularly the case given that mainstream economic development is generally credited with improving environmental health; however, there can be unintended consequences. The construction of hydroelectric dams in parts of the developing world disrupts biophysical conditions, and has made individuals and communities vulnerable to schistosomiasis and malaria. The increasing use of chemical fertilizers and pesticides in global agriculture has increased the risks to agricultural laborers and ecosystems. Sustainable development is defined in multiple ways, but is generally understood as addressing the social and economic needs of the present generation without compromising the ability of future generations to meet their own needs. Global conferences, such as the 2002 World Summit on Sustainable Development held in South Africa, were intended to make concrete links between economic and environmental wellbeing and to encourage policies that ensure sustainable practices across multiple settings and scales. Declarations from the 2002 World Summit emphasized that sustainable development cannot be achieved as long as there is a high prevalence of illness and poverty. Additionally, it is understood that environmental degradation, the unsustainable use of natural resources, and unhealthy consumption patterns and lifestyles impact health. These impacts can contribute to a downward spiral whereby poor health reduces the capacity of individuals and populations to move out of socioeconomic poverty.

In addition to existing factors, a public health bulletin from the World Health Organization (2011) emphasizes that new health hazards could develop in an increasingly urbanized world. Road traffic injuries are the ninth leading cause of death globally, with most occurring in low-
ENVIRONMENTAL HEALTH

and middle-income countries. It is estimated that urban air pollution kills around 1.2 million people globally each year, primarily due to cardiovascular and respiratory diseases. Infectious diseases, such as tuberculosis, can concentrate in large urban centers. In New York City, the tuberculosis incidence is four times higher than the national average. Lastly, the World Health Organization indicates that urban environments are not always designed to support physical activity or promote healthy food consumption. Participation in physical activity is constrained by a variety of urban factors including overcrowding, high-volume traffic, heavy use of motorized transportation, poor air quality, and lack of safe public spaces and recreation facilities.

Geographic approaches to environmental health

The discipline of geography has a well-established interest in human–environment interactions and the ways in which they shape the lived experiences of people in various settings. Geographic research on human disease and health has been centered largely in the subfields of medical geography and health geography, although emerging research within development studies, political ecology, and feminist geography has advanced the frontiers of environmental health. Much of this scholarship contributes to environmental health by showing the social and ecological determinants that shape the spread of human disease and differential vulnerabilities across time and space.

Geographic scholarship has considered how environments are produced with either direct or indirect consequences for human health. As one example, medical geography focuses on disease ecology, mapping of disease, spatial analysis, and disease diffusion, in addition to locational analysis and the regionalization of health services. Medical geographers often use quantitative data that can be analyzed statistically. Geographic information systems (GIS) are also used to evaluate spatial patterns. Disease ecology is one of the earliest academic fields focusing on the interconnections between social and environmental systems in contributing to disease transmission. As Mayer (1996, 441) explains, disease ecology examines how “humanity, including culture, society and behavior; the physical world, including topography, vegetation and climate; and biology, including vector and pathogen ecology, interact together in an evolving and interactive system, to produce foci of disease.” Additionally, the underlying biophysical conditions that contribute to making individuals and communities vulnerable to disease are addressed to identify the spread of disease and vulnerabilities of human populations. Disease ecology has been foundational in showing how the relationships between humans and the natural environment can determine the spread of disease.

Other studies have shown how individual decision-making is simultaneously shaped by external political and economic systems. One geographic subfield that has addressed environmental health in this way is political ecology. From its beginnings, political ecology has provided a rigorous analysis of how political economy structures the decision-making opportunities for local actors and contributed to environmental change in various settings. As one example, deforestation in the Brazilian Amazon is presented not as a discrete act in one location but as the product of complex and interlinked systems that intersect across spatial and temporal scales. In the now classic Land Degradation and Society, Piers Blaikie and Harold
Brookfield (1987) demonstrate the relationships between social and biophysical processes, linking local management practices to broader processes that showed how choices to transform the landscape were inherently rational and the product of political and economic systems. While not directly focused on human health, these studies explained how individual actors and decisions are linked to broader systems that spread across multiple spatial and temporal scales. As such, to better understand the drivers of environmental change, greater detail on the determinants of human health and wellbeing is needed.

Other studies at this time demonstrated how decision-making was tied to external structures and capitalist relations of production that constrained the available opportunities to local populations. In *Silent Violence*, Michael Watts (1983) examines how famines serve as an interconnected process between society, political economy, and the environment to shape the periodic collapse of rural production and distribution systems in northern Nigeria. Watts considers various forms of surplus extraction and state intervention that increased local vulnerability to drought within rural households, and thereby provided a significant challenge to the view that famines result from an environmental collapse and subsequent decline in agricultural productivity. More recently, work within political ecology has shown how economic neoliberalism has produced new pressures for local populations and environments, either by decentralizing responsibility for management or by commodifying natural resources to justify particular management strategies that benefit external actors. All of this research, while different in their object of study, shows how environmental health is produced through multiscalar dynamics that shape the possibilities for human health and wellbeing.

**Environmental justice**

The concept of environmental justice has been utilized to emphasize how different groups are made vulnerable to health hazards emanating from toxic facilities, landfills, incinerators, or chemical plants. Environmental justice activists have therefore argued that environmental health is differentially experienced on the basis of socioeconomic class, race, gender, and age. An early example was the case of Love Canal, which showed how exposure to environmental toxins could have significant health implications. Love Canal is a community in upstate New York that, at the time of the exposure, was largely middle-class and white. The community was built on top of 21,000 tons of toxic waste that had been dumped by Occidental Petroleum Corporation, previously Hooker Chemical Company. In 1978 rainfall well above the historical average caused the improperly stored containers to leak their toxic contents into the basements of 100 homes and a public school. This generated widespread concern because the landfill was believed to contain 82 different compounds, of which 11 were suspected carcinogens at the time. Love Canal attracted national attention that crystallized through the formation of the Love Canal Homeowners Association, which pressured the state to relocate residents (see Figure 3). It represented a landmark event for environmental health by demonstrating how communities could unwittingly be exposed to toxic pollutants. It also helped establish the United States Environmental Protection Agency’s Superfund legislation, which identifies toxic waste sites for remediation.

The Love Canal case showed the American public how environmental health could be dramatically disrupted by unsustainable environmental practices. It also alerted the general population to the fact that they could be
exposed to toxic pollutants. Other cases showed the inequities in exposure to pollutants within the United States. Specifically, a series of cases involving the siting of landfills helped generate interest in the concept of environmental justice. In 1978 it was announced that a landfill to store polychlorinated biphenyls (PCBs) was to be placed in Warren County, North Carolina. The community directly impacted was Afton, an area of high socioeconomic poverty with a largely African American population. Community residents were strongly opposed to the siting of the landfill and employed litigation and nonviolent protests to try to prevent its opening in 1982. While they were unsuccessful in stopping the landfill, the Warren County case had lasting effects for the environmental justice movement in establishing links between exposure to pollution and social and spatial patterns.

Similarly, a proposal in the early 1980s to create the Whispering Pines sanitary landfill in a predominantly African American neighborhood in Houston showed how race, class, and environmental health are closely integrated. While African Americans made up 25% of the city’s population at that time, the five city-owned landfills (100%) and six of the eight city-owned incinerators (75%) were in African American neighborhoods. From 1920 to 1978, 11 of the 13 city-owned landfills and incinerators (84.6%) were built in these same neighborhoods (Bullard 2005). A lawsuit was initiated to prevent the Whispering Pines sanitary landfill from opening. Bean v. Southwestern Waste Management Corp. was the first lawsuit in the United States to argue environmental discrimination in waste-facility siting under the Civil Rights Act. As with the Warren County landfill, the lawsuit was unsuccessful in preventing the opening of Whispering Pines; however, it broke new ground in advancing claims of environmental justice through the application of civil rights legislation.

In addition to inequitable exposure to toxins and pollutants, environmental justice theory and practice have also been concerned with differential proximity to environmental conditions that can contribute positively to human health and wellbeing. Within urban settings in the United States, for example, there can be differences in terms of where greenspace, such as parks and bikeways, are located. This can be the product of long-standing urban planning as well as being driven by socioeconomic dynamics that benefit some urban residents and not others. Another example is variations in access to certain types of grocery stores that offer fresh produce and
healthy foods. Scholars and practitioners have used the concept of a food desert to refer to rural and urban locations that lack access to full-service grocery stores. Both of these dynamics show the relationships between environmental health and environmental justice in highlighting inequities between population groups. They also attest to the fact that environmental health is produced through a number of factors, whether it be capital and investment or deliberate planning processes. Human health, therefore, is not just a product of the natural environment; rather, it is produced through planning and political and economic processes that generate places and landscapes that produce inequities in infectious disease exposure or the conditions that contribute to noncommunicable diseases.

At the same time, healthy environments can be directly impacted by human disease. Recent reviews on the ecological effects of HIV/AIDS suggest that affected populations utilize natural resources in the short term through unsustainable practices (Talman, Bolton, and Walson 2013). Land-use systems can be modified or transformed such that agricultural land remains uncultivated, thereby disrupting food security. Additionally, research is showing that disease can pressure currently protected natural resource areas as a result of the increased need to mitigate the costly impacts. For example, some studies suggest that there is an increase in the hunting of wild animals or the collection of medicinal plants or wood as a strategy to offset the costs of managing health. These patterns demonstrate that healthy environments do not just produce health outcomes for human populations, but that disease and poor health can similarly produce unhealthy environments. Therefore environmental health must be seen as a series of interconnected and reciprocal relationships between humans and their natural environment. Environmental health necessitates attention not only to social processes but also to the ecological dynamics that shape the possibilities for human wellbeing and environmental sustainability.

Andreas Aagaard Christensen
University of Copenhagen, Denmark

The term “environmental history” has come into widespread use since the 1970s, initially among historians in the United States, and more recently in continental Europe and elsewhere. The first World Congress of Environmental History was held at Copenhagen in Denmark in 2009 to explore the historic relationship between people and the environment over time. The breadth of this ambition indicates that the practice of environmental history cannot be, and never has been, the purview of one discipline, and arguably history itself came late to the scene. Rather, environmental history is an interdisciplinary pursuit, with roots in geographical writing and contributions from a wide range of other subjects, such as anthropology, ecology, ecological economics, and environmental philosophy. It has developed as a form of environmental conscience that seeks to counter an increasingly powerful, forward-looking liberal theory of the environment.

The first section of this entry explores some of the early contributions to the field from geographers. It shows how these introduced the now recognized themes of environmental history: the human impact on the Earth and the ways in which this has been shaped by human understandings of nature and land – in other words, the relations between environmental ideas and materialities. The prophetic overtones of environmental history have, however, rarely been assembled into a coherent global-scale assessment of the accelerating environmental impact of people since the mid-twentieth century. The second section sketches how this might be achieved, while the third discusses the types of manufactured environmental risks that have become widespread as a result. The sort of narratives employed to explain changing people–environment relations are then discussed, before considering what environmental history can contribute in the future.

Geographical foundations

In 1955, as the pace and extent of environmental impacts in the postwar world were becoming clear, a now famous symposium was held at Princeton, New Jersey, in the United States. It brought together 70 scholars from the social, earth, and natural sciences to discuss the theme of “Man’s Role in Changing the Face of the Earth.” One of the symposium chairs was the eminent cultural geographer Carl O. Sauer; also participating was Clarence J. Glacken, a colleague of Sauer’s from the Berkeley campus of the University of California. Glacken later came to prominence as the author of one of geography’s seminal books, about nature and culture in 2000 years of Western thought. Towering above the Princeton meeting, however, was the figure of the nineteenth-century American geographer George Perkins Marsh: indeed, Sauer’s hope was for a “Marsh Festival” (Thomas 1955, 49).
ENVIRONMENTAL HISTORY

Marsh, who had been born in Vermont in 1801, was a nineteenth-century polymath and legislator, who also served the American government overseas, in Turkey and in Italy. In 1864 he published *Man and Nature; or, Physical Geography as Modified by Human Action*. Another edition, ten years later, was subtitled *The Earth as Modified by Human Action*. The book remained in print for prolonged periods. It first appeared at the height of colonial resource optimism, and through force of evidence and example argued against the prevailing belief that nature existed for people to use at will. Marsh’s experience of the degradation of Mediterranean environments made him anxious for America’s future. “Man has too long forgotten,” he wrote, “that the earth was given to him for usufruct alone, not for consumption, still less for profligate waste” (Marsh 1965/1864, 36). His practical impact at the time was on forest policy and watershed protection in his homeland and in British India; his broader intellectual contribution was to shift the perspective from humans endowed with a limitless nature to a longer-term understanding of their use and abuse of, and the need to care for, the Earth.

Carl Sauer’s admiration of Marsh owed much to this latter point. Sauer’s early experience with the Michigan Economic Land Survey revealed that land use was not always wise and that people could damage as well as improve an area. His subsequent fieldwork in Mexico was driven by his curiosity to discover the ways in which, at different times and in different places, culturally differentiated landscapes were produced. He worked closely with anthropologists at Berkeley to achieve a greater understanding of place, process, and period. His perspective was shaped by a strong anti-utilitarian sensibility; he believed that the variety and wealth of human inventiveness manifest in the landscape was in danger of being sacrificed to the short-term growth agenda of a modern liberal economy. His involvement in the Princeton meeting gave him the opportunity to frame the debate not in terms of technical solutions for the future but by asking “How did we get to where we are?” and “How can we construct an intelligible description of where we are?” (Williams 2014, 155).

Clarence Glacken’s great work, *Traces on the Rhodian Shore* (1967), also took the long view into the past. It is the most complete survey we have of three persistent ideas that have characterized human thinking about nature since the time of classical Greece. The first is the one that Marsh challenged, that of a “designed Earth” purposively made for human use. The second is the influence of the environment in molding the nature of individuals and the character of culture. This was a perspective once popular in American geography as “environmental determinism,” and roundly rejected by the young Sauer. The third, which Glacken concluded was not as well formulated in antiquity as the other two, was that which motivated both Marsh and Sauer: charting the human transformation of the world.

These three ideas were for a long time not seen as contradictory, which is why each persisted with varying emphases through time. A designed Earth could also be one in which all life was understood to shape itself to purposefully created harmonious conditions, just as human beings also fulfill their role of finishing creation, bringing order to nature as God’s stewards. Marsh saw that human actions need do no such thing, with his *cri de coeur* that the “earth is fast becoming an unfit home for its noblest inhabitant” (1965/1864, 43). But his choice of words is consistent with Glacken’s observation that, as early as the Hellenistic period, “the fundamental cleavage of human from other forms of life” (1967, 708) was recognized. Over time this cleavage came to legitimate the role
of people as supreme in creation. It fashioned seventeenth- and eighteenth-century Enlightenment thinking that to understand the world is the way to reshape it for our own ends. The anthropocentrism that underlies the ambition of human activity and its designs on nature thus has deep cultural roots in the West, even if its destabilizing potential has been realized much more recently.

The great acceleration

The sense of crisis that pervades writing in environmental history reflects concerns in a growing number of disciplines that there have been both qualitative and quantitative shifts in human impacts on the Earth during the Anthropocene period. This term was coined around the turn of the present century to describe the recent era of environmental change in which people have become global change agents in their own right. There is some debate about an appropriate starting date for the Anthropocene. But there is broad agreement that it was during the late eighteenth century that fundamental alterations in the relationship between people and the environment were set in place, as the Enlightenment encouraged the development of scientific and technical knowledge, and industrial culture. It is in the second half of the twentieth century, however, that levels of resource use took off, with every indicator of human activity undergoing a sharp rise from about 1950. This increase is known as the “great acceleration” (Steffen et al. 2011).

Human population reached 1 billion around 1820, but over the next two centuries it climbed precipitously to more than 7 billion, with energy use growing about 40 times and economic output about 50 times. The upturn began in northern Europe in the eighteenth century with the development of capitalist forms of production and the spread of private means of landownership. Agricultural experimentation allowed more people to be fed in rapidly growing towns, and gradually improving nutrition enabled them to survive and to live longer. Simultaneously, the energy bottlenecks of the preindustrial world were broken with the increasing use of coal. Preindustrial enterprises had relied on the power of human and animal bodies and inefficiently harnessed wind and water; new capitalist firms were powered by machines capable of converting into mechanical energy the biomass stocks that had accumulated over millions of years of geological time (McNeill 2000).

These changes depended on a new conception of land and of the ownership of resources. As formulated by English liberal writers, but usually ascribed to the late-seventeenth-century author John Locke, the right to property depended not on custom but on human toil. Resources held in common, or for which no ownership regime was deemed to apply, such as indigenous territory, were considered by the application of personal labor to be “improved,” or removed from a state of nature. This was the essential condition for private ownership, which in turn was marked on the ground by the process of enclosure, and protected in the legal domain by right of personal security. English law, in contrast to Roman law or Chinese and Islamic custom, did not subject these rights of ownership to countervailing social rules; instead it gave liberty to use the land’s resources and legal protection to the private owner (Linklater 2014). In these ways, the holders of enclosed lands were guaranteed the yield of their agricultural improvements as well as the right to exploit the energy stocks that lay beneath them. The resulting surplus enabled the spatial extension of capital beyond Europe into the neo-Europes of the Americas and Australasia. New fields of resources from which to profit were opened up to produce huge quantities
of food and oil. The private property calculus thereby underwrote an immense expansion of enclosure, “improvement,” energy exploitation, and population growth.

This dynamic explains how the drivers of the Anthropocene initially occurred in very uneven ways across the globe. But if the surge in human numbers began with European populations, by the 1950s these had passed through a demographic transition from high to low fertility and mortality rates. Paradoxically, it was at this point that the great acceleration began. Consumption levels soared, and with this demands for natural resources and levels of waste generation. The Western model of development was exported to other parts of the world as surplus capital sought wider arenas for investment, along with modern health-care systems and a “green revolution” in food production in Asia, Latin America, and Africa. With populations beginning to age in Europe and North America, the number of human beings in the world boomed as developing nations moved into the expansionary stages of the demographic transition. In 1950 the population of Africa was about half that of Europe, whereas today they are about equal, and by 2050 Africa’s population is projected to be three times that of Europe.

If it was the Industrial Revolution and the international expansion of capital that led to the dramatic shift in human relations with the natural world, then it was the great acceleration after 1950 that normalized it. An ever-expanding global population expressed growing wants as well as needs, consuming resources and producing waste in ways never before seen. The rise in the use of inanimate energy, notably fossil fuels, illustrates this. It has tracked a more than fivefold increase in gross world product since 1960, and is directly reflected in the rise of carbon dioxide in the atmosphere. Emissions of methane, an even more potent greenhouse gas, have risen faster still. It is no coincidence that the term “Anthropocene” was popularized by Paul Crutzen, an atmospheric chemist (Steffen et al. 2011). In parallel, carbon sinks have been undermined as tropical rainforests are converted to farm and plantation land to supply products such as palm oil that are ubiquitous components of food manufactured on industrial scales. Today, therefore, we “live in a global system in which our most critical problems go well beyond regional and national borders” (Costanza et al. 2007, 522).

It is climate change that has brought into focus the ability of humans to reshape their environments not just in immediate and discernible ways but, rather as George Perkins Marsh feared, at the scale of the Earth as a whole. Humans have significantly altered other biogeochemical cycles, such as those for nitrogen and phosphorous; strongly modified the terrestrial water cycle through intercepting river flows to the sea; have caused widespread land cover change; and are “likely driving the sixth major extinction event in Earth history” (Steffen et al. 2011, 843). These changes are a product of the need for food and resources for growing populations that are simultaneously increasingly urban. In 2007 the number of people living in towns and cities worldwide moved into a majority for the first time. The logistical and infrastructure networks of city systems have been built to supply the growing appetite for material consumption that accompanies urbanization.

The imprint of human enterprise on the Earth–atmosphere system is therefore now unmistakable, and shows no signs of moderating as the locus of growth in economic activity shifts from Europe and what were its overseas settlements to the countries of East, Southeast, and South Asia in particular. China’s carbon emissions exceeded those of America in about 2007, and by most measures its economy will
be the larger of the two within a few years. But such observations are still usually made outside of an environmental frame of reference, and “much discussion of human–environmental interactions continues to lack a long-term, temporal dimension” (Costanza et al. 2007, 522).

One environmental historian summed up the history of the twentieth century in saying that the “human race, without intending anything of the sort, has undertaken a gigantic uncontrolled experiment on the earth” (McNeill 2000, 4).

**Environmental risk and hazard**

It is a paradox that, as people have seemed to move further from nature with the making of what is sometimes called “second nature,” or nature reshaped by human action, we have created what Anthony Giddens (1999) has termed a “runaway world.” The economic, cultural, and technological processes of globalization simultaneously generate highly interconnected problems. This is an essential difference between social experience today and that before the Anthropocene. In the past, when civilizations were threatened or collapsed, they did so with few, if any, implications for people living elsewhere on the planet. That is no longer the case. The distinguishing feature of industrial culture is that it has been framed by risk and opportunity. The embracing of risk has been the driving force for the creation of wealth in modern economies. Risk management has been the means by which industrial societies have endeavored to determine their own futures, rather than leaving things to the forces of tradition or of nature. They have invested in future opportunity, through calculations of profit and loss, at the same time as seeking trade, resources, and capital accumulation in distant places. With this has come a new set of regional, and even global, environmental problems.

This forward-looking, interdependent world has therefore not eliminated risk. Rather, the nature of risk has changed, from what Giddens describes as “the predominance of external risk to that of manufactured risk” (1999, 26). If external risks are those coming from nature, then manufactured risks are those generated by the increasingly assertive and widespread patterns of capitalist activity that so concerned Marsh. A good example comes from studies of nineteenth-century Western agricultural expansion into the lands of the European new world. Often such areas, in the western United States, Canada, and Australia, were resettled by people driven from Europe by external risks such as famine, hunger, and disease. In these new environments, they faced new risks. The story of the American Dust Bowl in the 1930s, for instance, “is less about the failures of nature than about the failures of human beings to accommodate themselves to nature” (Cronon 1992, 1348). The progressive assumptions of a forward-looking people, that the “wilderness” would inevitably yield to linear “improvement,” came into conflict with the cyclical environmental rhythms of these dry grassland areas.

A classic of geographical writing in this vein is Donald Meinig’s (1962) study of the wheat frontier in South Australia, *On the Margins of the Good Earth*. Much of the area inland from Adelaide was “mallee country,” a scrub forest with thick shallow roots and a low– to medium–height canopy. Mallee clearance required a big investment of time and work, taking the chance that the effort would pay off in the future. The environment, however, was uncertain and unpredictable, and in 1865 the surveyor–general G.M. Goyder was sent through the outlying districts to identify and demarcate those pastoral areas then in drought. What became known as Goyder’s Line was
taken subsequently to represent and formalize the outer limit of agriculture, and it came under severe pressure from settlers wanting to move beyond it when wetter years returned in the 1870s. But they were confounded by the recurrence of severe drought in the 1880s.

Attempts to transform climatically volatile regions into cropping areas were driven by the opportunities of feeding new industrial cities. A prominent theme in environmental history has been the problems and politics of urban pollution from industrial and infrastructure development. This is a clear case of manufactured risk. There have been increasing attempts to manage pollution in Western, and now Asian, cities during the great acceleration. These have been characterized as the product of a change in environmental values as higher standards of living have prompted a search for improved environmental quality and higher levels of amenity (Hays 1987). The search has had varied outcomes, not least a growing focus on air and water management, and the paradox of highly consumptive but outwardly clean suburbanization.

Urban environmental issues of this sort, although experienced by cities throughout the world, are essentially the product of local-scale activities and are amenable to local solutions. The more intractable sources of manufactured risk are those expressed at much bigger spatial scales. A good example is the threat to coastal cities from tidal flooding and extreme weather events as climate change becomes more pronounced, at the same time as more people seek to live or develop trading facilities by the sea. The cities most in jeopardy are those in Asia, such as Shanghai and Mumbai, and those on the Gulf and East Coasts of the United States. Hurricane Katrina, which devastated New Orleans in 2005, and Hurricane Sandy, which badly affected New York City in 2012, are widely seen as warnings. Often this is imagined to be a case of external risk rather than one of manufactured risk on coastlines made vulnerable through human action.

In an analysis of the New Orleans situation, Freudenburg et al. (2009) take a particular view of this issue. The title of their book describes Hurricane Katrina as a “catastrophe in the making,” in which the “growth machine” of industrial capitalism set in train destructive processes that led to an inevitable outcome. These included the extension of the city into low-lying, flood-vulnerable districts; the driving of the main export canal through the Mississippi Delta into the teeth of Gulf hurricanes; and, critically, the damaging intrusion of oil industry infrastructure and wastes across the deltaic wetlands, undermining their buffering functions to storms. For them, “New Orleans is by no means unique in the ways in which local leaders have increased their communities’ vulnerability to ‘natural’ disasters” (Freudenburg et al. 2009, 11). They see the story of Katrina as a parable of the consequences of manufactured risk. It also highlights the key difference between the modern preoccupation with short-term decision-making and environmental history’s focus on long-term analysis.

Stories in environmental history

The most common form of environmental history is narrative, or the organization of understandings about people and environment into story form. Storytellers select certain events, processes, and places to emphasize, and particular relations to highlight. At the same time, other players and connections are downplayed, and “the discontinuities, ellipses, and contradictory experiences that would undermine the intended meaning” of the story are hidden (Cronon 1992, 1349–1350). The most effective environmental history works by telling stories about stories about nature.
The analysis of the impact of Hurricane Katrina on New Orleans illustrates this point. Freudenburg et al. (2009) argue that engineering evaluations of the causes of that extreme event, including that of the US Corps of Engineers which had built the walls and levees that failed, avoided any attribution of blame to the construction of the main canal through the delta. The consequences for the wetlands were ignored, including the destruction of large areas of swamp cypress that had earlier mediated the impact of floods, as was the “levee effect,” or the acceleration of urban construction behind flood defenses that were assumed to give greater security than they could ever have done. Instead, for the engineers, the disaster was the result of structures that performed inadequately. The larger point is that the story that frames this engineering perspective is one that, like the “growth machine” that supports it, embodies Enlightenment notions of progress and “improvement.”

William Cronon (1992) identifies two main “plot lines” for stories in environmental history, illustrating these with a range of narrative accounts of settler encounters on the Great Plains. The most famous of the progressive narratives in this context is the frontier thesis of Frederick Jackson Turner, which described a rising arc of landscape transformation from wilderness to trading post, farm, and boomtown. Turner’s account, unproblematic in that it did not highlight struggles and setbacks, was followed by many other progressive story lines that did, in which the narrative role of such problems was “to play foil to the heroes who overcame them” (Cronon 1992, 1353). At the same time, there have been competing stories that trace more negative outcomes, stories that are tragic or declensionist in form. Meinig’s (1962) interpretation of the South Australian frontier is a story about both types of story – about eager settlers in times of rain, and anxious administrators aware of cyclical drought.

Such narratives often silence other human or nonhuman actors. Since the mid-1980s there has been some correction of the omission of indigenous voices from these accounts; experiences from the other side of the frontier are now more conspicuous than before, as are environmental histories of non-European parts of the world. This has been matched by the use of different forms of narrative, including critical engagements with cartography and photography. There have been experiments with re-photography to illustrate the nature and extent of change over time, and also with environmental art. The Strata project, about Puritjarra in western central Australia, engaged Aboriginal artists with an artist of Australian settler meanings, alongside an archaeologist and an environmental historian. Their purpose was to uncover different kinds of knowledge and ways of knowing place and, through co-understanding, to access something of the deep time that is lost in Eurocentric stories of colonizer experience (Martin, Robin, and Smith 2005).

The future

In his reflection on the value of stories, William Cronon suggests that “the task of environmental history is to assert that stories about the past are better … if they increase our attention to nature and to the place of people within it” and encourage us to look at these in new ways (1992, 1375). Such stories are told at a range of scales, from the local to the global. The canvas is both ideas and materialities, or how people know nature as well as the material outcomes of their interactions with it. The aim is to understand environmental changes in the long run, such as the great acceleration, and to analyze how
past variability in natural systems exposes the assumption that has held sway for much of the Anthropocene: that conditions favorable to human activity will always prevail.

The best environmental history therefore reveals the consequences of the spread of liberal capitalism and the unexpected opposition that its short-term futurism has prompted from the planet itself. At this juncture, rather than “grit our teeth and hope for a miracle,” as Bruno Latour (2013) puts it, “we could inquire into what this modern project has meant so as to find out how it can be begun again on a new footing.” This raises two points that only a few environmental historians (e.g., Dovers 2000) have attempted to explore. First, what does an understanding of past environmental transformations mean for the analysis of society today, its priorities, structure, and agency? And, second, how can such knowledge be translated into solutions and policies? These questions pose extended interdisciplinary challenges for environmental history. But doing the work toward answering them may encourage a wider and more reflective social engagement with nature, in keeping with Marsh’s view of the human being as earth’s “noblest inhabitant.”

Environmental impact assessment

Richard K. Morgan
University of Otago, New Zealand

Environmental impact assessment (EIA) is a structured process for considering the implications of proposed actions for people and their environment, while there is still an opportunity to modify (or even, if appropriate, abandon) the proposals. In principle, it can be used at all levels of decision-making, from policies and plans through to specific projects; in practice, project-level application has dominated its use around the world.

Brief history of EIA

The institutionalized forms of EIA now so evident around the world had their origins in the late 1960s with the enactment of the National Environmental Policy Act (NEPA) in the United States. The requirement to produce an environmental impact statement (EIS) was a late addition to the act, to provide an enforcing mechanism that ensured federal agencies showed explicitly how they were implementing the environmental policy in their own major policy and project initiatives. The very process of producing an EIS achieved its own identity and was adopted, within a few years, as an environmental management tool by a number of other countries, including Australia, Canada, and New Zealand. The following decades saw the process, by then more generally known as environmental impact assessment, spread to more and more countries. Following the 1992 United Nations Conference on Environment and Development (UNCED), all UN agencies developed internal impact assessment procedures; this was a significant but perhaps relatively unheralded expansion of the reach of the process. In addition, impact assessment has gained greater explicit recognition in international law, the more notable being the Convention on Transboundary Environmental Impact Assessment; the Convention on Wetlands of International Importance; the Convention on Access to Information, Public Participation in Decision-Making and Access to Justice in Environmental Matters; the United Nations Framework Convention on Climate Change; the United Nations Convention on the Law of the Sea; and the Protocol on Environmental Protection to the Antarctic Treaty. Whether through national statutes or international legal instruments, impact assessment procedures are now recognized by virtually every member country of the United Nations (Morgan 2012).

A significant milestone in recent years has been the development of the Equator Principles (EP) to establish guidelines on the use of EIA by private-sector financial institutions. As funding of major development projects by the members of the World Bank group declined significantly as a proportion of total global funding, it became obvious that the bank’s Safeguard Policies were in danger of being marginalized. Therefore, in 2002 the International Finance Corporation (IFC) met with several major banks and initiated discussion that led to the launch of the Equator Principles in June 2003; by 2014, 81
private-sector financial institutions had signed up to the principles. The EP are based on the IFC’s social and environmental performance standards, and the World Bank’s environmental and health and safety guidelines, all of which give EIA a prominent role in the decision-making process.

Nature and purpose of EIA

The purposes of IA are:

- to provide information for decision-making about the biophysical, social, economic, and institutional consequences of proposed actions;
- to promote transparency, and the participation of the public, in decision-making;
- to identify procedures and methods for the follow-up phase (e.g., monitoring and mitigation of adverse consequences) in policy, planning, and project cycles; and
- to contribute to environmentally sound and sustainable development.

The process of IA benefits proponents, stakeholders and local communities, and decision-makers. Although it has been criticized since its introduction for being a technocratic tool, based on rational decision-making models (Richardson 2005; Weston 2010), much of the contemporary literature on IA principles tends to emphasize a participatory, inclusive approach, which recognizes different types of knowledge and the importance of representing the views of different groups in society, regardless of their economic and political status (e.g., Spaling, Montes, and Sinclair 2011). As such, environmental and social justice considerations, including the consideration of human rights, are important guiding principles of impact assessment (Kemp and Vanclay 2013).

In recent years, IA has become strongly linked to sustainability concepts, and some would argue that sustainability is an integral part of all IA activities (Gibson 2013). On the other hand, it is possible to conduct impact assessments within
other policy contexts, without direct or indirect reference to sustainability thinking.

**Practice of EIA**

EIA involves the identification and characterization of the most likely impacts of proposed actions (impact prediction/forecasting) and an assessment of the social significance of those impacts (impact evaluation). Most methodologies break these two basic components into a series of steps comprising some or all of the following:

- **Screening**: Should an impact assessment be carried out? Many countries use lists of activities that require an EIA, perhaps supplemented by lists of those activities that may require an EIA if they meet certain size/capacity characteristics.
- **Scoping**: The core of the impact assessment process, scoping involves the identification of significant potential impacts and establishing a work program to investigate these further.
- **Impact prediction**: The phase during which potential impacts are investigated by appropriate methods, to assess their likelihood and the consequences of their occurrence. Methods will vary according to the impact type (e.g., social versus ecological), and also according to cultural context; indigenous environmental knowledge can often provide valuable insights based on a long history of resource usage that inform predictions, which also embed social and cultural values.
- **Significance evaluation**: The impacts that are likely to occur need to be evaluated for their social significance. Many systems leave this to the public submission process during formal decision-making, but both monetary and nonmonetary evaluation methods can be used within the EIA process to capture significance.
- **Impact management provisions**: Significant impacts will require some form of response to avoid or mitigate the impacts. This may be through design changes to a proposal, by instituting measures to protect people and/or the environment, or by compensating affected parties. Managing impacts through the life of the proposal is an important part of EIA, so the development of impact management plans, together with monitoring provisions to ensure compliance and the effectiveness of those plans, is critical to the whole process.
- **Reporting/communication**: Effective communication of the information generated through the EIA to the people who need to use the information is vital. Potentially affected communities and other stakeholders need the information in a form that enables and empowers them to participate in decision-making processes. And decision-makers need the information in a form that allows their decisions to be fully informed.

Some jurisdictions use a narrow definition of “environment” to mean just the natural environment; others consider environment to also include people and their activities and structures. The trend in the international research and practitioner community, as exemplified by publications from the International Association for Impact Assessment (IAIA), is to follow the second of these interpretations.

An important stimulus for the development of EIA was the failure of existing procedures (typically dominated by cost–benefit analysis) to anticipate the less obvious environmental consequences of developments. Prominent examples from the 1960s include the effect of
the agricultural pesticide DDT on bird-of-prey populations (biomagnification of DDT residues resulting in fragile eggshells and hence decreased reproduction rates), publicized by Rachel Carson in *Silent Spring* (1965); and the increased incidence of schistosomiasis among local people in tropical environments due to changes in water snail habitat following the construction of hydroelectric dams (Edington and Edington 1977). In both examples, dramatic impacts resulted from changes that had not been anticipated and that involved a series of intermediate stages before the significant impact was manifest.

Significant direct impacts of major activities are usually well known and, in most cases, environmental engineering solutions have been developed. For example, modern dams usually have structures (e.g., fish ladders) to allow fish migration upstream to continue once the dam is completed. The more problematic issues are the indirect impacts, which typically result from more complex cause–effect pathways, and may be separated in space and/or time from the original action. An important purpose of EIA, then, is to recognize the possibility of indirect impacts and to attempt to predict what they might be, and the likelihood and implications of their occurrence.

Another important consideration is cumulative impact. This concept recognizes that, in many situations, other previous activities (typically projects) have already created a legacy of effects on the local environment. If a further activity is allowed to proceed, the analysis of cumulative impacts considers how the impact of the proposed activity will add to and perhaps interact with existing conditions. Given the complexity of such questions, it is unsurprising that cumulative effects assessment is generally seen as one of the more problematic and least developed of the impact assessment methods. There is also a view that such considerations are best managed not on a project-by-project basis but at a regional or national level by setting limits to development or establishing some form of carrying-capacity thresholds on resource use.

Public participation is now given prominence in EIA writing. Many evaluations of public participation in EIA have identified similar, largely mechanistic, procedural problems, including proponent reluctance to engage with local communities, poor public understanding of statutory processes, barriers that limit public access to information, and lack of decision-maker sympathy for public involvement (Hartley and Wood 2005). In contrast, more recent studies have tended to place greater emphasis on evaluating practices against the expectations of deliberative democracy or collaborative planning (Petts 2003). The postrationalist thinking of recent years emphasizes the development of constructive relationships between public, proponents, and decision-makers, and changes in the structure and power relationships of decision-making (Diduck *et al.* 2007). However, social, political, and cultural settings and traditions are important determinants of the development and practice of these processes, especially in those countries where such practices are still new. Therefore, concepts of social and organizational learning are also important considerations in evaluating the progress with, and nature of, participatory processes in impact assessment (Sinclair, Sims, and Spaling 2009).

**Forms of EIA**

Ideally, impact assessment will be an integrated treatment of the likely impacts on any of the facets of the natural and human-modified environment, including people, communities, and their wellbeing. However, different sectors of the environment can pose rather different methodological and technical challenges for
impact assessment, resulting in communities of practitioners who focus on the use of specific methods for the assessment of particular impact phenomena. Any given proposal may require a different array of impact assessment methods, reflecting the range of potential impacts associated with the proposal. The challenge for the impact assessor is to bring all that information into an integrated assessment.

Under the umbrella of EIA a number of specific forms have become firmly established since the 1970s, including social impact assessment (SIA), ecological impact assessment (EcIA), health impact assessment (HIA), and strategic environmental assessment (SEA). To some extent, each tends to have arisen through some level of dissatisfaction with EIA as it has been practiced – SIA, for example, developed strongly in the late 1970s and 1980s as EIA, especially in the United States, was considered to have a strongly biophysical emphasis and to neglect social impacts. SEA has been vigorously promoted as a way to extend impact assessment to higher-level decision-making at policy, program, and plan levels, a reaction to the project orientation of most EIA applications.

Theory and EIA

Dissatisfaction with the lack of serious critiques of EIA as a process gained momentum in the late 1990s, as the influence of debates in related disciplines finally began to reach the impact assessment community. The resulting literature has explored the historic roots of EIA in the rationalist decision-making model, and examined the way critiques of that model in related fields such as planning, environmental management, decision theory, political science, sociology, and economics have provided alternative ways to think about EIA.

One important source of thinking represented in subsequent literature has been the link to models and theories of planning and decision-making. Bartlett and Kurian (1999) identify six models they consider to have been implicit in discussions of EIA in the literature:

- the information-processing model: essentially the rationalist, decision-support model;
- the symbolic politics model: EIA is used to suggest accordance with certain values but not necessarily for holding to those values;
- the political economy model: EIA is used by the private sector to reduce financial risk, and if possible increase financial opportunities by internalizing environmental externalities;
- the organizational politics model: changes occur in the internal politics of those organizations required to use EIA;
- the pluralist politics model: EIA process is used to open opportunities for negotiation and compromise between different interest groups; and
- the institutionalist politics model: political institutions are changed significantly by the effect of EIA on values, actions, and perspectives in their policy-making processes.

Leknes (2001) uses a simpler threefold categorization of decision-making approaches: the rational, the new institutionalist, and the negotiation perspectives. The common theme in these and similar contributions is the critique of the rationalist model of planning/decision-making, and by implication of EIA, and the exploration of alternative models that embrace new thinking about planning and decision-making processes in their wider social, cultural, political, and economic contexts.

The rationalist model rose to dominance after 1945 in organizational and decision-making thinking, and is characterized as having a strong
ENVIRONMENTAL IMPACT ASSESSMENT

technical emphasis, with planners and other professionals acting as neutral processors of information, producing independent evaluations of alternatives to be provided to the decision-makers. As the basis of the rational comprehensive planning theory which dominated strategic and development planning in many Western countries in the 1960s and 1970s, this model has been the subject of significant criticism. One theme has been the impossibility of recognizing all possible alternative solutions, from which to select the “best” solution; hence, more constrained and practice-informed models of the rationalist approach have emerged (such as the bounded rationality model, the incrementalist model, and various other pragmatist models). However, they still carry the rationalist imprint, and they have continued to attract criticism for their failure to recognize the political and value-based nature of decision-making, and especially issues related to the use of power (Richardson 2005). This has encouraged the promotion of deliberative and collaborative approaches to planning and decision-making processes, drawing on the work of Habermas: bringing stakeholders and communities into the processes, emphasizing the importance of communication as a means of negotiating a consensus solution that captures the values of those participants, and moving the professional technocrats from a controlling to a facilitating role in the decision-making process.

These collaborative and consensus-oriented models have themselves been criticized by those influenced by Foucault for not recognizing sufficiently the issue of power relations between participants, which will inevitably affect the ability of different groups or individuals to enter social negotiations in an equitable way (Richardson 2005).

Evidence suggests that the center of gravity of EIA thinking, and especially practice, is still firmly rooted at the rationalist end of that spectrum (Morrison-Saunders and Sadler 2010). But it is important to recognize that EIA thinking since the beginning of the twenty-first century has been affected by wider debates more clearly seen in the major disciplines, and that these ideas are being explored and reinterpreted in ways that will encourage EIA practitioners to reflect on their practices.

The prevailing view in the theoretical literature would seem to be that EIA is in essence a rationalist, information-based process that is used to support decision-making, but that the value dimension of the process has to influence the way impact assessment is designed and carried out, and that the context within which EIA is used must be recognized as influencing its effectiveness. In particular, wherever significance judgments are to be made, the process has to accommodate the values of those potentially affected by the proposed activity, and that must include as a minimum, for example, the scoping phase as well as the impact evaluation phase. How this involvement should be managed to promote inclusion and ensure equitable participation in a socially and culturally appropriate way has been the subject of a burgeoning public involvement literature in recent years. It reflects an increasing awareness of and sensitivity to, among other things, the inherent power relations found in rationalist decision-making processes, so one challenge has been to develop new approaches to impact assessment that address these problems (Morgan 2012).

Effectiveness of EIA

The final report of the International Study on the Effectiveness of Environmental Assessment in 1996 concluded that, while EA had made its mark since it was introduced 25 years earlier, it would be necessary to maintain the
efforts to improve its performance if it was to make a substantive contribution to the goal of sustainable development (Sadler 1996). The theme of effectiveness of EIA has been ever present in the literature since then, but as Cashmore et al. (2004) observe, the bulk of that literature addresses procedural issues, with a much smaller proportion concerned with substantive issues. Both are important parts of the overall assessment of effectiveness but, while the procedural aspects are more amenable to study and analysis, substantive considerations raise more difficult questions.

Where EIA has been incorporated into environmental or resource management, or planning legislation, it supports the wider policy aims of those statutes. Effectiveness then has to be judged in large part in those terms, and will vary from country to country. Yet there are still criticisms of EIA for falling short of other aims, such as sustainability goals. The wider policy process within which resource exploitation takes place must be the focus of scrutiny and criticism, not the enforcing mechanism per se. Using the political models of EIA suggested by Bartlett and Kurian (1999) – or indeed the various planning or decision-making models – effectiveness can be seen from a number of different, politically oriented perspectives. Has the process opened opportunities for local people to be more involved in decision-making? Have companies become more aware of environmental issues through EIA and modified their practices accordingly to gain competitive advantage? Has change been brought about in government bodies dealing with, say, natural resources, to internalize EIA thinking? Do decision-makers and other stakeholders understand and use the EIA information provided to them?

ENVIRONMENTAL IMPACT ASSESSMENT

Further reading

IAIA (International Association for Impact Assessment) wiki: http://www.iaia.org/iaiawiki/.

Public understanding of environmental issues does not draw simply on scientific facts and expert information, but on a range of familiar knowledges, personal values, commitments, and responsibilities. People learn about environmental issues through everyday social practices at work, at home, and at school as well as through media reporting on local and global problems. And “the public” are not a homogenous, undifferentiated lump, but differ greatly in terms of age, gender, class, race, outdoor activity levels, educational attainment, and geographical location. This means that public understanding of environmental issues is complex as people can hold multiple beliefs at any one time; beliefs that can be contradictory, in opposition, or scientifically impossible.

Learning about environmental issues can happen in situ and ex situ. In situ learning takes place in the environment that is being studied, perhaps as part of a fieldwork program or during a holiday or hobby activity. For example, Figure 1 shows a park ranger in Yellowstone National Park, USA, explaining to visitors how geysers work and how they are damaged by people throwing in litter. Public understanding may thus develop through embodied practice and sensory experience of unfamiliar environments while a tourist, or of familiar environments while walking to work or school as part of everyday life. Ex situ learning takes place outside the environment being studied, for example, in classrooms through formal education or more informally in homes when people read about environmental issues, watch television documentaries about wildlife, or surf the Internet for fun.

One challenge for public understanding is that the global scale of many environmental issues, such as climate change, make them more difficult for members of the public to grasp and engage with than more local, more visible, and everyday issues, such as taking more environmentally friendly forms of transport to work.

Another challenge is that discussion of public understanding remains largely in the Global North, with little attention paid to this important question in the Global South. Postcolonial geographies of public understanding are required to avoid an Anglo-American focus on global issues. The public understanding of environmental issues is thus inherently geographical in both the ways that it is influenced by context – environmental, social, cultural, and personal influences on the public – as well as the ways in which those environmental issues will influence people’s lives into the future.

Science, the media, and pressure groups as influences on public understanding of environmental issues

Public understanding of environmental issues also depends upon claims made by powerful actors
ENVIRONMENTAL ISSUES AND PUBLIC UNDERSTANDING

Figure 1  Park ranger and visitor near Old Faithful geyser, 2002. Photo by Sally Eden.

about what issues matter and why. Specialists or elite groups such as scientists, businesses, governments, nongovernmental organizations (NGOs), and pressure groups are powerful actors in identifying and articulating environmental issues through making claims about their science, severity, and possible solutions.

Many environmental issues originate in scientific work, which often identifies and measures the issue, for example, stratospheric ozone pollution or climate change. This is one reason why opinion polls often report that the public trust scientists more than any other profession in society, including business and government, to tell the truth about environmental issues. Because of their specialized training and expertise, scientists are often regarded as being knowledgeable about environmental issues and as having solutions or answers to environmental problems as well as pursuing facts, data, and truth for its own sake without being affected by the need to make a profit as a business might do.

Scientists and scientific writings, such as journal articles or reports, can be particularly important in influencing public understanding of environmental issues because many environmental problems cannot be perceived by ordinary people, maybe because invisible pollutants are involved that can only be detected with specialist equipment and/or their effects occur beyond normal human perception. For example, in the 1980s, stratospheric ozone depletion many kilometers up in the skies above the Antarctic was detected using specialist monitoring and computing equipment and climate change today may be invisible to the average person because the effects are often felt far away from home and the timescales of change can be longer than a human lifetime.

But the success of scientists in influencing public understanding of environmental issues depends also upon media coverage of their work because very few ordinary people encounter science directly. Many environmental issues are therefore communicated to the public through media coverage of science; coverage that often tags them with memorable names as well, such as “the ozone hole” or “global warming.” In the case of stratospheric ozone depletion, there was rapid and unequivocal coverage in the mass media of the thinning of the ozone layer over the Antarctic using NASA data and visually striking maps. This led to a rapid rise in public awareness and, subsequently, international policy to reverse the damage. In contrast, in the case of climate change, public understanding of climate change has been more difficult to build with different scientific claims made for and against the evidence for human-induced climate change at a global scale.

In addition, media coverage of environmental issues is diverse. News reporting, representations of nature in the form of television documentaries about wildlife made by Disney or David Attenborough, movies about environmental catastrophes from *The Day After Tomorrow* to *Wall-E*, and even adverts that use images of lush green landscapes to promote corporate reputations can all
contribute to public understanding and appreciation of environmental issues (e.g., Burgess 1990).

Pressure groups and nongovernmental organizations (NGOs) are also important in raising public understanding of environmental issues. In the past, these groups used newsletters, rallies, petitions, and, especially, symbolic embodied protests, such as Greenpeace sailing dinghies near whaling ships, which were then communicated to a mass readership through media coverage in newspapers and television news. Today, social media and self-publishing on the Internet mean that NGOs and campaigning organizations of all kinds can publish their awareness-raising materials themselves in order to communicate more directly with the public. As with scientists, opinion polls often report high levels of public trust in what NGOs say about environmental issues, usually much higher than the trust given to business and government as providers of information about environmental issues.

These processes of making and judging claims to knowledge can have a big effect in terms of public understanding and behavior. For example, research studying two communities in the United Kingdom and Netherlands revealed that an inability to establish the legitimacy of expert claims, confusion around environmental facts, and a distrust of government led to a reduction in people taking personal responsibility for environmental issues (Burgess, Harrison, and Filius 1998).

Public understanding of science (PUS) and environmental issues

Research into the public understanding of environmental issues has been informed by work on the public understanding of science (PUS) more generally in the social sciences. This work began in the 1980s when the public understanding of science was seen as limited because scientists were regarded as knowledge-holders or “experts,” whereas ordinary or “lay” people were regarded as holding little or no scientific knowledge. Scientists, policymakers, and governments commonly thought of ordinary people as having insufficient knowledge about science to be able to understand the debates on how to govern it, with public perceptions of new technology or scientific claims often being dismissed as uninformed, misunderstood, or even nonsensical.

The assumption was often made that the public should be given more information so that they could not only understand new science and its risks for human health, for example, from vaccination, genetic modification, or stem cell research, but also learn to support decisions about how new science and its risks were governed. This argument also emphasized “scientific literacy,” that is, the level of knowledge that people have about basic scientific principles, such as laws of motion, energy, and genetics. Again, the assumption was that, without this basic level of scientific literacy or knowledge, people would be unable to debate the issues that arose around new scientific findings or technological applications and unable to make informed decisions.

Social scientists working in PUS were critical of these assumptions, referring to the whole approach as the “deficit model,” because it assumed a knowledge deficit in public understanding of science and because it kept (supposed) experts and nonexperts apart. They argued that this model failed to comprehend fully how ordinary people understand science and the consequences of that assumption on their behavior and feelings about scientific applications and governance. These arguments were applied particularly to environmental issues such as climate change and genetically modified foods in the 1980s and 1990s.
The deficit model was challenged by alternative models, such as that of “post-normal science” (Funtowicz and Ravetz 1993), which argued that environmental issues such as climate change or genetic modification were too high risk and too uncertain to be dealt with through traditional, “normal” scientific methods. Instead, such issues required science not only to change itself by moving into a “post-normal,” reflexive mode of thinking about its own assumptions, but also to change its relationship with others to a more participatory, dialogue-based model, which would include “lay” public in debates. This “extended peer community” would include a wide range of participants beyond the traditional scientific “experts.”

Such alternative theorizing can be seen as part of a democratic turn toward promoting the participation of citizens in science and environmental issues, as well as part of critiquing (and thus attempting to replace) the deficit model. Scientists and other elites also criticized such proposals in turn, fearing the dilution of science’s traditional authority by forcing scientists to share it with what they saw as less (or un-)qualified publics, and also as politicizing issues that should remain outside the realm of politics.

Lay knowledge

Academics and others who rejected the deficit model have been arguing for some time that public understanding of environmental issues can be as useful and valid as scientific or expert knowledge. Ordinary people are argued to have important “lay knowledge” that can feed into understanding of environmental issues, knowledge that arises not from formal education or training, but from everyday life and experiences.

For example, people are often very knowledgeable about their local environments, but because such knowledge is not usually framed in the objective and rational way expected by science, it has often been discounted as worthless or at least unreliable. Recent social science work has, however, begun to re-value such knowledge, from using a person’s weather diaries to reconstruct climate change in the nineteenth century to incorporating local people’s folk memories of flooding into scientific models of hydrological management (e.g., Lane et al. 2011). Such local or “lay” knowledge will also take into account the emotional and subjective encounters, responses, and debates surrounding environmental issues as part of the context of learning and evaluating environmental change.

People may also have specialized knowledge about everyday practices because of their work or hobbies. A famous example analyzed by Wynne (1996) is that of sheep farmers in Cumbria, northern England. Following the Chernobyl nuclear accident in 1986 in Ukraine, the UK government banned the movement and sales of sheep from key areas, thus threatening farmers’ incomes, already fragile in a precarious industry. Government decisions were largely based on scientific modeling of the movement of radio-caesium and its movement through vegetation, soil, and the bodies of sheep grazing on the hills, modeling which initially predicted that contamination of sheep would only last for three weeks. However, when measurements of the sheep showed that contamination lasted far longer than predicted, the ban was extended from three weeks to become indefinite and there was also talk of a widespread cull. The modeling had assumed that clay soils were prevalent in the grazing areas, whereas peaty soils also existed and these mobilized caesium back from the soil into the grass upon which the sheep continued to graze. In contrast, the farmers argued that the contamination was not solely due to the fallout from Chernobyl in Ukraine, but from normal...
operations of the nearby nuclear power plant at Sellafield in England.

Wynne argued that the problem was not only that the scientists claimed complete certainty over their environmental modeling, a certainty that was clearly unrealistic, but also that they refused to listen to the farmers’ arguments, arguments based on local knowledge about where sheep grazed in comparison to where the highest levels of contamination had been measured, or about how the metabolism of sheep would respond to being penned up during scientific experiments. He concluded that the two “knowledge cultures” – lay farmers and professional scientists – made very different assumptions about agency, control, and predictability and also valued each other’s forms of knowledge very differently.

As a consequence of this kind of analysis, researchers have since argued that lay knowledge, often built up tacitly, without professional qualifications, without being written down or peer-reviewed, but instead embodied in everyday lived practices and experience of people’s local environments, as well as through folk memories, nevertheless has value in understanding environmental issues.

However, a tension between scientific knowledge and lay knowledge about the environment remains. Scientific knowledge, even where it is not strictly “universal,” is still assumed to be generalizable and big-pattern thinking, whereas laypeople’s knowledge is assumed to be much more narrowly scaled or piecemeal in its spatial coverage, focusing on the local rather than the global, the visible rather than the remote. Hence, science is often associated with higher scales of environmental knowledge and public views with much lower scales which are not seen as transferable to other places either. The hierarchy of knowing is therefore based not on what is known but how it is known – for example, formal qualifications, professional positions, and other credentials more frequently legitimate environmental knowledgeability than do recreational experiences.

Moreover, the validity of “lay knowledge” is also criticized when it is invoked in controversies over environmental issues. For example, local protests about the damage that new developments, such as an onshore wind farm, might wreak in a landscape are often denigrated as merely self-interested NIMBY (not in my back yard) concerns, undermining the legitimacy of local people’s connections to and understanding of their local environment. A more critical geographical perspective would be to understand such protests as reflecting lay knowledge arising from and supporting attachment to local places (e.g., Devine-Wright 2013).

### Indigenous knowledge

One particular form of lay knowledge is “indigenous knowledge,” which refers to knowledge held by aboriginal (and usually marginalized) groups in the Global South about their local environments and how best to use environmental resources for agriculture, medicines, education, and other benefits. Indigenous knowledge has been gained through living in those environments for generations, not through traditional scientific research, and is passed down the generations through oral traditions and rituals, rather than through written histories or formal education.

For example, indigenous people living in tropical countries may know about and make use of the medicinal benefits of plants unknown to modern science as part of what is called “ethnobotany.” Pharmaceutical companies try to tap into this indigenous knowledge in order to develop new medicines, making it potentially
very valuable and unfortunately therefore ripe for exploitation, particularly by companies from the Global North (e.g., Agrawal 2002).

In environmental issues, indigenous knowledge is often argued to be intrinsically in tune with natural processes, using fewer resources less intensively in order to support a particular way of living or a cultural group, and thus more sustainable than more “modern” methods of growing crops or managing the environment. Again, this emphasizes that environmental knowledge does not have to come out of the laboratory to be valid or useful, although critics have argued that such claims can romanticize some forms of environmental management which were necessarily exploitative (e.g., fire being used in hunting) rather than conservationist.

Citizen science

As well as lay and indigenous knowledge, both of which are argued to develop over time and be handed down through the generations, attempts have recently been made to increase public understanding of environmental issues through directly involving lay people in producing environmental knowledge in collaboration with professional scientists. Bridging recent work by science and technology studies (STS) and environmental geography, this coproduction of knowledge is another more recent approach to public understanding of science and the environment that rejects the deficit model. This approach argues that knowledge, understanding, and decision-making are no longer the sole domain of so-called experts, but produced in tandem with a wide range of stakeholders. As a result knowledge-making is a collaborative and joint activity between partners. An example is the role of coproduction of knowledge in Canada’s Arctic, bringing together knowledges from science and the indigenous First Nations to enable adaptation to environmental change.

Sometimes called “citizen science,” this takes many forms, including making science more available to lay people through experimental forms of science–society dialogue and interaction, such as “science shops” (Irwin 1995). Recently, the term has become more specific in referring to processes which involve lay people in the production of scientific knowledge. In this guise, “citizen science” has been heralded by academics and policymakers as a good way to engage citizens in environmental debates, as well as improving scientific literacy through education, training, and outreach, although so far empirical evidence for this is limited.

Involving ordinary citizens as “amateur” scientists is increasingly useful for scientists as a cheap way of generating a lot of data. Enrolling enthusiastic amateurs as (paid or unpaid) volunteers can extend the amount and scope of environmental fieldwork that conservation and environmental science can do, such as amateur naturalists collecting biodiversity data for the state (Ellis and Waterton 2004, 2005).

There are numerous recent examples. The 2013 OPAL (Open Air Laboratories) Tree Health Survey involved two government science agencies recruiting and training a cadre of citizen experts to notify the authorities of early sightings of tree pests and diseases that threatened both landscape and economy in the United Kingdom (Figure 2). Members of the Climatological Observers Link (COL) record weather and climate in great detail and for many years as a hobby, but have been approached by scientists to contribute their data to wider research programs, often for free.

Citizen science has also been adopted by NGOs with large memberships but small budgets. The United Kingdom’s Royal Society for the Protection of Birds runs Garden Birdwatch, with up to 280,000 people participating by reporting bird
counts and, in the USA, the Cornell Lab for Ornithology and the National Audubon Society run the Great Backyard Bird Count, with over 80,000 counts submitted, as part of their “citizen science” program (Bonney et al. 2009).

As well as engaging in the scientific process, it is argued that citizen scientists can gain scientific knowledge, explore the environment, reflect on science, and develop positive attitudes toward science. At best, citizen science can be led by citizens from the bottom up, prompted by community concerns such as monitoring water pollution in local rivers, rather than by more esoteric academic questions. This can challenge what constitutes expertise and also open up research and policy processes to on-the-ground challenges faced by citizens. In this sense, citizen science offers hope for expanding public understanding of environmental issues and reflexively shaping the agenda of environmental science itself in future, not through reducing scientific authority but through increasing and redistributing it (Lave 2015) among more diverse knowledge producers.

But the idea of bringing science out of the laboratory into the public sphere has also been criticized. First, citizen scientists may be well aware of how the data they submit is used to make environmental management decisions and may intentionally modify it accordingly. For example, anglers and hunters have been shown to adjust the catch numbers they report to state agencies, numbers which often form the basis of national wildlife statistics, in order to strategically influence subsequent management policies.

Second, the citizens involved may be exploited, not only being unpaid but receiving little in return for their data, not even information or support. Third, citizen science initiatives may simply reinforce the traditional hierarchy of professional scientists telling lay people what to do, with little reward for the latter (Ellis and Waterton 2004, 2005; Lave 2015).

Methods for analyzing public understanding of environmental issues

Another area of critique surrounds the methods used to measure the public understanding of environmental issues. Surveys are often used to identify what the public know about scientific or environmental issues and to compare levels of knowledge across time and space, especially between countries. Surveys and opinion polls are often conducted by government bodies, providing a snapshot of public attitudes at one point in time, a snapshot that can prove powerful when it is used to shape future policy. For example, the United Kingdom’s Department of Energy and Climate Change surveys the general public regularly about whether they think natural processes or human activity are more important in causing climate change.

Academic researchers have also employed quantitative surveys to measure public understanding of environmental issues. For example, Whitmarsh, Seyfang, and O’Neill (2011) surveyed over 500 people in England by post about...
ENVIROMENTAL ISSUES AND PUBLIC UNDERSTANDING

their understanding of the main causes of climate change and what “carbon” means, analyzing the results in terms of what are scientifically “correct” or “incorrect” answers. They interpreted linking ozone depletion with carbon dioxide emissions as a “misperception” of the scientific consensus, rather than an attempt by the public to make sense of highly technical terminology.

However, surveys are not the only or even the most meaningful way of evaluating public understanding of environmental issues. Polling methods do not account for the multiple and complex ways in which people engage with environmental issues because surveys represent a one-off, one-time capture of data with little opportunity for a more nuanced understanding of the answer and little understanding of the attachment, emotion, and feeling experienced as a result of participation, nor of how environmental issues are embedded within wider cultures of value.

Other ways of researching public understanding of environmental issues have therefore been developed. The work done by geographer Jacquie Burgess and colleagues has particularly promoted qualitative methods in this context since the late 1980s. In a time when qualitative methods were largely distrusted in comparison with quantitative ones, methods such as focus groups and workshops (Burgess et al. 1998; Burgess, Limb, and Harrison 1988; Burgess 1996) and deliberative mapping (Burgess et al. 2007) produced a richer, more culturally sensitive analysis of how people understood and responded to environmental issues. Such methods have now become more widely used in human geography to analyze the complexities in public understanding of environmental issues (e.g., Macnaghten and Urry 1998).

Environmental issues in rural areas

Geoff A. Wilson
Plymouth University, UK

Human–environment interactions in rural areas over time

While urban areas have received much academic and media attention with regard to environmental issues and threats, it is often thought that rural areas have been less affected by recent environmental challenges (Woods 2005). Yet, most rural areas in a globalizing world have faced unprecedented environmental risks in recent years that are threatening the survival and resilience of many rural systems (Wilson 2007; 2012).

In the past, environmental issues in rural areas were closely associated with environmental impacts of agriculture — a human activity predicated on transformation of the environment through the replacement of one ecosystem with another, with a focus on maximum production of food for human consumption (Pretty 1995). In the preindustrial era, therefore, environmental pressures in rural areas were almost entirely associated with transformation of the environment from relatively undisturbed ecosystems to agricultural land through the burning or clearing of vegetation or the draining of wetlands (Simmons 1996). In the preindustrial era pollution from agriculture was almost nonexistent as all agriculture was organic and based entirely on human/animal labor and organic fertilizers such as manure or plant biomass.

With the onset of industrialization from the nineteenth century onward, and the associated emergence of large agribusinesses and “industrial farming” characterized by intensification and specialization, the environmental impacts of agriculture began to shift toward issues of pollution (pesticides, herbicides), the eutrophication of watercourses (overuse of nitrate-based fertilizers), health issues (e.g., antibiotics and hormones in meat; impact of pesticides on human health: Carson 1962), and the reduction in biodiversity (especially in large-scale monocultures) (Wilson 2007). In the twentieth century, this led to a realization that environmental problems were not only an urban issue but that they also severely affected rural areas. Especially during the 1970s and 1980s, critical human geographers began to highlight the major environmental challenges in rural areas caused by what has been termed the “productivist” era of mass food and fiber production based on large multinational agribusinesses that operate in even the remotest corners of the globe (Wilson 2001; 2007). The productivist era has been closely associated with environmentally harmful practices, especially increased soil and water pollution, further pressure to remove “unprofitable” and “unproductive” vegetation remnants (e.g., woodlands, hedges, ponds), and the substitution of farming focused on local and regional markets with globalized agrocommodity chains characterized by complex and multilayered stakeholder networks and capitalist interests (Robinson 2004). A particularly lively debate has emerged around the replacement of traditional crops with high-yielding and genetically modified (GM) varieties in productivist farming.
ENVIRONMENTAL ISSUES IN RURAL AREAS

systems and its environmental repercussions. While some commentators have argued that GM crops have resulted in the reduced need for fertilizer, pesticide, and herbicide applications (as plants can be tailored more specifically to local climatic and edaphic conditions), others have warned about “genetic pollution” with hitherto largely unknown environmental consequences and, in particular, the path dependency induced by farmers adopting GM crops who are increasingly locked into multinational agribusiness and knowledge trajectories over which landholders have less and less direct control (Wilson 2007).

Environmental implications of productivist, nonproductivist, and multifunctional pathways

Since the 1970s there have been substantial shifts in the role of agriculture as an economic sector, with new environmental challenges emerging for rural areas. Most of the developed world has witnessed two distinctive pathways: on the one hand, new technologies and increasing mechanization have led to an intensification of agricultural production in the most productive and globalized agricultural areas (e.g., the American Midwest, the Paris Basin, most of the Netherlands, Emilia-Romagna in Italy, the Australian wheat belt), while, on the other hand, geographically marginal and upland areas (especially in the developed world) have often seen a relative withdrawal of agriculture and extensification of production with associated “deagrarianization” (Robinson 2004). Critical commentators have referred to this process as multifunctional territoriality (Wilson 2001), where some agricultural territories have become more specialized with regard to intensive production (productivist globalized areas), while others have embarked on nonproductivist pathways characterized by environmental conservation, extensification, and production of specialist and (usually) environmentally friendlier high-quality foods (Marsden 2003; Wilson 2007).

However, these processes have not been spatially uniform and human geographers from Australia and New Zealand, in particular, have highlighted that multifunctional agricultural and rural development pathways have taken different form in the Antipodes characterized by neoliberal ideologies and ever more globalized agrocommodity chains (Dibden and Cocklin 2009).

Nonproductivist pathways characterized by the extensification of agriculture have often been the result of external pressures in marginal rural areas rather than endogenous forces. This has been particularly the case in areas where outmigration and a lack of willingness of young people to take over their parents’ farms (e.g., in most of Europe), or where mass rural–urban migration (e.g., China where 300–400 million rural people have moved to urban areas for better job opportunities) have eroded social and economic capital in rural communities, leading to “enforced” nonproductivist pathways based on pathways of deagrarianization (Rigg 2006; Wilson 2012). As a result, in many nonproductivist rural areas the most severe environmental threats no longer emanate from a dwindling agriculture but from other pressures associated with rapidly globalizing societies. Human geographers have, therefore, increasingly focused on processes such as counterurbanization and urban sprawl as new environmental threats in many rural areas, in particular through the increasing loss of fertile agricultural land near rapidly growing megacities (e.g., thousands of square kilometers of fertile agricultural land lost in China every year to rapidly expanding urban conurbations), but also with regard to the loss of productive agricultural land to “counterurbanites” who purchase agricultural land for...
recreational purposes rather than for food production (Robinson 2004). Similarly, increasing attention is paid to the impacts of climate change in rural areas, especially in arid and semiarid rural areas which rely on constant water supplies for the continued production of food and fiber (e.g., Australia, parts of the American West Coast, the intensively farmed areas of the Ukrainian and Russian steppe). Research is increasingly suggesting that climate change, in particular, is often exacerbating existing socioeconomic problems in rural areas (e.g., compounding the loss of land through urbanization/counterurbanization, increased tensions over the demand for water from both agricultural and counterurbanization processes, outmigration of young people), often leading to a loss of resilience in already vulnerable rural communities (Wilson 2012).

In an academic research context, the changing role of agriculture as an increasingly less important component of rural society has led to a change in focus away from “pure” agricultural research that predominated until the 1930s (e.g., the now largely defunct subfield of agricultural geography) to an increasing focus on rural issues (rural geography), where agriculture is conceptualized as only one of many processes influencing rural development and environmental pathways – possibly best illustrated by the emergence of specialist academic journals such as *Rural Sociology* (established 1936), *Sociologia Ruralis* (1960), and the *Journal of Rural Studies* (1984), where issues of environmental threats to rural areas feature more and more prominently (Woods 2005; Cloke, Marsden, and Mooney 2006). Rural geography research is, therefore, also increasingly acknowledging political issues in rural areas linked to tensions between multiple and multilayered stakeholder groups with vested interests in rural areas (e.g., farmers, developers, planners, multinational corporations) and associated environmental repercussions (Winter 2004).

Particular attention has been given to increasingly complex tensions between environmental conservation groups, landholders, and developers in the context of protected areas management (e.g., national parks, biodiversity reserves) and environmental management issues (e.g., ground and surface water protection, soil management, rural ecosystem services).

**The changing rural environmental policy context: internal and external drivers**

These environmental issues in rural areas are influenced by both internal and external processes. Much research has been conducted on internal drivers of change linked to understanding the environmental attitudes and perceptions of landholders. There is general consensus that, in general, landholders are increasingly appreciating the importance of environmental conservation on their farms (Wilson 2007). This is highlighted in the continuing importance of organic farming and what has been termed “alternative agri-food networks.” Although driven partly by market forces (e.g., higher prices for organic products) and a relative leveling off of organically farmed land since 2000 at about 10% of globally farmed land, organic farming and alternative agri-food networks suggest an increasing appreciation by both farmers and consumers of the negative environmental and health-related side effects of modern productivist agriculture (Goodman 2004). Yet, as Burton and Wilson (2006) have highlighted, farmer environmental attitudes remain complex and multilayered and can change rapidly from environmental conservation to capitalist pragmatism based on market conditions and personal circumstances. There is no doubt, however, that the professionalization of farming in the developed world (and increasingly...
in the developing world), associated with better access to environmental education, has led to a recognition by landholders of the threats linked to climate change, productivist agricultural pathways, and resultant land degradation.

*External* processes influencing environmental management in rural areas are closely associated with state policy and planning. To be sure, regulation has been part and parcel of human attempts to regulate human–environment interactions in rural areas since the dawn of agriculture, epitomized by, for example, strict regulation of water use in early “hydraulic” societies to safeguard precious water resources and provide equitable distribution of water to affected stakeholders, or, more recently, the establishment of national parks and protected areas to protect vulnerable fauna and flora threatened by agricultural and urban expansion or the implementation of green belt policies in rural areas near large conurbations to prevent urban sprawl and impacts on remnant biodiversity (Simmons 1996; Wilson 2007).

Possibly the most important suite of external regulations attempting to protect the rural environment has been related to *agri-environmental policies*. Today, such policies are devised nationally by most nation-states, but the most comprehensive agri-environmental policy package comes from the European Union’s CAP (the so-called Pillar Two policies) in the wake of substantial CAP reform since the mid-1980s (Buller, Wilson, and Höll 2000). Agri-environmental schemes (e.g., Environmentally Sensitive Areas Scheme in the United Kingdom, the MEKA Programme in Germany, the ÖPUL Programme in Austria) reward farmers financially for protection of the environment. While they take many different guises based on national environmental priorities, they usually encourage farmers to protect remnant wildlife habitats on farms, to extensify production (often with a payment per hectare to farmers for income foregone), to reduce livestock densities, to plant or maintain private forests, or to reduce or abandon the use of environmentally harmful fertilizers, pesticides, and herbicides. However, academic research (with the involvement of many human geographers) has shown that the success of agri-environmental policy has been questionable in environmental terms, especially as many agri-environmental schemes are rewarding farmers for carrying on with business as usual—in other words, while many studies have shown that agri-environmental schemes have benefited the environment by preventing further productivist intensification and possibly helping change farmers’ attitudes toward conservation, the schemes have rarely led to a substantial improvement of the environmental condition of rural areas (Buller, Wilson, and Höll 2000).

Since the early 1990s, a wide-ranging ideological debate has emerged between different rural environmental policy priorities in Europe and other developed countries. Critical commentators have argued that environmental trajectories in rural areas may be different in Europe compared to New World countries because of the different historical pathways of human landscape evolution, thereby generating different policy needs. In Europe, for example, the focus has been more on the preservation of cultural landscapes with a complex mixture of productivist and nonproductivist (or, often, less productivist) territories through policies emphasizing the multifunctionality of the rural landscape, suggesting that productivist production and environmental preservation are not incompatible (Wilson 2007). In the New World, meanwhile, policy has tended to focus more on the setting aside of areas in which agriculture and human settlement is largely prohibited (e.g., national parks in the United States and Australia), while the environmental regulation of agriculture in nonprotected areas has been
less stringent. Inevitably, these processes closely intertwine with philosophical-political debates related to dominant ideologies, with many arguing that neoliberal agendas in countries with large agricultural export markets such as Australia, New Zealand, and the United States are the key explanation for less stringent rural environmental policies compared with less neoliberalized (and less agricultural export-oriented) European countries (Dibden and Cocklin 2009). These often incompatible policy ideologies have come to a head in attempts to harmonize trade in food and fiber through recent rounds of the World Trade Organization, and increasing demands for developing countries to provide more environmental protection for their rural areas. The outcome has been, for the near future at least, a relative stalemate between advocates of more protectionism (EU countries in particular) and those advocating free-market ideologies (e.g., United States, Australia, New Zealand) (Potter and Tilzey 2005; Rigg 2006).

Future challenges for managing environmental issues in rural areas

The discussion has highlighted the complexity of environmental issues affecting rural areas around the globe. These challenges are only likely to increase in the future because of several interlinked factors. First, global human population growth is forecast to peak at approximately 9.5 billion around 2050, with the addition of over 70 million new mouths to feed per year for the foreseeable future. While Malthusian and neo-Malthusian arguments about maximum global human carrying capacity in relation to food and “people overpopulation” have been largely discredited on the back of continuing rising agricultural productivity linked to technological innovations (Green Revolution, genetically modified crops, high-yielding crops), changes in diet toward increased meat and dairy product consumption in high population countries such as China and India (“consumption overpopulation”) are putting further pressures on global food systems (Wilson 2007). Second, these processes will be exacerbated by further urbanization and increasing urban sprawl, with over 50% of the global population now officially living in urban areas, leading to the further loss of productive land, more pressure for rural–urban migration with associated deagrarianization, and the possible loss of agricultural productivity. Third, and possibly most importantly, IPCC predictions increasingly highlight further severe impacts of climate change on agricultural productivity in most rural areas of the globe (2–4°C temperature rise by 2100 now most likely). Although these impacts will be geographically highly diverse, with northern latitudes likely to benefit from a milder climate, climate change will particularly threaten the livelihoods of people living in arid and semiarid rural areas that are already facing severe water shortages (Mestre-Sanchis and Feijoo-Bello 2009).

These processes combine to put additional pressures on often already strained agricultural systems. Likely scenarios involve pressures to further intensify food production on ever-shrinking agricultural land (squeezed by urban sprawl, climate change, and, in places, irreversible land degradation), with an emphasis on intensifying productivist pathways that will leave less room for environmental conservation. These processes have been termed either “neoproductivist” in relation to rural areas that have recently witnessed extensification and deagrarianization but are being recruited back into the productivist fold, or as “super-productivist” in the case of already highly productivist areas that will be forced to further intensify food and
fiber production to meet rising global demand (Wilson 2007; Wilson and Burton 2015). The key question over the next few decades will therefore be whether this still leaves room for multifunctional or non-productivist pathways, with an emphasis on environmental protection of rural ecosystems, or whether environmentally unsustainable productivist pathways will prevail.

Environmental knowledges and expertise

Carol Morris

University of Nottingham, UK

The production of knowledge about natural environments is one of the major concerns of the discipline of modern geography. This disciplinary focus recognizes that it is necessary to know in order to make assessments about the kinds of environmental problems that confront society and how these might be resolved. However, since the 1990s environmental knowledge has itself become the object of geographical research interest for a range of geographers identifying mostly, but not exclusively, with one or more of the human geographical sub-disciplines. For these geographers, questions of environmental knowledge have come to be seen as central to examining the governance and management of environmental issues. However, the drivers of what can be called this “cognitive turn” in the Global South are distinct from those in the Global North. In the former, the study of environmental knowledge has been stimulated by the emergence of participatory approaches to development in which “indigenous environmental knowledge” is taken more seriously than in traditional, top-down models of development. This way of thinking has also influenced research into environmental knowledge in the Global North which is the focus of this entry. However, more significant in the Global North have been other interrelated societal debates leading to the notions of citizen science and of public involvement in environmental decision-making as characterizing the approach to the study of environmental knowledge.

The first of these debates concerns the relationship between science and society, in which declining public trust in expert institutions and the knowledge they produce about environmental and other issues has prompted interrogation of scientific knowledge claims, how these circulate and are contested by “lay publics” that claim to know environments differently. A widely cited example of this is the clash between sheep farmers and scientists working for the United Kingdom’s Ministry of Agriculture, Fisheries and Food in the management of the Cumbrian hills following the radioactive fallout from the Chernobyl nuclear plant accident (Wynne 1996). The farmers drew on their unaccredited, experience-based expertise in mountain ecology and sheep behavior to challenge the inappropriateness of the management prescriptions developed by the scientists. A second debate is about broader shifts in the political landscape toward more participatory forms of democracy which have opened up opportunities for a range of noncertified knowledges in environmental decision-making. For example, the knowledge about fish stocks that anglers develop through their fishing practices on particular rivers is utilized by the public organizations that are responsible for managing rivers in the United Kingdom. Third, and increasingly pronounced since the financial crisis of 2008, is the reduction in public sector funding for science which has undermined the institutional capacity of professional environmental knowledge production. In these conditions scientists have begun to recognize the potential of volunteers and
amateurs/enthusiasts as legitimate providers of environmental knowledge within both the context of crowdsourcing initiatives and more formalized participatory monitoring networks. Geographical exploration of these developments has been conducted alongside and in dialogue with a range of cognate social sciences, among which science and technology studies (STS) have been particularly influential.

Defining, conceptualizing, and categorizing environmental knowledges

Knowledge is a spatially and temporally dynamic means of representing the world that is developed through observing and interacting with people and the nonhuman world (Castree 2005). Important within recent conceptualizations of knowledge is the idea that knowledge is a relational phenomenon, produced in association with others, both human and nonhuman. It is also suggested that knowledge exists as more or less established bodies of knowledge that are shared by distinct groups of people, leading to the use of the term “knowledges” to capture the notion that there are multiple forms of knowledge. Beyond this broad definition, three distinctions are often made in debates about environmental knowledge that are used to help understand the character of that knowledge.

The first distinction is that all knowledge has a point or points of origin (i.e., institutions, groups, or individuals who promulgate a particular body of knowledge or specific knowledge claims); a referent or referents (i.e., those particular things referred to in any knowledge claim or body of knowledge and can either be material things or other bodies of knowledge); an addressee or addressees (i.e., the intended audiences of a body of knowledge or the consumers of knowledge). This trio of origin(s), referent(s), and addressee(s) enables one body of knowledge to be distinguished from another (Castree 2005). For example, a university-based marine biologist who undertakes research into the management of fish populations will know about fish in ways that are likely to be distinct from individuals and communities who rely on fishing for their livelihoods but who may not have received any formal training or education.

The notions of tacit and codified knowledge bring us to a second distinction that is often drawn in debates around environmental knowledge. Tacit knowledge is informal and “ordinary” knowledge that is made use of in everyday life and so deeply internalized that it is taken for granted or regarded as common sense. It is a form of knowledge that emphasizes knowledge as practice as well as cognition, and explains the use of the term “knowledge practice” and an emphasis on knowing rather than knowledge. This concept has similarities with Ingold’s (2000) notion of “environmental perception” in which the environment becomes meaningful only within the context of everyday acts and direct experience of other people and the nonhuman world. Understanding knowledge in this way suggests that knowledge of the environment is in large part likely to be situated and context-specific – hence “local” and “indigenous” knowledge – emerging through routinized, site-specific practices and produced in close association with the wider objectives and identity of a particular social group. Meanwhile, codified knowledge is formal, explicitly articulated knowledge which can be standardized and systematized, written, stored, and easily transferred from one location to another. Codified knowledge is typically technical and specialized in nature such as the environmental knowledge
produced and promulgated by science and formal systems of education. It is recognized that all forms of knowledge can have a tacit dimension, including those that are codified.

The third distinction recognizes that a body of environmental knowledge comprises four different elements. First, know what refers to knowledge about facts and is an element of knowledge that is largely codified, involving the systematic and formalized collection of information. Second, know why is the knowledge of principles and rules, and is a significant feature of science and technology. Third, know how refers to the practical ability to enact something and implies a set of skills, while, fourth, know who is the knowledge of people who can provide assistance in undertaking tasks. There is some debate around whether there are distinct differences between these components of knowledge or whether they are complementary and relational (Ingram 2008). For example, know what may provide the basis for know why, and know why, although mostly codified, can be seen to rely considerably on tacit knowledge for interpretation particularly at the level of individual understanding. It has been suggested that know how is particularly significant within tacit knowledge, while know what and know why are key elements of codified knowledge (Ingram 2008).

Research on forms of knowledge continues to be important because of the ongoing problem of nonexpert knowledge being ignored and devalued in processes of development. However, some geographers have questioned the essentialism (i.e., fixed or given) that is implied in the prefixes “expert,” “lay,” and “local.” This has been prompted in part by the efforts of scholars whose geographical focus of interest is outside the Global North and who have undertaken considerable conceptual work in problematizing the divide between “scientific” and “indigenous” knowledges in natural resource management (e.g., Agrawal 2002). Focusing on types or forms of knowledge runs the risk of reifying and fixing that knowledge. Instead, there is a need to conceptualize knowledge as dynamic and fluid, being continuously reproduced through ongoing social interactions. Moreover, the content and epistemology of knowledge is believed to be less significant than the links between power and knowledge, or the politics of knowledge. As such, what is required is examination of the social, historical, and institutional relations in which knowledge develops and is recognized as valid or legitimate (e.g., the knowledge of government scientists) while other claims to knowledge (e.g., those made by sheep farmers) are delegitimized.

The concept of a knowledge culture has been developed as one response to these concerns and applied in the context of the environmental management of agriculture in the United Kingdom. Central to the notion of knowledge culture is that an understanding of an environment or environmental process is collectively achieved or produced through routinely executed knowledge practices and discourse, for example within the context of farming, veterinary science, or policymaking. This shared understanding – a knowing from within as it is characterized by Tsouvalis, Seymour, and Watkins (2000) – enables people within that knowledge culture to relate and respond to one another. In order for knowledge cultures to become established and be sustained, they develop sets of rules about what counts as legitimate knowledge practices, for example, within policymaking this is likely to be scientific knowledge of one form or another, while within farming experiential and practical knowledge are likely to be emphasized. These rules can be challenged both from within and without the knowledge culture (e.g., through contact with other knowledge cultures associated with
new technologies or policies, or through wider societal demands), and the ensuing knowledge struggle can lead to the evolution or dissolution of a knowledge culture. The concept of a knowledge culture does not mean that it is no longer possible to talk about different knowledges; rather, the emphasis is on exploring how these knowledges come into being, come to be recognized as particular forms of knowledge, and how they are reproduced through complex social processes and power relations within the context of knowledge cultures.

Although knowledge cultures are understood as dynamic, based on ongoing social interaction and exchange and, as already implied, subject to contestation, they can become very durable, with their boundaries becoming relatively fixed. This stabilization takes place either through a process of institutionalization, that is, where the “rules” of knowing become formalized and codified and/or when a knowledge culture starts to constitute individual or group identity, that is, I/we know – in particular ways – therefore I am/we are. The identity of a particular community, and the individuals that make up this community, are part and parcel of its knowledge culture. For example, within the context of a farming community what it means to be a “good” farmer has come to be associated with knowledge of intensive agricultural techniques and being seen to farm in a “tidy” fashion. This identity can be brought into relief at times when a knowledge culture is challenged. For example, EU policies since the mid-1980s have incentivized farmers to use more environmentally friendly farming practices but these can challenge the pre-existing “agrarian” knowledge culture because they demand engagement with new knowledge practices that appear antithetical including encouraging farmers to manage their land in ways that may appear to be “untidy” but are beneficial for biodiversity. One advantage of a knowledge culture approach is that it does not assume at the outset the particular character of knowledge(s) that distinguish the knowledge culture. However, this perspective has been less sensitive than some others to the role of nonhumans, both living and artificial, in the relational production of environmental knowledge.

Noncertified environmental knowledges

In spite of some of these concerns, the most prominent theme within geographical research on environmental knowledges has been noncertified knowledges, that is, those produced outside formal, official, or professional processes and institutions of knowledge production. These are variously labeled lay ecologies, local, indigenous, traditional, practical, and experiential environmental knowledges. As some of these monikers suggest, research has examined the environmental knowledges produced by indigenous communities, for example First Nations peoples in Canada or Aboriginal groups in Australia, as well as those produced by the other residents of particular places and by specific occupational and recreational communities such as farmers, anglers, and amateur naturalists and meteorologists (e.g., Endfield and Morris 2012). It is typically assumed that livelihood dependencies, recreational activities embedded in specific localities, or long-term residence result in a very intimate relation between humans and (aspects of) the nonhuman world. Such is the closeness and sustained nature of this relationship that people develop a very detailed knowledge of local environmental conditions. Such knowledge accumulates and can be handed down through generations by cultural transmission but is also understood to be dynamic, as evolving over time through adaptive processes. Understanding how local and indigenous environmental knowledges
are produced and evolve has been one concern of this research.

A number of other key features of this scholarship can be identified. First, researchers have been at pains to draw attention to the ways in which local environmental knowledges are often ignored or marginalized in modernization and development processes, both in the Global North and Global South, but also within the development and implementation of environmental policy. Second, the differences between noncertified and expert knowledges have been explored, and how these can lead to tension and struggles over both the identification and definition of environmental problems and, by extension, the formulation of solutions to those problems. This concern for the politics of environmental knowledge takes a slightly different form in work that examines the treatment by professionals of amateur knowledge producers whose environmental data collection has become even more vital in an era of significant constraints on public finances (Lawrence and Turnhout 2010). Here, exploiting volunteered environmental data and the volunteers who provide them risks discouraging these actors from continuing to contribute to environmental knowledge production. Third, in spite of an identified “epistemological anxiety” concerning noncertified environmental knowledge among both experts and nonexperts, and the persistence of an expert deficit model of lay knowledge that is based on the idea that the public misunderstand environmental issues, research continues to assert that this way of knowing can and should make a valuable contribution to the governance and management of natural environments, including the resolving of specific environmental problems. Noncertified environmental knowledge, it is argued, needs to be taken more seriously by environmental “professionals” including policymakers and scientists.

Another theme within environmental knowledges research pertains to the mechanisms by which the integration of noncertified and expert environmental knowledges could take place, or, in the language of recent studies, the means of their “coproduction.” Specifically, attention has begun to be given to a range of participatory or collaborative approaches to environmental governance, research, and management which, in theory, provide more of an opportunity for local/noncertified environmental knowledges to be integrated into decision-making. For example, Landstrom et al. (2011) explore the potential of “competency groups” in which members of the public worked with scientists to coproduce new environmental knowledge about flood risk and its management. Competency groups are distinguished from some other models of participation in environmental decision-making as they are not constituted by representatives of institutional stakeholders or groups of local residents who may have particular, established agendas or political aims. Instead, competency groups require “participants to be willing to engage as individuals, with their own particular knowledge, skills and expertise” (Landstrom et al. 2011, 1619). As a result, this approach diversifies the range of publics with whom scientists have previously been prepared to collaborate. Expertise, so this study argues, can be effectively redistributed between science and affected publics through this new form of “research collective.” However, it involves a repositioning of scientists with respect to their flood modeling practices which may be threatening to their professional identities.

One of the challenges identified in the coproduction of environmental knowledge is the importance of an ongoing relationship between lay publics and experts to ensure that the tacit knowledges of the former are given the attention they deserve. It also concurs with research that
calls for a focus on “learning” among environmental actors as a means of addressing the challenges of integrating local environmental knowledge into environmental governance. Framing the task in this way aims to avoid the problem of differentiating between forms of knowledge and demarcating which forms are perceived as valid and which are not in environmental decision-making.

**Expert environmental knowledges**

A distinct form of research on environmental knowledge to that discussed in the previous section focuses on formally accredited environmental expertise and the activities of associated experts, such as environmental advisers, identified as expert through their scientific training and/or occupation. Some of this work involves geographical historiographies of certified expert environmental knowledge domains such as global environmental change (e.g., Hulme 2010). Other research relates to that discussed in the previous section when it examines how, where, and why certified expert knowledge wins out over noncertified environmental knowledges in the context of resource management disputes. One specific process of interest here is “boundary work,” a concept coined by Thomas Gieryn (1983) to make sense of the efforts to distinguish one domain of knowledge or expertise from another, notably scientific knowledge from non-science. For Gieryn, rather than trying to understand the characteristics of science that demarcate it from other intellectual activities, the focus should instead be on the ideological efforts by scientists to distinguish their work from non-scientific intellectual activities, that is, how scientists attribute selected characteristics to science that enable them to draw a social boundary around their work that sets it apart from non-science to make it legitimate and authoritative, particularly in the public domain. Gieryn suggests that it is helpful to explore and conceptualize boundary work through a focus on the rhetorical style of scientists’ ideological statements. Gieryn argues that boundary work is seen as a particularly useful stylistic resource for any profession or occupation when the aim is expansion of authority/expertise into domains claimed by other professions or occupations; monopolization of professional resources and authority; and/or protection of autonomy over professional activities.

While Gieryn’s concept was developed within the sociology of scientific knowledge, it has been deployed by geographers interested in environmental knowledge. For example, Eden, Donaldson, and Walker (2006) explore processes of boundary-making by environmental nongovernmental organizations (NGOs), conceptualized as both scientific and political actors and involved, therefore, in both the consumption and the production of scientific knowledge within the context of wider processes of democratizing expertise. The winning of boundary disputes by NGOs enables them to gain influence and access to resources. However, sometimes the boundaries around scientific environmental expertise are drawn very tightly and at other times much more loosely, depending on the particular agenda that is being pursued by an NGO. This leads Eden, Donaldson, and Walker (2006) to conclude that boundary work is highly contextual, tactical, and adaptable.

A further dimension of the utility of boundary work is the demarcation of disciplines or theoretical orientations within science. This is illustrated in Bell and Sheail’s (2005) historical geographical study of ecology as a discipline which explores when, where, and how an ecological expertise came to be defined in the early twentieth century. They identify that it was both accredited and nonaccredited groups, in specific geographical locations, that were important in
this process. The study reveals the fluidity and imprecision of the boundary between specialist and lay knowledge of ecology and in so doing reinforces the conclusions of Eden, Donaldson, and Walker (2006).

Another theme is the doing or practicing of formal environmental expertise in the field (as opposed to other spaces associated with this expertise such as the laboratory, zoological/botanical collections, or scientific societies) by particular types of knowledge worker. Here, the focus of concern shifts away from controversy and dispute in environmental governance and management to examine the “how” of environmental knowledge coproduction. The particular fields of interest have included forests being managed under certification schemes that promote sustainability (e.g., Eden 2008) and farms participating in agri-environmental schemes (e.g., Proctor et al. 2012). The knowledge actors investigated are field-level advisers who mediate between scientists and actors such as farmers and foresters, and who work with specialized environmental knowledge to facilitate the implementation of certification standards and policy prescriptions. Concepts from STS are here mobilized to reveal the heterogeneity of field-based environmental expertise, that is, its production in association with many other human actors, including, in particular, other environmental experts but also the diversity of plants and animals comprising farms. Also revealed are the uncertainties of environmental science but these are rendered beneficial within the field context because they provide knowledge workers with an important degree of flexibility as they negotiate and enable environmental management tasks to be realized in practice. Another important finding of this work, and one which deserves further investigation, is that intermediary knowledge workers are vital actors in environmental governance and management, and yet their role can be significantly constrained. For example, in the public policy context of agri-environmental schemes it has been shown that field advisers are limited in the extent to which they can encourage a wider environmental learning among farmers as opposed to simply ensuring that scheme objectives are met.

The ongoing commitment to participatory forms of decision-making among policymakers suggests that the challenges involved in coproducing environmental knowledge will continue to exercise geographers. Future debates about environmental knowledge will also need to be extended to provide greater understanding of particular categories of environmental knowers who have been relatively neglected in research to date including, for example, children, young people, and women; and of the politics of environmental knowledges associated with institutional contexts beyond farming and forestry that constitute major uses of land and present significant environmental challenges, for example resource extraction industries and sport.

Environmental management

Robert A. Francis
King’s College London, UK

Definition and overview

Environmental management essentially encompasses the different types of human intervention put in place to ensure that environmental forms, processes and functions (i) are not degraded to an unacceptable level by human action and/or (ii) do not pose an unacceptable hazard or risk to human societies. It is therefore the management of our impact on the environment, and the environment’s impact on us, rather than direct management of the environment itself. Most specifically, management refers to the methods and processes used to predict, measure, and mitigate environmental impacts. Management is usually performed to address environmental legislation or policies, which are laws, regulations, or guidelines put in place to ensure that impacts are limited to an acceptable level. Improvement of degraded conditions may also be considered a form of management, though usually the terms restoration, rehabilitation, or improvement are used in this context.

The concept and practice of “management” not only implies but necessitates control of something; in this case, the environmental system, subsystem, component, or process under consideration. Management of the environment therefore presents a major challenge, particularly given the complexity of environmental systems, our limited understanding of both the systems themselves and the impacts we may cause, the many different demands that we require the environment to meet, and our limited ability to guide environmental processes in the ways we desire. It includes the application of a wide body of knowledge housed within a range of disciplines, including environmental science but also political ecology, environmental law, information theory, environmental engineering, and environmental economics.

Many activities could be considered environmental management at some level and the principles, methods, and processes of management are therefore broad. For example, the term may be used to refer to “sustainable” or environmentally conscious business practices such as low-impact resource utilization and production (reducing water use or carbon emissions in production of industrial materials) as well as to attempts to maximize environmental resource production (such as the use of pest control techniques to improve crop yields). Over recent decades, environmental management has moved from a focus on individual environmental components or processes to broader environmental systems.

A brief history of environmental management

Although some management of environmental impacts (both to and from humans) has been performed for millennia, much of our understanding and application of management techniques has emerged relatively recently. This
has followed increased environmental awareness, originating in the nineteenth century in response to increasing industrialization and the impacts it generated, particularly in terms of air and water pollution and the degradation of traditional landscape aesthetics. General public health and aesthetic concerns led to early forms of environmental regulation and legislation, such as the various clean air and water acts passed in the nineteenth and twentieth centuries (e.g., the Public Health Act 1875, River Pollution Control Act 1876, and Clean Air Act 1956 in the UK).

A shift in focus from human impacts resulting from environmental degradation to the environment itself as an entity deserving of protection came about following recognition of extensive land-use change and declines in wildlife populations in the late nineteenth and early twentieth centuries, and is closely linked to the development of the conservation movement (Adams 2003). The rapid increase in land-use change and the development and use of chemical fertilizers, pesticides, and herbicides in the mid-twentieth century, highlighted by landmark publications such as Rachel Carson’s *Silent Spring* (Carson 1962) led to an increase in environmental concerns and the widespread development and formalization of “environmentalism” as a social movement. These concerns led to the development of key regulating agencies, organizations, or branches of government, such as the US Environmental Protection Agency (1970), or the UK Department for the Environment (1970). Over the last five decades, the number and extent of environmental organizations and agencies set up to help determine policy and guide environmental management efforts has increased dramatically, to the extent that the vast majority of countries now have environmental organizations that guide management practices and enforce regulations, though the authority and efficacy of such organizations naturally varies.

In recent decades, further changes have increased the need for effective environmental management. The overall quality of the global environment has continued to decline despite some local improvements, while at the same time both human populations and our reliance on environmental resources and ecosystem services have increased and will likely continue to do so (Wackernagel et al. 1999). As a result both the potential for and consequences of environmental mismanagement have been amplified. This may be seen in global increases in both frequency and impacts of natural disasters such as flooding and ongoing failures to curb global biodiversity loss (Butchart et al. 2010; Jongman, Ward, and Aerts 2012).

Alongside this, novel forms of environmental hazard have emerged that have required new approaches to management. Increasingly complex or unknown forms of pollution, such as (to draw on two simple water-based examples) endocrine-disrupting hormones or plastic debris in aquatic ecosystems as well as further environmental changes (for example, anthropogenic climate change, greater socioeconomic disparities between the poor and wealthy), have magnified the risks of both environmental degradation and human impacts.

This increasing need for management has led to the further development of national and international environmental legislation and policy to set targets and guide management efforts. Globally relevant examples of such instruments include the Convention on Biological Diversity (CBD), which requires all member states to sustainably manage their biological resources; the UN Framework Convention on Climate Change, which requires member states to limit atmospheric greenhouse gas concentrations and therefore prevent anthropogenic climate change; and the Convention on Long-Range
Environmental management is based around the principle that while some environmental impacts are inevitable as we use environmental resources, these should be limited as far as possible so as to ensure that such resources are not permanently depleted and so that wider effects that may be detrimental to both the environment and people do not occur. It is therefore a weak form of the precautionary principle, which holds that as impacts are so complex and potentially irreversible the safest thing is to prevent impacts at all. In reality, complete prevention of impacts is not possible and so the aims of management efforts must be practical and achievable. Where management is performed to minimize risk to humans from environmental hazards, again there is recognition that some form of exposure to risk is unavoidable, but that the environmental processes can be managed to keep these at an acceptable level.

All forms of environmental management essentially proceed through potentially cyclical stages of assessment, planning, action and monitoring, though the emphasis will vary from case to case (Figure 1). The broad stages are as follows.

1. **Assessment of current environmental condition and potential impacts.** Any attempt at management must be based on an understanding of the environmental system and impact(s) that is to be managed. This is a fundamental aspect of management planning. Where impacts are yet to occur (for example, when building development is being planned), pre-impact assessments are used to determine the value of the environment and the potential risks from the development. These are usually termed environmental impact assessments (EIA). These have emerged in many countries in the past 40 years, and are essentially procedures wherein proposed actions (e.g., building construction) are assessed for their environmental impacts in order to inform decisions prior to commitments being made, and to ensure potential impacts are addressed either pre- or postaction, where possible (Morgan 2012).

EIA utilize a substantial skills base and require those involved to be well trained in the environmental sciences, including experts in ecological and environmental surveying, monitoring, data analysis, and sometimes environmental modeling. Knowledge of national legislation and policy is also important to ensure that regulations are followed. Individual countries have their own specific operational processes and legislation.
related to EIA, but the broad principles of EIA are relatively universal. Nearly all of the 193 member nations of the United Nations have either domestic EIA legislation or have signed international agreements that incorporate EIA in some form (Morgan 2012). Many international funding bodies, such as the World Bank, require EIA to be implemented for major projects that they support financially, regardless of location.

But EIA can have limited efficacy, usually stemming from limited practitioner availability and training or a lack of resources required to fully establish the potential extent of impacts; but also sometimes because of a lack of a wider understanding of environmental systems and an inability to accurately quantify indirect, cumulative, and multiscale impacts. There can also be significant pressure for regulators to prioritize development before environment and make EIA cursory rather than comprehensive, further undermining the process. In situations where impacts have already occurred, the assessment process may determine the extent and severity of these as well as current environmental conditions to inform subsequent management activities. Where the assessment stage involves planning for prevention or mitigation of environmental hazards (e.g., flooding), the assessment may involve the prediction of probability of an event of a given size happening over a given time frame (e.g., a one-in-hundred flood event, which has a 1% probability of occurring in any given year) as well as potential environmental and societal damage. In such cases, expertise in, for example, economics, engineering, and disaster planning can become particularly important to the assessment process.

Overall, the assessment stage requires a substantial skills base and utilization of resources to determine potential impact, along with clear guidance relevant to the particular type of assessment being conducted (e.g., construction planning, limiting flood risk) and national or regional legal requirements. It is the foundation upon which all further efforts are built.

2 Planning of management activities. Based on the findings of the assessment stage, a plan is formulated to limit impacts. The plan will be guided by relevant legislation and policy and should have achievable and quantifiable objectives. A relatively universal example is biodiversity action plans (BAPs). The Convention on Biological Diversity (1993), which 191 nations have ratified, requires member nations to sustainably manage their biological and ecological resources at a range of scales, from genetic variability within species up to entire ecosystems. Biodiversity action plans, or their equivalents, are the primary mechanism that some (though by no means all) countries have chosen to achieve this. The plans are informed by an assessment stage that involves species inventories and measures of geographical distribution and abundance, and review of the conservation status of species. They are essentially plans for sustainable management of species (including conservation and restoration). These are then used to highlight potential impacts as well as to guide management activities that are intended to benefit species considered to be of conservation concern.

As with the assessment stage, the planning stage also involves a range of expertise, often involving modeling and prediction of the likely impacts of different management actions, again supported by knowledge of relevant legislation. Crucially, the planning
stage is where aims, objectives, and relevant timelines for project completion are set; these are the criteria through which the success (or otherwise) of management activities will subsequently be measured.

3 Management actions. The plan is put into action in the next stage. This may be construction of flood defenses, changes to the organization or behaviors of a company with regards to waste disposal, construction of buildings with mitigation strategies such as biodiversity offsetting, and so on. This may occur over several years and involve distinct phases of activity, including some ad hoc revision of the management plans if it rapidly becomes apparent that they are not achievable. As an example, management efforts to achieve “good ecological status” or “good ecological potential” in rivers throughout Europe in response to the Water Framework Directive (2000/60/EC) have often been revised or adjusted due to complications in identifying appropriate reference systems, improvement in methods and techniques, quantifying uncertainty and appropriate environmental indicators, and overly ambitious timescales (Hering et al. 2010). Usually specialists are responsible for enacting the management activities, guided by the prepared plans and other relevant experts.

4 Monitoring the effects of management actions. It is important that the management actions that have occurred are in some way monitored to ensure that their success (or lack of it) is based on evidence. Monitoring essentially involves reassessment of the environment and impact to determine if the outcomes are what was expected. If outcomes are not as expected, the cycle continues through further planning and intervention if resources permit. Monitoring requires expertise on the environmental system being evaluated as well as the indictors used (for example, changes in biodiversity of a river if water quality is improved or the ability for a flood defense wall to remain functional over time following flood events). The expertise and long timescales involved mean that this is the stage of management most often under-resourced and therefore compromised. Ideally, monitoring efforts should be supported by publication of findings so that they may inform the planning stage of other management efforts.

These four stages are demonstrated in environmental management systems (EMS), which are most specifically aimed at ensuring that (usually manufacturing or servicing) organizations are compliant with regulations that seek to limit environmental impact, and that both resource use and production of waste are minimized. With environmental management systems, the organization’s systems of operation are usually assessed to determine where production processes can be made less environmentally harmful (e.g., by using chemicals that are less likely to impact the environment, use of biodegradable materials, reducing resource use, or recycling materials). Plans are made based on this initial assessment, taking into account cost–benefit analyses and environmental regulations. Actions are usually linked to changing the behavior of the organization and may range from relatively simple changes, such as where manufacturing materials are sourced from, to large-scale changes that radically alter, for example, a manufacturing process or the way a service is delivered. Finally, monitoring of the changes against set objectives determines the effectiveness of the actions to inform decisions on whether further changes should be made – for example,
whether changes in manufacturing materials resulted in a reduction in carbon emissions during the manufacturing process, and whether this was at the level expected.

Environmental management systems are often informed by the International Organization for Standardization (ISO) 41000 standards. These are a group of voluntary standards that are aimed at helping organizations to set up effective environmental management systems, and (because they are universal) allow comparisons of best practice between organizations. The standards also include a commitment to continual improvement, so that the processes of environmental management are revisited to allow further progress as new challenges and opportunities (e.g., technological developments) arise. Conformity to ISO 41000 standards is usually validated by appropriate external parties (not the ISO), and helps to show environmental awareness and responsibility on the part of the organization implementing the environmental management system. The ISO 41000 standards have been an important part of European Union’s Eco-Management and Audit Scheme (EMAS), the latest version of which (EMAS III, which again is universal and not limited to the EU) was initiated in 2010. This represents the most recent phase in the developments of universal environmental standards for organizations.

All of these management activities, while guided by appropriate legislation and policies, can sometimes have limited effectiveness and may face many challenges in achieving their objectives. In many cases this is simply because limited knowledge exists on the environmental systems and processes that we are attempting to manage, and they are more dynamic and complex than is often assumed.

Environmental management has been limited by a perception of the environment being formed of relatively simple and predictable systems composed of components that may interact, but can be understood in relative isolation. This has stemmed from a reductionist approach to understanding natural systems, which proceeds from the view that the behavior of a system can be understood by investigating individual components or subsystems in isolation and then fitting them together, like a machine. Some scientific disciplines (e.g., biology, chemistry) have historically been firmly grounded in reductionist approaches and have restricted fields of acceptable enquiry that limit more holistic understandings of systems at higher levels of organization. Though ecology and environmental science have never had fiercely reductionist approaches to scientific investigation, early studies did emphasize particular ecosystem components or processes and their capacity for prediction. An example can be found in early ecosystem concepts such as succession, which originally emphasized predictability of ecological community composition and dynamics, with a climax state that would remain stable unless disturbed. Presently, the many subdisciplines of ecology that focus on specific ecosystem components (mammal ecology, landscape ecology), biogeographical contexts (tropical ecology, desert ecology) or applications (restoration ecology, ecological engineering), and the many branches and scales of investigation found within environmental science, to some extent reflect this tendency for reduction.

This influenced many early forms of environmental management, which tended to focus on only a limited number of system components or processes as with the following two examples.
1 Management of a species population that is harvested on a regular basis, such as marine fisheries (Gaichas 2008). A reductionist approach using relatively simple single-species population models would often be employed, sometimes supported by population monitoring, to provide a measure of the maximum sustainable yield (MSY) that could be removed from an area within a given timeframe (a year, for example) without causing decline or collapse of the target population. However, such approaches failed to account for variability in population dynamics and wider (nonharvest) impacts on fish populations, with the result that target populations in some fisheries have crashed (Gaichas 2008).

2 The setting of critical loads for contamination by environmental pollutants. Critical loads for pollutants are those below which there is considered to be no significantly harmful environmental effect (Payne et al. 2013). Determining the critical load of a pollutant within a given environmental system, and then setting industry standards for pollution emissions, is difficult. Critical loads that were set based on a limited set of indicators and scales of investigation (such as individual species or environmental systems) have repeatedly been shown to miss chronic impacts that may result from accumulation over time (e.g., lead accumulation and adverse health effects in humans due to environmental exposure) and the breaching of thresholds for significant change (e.g., eutrophication in lakes due to nitrogen and phosphorus inputs). This approach also failed to recognize the differential sensitivity of ecosystems to pollutants, such as the varied responses of particular ecosystems or plant communities to nitrogen deposition (Payne et al. 2013). Consequently, critical loads are frequently shown to be limited in their capacity to prevent or mitigate environmental impacts from pollutants.

The “traditional” forms of management exemplified above generally assumed that (i) the component, process or subsystem under consideration was understandable and manageable in isolation from the wider system, and (ii) that an environmental system that was disturbed in some way would return to an equilibrium state and therefore ecological components and processes (which we now recognize as forming the basis for ecosystem services) were infinitely recoverable or replaceable when impacts ceased. But initial faith in these approaches was lost partly because they relied on modeling and all models are simplifications of complex systems with limitations that, when not fully appreciated, may create false confidence in predictive ability. This is true at a range of spatial and temporal scales; for example, early attempts to model ecosystems more holistically and enhance predictability met with limited success due to over-simplification, though of course wider understanding of ecosystem process and function was gained. As an example, management of biological resources often requires an understanding of food webs and the interdependencies of species. Despite ongoing research spanning the best part of a century and the establishment of general laws relating to food web structure, processes, and characteristics, food web models still retain substantial uncertainty and limited predictive capacity in relation to environmental change, somewhat restricting their potential as a management tool (Chiu 2013).

The reductionist approach to environmental phenomena gradually began to be replaced by systems thinking, which emphasizes patterns, relationships, and interactions between components, rather than the isolated study of particular
components or processes. With the advent of complexity theory, chaos theory, nonequilibrium thermodynamics, and self-organization from the 1970s, environmental systems increasingly began to be seen as complex adaptive systems, wherein the broader system emerges from multiple and complex interactions between components and subsystems occurring at more local scales, and is therefore dependent on the outcomes of those interactions (see Levin 1998).

Environmental management consequently became much more complex because a narrow focus left substantial uncertainty that can limit effectiveness. It is increasingly recognized that systems thinking that considers complexity and dynamics is important for guiding management efforts and this has been something of a shift in management principles.

Adaptive cycles and resilience in environmental systems

It is now well established that environmental systems demonstrate notable dynamism and nonlinearity in their functioning. For example, woody species exhibit increased growth as atmospheric CO$_2$ levels increase, but at some point a threshold is reached whereupon further additions have no effect. Likewise, a temperature threshold exists at which permafrost in the soil thaws, releasing stored carbon and leading to a positive feedback in atmospheric warming. Increasingly, coupled human–environmental systems across a range of scales have been found to display nonlinear processes and threshold effects. All of the major global environmental issues that humanity is faced with in the Anthropocene (including climate change, biodiversity loss, freshwater use and land-use change, as examples), display such characteristics, which creates substantial uncertainty in their understanding and management.

These characteristics are also illustrated in the concept of the *adaptive cycle* that environmental systems experience (in particular socioecological systems, which are composed of the biophysical environment and the human activities and societies that are linked to, rely upon, and fundamentally influence, that environment) (Holling 2001; Figure 2). The adaptive cycle represents several phases through which a system progresses. Some phases exhibit the relatively steady accumulation of “resources” (e.g., biophysical aspects such as species, nutrients, soil quality alongside social aspects such as knowledge, productivity, quality of life), while others display a rapid release of resources and system reorganization. The four phases are the following.

1. Exploitation ($r$), wherein a system is in an emergent state and available resources (e.g., nutrients, seed banks, financial capital, labor) are rapidly being utilized.
Conservation ($K$), wherein the system experiences some dynamic stability, and resources that have been utilized in the exploitation phase are again accumulated (nutrients are returned to the soil, crops are produced, money is made, quality of life increases).

Collapse or release ($\Omega$), wherein the system experiences some form of disturbance (whether externally or internally induced) and is pushed over a threshold into a new phase or “state” (see below), and accumulated resources are released.

Reorganization ($\alpha$), wherein a new system or state begins to form and potentially new components, processes and configurations may emerge, prior to the beginning of the exploitation phase.

The adaptive cycle recognizes that environmental systems can go through significant changes over time and may therefore exist for long periods of time in relatively stable “states” that differ substantially from each other. As environmental stresses or disturbances occur, the current system configuration is pushed toward a threshold and the system becomes less stable and more “precarious,” until finally the threshold is exceeded and the system changes state into a configuration no longer representative of the key characteristics, functions, or processes that originally defined the system. It is important to recognize, however, that the adaptive cycle is not “fixed” so that the same states will cycle indefinitely, but rather that random or unpredictable processes operating throughout the cycle will influence the states that may emerge. As a result, there are multiple possible trajectories of change within the cycle and there is a dependency of a given state on what has happened in the past (sometimes considered a form of “path dependency”). Consequently, two conservation ($K$) phases may be quite different, representing different stable states based on, for example, past changes to the components present within the system.

The capacity of a system to remain within a given phase or state despite disturbance is termed “resilience” and this has recently become an important concept in environmental management (Groffman et al. 2006). Human impacts on the environment tend to reduce resilience and accelerate change, pushing the system toward thresholds where it may move to another phase and/or another stable state. So much environmental management is fundamentally aimed at ensuring that a particular environment or socioecological system remains within the phase/state that is most appropriate for human use. This is usually the conservation phase ($K$) wherein resources are accumulated. Though management is rarely expressed using resilience terminology, recognition of this is useful for forming more comprehensive approaches to management. Historically, the focus of management has been on maintaining environmental stability and preventing impact where possible, but there is now greater emphasis on allowing flexibility in management approaches, recognizing that systems are complex and that responses may not be as anticipated. There is increasing focus on not just avoiding “critical loads” but also improving adaptive capacity, or flexibility of response, within environmental systems as a form of management. An example is response to the potential impacts of climate change in cities, which has moved beyond simple local or regional mitigation of greenhouse gas emissions to urban planning efforts that incorporate green building design and use of green space with an anticipated level of climate change to ensure that cities are “future-proofed” against, for example, increasing temperatures and reduced water availability (e.g., Hamin and Gurran 2009). Ultimately, systems theory has led to a paradigm...
shift in environmental management principles, though it is taking some time to work through to practice.

New approaches to environmental management

Environmental management is increasingly moving away from simple regulatory exercises and the imperfect practice of the precautionary principle. New ways of approaching and understanding environmental management from a systems perspective have emerged, such as incorporation of a wider range of interdisciplinary expertise in the management process through the application of postnormal scientific approaches, the practice of adaptive management, and incorporation of a sustainable development framework.

Postnormal science is a modern approach to addressing environmental issues that require action, but which involve significant complexity and uncertainty so that management outcomes are not always obvious or easy to predict. It encourages the contributions of a wide range of stakeholders who may hold forms of knowledge that are relevant to the environment system to be managed (e.g., local environmental knowledge or the desirability of management outcomes for the local community), and therefore adds to any scientific expertise that is brought to bear on the issue. This wider group of stakeholders is termed the “extended peer community.” These different levels of expertise fit into the management stages described above and may help to ensure success by utilizing local knowledge, harnessing societal resources (such as the use of citizen science for assessment or monitoring), and ensuring that management aims and objectives are realistic and appropriate.

Postnormal thinking has been applied to environmental management issues such as biological conservation, climate change, agroecosystem health, and sustainable development (e.g., Turnpenny, Jones, and Lorenzoni 2011). Importantly, it involves an acknowledgment that the complexity of many environmental issues means that multiple management responses and outcomes are possible, and that these may not remain static over time. As a variety of management outcomes are possible, these will be valued in different ways by stakeholders, and it may be difficult to find solutions that satisfy everybody. Because of this, it is important that the “extended peer community” includes stakeholders who can both contribute useful knowledge and work with others toward satisfactory management outcomes for the community as a whole.

Within this context, interdisciplinarity is increasingly defining modern approaches to environmental management. Mismatches between disciplinary principles and practices remain challenges that need to be overcome to maintain progress, but this remains an area where lots of expertise is being combined, facilitated by the extended peer community. For example, wildlife management efforts may be more effective when modern scientific approaches (e.g., population monitoring and modeling, systems analysis) are combined with sociocultural understanding, such as local ecological knowledge that informs on how and why the species under consideration may be valued by communities, and what localized actions are most likely to be successful (e.g., Pretty 2011).

These elements are brought together to some extent in the concept of adaptive management, which holds that management is a process of continued learning and response, without necessarily a neat solution or stable endpoint and which relinquishes some ideologies of control over the system (McLain and Lee 1996). It also embraces
different types of knowledge and recognizes that different stakeholders may hold varying types of expertise, opinion, and objectives, which may need to be reconciled in management. Adaptive management approaches are increasingly being applied to environmental problems and ultimately accept the dynamism and resilience inherent to environmental systems and thus that management practices must become less rigid and more accommodating of uncertainty, including of outcomes of interventions. The shifting template for urban river improvement in response to the Water Framework Directive mentioned above is an example of adaptive management. Likewise, attempts at control of sewerage discharge into urban rivers during high rainfall events, for example, within an adaptive management framework, would incorporate the recognition that changes in factors such as urban weather patterns, population and building density, and river hydrology may mean that some discharge is unavoidable on certain occasions and adapt management objectives and actions with these limitations in mind.

Linked to adaptive management is adaptive co-management. In this case, the continued learning and response of adaptive management is tied to the principles of co-management, wherein government agencies or other authorities share the rights and responsibilities of management with the stakeholders who use the environmental system or its resources. This may be exemplified in the Biodiversity Action Plan framework in the United Kingdom, in which several governmental and nongovernmental partners are responsible for managing particular species or habitats, with further assistance from local stakeholders such as conservation volunteers. Adaptive co-management allows for management plans and actions to be tailored to local requirements and for rapid exchange of information between stakeholders as well as a sharing of power and responsibility that ideally encourages more effective collaboration.

Environmental management is also central to the concepts and applications of sustainable development, which represents an increasingly ubiquitous and normative approach to the environment – that our interactions with the environment should not compromise its ability to function to an appropriate level and therefore it may support future generations. Within a socioecological system, sustainability may most accurately be considered the creation, validation, and maintenance of adaptive capacity over time. It therefore means the sustainability of the system’s capacity to cope with change, including change that may be unpredictable or unknown. Environmental management for sustainability should operate within this framework and not simply be interpreted as ensuring that environmental resource use can continue indefinitely. It requires an understanding of how pressures on interacting components may have wider impacts on the behavior and functioning of the system and is increasingly becoming the focus of management efforts.

Increasingly, a geographical perspective is recognized as being important for environmental management, for two main reasons. First, any environment must be understood within the particular context of its spatial extent and boundaries, its situation within hierarchies of scale, and the place that it represents to the humans that inhabit it – all of which are major geographical concerns. Second, geographers are primarily concerned with human–environment interactions, appreciation of which is essential for understanding how any form of management will influence the environment, both positively and negatively.

Environmental movements and protest

Anthony Bebbington
Clark University, USA

While “social movement” can be a slippery term, it is generally taken to refer to forms of collective action that are sustained over time in pursuit of goals that have some sort of political and normative resonance and are linked to a notion of rights. Thus, a self-help housing process might have very practical and material goals (e.g., to provide housing and basic sanitation), but when the process is also bound up with claims about rights to shelter, to the land on which to build that shelter, and to basic environmental services, or about the failure of government to meet citizens’ basic needs, then most observers would have no qualms at all about calling the process a movement (as, for instance, in the case of the Shack/Slum Dwellers International movement, or SDI: www.sdinet.org).

On the basis of this broad conception of social movement, environmental movements would be those whose agendas have some relationship to a politicized conception of nature (Peet and Watts 2004). That still leaves much latitude of course, reflecting the diversity of politicized “environmentalisms” that circulate. This entry first addresses the range of environmentalisms that might be mobilized through such sustained forms of collective action. It then discusses examples of phenomena that might qualify as environmental movements, drawing attention to the fact that while each is politicized, their political orientation is not necessarily the same. The examples also serve to reflect on movement structures and strategies – which can range from overt and violent protest through to the most muted forms of critique that can all but disappear behind an emphasis on negotiation and dialogue. These diverse strategies constitute part of the broader context of environmental governance in the areas and domains in which they unfold, and the final section comments briefly on the nature of protest and its possible interactions with other governance arrangements.

Environmentalisms

The environment becomes politicized in many ways and these are reflected in different forms of environmentalism. One possible mode of classifying such environmentalisms might be to distinguish among those that emphasize conservation, deep ecology, justice, livelihood, and nationalisms. Of these, conservationist environmentalisms are perhaps the most clearly present in the public sphere and are visible in the form of advertising, media campaigns, and iconic features in the landscape such as protected areas, nature reserves, or private conservation areas. While often cast as conservative (perhaps unsurprisingly given that the concern is to conserve), these are nonetheless sets of ideas that politicize species, biodiversity, and notions of access to the environment (not least because in many instances they strive to impede human access in order to conserve species). Deeper ecologies are similarly conservationist in intent, but for differing reasons. Deep ecological environmentalisms draw on much more profound commitments to
ENVIRONMENTAL MOVEMENTS AND PROTEST

the rights of species and the absence of hierarchy between the rights and needs of nonhuman parts of nature and those of humans.

Other environmentalisms are much more explicitly social in how they politicize the environment. Again at a popular level, perhaps the most widely recognized variant of such environmentalisms is that grounded in ideas of environmental injustice (and its embodiment in environmental justice movements). With particular roots in the United States, environmental justice agendas draw attention to the structurally unequal distribution of environmental costs and benefits, frequently drawing attention to the concentration of environmental damage caused by noxious facilities, waste, highways, and the like in areas occupied by populations that are poorer and frequently not white (Pellow 2007). Environment is politicized here through focusing on the ways in which it is structured and distributed. The “environmentalism of the poor” (Martínez Alier 2002) is also a form of environmental justice, but places much more emphasis on questions of livelihood and access to environmental resources that can in some way enhance the quality, security, and sustainability of poor people’s lives. Finally, there are those bodies of thinking that emphasize the relationship between “nature and nation” (Perreault 2013) and the idea that the environment is central to nationalist projects. There are many forms that this coupling of nature and nation can take ranging from those underlying disastrous forms of politics (as, for instance, in the place of nature within Nazi-ism) through to resource nationalist arguments seeking greater sovereign and social control over environmental “assets” that have been previously controlled by private and generally foreign interests.

These “environmentalisms” cross a very broad spectrum of politicizing discourses on nature and clearly pull in different directions ideologically. The centrality of the “natural” environment is also clearly not the same in each of them. Indeed, in some cases, critics who would seek to delegitimize those using the more socially explicit discourses on nature will argue that the concerns at stake are not environmental at all, and that the term “environment” is being used as no more than a cover for other agendas. However, these are all environmentalisms in that they each politicize the environment and constitute an axis around which sociopolitical movements emerge and organize.

Environmental movements

Environmental movements have emerged for reasons that range from resistance to the destruction or enclosure of natural resources, to struggles to secure access to resources, or to overturn the practices, policies, and structures that drive climate change, through to the desire to build alternative environments and relationships between environment and society. These imagined alternatives can themselves be diverse, including anything from visions for the expansion of green space in cities through to efforts to shift the trajectory of whole political economies toward postextractivist relationships with nature.

Some environmental movements are quite explicitly grounded in conservationist concerns. One example would be the sustained and far-reaching global mobilization surrounding biodiversity conservation and protected area management. At a transnational level, this movement is arguably anchored in large non-governmental organizations (NGOs) such as The Nature Conservancy, Conservation International, Worldwide Fund for Nature, Wildlife Conservation Society, various zoological and botanical societies, and the sorts of foundations that support them (the Gordon and Betty Moore
ENVIRONMENTAL MOVEMENTS AND PROTEST

Foundation, Macarthur Foundation, etc.). But the network is also made up of all the NGOs and groups outside the OECD who work with these organizations, the myriad professionals and scientists that work in or alongside them, networks of givers and volunteers, and so on. While this sort of composition does not look much like the sorts of social movement invoked by the contentious politics literature, it is hard to suggest that something of this size and scope, that has grown over time and secured such presence in public life does not constitute a broad-based movement that has sought to make biodiversity and species protection a global political issue.

That said, there are other similarly global and national apparatuses that also pay attention to conservation but which do look more similar to the types of political actor invoked by literatures on contentious politics. This would be the case, for instance, of the movement constituted by the loose, sometimes organic, sometimes tense, relationships among organizations like Friends of the Earth International, Greenpeace, International Rivers Network, Rainforest Action Network, Amazon Alliance, the Goldman Environmental Prize, the many national and local NGOs, social movements, public interest lawyers and activists that work with them, and the foundations and individuals that mobilize resources to support the activities of these organizations and activists. In some sense, this network is also a movement of movements.

The increasingly visible and important movement against climate change shares similar characteristics: indeed it involves many of the actors noted above while having iconic organizations of its own (such as 350.org). In the final instance this is a movement about conservation – of both human and species’ occupation of a habitable Earth – but with notions of global conservation that are more and less assertively politicized. Degrees of contentiousness vary across the movement, but as a whole the actors involved in this struggle seek to change the beliefs and ideologies that legitimate, deny, or ignore climate change as well as transform the material structures and practices that drive the production of greenhouse gases. Some understand these structures as problems of capitalism, other as problems of technology, and others as problems of culture, and as a result the tone and targets of their interventions vary – from stopping coal production worldwide through to promoting broad-based “green” technological change and much else.

While these examples suggest a transnational dimension, most movements are, of course, national and subnational in scope. Such movements also manifest a similar type of networked structure embracing local groups, NGOs, activists, scientists, lawyers, and citizens. In their analysis of how Brazil slowly but surely saw a greening of its government agencies, laws, and public debate, for instance, Kathy Hochstetler and Mimi Keck (2007) draw attention to the cumulative effects of just such a loose network of activists and organizations running the range from the local to the national scale. Their study also draws attention to the deep historical roots of such processes.

Just as transnational movements are constituted by actors operating at different scales, so too national environmental movements tend to be made up of a mix of national organizations and subnational movements. While such subnational movements may well have narratives on national and global environmental politics, their primary concerns tend to be with locally and regionally specific environmental issues. The literature in political ecology, especially within geography and anthropology, explores many examples of such movements. Once again, the nature of such movements and the issues that they politicize are diverse. Some of these movements address highly localized issues such as specific dams, mining
projects, oil contamination, or urban waste management. Others, however, may address issues that while still “subnational” reach over wide areas. The US “Wise Use” movement, for instance, extended across a large part of the American West (McCarthy 2002).

As noted earlier, a characteristic of many such movements is that, reflecting the underlying environmentalisms at play, they are often as much about race, ethnicity, and class (less often gender) as they are about the environment. That is, deep down the issues of contention that move them are ones of social injustice as much as of environmental quality. In part for this reason some observers prefer to speak of socioenvironmental movements rather than purely environmental movements – both to be more descriptively accurate and to draw attention to the fact that the issues at stake in environmental disputes are very often ones of rights, justice, and distribution.

In a similar sense, “environment” can often become a part of the narrative of movements that have emerged because of other agendas and then begin to take on environmental issues. Indigenous and aboriginal movements, for instance, typically emerged to address the systematic infringement or complete disregard for their rights to land, territory, language, or existence. With time, however, many such movements have also taken up environmental issues because their territories and livelihoods hinge around forests, rivers, or rangelands that have become subject to enclosure and encroachment by other interests. In New Caledonia, for instance, Kanak people have mobilized around conservation but primarily “as a means of reinforcing their cultural identity through preservation of their cultural heritage, grounded in the landscape” (Horowitz 2008, 258). Indeed, with time some indigenous movements have seen the advantage of assuming this environmental mantle as a way of relating their specific concerns to broader concerns for environmental quality, biodiversity, or climate change and in that way widening the purchase of their narratives and the alliances that they are able to build. While such movements are not environmental movements, environment has become central to their agendas.

In other instances, an apparently environmental mobilization in contexts where there is no prior indigenous movement might still not be best understood as “environmental.” Thus, for example, when the Ok Tedi mine in Papua New Guinea dumped tailings into riverine systems and so induced the mobilization and protests of communities downstream in a process that ultimately built a wide network of transnational alliances and led to lengthy legal disputes in Australia, it is an open question as to how far the initial mobilization was because of the environmental impact qua environmental impact, or because this caused massive disruption to modes of livelihood and living that were central to the identities of groups living downstream (Kirsch 2014). While at one level this distinction may seem like splitting hairs, analytically it is important because it has implications for how these movements are spoken of and how the larger issues at stake in such protests are understood.

In contrast to indigenous movements, human rights movements have been more ambivalent to incorporating environmental concerns into their agenda. In Peru, for instance, the national human rights coordinator (an umbrella group within the human rights movement) was relatively slow to accept the membership of environmental defense organizations that were offering legal support to communities affected by extractive industries. The rationale appeared to be that traditional human rights concerns (incarceration, post-internal conflict reparations, political liberties, etc.) were still too far from being secured to justify a broadening of the coordinator’s agenda. In a somewhat similar
way, environmental rights are not especially visible in the campaigns of those transnational organizations such as Amnesty International that have traditionally anchored the global human rights movement. While this is changing slowly, reflecting the increasing coupling of natural resource enclosures and severe human rights abuses, what is especially interesting is that some human rights organizations based outside the OECD but with ambitions of greater global projection do pay more attention to environmental rights (see, for instance, the Colombia-based organization, Dejusticia: www.Dejusticia.org).

Finally (for the purposes of this section, certainly not for the breadth of the issue) are those movements organized around principles of deep ecology, nature’s rights, and animal rights. Here the focus is much more clearly on environment qua environment, with movements that are both national and local in scope. Examples of the sorts of organization that anchor such movements might include Earth First! or PETA (People for the Ethical Treatment of Animals), though the ideological orientation and political motivations of people involved in such movements can again run a very wide range from those who are radically committed to direct action to people who are more likely to vote conservatively in national elections but who are deeply committed to the wellbeing of nonhuman species.

“Environmental movement” thus covers a very wide canvas. This reflects, perhaps, the many ways in which “environment” is present in agendas that are not self-consciously environmental, the fact that an environmental ethic can range from the deeply conservative to the equally deeply militant, and also the depth of human transformation of nature meaning that environmental problems, crises, and injustices present themselves in so very many domains of social life. This diversity makes simple classification of movements risky and suggests the importance of understanding member motivations in detail and of recognizing that multiple motivations and identities are often at play in any one given movement. Another implication of such diversity is that approaches to “protest” also differ wildly among these different movements. First, though, this entry presents a commentary on the ways in which such movements are structured.

Environmental movement structures

The organizational and social structures that can sustain “forms of collective action that are sustained over time in pursuit of goals that have … some relationship to a politicized conception of the environment” are diverse. These structures may, or may not, reach across different scales, may or may not involve formal nongovernmental organizations, may or may not incorporate people with presence in government, and may be more, and less, formalized. That said, much literature would suggest that most movements – environmental or not – have to involve “social movement organizations” (McCarthy and Zald 1977) that are able to serve as vehicles that coordinate actions, keep movements moving during periods of relative quiescence, or steward the physical and financial resources that are so essential for movement survival and growth. These more formal organizational roles have been played by NGOs, religious organizations, student associations, political parties, or environmental clubs, among others.

The role of such organizations within environmental movements is critical but awkward. Because they tend to centralize and anchor they can easily become dominant within movement processes, leading easily to tensions with other parts of movements especially when the movement organizations use this dominance to pursue their own institutional agendas and views on
movement strategy. This has been a recurring problem with large international environmental NGOs who have been the object of much criticism in that they have imposed their agendas and strategies within global and national conservation movements and in the process have excluded the views of local communities, indigenous organizations and other environmental NGOs (Chapin 2004). This is a particularly acute problem, but the issue at stake is a more general challenge for environmental movements: to hold in check the centripetal forces surrounding the movement organizations whose capacities are so vital to movement strength but also so potentially disruptive to movement cohesion.

A second generic structural issue for environmental movements derives from themes raised in the preceding section and relates to the question of boundaries: where does one movement end and another movement start, and when is a particular organization part of a movement or just an ally of the movement around specific issues? Is an indigenous federation that is concerned with forest protection part of a broader environmental movement, or merely an ally on specific issues related to forest governance? Can an indigenous peoples’ federation be part of both an environmental movement and an indigenous movement at the same time? At one level these questions can again seem like splitting hairs, but they also matter for how these movements are talked about, how strong one takes the “environmental” movement to be, and the sorts of environmentalism more likely to dominate the ways in which movements frame their protests and the alternatives that they pursue.

Protest, strategy, and environmental governance

The title of this entry combines two phenomena that are not necessarily associated with each other: not all environmental movements are involved in the business of overt protest and not all protests necessarily involve movements. Some protests can reflect relatively spontaneous mobilizations in the face of some sort of environmental concern, mobilizations which can then unravel almost as quickly as they form; and some movements can emphasize negotiation and persuasion rather than confrontation and protest as strategies to pursue their ends. This then makes the conjunction of environmental movement and overt protest especially interesting, raising questions as to what constitutes “protest,” what leads environmental movements to engage in more explicit protest, what the effects of protest might be and the factors that might lead protest to have effects on environmental valuation and governance that are in line with the objectives of those protesting.

Protest can range from everyday foot-dragging (Scott 1985) through to the coordination of collective, publicly visible, and violent direct action. Across this spectrum of protest options, movements evidently fall under the collective and coordinated. Some movements, and especially some social movement organizations, prioritize direct action: blocking access to laboratories doing animal testing, camping out in trees slated for clear-cutting, closing access roads to mine sites, organizing mass climate protests in downtown New York, and more generally confronting the objects of their (socio-)environmental grievances head on. At the other extreme, some movements – and again, in particular some movement organizations – prioritize avoiding confrontation and violence at all costs. Here the emphasis is instead on finding ways to negotiate with, coax, and cajole other parties to change their environmental behavior. This is a strategy that favors dialogue, behind the scenes discussions, and joint implementation of activities oriented toward changing behavior,
among other options. Such strategies might still be thought of as protest, insofar as they reflect some level of complaint and dissidence at the current state of affairs. But these are actions of protest in spirit more than in action.

Protest can also be pursued through the crafting of alternative narratives as much as through overt contention. Indeed, there is a strong strand in social movement thinking that would say that the primary contribution of movements, indeed the feature that defines a phenomenon as a movement, is the crafting of discourses that contest taken for granted ideas and build different ways of viewing the world. In the domain of environmental movements, an example of such crafting of narratives would be the very act of building and communicating ways of understanding nature, and the relationships between society and environment that imply significant rethinking of the organization of the economy, for instance. Another example would be the movements that have steadily fostered a reframing of climate change debates in the public sphere.

Where movements fall across this range of strategies (dialogue, contention, narrative) depends very much on their origins, their relationships to private finance (movement organizations receiving corporate contributions are much more likely to focus on negotiation than confrontation), their internal culture, and their assessment of the political environment in which they operate (what some refer to as the “political opportunity structure”). In some instances, even for militant organizations, protest may seem simply too dangerous and likely to elicit repression. It may also be the case that some forms of direct action (such as road blocking) have been criminalized, leading some movements to step back from them. Other movement organizations may come to the view that it makes more sense to work with change agents within the companies or government agencies that they seek to affect. Whether they come to this view or not depends also on the existence or not of such change agents, and indeed other organizations may come to opposite conclusions and decide that there are so few opportunities for change within existing structures of private and public governance that they are left with few options but to protest openly.

Another calculation facing movements regards whether to use violence or not. While it may well be that movement leaders and organizations are unable to control the mood of mobilizations or the provocations of other parties, with the effect that violence occurs anyway, calculations over the role of violence can be very real discussions within socioenvironmental movements. One line of reasoning draws on the historical record of contentious politics to argue that at certain times certain forms of violence have been critical in catalyzing progressive institutional change. Other lines of argument reason that acts of violence serve to undermine the legitimacy of the movement’s agenda (which is often one of its most important resources) and almost always induce a hardening of state authority and restrictions on freedoms of expression. There can clearly be no simple response to such debates, and at times both arguments can seem simultaneously correct.

As one example, a large scale socioenvironmental protest in lowland Peru in 2009, led by indigenous movement organizations but involving many more than just indigenous people, culminated in the death of 33 people, 23 of whom were policemen. Many have argued that the Peruvian government’s passage of legislation to enforce prior consultation with indigenous peoples before large scale investments can proceed in their territories was a direct result of this conflict. But it is also true that the Peruvian state has used the violence as a pretext to weaken movements,
with 53 indigenous leaders now being tried for crimes that the public prosecutor claims were committed during the protest. Some of these leaders face the possibility of life sentences.

A further strategic question facing environmental movements is how far to pursue their objectives domestically or internationally. This has much to do with movement structure on the one hand and political opportunity structures on the other. Movements which have only weak, or no, international members or allies almost by definition focus their attention on national and subnational levels, seeking to pursue their goals through changing national legislation, or the actions of corporations, governments, and others through national campaigns. Where national political opportunities limit what can be achieved domestically, movements have sought to exercise pressure outside their countries in the hope that this would ultimately lead to subsequent pressure on their own governments. Keck and Sikkink (1997) referred to this as the “boomerang” strategy, illustrating it with cases from environmental, women’s, and human rights movements. In this strategy, movement organizations that are unable to influence their own state directly, seek through their own action or that of allies to exercise influence indirectly via influencing other states, intergovernmental, or international bodies that have influence over their home state. For instance, Latin American environmental movement organizations have tried to influence their own states’ environmental policies by mobilizing the Inter-American Commission on Human Rights, the international Roman Catholic Church, International Financial Institutions, the UN, front page stories in The New York Times, or other similar international vehicles deemed to have leverage. In the private sector, a structurally similar strategy involves trying to influence activist shareholders or the corporate headquarters of international companies operating within their country. Other strategies, frequently led by international NGOs and legal support bodies, include efforts to influence home state legislation or regulation on environmental standards.

The drawbacks of such international strategies are many. National movements can easily lose control of them, as organizations based in Washington DC, Brussels, New York, London, and elsewhere take over. Perhaps more importantly, the decision to bypass national judicial, legal, and political institutions may reduce the scope for organizational learning and the extent to which these institutions ultimately change. The jury is very much out (and likely always will be) as to which of these options is “better,” not least because the answer to that question clearly varies depending on the case, the national context and the moment in time, and many would argue that the best strategies are those that address environmental problems by intervening across the whole reach of the global production network or global policy network at stake. By the same token, the choice between direct action and negotiation, though a real one for individual movement organizations, may be a moot one at an aggregate level where it is often argued that the best movement strategies are the “good cop/bad cop” ones which combine reform specific support and cajoling from good cops promoting changes within those private and public organizations that feel obligated to respond to the head-on and generalized pressure from the bad cop.

Environmental performance, practice, and affect

Gordon Waitt
University of Wollongong, Australia

Environmental performance, practice, and affect is a rich and variegated field of research that critiques dominant ways of thinking found within environmental science that conceives the environment as objective, external to people and inanimate. For most environmental scientists, the environment is “out there” waiting to be discovered, measured, and observed in a variety of ways. This notion of the environment as separate from and subordinate to people as well as having machine-like qualities is associated with the scientific method advanced in seventeenth-century Europe by Rene Descartes. This recourse to split the environment from humans is an example of the dualisms of much enlightenment thinking that privileges the mind over the body, solids over fluids, humans over nonhumans, and men over women.

Much work conducted by environmental scientists and environmental managers continues to draw on dualist thinking. Instead, critical geographers engaging with the environment seek to provide accounts that consider the different agencies, materialities, and dynamics. Environmental performance, practice, and affect is therefore a field of research that emerged within the context of poststructuralist approaches that advocate for new approaches that trouble understanding of the environment as pure, stable, and singular form. Instead, this field of research embraces the notion of the environment composed of multiple events, trajectories, and rhythms both human and nonhuman, over different scales, and comprised of a multiplicity of forces (social, cultural, and affective). Hence, the environment cannot be known in advance. Instead, the coming into being of the environment is conceived as an immanent process that involves human and nonhumans. The next section outlines how this field has opened up new conversations around environmental management, politics, and ethics. To conclude, similarities and difference are noted between two strands within this field (i) poststructuralist feminism and (ii) more-than-representational geographies.

Embodied practices and performed environments

What are the implications arising from a starting point of enquiry for environmental geography that does not begin with an already preconfigured environment, “out there,” waiting to be discovered? What if this account of the environment was just one of many social constructions of the nonhuman world? Nigel Thrift, Donna Harraway, and Bruno Latour have propagated lines of research challenging the purification of the world into two distinct categories, culture and nature, and advocate for an approach that rethinks the environment, subjectivities, and society, as always a relational achievement between human and nonhuman components. Environmental geographers now discuss “more-than-human” and “multinatural” worlds, epitomized by how places for nature and subjectivities

The International Encyclopedia of Geography.

are co-constituted, multiple, immanent, and enlivened through practice, performance, and affect. For example, recent explorations of the practice of walking by many geographers have sought to avoid erasing the agency of nonhuman life and instead explored the more-than-human spatialities performed by people, plants, and animals. These “more-than-human” accounts of the practice of walking moves geography toward understandings of the environment that is as impure, multiple, immanent, embodied, situated, and performative. For environmental geographers, an approach that shifts agency beyond human-centered accounts has important conceptual implications.

The first point is that there is no preconfigured environment, or indeed walker. Instead, there are embodied practices and emergent configurations of self and the environment. People actively become walkers as they make, and remake, places understood as appropriate for particular styles of walking. Such configurations in part rely on learning particular social norms; characterized by styles of dressing bodies, particular walking techniques and technologies, and following selective routes. In part, learning to walk illustrates the importance of knowledge-in-practice. Only through regular practice do bodies become attuned or trained to particular styles of walking. For geographers, particular styles of walking, like rambling in England, bushwalking in Australia, and tramping in New Zealand, may be understood as a place-and boundary-making process by helping to zone off particular locations as places for nature that may be spoken about as “natural environments.” At the same time, places designated as suitable for particular walking practices, such as national parks, nature/urban reserves, and beaches are often entangled within particular classed, gendered, and racialized geographies of belonging. For example, Waitt, Gill, and Head (2008) discuss how, in Australia, it is impossible to overlook the historical weight of colonial ideas that embed places designated as urban nature reserves, National Parks, or the “outback” in British and European settler ideas of wilderness and pristine nature. Yet, these are places Indigenous Australians continue to call home over thousands of years.

The second point is that the particular understanding of the environment configured by walking is always more than a human activity. As Wylie (2005) demonstrates there is the gradient, weather, and temperature to consider; as well as the sight, touch, and smell of animals, plants, rocks, and footpath. A performed and practiced environment must equally embrace both human and nonhuman life in a process of creativity, improvisation, and emergence. Here, attention turns to the affective energies of walking; characterized as the change in intensity of a non-conscious force or energy that flows within, between, or through bodies that guides human/nonhuman connections or disconnections. Fundamental to what motivates, or discourages, a particular practice of walking are non-conscious affective intensities that may be conveyed through a wide array of emotions including joy, love, wonder, awe, and frustration. Affectivity intensity is characterized as the ebb and flow of a force that helps inform how we become differently present by aligning us to our embodied histories, and telling us about our connection or disconnection with the present. There is, therefore, the possibility of an affective politics at work in the everyday choices people make that then play out in terms of, say, carbon emissions through modes of transport, heating, cooling, and eating.

The third and related point is that, while different practices of walking are embedded in particular essentialized ideas of the environment such as patriotism, Romanticism, the wilderness ideal, the frontier or the rural idyll that
“pure” spaces for nature, there is always the possibility of creativity, surprises, inventiveness, happenstance as nonhumans enroll the attention of walkers, not to mention the pain of the footsore. The sum effect is to sharpen us toward thinking about the environment not as a static backdrop of flora and fauna “out there” separate from humans. Instead, the environment is conceived as a relational achievement, a process of becoming – among a set of located, reciprocal, dynamic, and embodied connections and disconnections between humans and nonhuman entities. As such, the dynamics of the process of (dis)connections between human and nonhuman entities is conceived to make, remake, and undo a spatial order in the world. Hence, while people may draw on ideas that configure environments as seemingly pristine – such as a nature reserve, national park, or urban reserve – at the same time through the embodied skilled practice of walking, people may incorporate a whole set of practices and objects as enhancing or detracting from their experience – including mountain bikes, dams, bridges, music, footpaths, litter, rubbish-bins, signposts, benches, and restaurants. The taken-for-granted understanding of what, or who belongs, or is excluded from a particular spatial context may be made resilient or stretched.

A fourth point is that embodied environmental knowledge derived from daily walking through places designated as urban parks and reserves has important practical implications for environmental managers. Detailed ethnographic investigations reveal the multinatural modes of making sense of, and relating to the environment. In contrast to the conventional conversation story of human history that positions people as an environmental threat, a more-than-human approach has enabled possibilities to discuss the different ways in which people care for, and are attached to what they may make sense of as the environment. Such a conversation is possible by how this field of work abandons notions of a pure environment. Consequently, geographers are now thinking through the implications of environmental policies informed by the notion of multinatural approach, opening possibilities to acknowledge and appreciate the important role of people in the protection of plants, animals, rivers, and places. For example, environmental managers may better motivate people into conservation programs by tapping into the affective and emotional relations of awe, care, enchantment, loss, mourning, joy, and wonder; rather than programs characterized by the dispassionate technical ways of talking about the environment such as “buffer zones,” “green belts,” and “endangered species habitat.” At the same time, important questions are being raised in thinking through the practical application of a multinatural approach. Through what processes are people recruited? For what purpose? Who makes the decision? What ideas matter from the past?

Environmental politics as everyday practices

Environmental politics as everyday practice is emphasized in recent work that pays attention to affect, and investigates how bodily judgments inform everyday choices like laundering clothes, showering, waste disposal, refrigeration, cooking, eating, and shopping. Here, environmental performance, practice, and affect is located within a politics of change that centers around bodily judgments, “gut reactions,” and the visceral, rather than disciplining the mind. For example, many authors illustrate how the environmental politics, at various parts of the food chain, plays out around the bodily capacity to be affected and to affect. In grappling with what foods become accepted and or rejected from our diets, and thus shapes the environment
through agricultural practices, many geographers have chosen to emphasize the materiality of food (including texture, taste, smell, and color) to emphasize what food “does” through practices of production, marketing, shopping, preparation, plating-up, and ingestion, rather than focusing solely on what food “means.”

For example, Hayes-Conroy and Hayes-Conroy (2010) deployed a visceral approach to explore the politics of the “Slow Food” movement. Slow Food is often promoted as a rational environmentally sustainable choice. The pleasures of eating are aligned with being sensitive to the planet while supporting “local” business. The Slow Food movement exemplifies one way in which ideals of healthy bodies and sustainability plays out as a badge of social distinction for “good” consumer citizens to seek out what to eat. Hayes-Conroy and Hayes-Conroy drew attention to what they termed the “visceral politics” of food, characterized by bodily judgments commonly referred to as moods, sensations, or “gut reactions.” Ingesting food is shown to be how representations of food exist materially in the body. They reconceptualized taste within the visceral realm, recognizing that a taste for something cannot be viewed apart from the political locations we inhabit; for example, how people live their lives according to social constructions of class, gender, ethnicity, and age. The point is that visceral experiences of the textures, tastes, smells, and colors of foods (such as disgust or delight), provide important bodily clues to how everyday food choices are not simply an intellectual project, but also a corporeal one, and part of how a person inhabits the world. So, visceral responses to eating are a dynamic and differentiating force between bodies and they thus shape environmental politics through our everyday food choices.

Another example is kangaroo meat, which is rarely cooked in Australian homes despite environmental and climate change scientists supporting it because the digestive tracts of kangaroos produce less methane than either cows or sheep. Paying attention to the affective and emotional relations of shopping, cooking, and eating kangaroo shows how neoliberal climate change policies fail to connect with how food is bought, prepared, and eaten in everyday life. Embodied geographies provide vital clues to how the sensual body, affect, and emotions work alongside sets of ideas about food, parenting, home, and travel, to better understand the choices that compel participants to eat or not eat kangaroo in different places. Visceral disgust at the sight, smell, texture, and taste of kangaroo allowed gendered, classed, and racialized subjectivities to be felt, expressed, and questioned. Remaining alert to “gut reactions” provides valuable insights to the challenges of a changing climate by moving beyond highly simplified assumptions in neoliberal policies of people as rational “consumers.”

Rethinking environmentalism

Rethinking environmentalism is a central theme of the field of environmental practice, performance, and affect. Focusing on the embodied knowledge of practices that involve human–nonhuman animal relationships, this field questions human-centered ethical and political traditions of environmentalism, namely ecocentrism (ideas that emphasize the intrinsic importance of nature for humanity, such as wilderness or the sublime) and technocentrism (ideas that emphasize the instrumental importance of the environment and suggest human political, scientific, or technological ingenuity can resolve environmental challenges). Inspired by the work of Donna Haraway on interspecies relations, this works calls for rethinking environmentalism as an ethics of shared suffering and response abilities with nonhuman others, such
as cats, dogs, sheep, elephants, trees, and seeds. Finding ethical ways of living with plants and animals is conceived as an everyday practice. Animal/plant encounters are understood to comprise skilled practices that orient, dispose, make, and unmake people in affective ways. Through practice and physical engagement with nonhuman others, not only do we learn about difference, but also learn something about their world and find better ways of living with nonhuman others.

For example, Jamie Lorimer (2012) researched human–elephant relationships and their implications for rethinking environmentalism. Lorimer makes use of poststructuralist ideas that do not neatly align touch with texture, but rather conceives of touch (and indeed smell, sound, taste, and sight) as always multisensory, part of the process of making, remaking, and unmaking relationships across difference into a sociospatial formation that makes sense as a coherent whole. First, Lorimer demonstrates how the affective capacities of touching elephants, and the reciprocity of being touched by elephants, are an integral part of an experiential ecotourism economy; alongside touching other animals/birds framed as charismatic including koalas, kangaroos, whales, penguins, and dolphins. Lorimer discusses the tensions between Western volunteers and scientists who travel to Sri Lanka as “scientific ecotourists” in national parks. These are people who have paid for organized corporeal encounters; and often expect their bodies to be affectively charged through encountering an elephant in terms of risk and adventure. Lorimer argues how paying for encountering elephants operates as a form of entitlement. Through the workings of the experiential economy, private desires and access that help in part fashion becoming a scientific ecotourist may trump the ethics of park management schemes of environmental science that advocates against deliberate proximate encounters between humans and elephants. For these reasons, the concept of affect provides insights to the ethics of human–elephant relationships in the context of volunteer nature tourism where people pay for organized touching encounters.

Second, Lorimer illustrates another modality of the reciprocal touch of elephants, that of the embodied knowledge of an experienced mahout, a person who has normally worked with elephants in the forest since childhood. The mahout’s embodied knowledge of individual elephant’s sounds, smells, and touch illustrates how attunement, or training, is crucial to the logic of affect and interspecies communication. Over a lifetime, mahouts learn to attune to an elephant’s oral, haptic, and olfactory clues about its mood, thermal comfort, or appetite, while at the same time learning to be affected by their behavior. Lorimer illustrates how the interests of captive elephants are not well served by either intrinsic environmentalism that neatly categorizes elephants as wild or instrumental environmentalism that categorizes them as working animals. Instead he advocates for a model of companionship and a more-than-human account of environmentalism, arguing that “human-elephant flourishing must recognize how elephants are touched by humans and how, in turn, elephants touch us” (Lorimer 2012, 182). Paying attention to embodied knowledge, the circulation of human and nonhuman affects and knowledge, and the practices through which humans and nonhuman affect and learn to be affected in moments of encounter, are crucial to thinking anew about environmentalism of which geographers write.

**Multinatural ontologies**

There are a diverse array of research strands that bypass enlightenment thinking of the environment by drawing on different philosophers. One
ENVIRONMENTAL PERFORMANCE, PRACTICE, AND AFFECT

strand draws on feminist scholarship including Donna Haraway, Val Plumwood, Elspeth Probyn, Elizabeth Grosz, and Rossi Braidotti, while another resonates with Nigel Thrift’s (2007) non-representational theory (NRT) or affective geographies.

There are similarities but also important differences between these conceptual positions of rethinking the environment in more lively ways. Both approaches share an interest in: (i) relational over oppositional modes of power, which enables a future that is imagined as open to possibilities rather than predicted by uneven power relations; (ii) the significance of everyday practices; (iii) the located body as active in measuring, feeling, shaping, and reshaping our sense of self and place; and (iv) the capacity of affect to shape and transform our self and the world we live in. Equally, both approaches share conceptualization of the body not as a bounded solid whole, but rather as porous, permeable, and active. Strongly influenced by Deleuzian concepts, each emphasizes thinking through the ongoing, provisional process of bringing together diverse elements (bodies, ideas, things, and intensities of affect) into a working order that makes coherent sense (assemblages), where agency does not lie solely within the body-subject. Assemblages hold together, or fall apart, depending on how their diverse elements relate. Finally, both approaches call for methods that trace the textures of everyday life; injecting living, breathing, sensual, emotional, and affective bodies into geographical enquiry.

Nonetheless, there are important differences that can be identified within and between research strands into environmental performance, practice, and affect; particularly around mode of relating to human agency, the body, affect, and emotion (see Lorimer 2008). First, drawing on the work of Massumi and Thrift, non-representational accounts try to avoid thinking around bounded interacting bodies. In contrast, following Haraway one strand of ecofeminist geography emphasizes the organism as the entry point for analysis. Second, non-representational accounts distance themselves from research which privilege subjectivity and nameable emotions and focus on the capacity of bodies to affect and to be affected that precedes, and exceeds any stratified formations of power knowledge. Whereas, following Elspeth Probyn (2000), alongside the capacities of bodies to affect, and be affected, bodies are always located and entwined within discursively produced relations of power, including the most intense tracing of affect in and through the body communicable as emotions. Third, feminist geographers argue that affective geographies often ignore gendered bodily differences, and de-emphasizes the humanity of embodied experiences articulated as socially and spatially mediated emotions. This debate centers on how affective geographies reinstate dualist thinking of mind and body (see Thien 2005). In summary, Bondi (2005, 438) argued that “feminist geographers find research informed by non-representational theory too abstract, too little touched by how people make sense of their lives, and therefore too ‘inhuman,’ ungrounded, distancing, detached and, ironically, disembodied.”

Environmental planning

Graham Haughton
University of Manchester, UK

Environmental planning involves working within both statutory planning systems and wider systems of environmental management, such as water quality and flood risk management. It operates at and across a wide variety of scales, from the site through the local to the regional and beyond, with different types of approach relevant at different scales.

Reflecting its role at the interface of statutory and nonstatutory ways of planning and managing the environment, a central concern of environmental planning is the need to acknowledge and deal with multiple environmental and administrative geographies. Environmental geographies might include floodplains, watersheds, marine and terrestrial ecosystems, landscape character designations, and recreational parks. The geographies adopted by environmental organizations sometimes deliberately involve fuzzy and overlapping boundaries – ecosystems and river basin catchments, for instance, do not lend themselves to clear lines on maps. As a result we find that from forestry authorities to those concerned with species protection or soil preservation, many environmental organizations will create their own geographies that quite avowedly do not coincide with the political-administrative boundaries of local and metropolitan government. The importance of this is that it is the territorial units of government that have provided the mainstay of most statutory planning systems, where the legal and regulatory powers of planning most clearly come to bear.

We can begin to see from this how environmental planning exists as part of the statutory processes of land-use planning, and also in relation to a wide variety of other sectors and organizations – such as water and energy utility companies, state forestry commissions, and catchment partnerships. Each organization will have its own priorities, strategies, sets of stakeholders, funders, and preferred geographies. The challenge for environmental planners then becomes how to reconcile all these different possibilities, from the statutory to the nonstatutory, from the formal to the informal, mediating between often conflicting objectives, all the while seeking to find a balance between protecting private interests and promoting the public good.

Because an essential part of planning involves allocating or denying development rights of different kinds, it is also necessarily political since it involves redistributing power and resources. This has always been true, but it has been brought to the fore by recent work on urban political ecology, which strenuously opposes attempts to think in ways that present humans and nature as somehow separate, arguing instead that they are symbiotically interrelated (Swyngedouw and Heynen 2003). This framework leads to the inevitable conclusion that far from being a neutral science or arbiter of neutral expertise, environmental planning is always a political act, involving a redistribution of winners and losers. As recent scholarship on river basins has demonstrated, whilst those supporting work using river basin geographies can draw on the appeal of their seeming apolitical “naturalness,” in reality...
the decisions about empowering certain scalar fixes over others always involves deeply political choices, for instance privileging certain resource uses or ecological features over others (Molle 2009; Cohen and Bakker 2014).

In related vein, environmental planning requires a continuous negotiation between different understandings of the environment. As such it must find ways of mediating between the many actors who lay claim to privileged knowledge and understandings of how environmental systems work and their impacts on humans, from scientists of various kinds, to lay experts and local communities, each of which can make different types of knowledge claims, often in emotionally charged ways (Castree 2014). For instance, lying behind debates such as how to preserve “pristine nature” in national parks are difficult issues such as whether pristine nature is any longer a meaningful concept and how preserving one particular moment in a landscape’s evolution as somehow “best” privileges certain interests over others.

The need to understand debates around climate change provides an excellent example of how environmental planners must also work with multiple time horizons, dealing with the past, present, and near and distant future. Despite an inevitable obsession with maps and boundaries, environmental planning also requires thinking beyond horizontal planes and surface processes, looking deep into the Earth and oceans and up into the atmosphere – it requires three-dimensional thinking as well as thinking about the intersection of environmental, social, cultural, political, and economic processes.

Environmental planning then is always an exercise in complexity management, dealing with multiple spatial scales, complex interactions between highly variable relational and territorial geographies, different professional and scientific traditions, and disputed knowledge claims, working across a wide range of policy sectors and multiple time frames.

As a discipline, environmental planning has continued to evolve, reflecting wider societal debates and improving environmental knowledge and understanding of nature–society relationships. The evolution of environmental planning ideas is important precisely because they have been hugely influential in shaping our urban and rural landscapes for well over a century. To give a broad sense of how these ideas have developed over time, the remainder of this contribution focuses on two attempts to look at how dominant themes have emerged in different contexts. The first of these is based on a periodization provided by Thomas Daniels (2009) to explain the evolution of environmental planning in the United States – this sets out five broad eras of thinking, which have been refined a little here by reflecting on the emergence of environmental planning in the United Kingdom. The second approach, urban environmental transitions (McGranahan et al. 2001), looks more critically at the evolution
of environmental policy in relation to economic development, providing a framework more oriented to the problems faced in poorer nations and cities.

Daniels calls the first era in his periodization “Getting on The Green Path,” stretching from the nineteenth to the early twentieth century. This was a hugely important period in terms of generating ideas that would continue to influence environmental planning over the next century. In the United States key unifying themes that emerged at this time included the city beautiful movement, and later garden cities and suburbs, the urban parks and playground movement, wilderness protection and conservation of natural resources. Starting with Yellowstone in 1872, the designation of national parks was inspired by a desire to protect areas deemed to be of particular natural or cultural value, with the emphasis initially at least on what were seen to be wilderness areas relatively unblemished by industrial progress. In both the United States and Britain new conservationist movements sprang up in this period pushing for the conservation of land, such as the Sierra Club, founded in 1892 in the United States, and the National Trust, founded in 1895 in Britain.

From the British perspective, mid-nineteenth century legislation to improve the condition of slums in the industrial cities was particularly important. National legislation allowed local authorities to intervene in the market, enabling them to require landlords to make improvements and where necessary to demolish unfit housing. The importance of this legislative intervention was that it demonstrated a key role for central government in regulating to improve the urban environment, acknowledging the limits of unregulated markets, and in creating a new profession, environmental health. During this period too municipal authorities became increasingly active in investing in clean water supplies and in urban drainage and sewerage. Despite limited scientific underpinnings, much of the thinking that emerged during this era still resonates with some of the key themes in environmental planning today – clean water supplies, sanitation, protecting nature, providing places for recreation, and better quality residential areas in cities.

A second era, running from the 1920s to the 1960s, is broadly defined by Daniels as “Regional ecological planning,” involving an increasingly scientific approach to environmental management and the rise of techniques such as environmental impact assessment. In the United Kingdom, the key environmental themes of this period would include the emergence of green belt as a tool that has been ascribed various roles, preventing urban sprawl and the coalescence of neighboring towns, protecting the identity of historic towns, ensuring access to the countryside for urban residents, and encouraging urban regeneration. Following major disputes over allowing public access to the countryside during the 1930s and the changed national mood after World War II, new legislation was introduced in 1949 to allow the designation of National Parks and Areas of Outstanding Natural Beauty (AONBs).

Daniels refers to the third era in US environmental planning (1960s–1970s) as “The Birth of Modern Environmental Planning,” driven particularly by a desire to regulate better against industrial and agricultural pollution in the wake of Rachel Carson’s (1962) influential book *Silent Spring*. This led to the development of federal level legislation, including a Clean Air Act (1970), Water Pollution Control Act (1972), and Safe Drinking Water Act (1974), plus new initiatives for clearing up contaminated sites and addressing the disposal of solid wastes. In the United Kingdom, the great smog of December 1952, which resulted in around 12 000 deaths in
London, kick-started a growing environmental awareness and the emergence of new legislation, including the Clean Air Acts of 1956 and 1968.

By the early 1980s a backlash began to emerge against the earlier regime, which was deemed by some to be an overly centralized “command and control” approach, leading to inflexible and costly uniform standards that did little to incentivize the search for market solutions. This led to the fourth era in Daniels’s schema, “Backlash or Bridge to Sustainability” (1982–2008), during which new market-based approaches emerged, such as the “cap and trade” approach introduced to encourage innovation in how firms sought to reduce greenhouse gas emissions. In this period, economic growth was given greater primacy in policy, with environmental policies expected to demonstrate that they would not prove a drag on the drive for growth. This said, the 1980s and early 1990s also gave birth to the environmental justice movement, with its central concern about the socially and geographically inequitable burdens of polluting activities (Bullard 1994), providing at least some counterbalance to the growing “economization” of environmental planning.

Moving to the present, the dominant themes in environmental planning in the United States are characterized as “Planning for Sustainability and the Global Environment.” In Daniels’s schema, this era (1992–present) overlaps with the previous one, a device that might usefully be adopted for all the periods as there are inevitable overlaps and interplays as new dominant approaches emerge. The year 1992 is significant because of the Rio Earth Summit, which set out a global agenda for addressing sustainable development into the next
century. An equally significant date, however, was 1987, which saw the publication of *Our Common Future*, widely known as the Brundtland Report (World Commission on Environment and Development). This provided a definition of sustainable development that is still in common use today, namely that sustainable development must meet the needs of the present without compromising the ability of future generations to meet their own needs.

There have been many other attempts to define the concept, typically emphasizing the need to give equal consideration to environmental, social, and economic issues, or identifying core principles, such as intergenerational equity, intragenerational equity, and geographical equity (Haughton 1999). In 2004 the UK planning system was for the first time given a clear statutory purpose, to support the pursuit of sustainable development. This gives a sense of the importance of the sustainability debate for planning at this time, with attempts to devise win–win–win solutions (development decisions that provided environmental, social, and economic benefits, rather than trading one against another) gaining considerable professional attention. More recently there has been some disillusionment with the way in which sustainable development has been incorporated into the formal decision-making processes of planning; the fuzziness of the concept has allowed powerful lobby groups and politicians to argue for the primacy of economic growth over the environmental and social dimensions of sustainability in planning decision-making. For some commentators, the fuzzy nature of sustainable development and its associated technocratic apparatus of sustainability appraisals and so forth turned the decision-making process into an apolitical bureaucratic negotiation dominated by the views of those with powerful commercial interests, rather than a process in which open and meaningful debate is fostered about how best to improve environmental and social conditions (Swyngedouw 2007; Allmendinger and Haughton 2012).

This brief chronological account has focused on the US and UK experiences, so it is inevitably much less helpful in understanding events in other countries. Of particular interest here is the growing critique of postcolonial planning, referring to the ways in which Western ideas have continued to hold sway in poorer nations, sometimes being transferred in inappropriate ways, such as recent attempts to masterplan eco-neighborhoods for African cities (Watson 2014). Environmental discourses in such models are used to justify a form of planning which favors those pursuing a high-growth economic model that accepts or even accentuates growing social inequalities, where environmental benefits fall mainly to the rich.

It is in this context that it is helpful to examine the Urban Environmental Transition model (McGranahan et al. 2001; Figure 2). Broadly speaking this model shows how particular environmental problems tend to dominate policy concern at particular moments in specific local contexts, involving a broad distinction between “brown” and “green” agendas in environmental policy. For poorer neighborhoods in poorer cities, the main environmental problems faced tend to be immediate, highly localized in scale, and related to environmental health – poor access to clean water and adequate sanitation for instance leading to a range of debilitating illnesses that in turn impair ability to work, providing a mutually reinforcing downward spiral of poverty and disease. Here the need is for improved collective infrastructure, in particular, clean water, drainage, and sanitation. For cities moving through an industrial phase of economic growth, environmental problems are more typically manifest at city-wide and regional level,
with rising air pollution a particular problem. For wealthier cities, where polluting industries have tended to move out or have been subject to stringently observed regulation, the problems of consumption begin to dominate political discourse, including contributions to global resource depletion and global environmental change. Local problems will not have disappeared, they will, however, be less dominant in policy framing.

The value of this model is its sensitivity to spatial and temporal scale – from the local and immediate to the global and long-term. Particularly valuable is the differentiation between the so-called brown agenda, bugs and diseases associated with poverty, malnutrition, and poor infrastructure, and the green agenda, with its concerns about the long-term sustainability of society. Like all transition models there is a danger of overstating movements and of reading off trajectories as somehow universal, unavoidable, and reflecting some desirable end point. The authors of this model are very clear that their work is not intended to be interpreted in such ways. Rather it is a broad heuristic, which recognizes that even the wealthiest cities will have areas of concentrated poverty and very immediate issues of health and wellbeing, just as poorer cities will have wealthy areas which are relatively well-provisioned and very different from the conditions in nearby poor areas.

To conclude, environmental planning has long attracted the interest of both physical and human geographers and there is a considerable degree of critical interchange of ideas between geography and planning in terms of both academic debate and engagement with practice. In recent years the growing political interest in “sustainable development” has at one level helped encourage a growing interest in environmental planning. At another level, the fuzzy concept of sustainable development could be said to have diluted the focus of planning on environmental issues, as the term sustainable development has been appropriated in part by powerful interests pursuing a “business as usual” high-growth economic model. There is no doubt that environmental planning merits and indeed needs continuing critical scrutiny from geographers (Gleeson 2012) and others to ensure that policy in this important arena is continuously and rigorously critically examined.

Environmental policy

James R. Palmer
University of Oxford, UK

Environmental policy may refer to any consciously planned human activity that is designed to alter the conditions under which ostensibly natural (or, increasingly, nonhuman) landscapes, systems, and processes exist and operate. It is often but not always intended to reduce the impacts of deleterious human activities upon nonhuman forms of existence, ranging from the protection of sentient organisms from extinction through to the stewardship of nonsentient resources such as clean, safe drinking water, or a stable global climate system. Environmental policies can be conceptualized, implemented, and evaluated at a range of scales, from the local to the global. In formal terms at least, explicitly environmental policymaking can be traced, in both the United States and the United Kingdom, to 1970. Earlier policies in both countries, however, had borne characteristics that would today be recognized immediately as environmental (such as the Clean Air Act of 1956 in the United Kingdom and the Air Pollution Control Act of 1955 in the United States). In the twenty-first century, they assume a wide diversity of forms, and are undertaken not only by state governments, but also increasingly by a range of nonstate actors including local communities, civil society organizations, and supranational bodies of various kinds.

Human and environmental geographers, largely of the Anglo-American variety, have taken a diversity of approaches to engaging with environmental policy, particularly since the emergence of political economic analyses of capitalist wealth accumulation in the 1970s, and of more poststructuralist forms of analysis in the 1980s. Geographical work on environmental policy, whilst sometimes “applied,” has more often taken a critical approach to the complex processes by which knowledge is produced, policy objectives are formulated, and desirable environmental futures are identified in this field. This entry has two main sections. The first provides an historical overview of environmental policy, drawing principally from the post–World War II experience of Anglo-American polities. The second, meanwhile, offers an overview of the diverse geographical approaches to analyzing and engaging with environmental policy that have gained influence and credibility within the discipline since the 1970s. A brief final section then speculates on the future directions that geographical work on environmental policy might take, with a particular emphasis placed on the development of more indigenous geographical theory, as well as the attainment of greater policy impact.

The history of environmental policy

Environmentalism and the establishment of a “pollution control” agenda

Though today it is a taken-for-granted concept and domain of human concern, “the environment” arguably came to represent a distinct focus for political activity in Western countries only from the 1960s onwards. In the case of certain problems, such as air pollution, whilst public and private concerns were historically
well established, key “focusing” events in the postwar era were ultimately still needed to help bring remedial legislation into being. In the United Kingdom, for instance, London’s so-called Great Smog of December 1952, caused by a combination of unusual weather conditions and the widespread burning of coal for heating in homes, led to thousands of deaths, and served as the catalyst for policy designed to prevent a repeat of the situation. The resulting Clean Air Act of 1956 effectively enabled authorities to create “smoke-free zones” in the city, outlawing all emissions of black smoke and obliging local residents and factory operators to convert to smokeless fuels.

Beyond such “focusing” events, a far broader driver of environmental policy in this period was the emergence of an environmental movement, epitomized perhaps most famously in Rachel Carson’s 1962 publication of *Silent Spring*. This seminal text drew on many years of Carson’s own research to outline the negative impacts of indiscriminate pesticide spraying on the environment, and particularly on bird species. It is widely credited not just with introducing environmental concerns to much of the American population in the early 1960s, but also with bringing about a shift in American federal pesticide legislation in 1972, forcing a phaseout of the use of DDTs (dichloro-diphenyl-trichloroethanes) in agriculture. In the years immediately following *Silent Spring’s* publication, a highly combative and well-organized environmental lobby emerged on both sides of the Atlantic, embodied in the establishment of the Environmental Defense Fund in 1967 in the United States, and Friends of the Earth in 1971 in the United Kingdom.

By the end of the 1960s Western governments were coming under a great deal of pressure to respond to increasingly widespread environmental concerns. This pressure ultimately told in 1970, a year that witnessed both the bringing into effect of a new National Environmental Policy Act in the United States, and the formation of the first Department for the Environment in the United Kingdom. These new policy institutions and initiatives identified the environment as a significant additional area of responsibility for Anglo-American governments, beyond conventional state obligations. Initially however, their remit was confined almost exclusively to the reduction of gross pollution – whether of air, water, or land – by industrial contaminants of various kinds. In broad terms, a “pollution control” paradigm therefore prevailed over environmental policy in this period, with practitioners adopting a so-called end-of-pipe approach to reducing the impacts of industrial development. “Sound science” was here assumed capable of identifying the assimilative capacities of various sinks in the environment (e.g., oceans, lakes, rivers, the atmosphere), and so long as these capacities were not exceeded, industrial processes and products could be left fundamentally to continue as before. The definition and implementation of pollution standards was also characterized by close relationships between regulatory bodies and the industrial groups subject to regulation, with few apertures for environmental groups to become involved. Environmental policy institutions and initiatives of the 1970s, in short, were not wont to view environmental degradation as a structural component of wider socioeconomic practices and lifestyles.

**Ecological modernization and the rise of “integrated,” sustainable environmental policy**

Though Anglo-American environmental policies of the 1970s scarcely considered issues beyond the control of gross pollution, there was – in wider circles – much consternation...
over the more systematic problems of global population growth and natural resource use. The publication of *The Limits to Growth* by the Club of Rome in 1972, for instance, typified this overtly Malthusian trend by raising the question of whether continuous economic growth could be sustained within the confines of a single planet. In the same year, the first United Nations Conference on the Human Environment, held in Stockholm, had also generated 26 principles for governments dealing with environmental issues, many going far beyond questions of pollution control to embrace a more comprehensive view of the potential remit of environmental policy.

Though these new ideas were important and influential, the OPEC (Organization of the Petroleum Exporting Countries) oil crisis of 1973, and subsequent global economic downturn, ultimately conspired to suppress the political profile of environmental issues in many Western countries for the rest of the decade. Not until the mid-1980s can any real shift away from the paradigm of end-of-pipe pollution control be legitimately discerned. A succession of controversial environmental issues – some “transboundary” (e.g., acid rain and stratospheric ozone pollution), others rife with uncertainties (e.g., concerns over the possible impacts of nuclear power and lead in petrol) – contributed to a change in the lens through which environmental problems as a whole were interpreted. From this new perspective, the causal mechanisms leading to environmental degradation were widely recognized as complexly intertwined with existing modes of economic development (and their associated social practices). The end-of-pipe mentality of the 1960s and 1970s slowly began to give way to one of ecological modernization, under whose terms economic development and environmental protection would have to be fundamentally reconciled, rather than simply traded off against one another.

In contrast to previous, institutionally incoherent and fragmented approaches to environmental issues, ecological modernization served to promote the integration of environmental policy concerns across diverse areas of governmental activity. At the UK level, this was initially evidenced by the formation of Her Majesty’s Inspectorate of Pollution in 1987, a new body responsible for overseeing pollution control across multiple media. At the European level meanwhile, the passing of the Single European Act in 1986 saw the integration of environmental protection measures as a statutory requirement for all new policy proposals. Beyond this integrative trend moreover, ecological modernization was also promoting more anticipatory and precautionary approaches to pollution control. The idea that “pollution prevention pays” thus began to gain considerable credibility in this period, as did a sense that policymakers should consider the rights of both present and future generations (both human and nonhuman) to an unspoiled environment. Overall, ecological modernization encouraged a far more systematic approach to environmental policy, a stance reinforced in the United Kingdom with the establishment of the Environment Agency in 1995, and at the European Union level in the shift towards more preemptive modes of ex ante environmental assessment and policy appraisal from the mid-1990s onwards. Despite its apparent promise, however, ecological modernization has more recently come to be associated with the dilution and mollification of radical, environmentalist rationalities under more conservative, economic modes of thinking. Whilst its influence over environmental policy today therefore remains strong (see Market-based measures and the rise of global environmental issues, below),
the extent of its success in actually ameliorating environment policy outcomes remains contested.

Beyond its tangible impacts upon environmental policy from the 1980s onwards, one can also discern within ecological modernization the seeds of an even more powerful concept – one that would arguably become the most influential of the 1990s – *sustainable development*. With the publication in 1987 of the UN World Commission on Environment and Development’s now famous Brundtland Report, approaches to environmental policy came increasingly to be influenced by this concept, defined as “development that meets the needs of the present without compromising the ability of future generations to meet their own needs” (WCED 1987). The subsequent formalization and promotion of sustainable development at the Earth Summit – a UN Conference on Environment and Development held in Rio de Janeiro in 1992 – marked a watershed moment for Western environmental policy. The promotion of Agenda 21, for instance, served to institute sustainability as a routine concern for policymakers operating across diverse spheres, at the local, national, and global levels. Beyond this, the Earth Summit also opened three legally binding agreements on major environmental issues for signature by nation states: the Convention on Biological Diversity, the United Nations Framework Convention on Climate Change, and the United Nations Convention to Combat Desertification. These latter initiatives epitomize two broad shifts in environmental policy that have been discernable since the 1990s. The first, typified by climate change in particular, involves the move towards assessing and addressing major environmental problems at the “global” level, often through market-based measures. The second, meanwhile, has involved the establishment of environmental protection as the responsibility of both governmental *and* nongovernmental actors of various kinds (a change that has come to be labeled widely as a shift from government to governance). The following sections now deal with each of these transformations in turn.

**Market-based measures and the rise of global environmental issues**

For the past two decades, it is undoubtedly the issue of climate change that has come to function as an “emblem” of the “environmental problematique at large” (Hajer 1995, 5). Climate change’s profile owes much to the work of the Intergovernmental Panel on Climate Change (IPCC), a body established jointly by the World Meteorological Organization and the United Nations Environment Programme in 1988. Since the publication of its first report in 1990, the IPCC’s status as the foremost source of expert scientific knowledge and evidence pertaining to the magnitude, causes, and implications of climate change has grown substantially. Its most recent Fifth Assessment Report (5AR) of 2013–2014 delivers the most unequivocal verdict yet on the extent of man’s imbrication in the processes that lead to climate change. Despite this consensus, however, policy interventions designed to mitigate climate change have enjoyed only mixed success. Whilst the 1997 Kyoto Protocol saw many advanced industrialized countries (though notably not the USA or Australia) adopt legally binding targets for the reduction of greenhouse gas (GHG) emissions, many countries have failed to meet these in practice. Moreover, whilst 195 countries signed the Paris Agreement in December 2015, agreeing on paper to reduce their GHG emissions “as soon as possible,” questions remain about the extent to which individual states’ commitments in this regard will prove legally binding. Even in the United Kingdom, where targets subscribed to under the Kyoto Protocol were...
met, this achievement can be attributed almost in its entirety to the so-called dash for gas of the 1990s, whereby a newly privatized electricity industry replaced large numbers of coal-fired power stations with cleaner gas-turbine equivalents. The passing of a UK Climate Change Act in 2008, which stipulated targets for significantly reducing carbon dioxide emissions compared to 1990 levels before 2050, is likely to pose a much tougher long-term challenge. Whether implemented nationally or negotiated internationally, GHG emissions targets however represent only one of many potential tools available for addressing climate change. Indeed, and as theorists of ecological modernization would expect, more obviously economic (or market-based) approaches to tackling climate change have also become prominent in many developed countries since the mid-2000s. So-called cap and trade carbon markets, for instance, aim to mitigate climate change by forcing companies to buy GHG emissions allowances that they can then trade with one another as desired. The most significant such market, formed in 2005, is the European Union’s Emissions Trading System (EU ETS), which covers around 45% of the European Union’s emissions today. By putting a price on carbon, these schemes effectively seek to correct a perceived “market failure” in which the costs of environmental degradation are externalized and borne by wider society, rather than retained internally, to be borne by those who instigate the degradation in the first place. The distinctly economic take on climate change that is offered by carbon markets has been reinforced elsewhere too, most notably in the United Kingdom by the Stern Review of 2006. Commissioned by the UK government’s Treasury, this influential report argued that to deal with climate change sooner would cost developed economies far less in the long run than delaying action into the future – in effect echoing the mantra that “pollution prevention pays,” another longstanding principle of ecological modernization. The pervasive infiltration of economic rationality into attempts to tackle climate change is instructive for those studying other spheres of contemporary environmental policy too. In urban environments, for instance, attempts to enhance air quality have sometimes been predicated on congestion charging, which effectively prices large numbers of motorists out of the market for road space in major cities like London, Stockholm, Singapore, and Milan. In the realm of conservation policy, meanwhile, many contemporary initiatives aim to meet targets and objectives through schemes that provide conditional “payments for ecosystem services” to the owners of environmental goods. Ecosystem services are understood to include a diverse portfolio of benefits that accrue to human populations from the functioning of natural (or nonhuman) systems, whether regulatory (e.g., maintaining soil quality and nutrient cycling), provisioning (e.g., supplying clean water or agricultural crops), or cultural in nature (e.g., sustaining unique habitats or species for future generations to experience). In 2010, the publication of a major report entitled The Economics of Ecosystems and Biodiversity (TEEB) served to reinforce this economic approach to conservation, in much the same way as the Stern Review had done for climate change four years earlier. More recently, the foundation of a new Intergovernmental Platform on Biodiversity and Ecosystem Services (IPBES) in 2012 stands as a testament both to the intuitive appeal of market-based approaches for conservation, and to the influence and credibility that has been gained by cognate, global-level organizations in other fields, most notably the IPCC.
ENVIRONMENTAL POLICY

From government to governance: public engagement and the reconfiguration of expertise

A further broad set of developments in environmental policy that can be discerned, particularly since 2000, is found in the increasingly routine engagement of wider stakeholders in decision-making processes. Whilst mechanisms designed to permit stakeholder involvement in environmental policy have a long history, historically such practices were highly constrained, limiting input to formal consultations whose remit, duration, and relationship to actual decision-making were all determined exclusively by governmental actors. Today, considerable moves have been made towards more inclusive and deliberative modes of governance that engage wider actors throughout the policy process, from initial problem definition and policy design through to implementation, monitoring, and evaluation. Such a trend arguably stems from two broad sources. First, the cumulative effects of neoliberalism – including deregulation, privatization, and budget cuts – have in many Western countries opened the way for corporations and consumers themselves to wield power over environmental policy. Second, the application of continued pressure from the environmental movement, facilitated both through traditional campaigning and through newer forms of protest and activism using social media and the Internet, has itself served to secure greater influence for nongovernmental organizations of various kinds.

One area where these broad shifts can be discerned particularly clearly in the United Kingdom is in the practice of environmental risk assessment, particularly relating to the introduction of new technologies such as genetically modified crops, or to food-related scares such as the “foot-and-mouth” and BSE (bovine spongiform encephalopathy) crises in the United Kingdom. Initial approaches to engaging wider stakeholders in risk assessment in these fields were almost always informed by an “information-deficit” model, in which public resistance to, and mistrust of, policy decisions was deemed to result exclusively from a lack of “rational” scientific knowledge and understanding. More recent initiatives have, however, moved away from this stance, focusing instead on facilitating what is frequently termed “upstream” public engagement, where the definition of who is to count as an environmental expert in the first place is kept open. Here the implicit assumption is that wider stakeholders might offer productive new perspectives and rationalities with which to approach the management of complex environmental problems, beginning from the definition of what constitutes an unacceptable risk in the first place. Consensus conferences, citizens’ juries, and other forms of deliberative experiments have therefore been deployed throughout many European countries and in the United States, in areas relating to genetically modified crops, nanotechnology, and nuclear power, amongst a host of other areas. Despite the shift in philosophy associated with these schemes, however, questions remain about the extent to which inclusive deliberation genuinely impacts, positively or otherwise, on eventual environmental policy decisions.

In the case of more systemic environmental issues such as climate change and biodiversity conservation, wider stakeholder and public engagement has arguably been manifest in even deeper ways, with responsibility for policy implementation itself increasingly being shared amongst governmental and nongovernmental actors. The UN’s Reducing Emissions from Deforestation and Forest Degradation (REDD) program, for instance, which encompasses a large number of policy measures ranging from carbon payments through to the clarification of land
tenure arrangements, is premised on the substantive involvement of a diverse set of stakeholders in implementation efforts at both the national and the global level, including forest-dependent and indigenous groups. Other examples, meanwhile, point to even more fundamental shifts in the way that the basic building blocks of environmental knowledge are constructed, with an increasingly significant role played by non-scientific actors of various kinds. The establishment of The People’s Agreement at the 2010 World People’s Conference on Climate Change and the Rights of Mother Earth, held in Bolivia, for instance, has served to counteract the globalizing thrust of the IPCC’s Assessment Reports on climate change, prioritizing instead modes of governance that are “in harmony with Mother Earth and appropriate to local cultural contexts.” The emphasis on place-specific knowledge and cultural sensitivity is not insignificant here. Indeed, as the twenty-first century unfolds, producing genuinely meaningful knowledge about many of the ostensibly global issues that have dominated the environmental agenda since the 1990s seems to be destined to require ever more place-specific, bespoke modes of inclusive, deliberative governance (Hulme 2010).

Geographical approaches to environmental policy

Geographical work on environmental issues today bears a heterogeneous array of theoretical and empirical characteristics. Indeed, the question of what makes for a quintessentially geographical interpretation of environmental policy today is remarkably difficult to answer (Castree 2004). Arguably, this is so not only because the very concept of the environment itself permits multiple epistemological (and indeed ontological) interpretations, but also because much work undertaken by geographers addressing the subject has inherited ideas, concepts, and theoretical approaches from other disciplines (including amongst others environmental sociology, science and technology studies, philosophy, and anthropology). For these reasons, any attempt to categorize major areas of geographical work addressing environmental policy will always, in some senses at least, be flawed or incomplete. The approach taken here represents just one of many possible heuristics for grasping diversity in the field today.

“Applied” environmental policy research

Applied investigations into the impacts and consequences of environmental policies in particular geographical contexts have formed a key research interest now for many years. The focus for these inquiries is diverse, ranging from local initiatives (such as those affecting waste management or household energy use) through to international-level environmental negotiations over complex, “transboundary” issues. Given its prominence as an emblematic environmental issue, another major focus is found in climate change adaptation policies, with many choosing to explore the prospects for more sustainable modes of consumption and ecological behavior patterns in the future (Pelling 2010). In line with the emergence of complex governance networks, particularly since the 1990s, the focus of this research encompasses not just state governmental actors, but also businesses, consumers, and other civil society groups.

Research in this strand does not explicitly critique the interpretive frameworks through which environmental problems are identified and addressed in wider society. Rather, it can be viewed as contributing greater levels of sophistication to conventional environmental impact assessment processes, in the sense that it supplies detailed and nuanced evidence about the
consequences of particular measures, as well as explanations of how and why these consequences vary over space. An implicit aim, therefore, is to identify more efficient, fair, or otherwise desirable means of implementing existing environmental policies in the future. In this respect the potential audience for such work goes beyond academic communities to include the very groups and actors whose attempts to intervene in society–environment relationships are being studied. Future research in this area is likely to continue to address a diverse range of environmental practices, including the “greening” of the private sector, the inducement of more environmentally friendly behavior amongst individuals and communities, and the impacts of various state interventions designed to help promote more sustainable forms of socioeconomic activity.

**Political economic approaches to environmental policy**

A more critical take on environmental policy is offered by research that adopts the tenets of political economic analysis, drawing directly from earlier Marxist and neo-Marxist work in economic and political geography. Here, environmental transformations of various kinds are seen as inextricably intertwined with power relations, social inequalities, and livelihoods. Research focuses on environmental policy and its effects in both the developed and the developing world, but also goes beyond the mere assessment of those effects to question the deeper worldviews and value judgments that underpin dominant problem definitions and preferred policy solutions in particular social contexts.

Perhaps the most significant recent strand of research in this guise explores the ways in which neoliberal market principles have been applied to contemporary environmental governance (Castree 2008). Scholars here have sought, for instance, to explore how, and with what consequences, natural resources are “produced” (or socially constructed) by capitalist societies. The transformation of previous public goods such as drinking water into private, ostensibly scarce commodities, a process labeled by Harvey (2003) as “accumulation by dispossession,” is particularly well studied in this regard. Additional research examining extractive industries (whether relating to fossil fuels or other biophysical resources) has, similarly, illuminated the inherently unequal social and economic effects of capitalist resource governance regimes. In many cases such research has also sought to document how the irrevocably material character of biophysical resources is itself consequential for the ways in which they are then appropriated, commoditized, and marketed. Since the very status of natural resources as *nonhuman* elements of the production system often precludes their full integration into capitalist production and distribution systems, researchers have been prompted to explore in depth the complex politics of resource access, use, and environmental impact in different settings.

A further and related area of work in this strand, though arguably with a longer lineage and a strong bias towards American contexts, is found in environmental justice research. This overtly political subfield explores the social processes, political interests, and institutional structures that collectively determine the distribution of negative environmental externalities associated with industrial capitalism. These externalities include toxic pollution of rivers, groundwater, or air, or else relate to the siting of potentially dangerous industrial facilities (such as nuclear power stations), usually in locations inhabited disproportionately by groups with low levels of resilience and insufficient resources to move elsewhere. Having long been associated with the environmental justice movement in
the United States, such research aims not just to document the unequal distribution of these environmental impacts, but also to advocate for measures that would serve to redress them, whether through holding polluters more firmly to account for reducing their waste outputs, or through better representing the interests and rights of vulnerable groups in society in the environmental planning process.

In addition to these streams of activity, critical research of this kind has also been undertaken in developing world contexts. Sometimes referred to as “third world political ecology,” this work seeks, at the broadest of levels, to document the interrelations of environmental policy, development, and livelihoods in non-Western societies, particularly in the rural context. A particularly fecund strand of work, dating back to the 1980s at least, has for instance explored the politics of conservation initiatives in the developing world, and particularly their consequences for local communities and land users (Adams 2009). More recent research, meanwhile, has centered on the governance of food and bioenergy production systems. Policy measures ranging from biofuel targets in the Global North, through to renegotiated land tenure arrangements and even intellectual property laws, are frequently interpreted here as “neoliberalizing” tools designed to concentrate the ownership of land, water, seeds, and other agricultural inputs into the hands of a few powerful actors. Particularly in the context of anthropogenic climate change, the consequences of these arrangements for local and regional food security in the Global South, as well as for land rights, are argued to be potentially profound.

Environmental policy as the coproduction of knowledge and social order

In a manner quite distinct from Marxist political economy, a further set of critical approaches to environmental policy serves to examine the construction, and political effects, of knowledge about the environment itself. From this perspective, knowledge is viewed not as an epiphenomenal variable in environmental decision-making, but as an independent variable of considerable consequence, particularly where the initial meaning of an issue is socially contested, or otherwise obscured through epistemic uncertainty. The fundamental starting point for all of these strands of work is thus the outright rejection of a view in which science (knowledge) and politics (power) can ever be kept separate from one another. Researchers instead regard environmental knowledge and wider policy objectives as fundamentally coproduced. Whilst the theoretical terminology used in this field is often overtly poststructuralist – key works have explored the influence of “discourse” and “framing” over environmental decision-making, for instance – it stops short of endorsing outright relativism. Facts and values may well be inseparable, but this does not mean that all environmental knowledge is fictitious. The claim made is simply that the definition and meaning of all environmental problems necessarily emerges from the complex interaction of knowledge and evidence with other more material and institutional factors, and that the terms of this interaction are influenced by wider social, cultural, and political contexts.

Much geographical work in this subfield has drawn on theoretical ideas developed in the policy sciences, science studies, and science and technology studies to explore the role of knowledge in environmental policymaking processes in the developed world. One particularly well-explored question concerns how social considerations and political interests shape the working assumptions, and thus the outputs, of environmental science, often in pervasive ways. Here work addressing the production of
knowledge about new or “risky” technologies such as genetically modified crops and nuclear power has proven influential, as has work examining the treatment of uncertainty and complexity in climate change science and global climate modeling (Demeritt 2001). Closely related work has also explored the social and political processes through which environmental expertise, as a supposedly superior category of environmental knowledge, is established in relation to particular problems. The rise of market-based measures in the environmental sphere, for instance, has witnessed a concomitant increase in the credibility of knowledge produced by environmental economists and ecological economists, particularly within policymaking circles. Expert or “policy-relevant” knowledge, for this perspective, cannot be defined in a vacuum, but gains its status in relation to wider power relations that serve to perpetuate particular sets of normative beliefs (Owens 2005).

The potential ramifications of uncertainties for environmental decision-making, both epistemic and ontological, have also served as a clear focus for research in this field. Work on risk management practices in the context of natural hazards, for instance, has documented both the intensely subjective ways in which uncertainties are interpreted, and the sociocultural factors that influence what counts as a tolerable risk for different groups in different contexts. More recent work has subsequently extended these insights to the governance of wider environmental risks, highlighting “lay expertise” (or citizen science) as a source of knowledge about complex problems that is no less valid or rational than science itself. A key contention implicit in much of this work is therefore that environmental policymaking should be institutionally recast to facilitate more participatory and inclusive deliberation, in which multiple rationalities and perspectives on problems are valued equally. Instead of privileging only scientific knowledge and evidence, diverse groups of actors should be allowed collectively to define both the initial objectives of policy, and the best means of achieving those objectives. Recent transdisciplinary and experimental research work undertaken in the context of flood risk in the United Kingdom, for instance, has outlined the potential value of precisely these types of institutional reconfigurations (Lane et al. 2011). Despite such advances, however, significant difficulties remain in determining what counts as a successful or effective mode of participatory governance, just as they do in bringing about genuinely inclusive deliberation on environmental issues at scales beyond the local.

More-than-human approaches to environmental policy

Despite providing a wealth of insights into the nature and consequences of environmental policy processes, geographical work in the previous two strands has been criticized by some for focusing too exclusively on human accounts of the environment, and for privileging human agency over that of other, nonhuman actors. An increasingly prominent strand of research that counteracts this trend has therefore emerged, particularly since 2000, with its roots to be found initially in actor-network theory (Latour 2005). At the most fundamental level, research of this kind seeks to account for the agency of the “more-than-human” world in determining the outcomes of environmental policies, with the modernist dualism of society and nature being rejected outright in favor of a new, “hybrid” ontology.

This hybrid geographical approach has significant implications for our understanding of the objects, and objectives, of environmental policy. Categories labeled by humans as “society” or
“nature,” “human” or “animal,” far from being ontological givens, become from this perspective the contingent outcome of a network of interrelations amongst diverse actors (or actants). Work exploring the governance of genetically modified crop trials, for instance, might pinpoint not just scientific research and human intentionality, but also bees, butterflies, and bacteria as independent, autonomous agents whose interrelations with one another, and with humans, have the potential to generate entirely unexpected or undesirable outcomes (Bingham 2006). By exploring specific, situated human–animal relationships, a burgeoning new literature on “animal geographies” has also sought to demonstrate the diverse ways in which nonhumans might impact profoundly on the outcomes of conservation and agroecological policies, in a range of settings. Far from imposing a fixed, human-centric view of what counts as pristine wilderness (or simply what counts as natural) upon particular animals, such work contends that conservationists would gain much from embracing the openness and contingency of nonhuman species’ “lively biogeographies” (Lorimer and Srinivasan 2013). In the urban context, for instance, an appreciation of the more-than-human agencies that enable some species to adapt to ostensibly “unnatural” city environments forces us to re-evaluate dominant conservation agendas, from both an ethical and a political perspective.

Progressing environmental geography: the need for indigenous theory and policy impact

Over a decade ago, Castree (2004) remarked of his surprise that geographers had not interrogated more deeply the implications of the term “environment,” choosing instead to direct critical scrutiny towards its close correlate – nature. Though it has often been taken for granted as a category of academic inquiry that is distinct from the economy, culture, politics, or society, in reality – and as the brief account of the geographical research agendas outlined above has made clear – environmental issues are always inextricably economic, cultural, political, and social issues as well. Today, it is arguable that only more-than-human approaches to understanding society–environment relations have made real headway in exploring the full implications of this complexity. Even here, moreover, and despite geography’s claims to be the first truly environmental discipline, the most progressive and influential contributions frequently draw on theoretical approaches derived from other parts of the social sciences and humanities.

Future geographical work addressing environmental policy certainly has a rich array of contemporary problems and issues to address, particularly in an era that is almost certain to remain dominated by global climate change. The emergence in the past 10 years of the concept of the Anthropocene – a supposedly new geological era in the Earth’s history characterized by un fettered human influences on the environment with potentially irreversible consequences – has in some senses begun to initiate a paradigm shift in the way that policymakers, scientists, and other academics conceptualize society–environment relations. This is an era ripe with opportunity for geography to establish itself as a discipline with something unique and crucial to say about changing environments, how they might best be governed, and to what sorts of equitable and sustainable ends. Contributions of uniquely geographical provenance to these debates, however, remain rare. One clear exception is found in Mike Hulme’s (2009) groundbreaking book, Why We Disagree About Climate Change, which calls for a “re-culturation” of climate policy to
ENVIRONMENTAL POLICY

take better account of the diverse, place-specific ways of knowing and living with changing climatic conditions. Whilst these ideas may take some time to impinge on dominant, broadly global approaches to understanding climate change, they should nonetheless be applauded for demonstrating the special contribution that geography as a discipline can offer in the context of this complex environmental issue.

Ultimately, whether the issues addressed by future work in geography are familiar (involving questions of environmental justice, of pollution control, or of engendering more sustainable lifestyles) or novel (centering on geoengineering, on the prevention of new biohazards resulting from climate change, or on the political implications of scientific efforts to map so-called planetary boundaries), for researchers to be content with the mere expansion of pre-existing, insular literatures on environmental policy would represent a major dereliction of their wider social responsibilities. Pushing for greater policy impact on environmental issues must become a central priority for geographical researchers in the coming years and decades. Though their work on environmental policy to date has seen much progress forged in academic circles, for geographers to make the leap towards real, tangible progress and practical influence of this kind will arguably require them to “fly the nest” offered by wider social scientific theory and develop their own, indigenous approaches to understanding and resolving the most pressing issues of the twenty-first century.

Environmental racism

Laura Pulido
University of Southern California, USA

The concept of environmental racism emerged in the United States in the 1980s to refer to the socially uneven distribution of pollution and resources along racial lines. The term “environmental justice” initially referred to the movement that arose to confront environmental racism, but has since expanded to encompass multiple forms of environmental inequities and problems. The term “environmental (in)equality,” which is also used in relation to environmental racism, refers to the goal of a more equitable distribution of pollution and environmental amenities, and is frequently used by policymakers and some researchers. Many activists see the term “environmental equity” as a depoliticized concept devoid of a larger critique of structural racism, economic inequality, and environmental degradation. Accordingly, both “environmental racism” and “environmental justice” are more oppositional terms than “environmental equity.” Some have aptly described environmental justice as a marriage of environmentalism and social justice.

Origins of the term

Most scholars trace the origins of the term “environmental racism” to Warren County, North Carolina, in 1982. Trucks had been dumping soil tainted with polychlorinated biphenyl (PCB) along the side of the road in the area. Subsequently, officials decided to site a dump in Warren County. The county, which contained both African American and white residents, mobilized in opposition; however, a number of the African American leaders involved in the struggle had long histories in the Civil Rights Movement and consequently drew on its tactics, such as civil disobedience, and applied a racial frame to this particular problem, which became known as “environmental racism.” The Reverend Benjamin Chavis is often credited with having coined the term. Scholar and activist Robert Bullard (2000/1990, 98) defines environmental racism as “any policy, practice, or directive that differentially affects or disadvantages (whether intended or unintended) individuals, groups, or communities based on race or color.”

Although the struggle of Warren County was extremely important, it must be placed within its larger historical context. In fact, Warren County was just one of many communities experiencing extreme pollution problems. Other communities that attracted widespread attention at the time include Love Canal, New York, and Times Beach, Missouri. Activists from these communities began connecting and developing their own identity and discourse as the “anti-toxics movement.” Indeed, as Luke Cole and Sheila Foster argue in their book From the Ground Up: Environmental Racism and the Rise of the Environmental Justice Movement (2001), the movement arose from multiple strands, including the Black Civil Rights Movement, the labor movement, Native American struggles, the mainstream environmental movement, and the antitoxics movement. Of these various strands, environmental racism arguably became

the most prominent strand within the larger environmental justice movement.

The environmental justice movement

While many activists identified with and laid claim to the term “environmental justice,” the section of the movement focused on racism was able to gain the most traction. This was reflected, for example, in the National People of Color Environmental Leadership Summit in 1991, a research agenda focused heavily on race, Executive Order 12898, and the fact that the Environmental Protection Agency established an Office of Civil Rights. Although these initiatives did not serve only communities of color, there was no doubt that they had been inspired by charges of racism and inequality. During the 1980s and early 1990s the last embers of the Civil Rights Movement were still burning, and evidence of racial inequality was sufficient to trigger a reaction. Moreover, activists emanating from the Civil Rights Movement and other antiracist struggles built on earlier strategies that they felt had been successful, such as the Civil Rights Act and the Voting Rights Act, or at the very least were familiar. In many ways, environmental justice can be seen as one of the last struggles when the state gave at least lip service to racial equality – before neoliberalism became fully entrenched. In contrast, discriminating against communities because they are poor has never been illegal or even recognized as a problem in US society and culture.

Regardless of this tension, all environmental justice activists shared an outsider’s position, as they were not part of the mainstream environmental movement. Focusing on other priorities, the mainstream movement was slow to get involved in environmental racism. Environmental justice activists did not hesitate to critique the elitist and exclusionary nature of the mainstream movement as well as state regulators. They demanded transparency and accountability on the part of the state and polluters; challenged the privileged place of science in the policy process, especially when it overlooked or dismissed local knowledge; insisted on the need to prioritize local, everyday environments; and challenged the perceived elitism of mainstream environmentalism. This culminated in a letter sent to 10 leading environmental organizations in 1990 not only charging them with being racist, but also making clear that they did not speak for those communities in which they were not embedded, namely working class and communities of color. The idea “We speak for ourselves” emerged as a powerful theme of the environmental justice movement.

As increasing numbers of communities were impacted by pollution, they began to form networks to share knowledge and support each other. These networks were both geographically based, such as the Southern Organizing Committee for Economic and Social Justice and the Southwest Network for Environmental and Economic Justice, as well as racially based, as can be seen in the Indigenous Environmental Network, the Asian/Pacific Environmental Network, and the National Black Environmental Justice Network. In addition, several resource centers emerged around the country, such as the Environmental Justice Resource Center at Clark Atlanta University, which serves local communities battling environmental hazards. A second People of Color Environmental Summit was held in 2002, and numerous states have implemented environmental justice initiatives. Thus, there are a variety of structures and positions that characterize the movement.

Throughout the 1980s and into the 1990s the movement grew rapidly, and activists developed a philosophy and culture that distinguished it
from mainstream environmentalism. As previously mentioned, activists forcefully challenged conventional scientific practices and the right of mainstream environmentalists to speak for aggrieved communities. Another distinguishing characteristic of the movement was its rearticulation of the environment as “where we live, work, and play.” In so doing, activists crafted an environmental ethic centered on urban and poor places, in contrast to the environmental concerns of the mainstream movement, which were characterized as centered on wilderness and wildlife. While this was not necessarily an accurate characterization of the mainstream movement of the time, there is no denying that it was overwhelmingly white and paid less attention to the urban, public health, and land-use issues which have become associated with the environmental justice movement.

A key point in the development of the movement came in 1991 when the First National People of Color Summit was organized in Washington, DC. This event united hundreds of activists from across the United States to strategize and pressure the federal government to act. Subsequently, in 1994 President Clinton signed Executive Order 12898, which mandated federal programs to design features to help them achieve environmental justice. While it did signal progress, the executive order did not offer a new remedy to fight environmental injustice. Accordingly, some activists have been pressuring for Executive Order 12898 to be transformed into an actual law. The other important achievement of the summit was the establishment of the Principles of Environmental Justice, which embody the politics of the movement in the words of the activists themselves (Box 1).

As can be seen, the principles articulate a fairly radical critique of industrial capitalism. The concerns reflect the history and experiences of people of color, poor people, and native communities. However, it has been criticized as being overly anthropocentric. Indeed, within the last five years or so there have been growing criticisms of the environmental justice movement in terms of both its efficacy and its politics. While some maintain that the movement needs to be more inclusive of the middle class, others assert that it has become far too accommodating and has lost its political edge. For example, Benford (2005) argued that the environmental justice movement has exchanged its emphasis on racism for a more generalized focus on justice. This shift made the movement more inclusive, both in terms of the antitoxics movement in the United States but also globally, since a racial analysis does not apply to all vulnerable communities experiencing environmental injustice. However, the drawback, as Benford points out, is that the discourse of “justice” is much less confrontational than mobilizing against “racism,” and such a shift has contributed to the waning political vigor of the movement. Others have suggested that the movement has become far too cozy with the state, and thus increasingly conservative. Indeed, in some assessments of the environmental justice movement it has been suggested that the civil rights framework has not led to significant improvements in the environmental quality of vulnerable communities and that a new strategy and framework are necessary.

Whatever the organizing problems of the movement, however, one cannot overlook the profound shift in US politics over the past several decades. Not only have antiracist initiatives come under attack, but so too has environmental regulation. There has been a concerted effort by corporations and right-wing activists to regain control of both the state and the larger political culture in order to create an environment more favorable for capital accumulation and white supremacy.
Box 1 Principles of environmental justice.

1. Environmental justice affirms the sacredness of Mother Earth, ecological unity and the interdependence of all species, and the right to be free from ecological destruction.

2. Environmental justice demands that public policy be based on mutual respect and justice for all peoples, free from any form of discrimination or bias.

3. Environmental justice mandates the right to ethical, balanced, and responsible uses of land and renewable resources in the interest of a sustainable planet for humans and other living things.

4. Environmental justice calls for universal protection from nuclear testing, extraction, production, and disposal of toxic/hazardous wastes and poisons and nuclear testing that threaten the fundamental right to clean air, land, water, and food.

5. Environmental justice affirms the fundamental right to political, economic, cultural, and environmental self-determination of all peoples.

6. Environmental justice demands the cessation of the production of all toxins, hazardous wastes, and radioactive materials, and that all past and current producers be held strictly accountable to the people for detoxification and the containment at the point of production.

7. Environmental justice demands the right to participate as equal partners at every level of decision-making, including needs assessment, planning, implementation, enforcement, and evaluation.

8. Environmental justice affirms the right of all workers to a safe and healthy work environment without being forced to choose between an unsafe livelihood and unemployment. It also affirms the right of those who work at home to be free from environmental hazards.

9. Environmental justice protects the right of victims of environmental injustice to receive full compensation and reparations for damages as well as quality health care.

11. Environmental justice must recognize a special legal and natural relationship of Native Peoples to the US government through treaties, agreements, compacts, and covenants affirming sovereignty and self-determination.

12. Environmental justice affirms the need for urban and rural ecological policies to clean up and rebuild our cities and rural areas in balance with nature, honoring the cultural integrity of all our communities,
Environmental justice calls for the strict enforcement of principles of informed consent, and a halt to the testing of experimental reproductive and medical procedures and vaccinations on people of color.

Environmental justice opposes the destructive operations of multinational corporations.

Environmental justice opposes military occupation, repression and exploitation of lands, peoples and cultures, and other life forms.

Environmental justice calls for the education of present and future generations which emphasizes social and environmental issues, based on our experience and an appreciation of our diverse cultural perspectives.

Environmental justice requires that we, as individuals, make personal and consumer choices to consume as little of Mother Earth’s resources and to produce as little waste as possible; and make the conscious decision to challenge and reprioritize our lifestyles to ensure the health of the natural world for present and future generations.

Scholarship on environmental racism

Scholarship on environmental racism can be divided into three categories. First, there is an established body of research that examines the relationship between race and proximity to environmental quality. This is the largest literature and what most people think of when they hear the term “environmental racism.” Second, there is a slightly smaller body of work on the efforts of activists to fight environmental racism. This literature, which includes contributions by activists, scholars, and journalists, offers many case studies and analyzes the politics, values, strategies, and cultural practices of the environmental justice movement. And, last, there is a still smaller body of work that explores the relationships between race and the environment more generally. One of the distinctive features of the first two sets of scholarship is the degree to which activism and scholarship are connected.

As part of the early effort to frame the distribution of pollution as racially discriminatory, studies were commissioned that analyzed the distribution of pollution and key variables, namely, race and income. The first two of these studies was the US General Accounting Office’s (GAO) Siting of Hazardous Waste Landfills and their Correlation with Racial and Economic Status of Surrounding Communities in 1983 and the United Church of Christ’s (UCC) Toxic Wastes and Race in the United States in 1987. These were the first systematic attempts to map known pollution sources with demographic data. The UCC study examined multiple cities across the United States, whereas the GAO study focused on the southeastern United States. These studies identified uncontrolled hazardous waste sites as well as hazardous waste facilities and landfills in selected cities and states across the country, and
compared them to the distribution of minority populations and income groups. *Toxic Wastes and Race*, in particular, was extremely significant not only in bolstering the claims of the environmental justice movement, but also in giving rise to an explosion of studies on environmental racism and inequity, more generally. While there had been previous research hinting at this relationship, such as work by Brian Berry and Susan Cutter in the 1970s, it did not invoke such a framework. The UCC study essentially announced a new field of study.

Geography contributed in numerous ways to this burgeoning research field. For example, geographers working within the tradition of hazards and risks sought to understand pollution patterns within the framework of hazards, while historical geographers provided insights into how such patterns had evolved. Political geographers raised essential questions regarding the state, rights, justice, and what constitutes fairness. Urban geographers sought to understand both the distribution of pollution and environmental justice activism in terms of larger urban processes, including gentrification, segregation, and neoliberalism. Economic geographers situated the problem of environmental injustice within a political economic framework. One subfield that was slow to embrace environmental racism and justice, but that had much in common with it, was political ecology. Perhaps because the roots of political ecology were based in the Global South and tended to be rural, whereas environmental racism had emerged in the Global North and was heavily urban, the two streams were slow to find each other. But they did and have since forged a vibrant relationship. Another closely related area of inquiry is the whole field of sustainability studies. Early on, scholars such as Berman-Santana saw the link between environmental racism and efforts to build more socially and ecologically sustainable communities.

One of the richest connections to emerge between geography and environmental racism was through geographic information sciences (GIScience). As it happened, research in the burgeoning field of environmental justice, specifically environmental racism, coincided with major advances in GIScience and geographers, among others, contributed new methods and techniques to help identify and analyze the spatiality of pollution and hazards. This includes research on such things as the best unit of analysis; clustering; and reconciling changes in census tracts over time. However, it is also true that this literature is characterized by a diversity of methodological approaches, which often makes drawing any definitive conclusions difficult.

While much of this research was concerned with testing hypotheses and new methods, there is also no denying that there were political motivations. Just as some scholars hoped to challenge the claims of environmental justice activists and show that racism and/or classism was not a factor, others were equally committed to showing that they were significant variables (recall Bullard’s definition of environmental racism). This contestation was the most palpable around racism. As previously mentioned, targeting poor communities does not seem to be politically problematic in the United States, but targeting communities based on race is recognized as unacceptable. The work of sociologist Robert Bullard deserves special mention in this context. Bullard’s book, *Dumping in Dixie: Race, Class, and Environmental Quality* (2000/1990), was the first scholarly text examining the question of environmental racism in the United States. Focused in the southeastern United States, Bullard’s work analyzed various forms of pollution and employed multiple methods to explore both the demographics and politics of environmental racism. His work was generative in that, along with *Toxic Wastes and Race in the United States*,
it not only inspired many other studies but also identified a series of issues which scholars would subsequently address, including: What is the best spatial unit of analysis? What constitutes a risk? What is the process by which people of color and working-class people become disproportionately exposed? What is justice? What does an environmental justice victory look like?

As noted, one of the key themes of this early literature was an intense focus on the relationship between race and class. One reason for this debate was the way conceptions of racism and economic processes were articulated. On the one hand, neoclassical concepts dominated the literature, in which race and class could be understood as distinct and separate variables, whereas studies rooted in critical human geography were more apt to see them as social processes. Another key theme was the question “Which came first, the hazard or the people?” This question reflected the position of some scholars, who maintained that environmental racism could exist only if hazards were placed near already existing communities, in effect, targeting them. In contrast, others maintained that such intraurban migrations, in which people move toward a hazard, could be understood only in light of larger racialized processes. While all of this research enhanced our understanding of the landscape of environmental racism, scholars were also talking past each other to a certain extent. As a result, while most studies of environmental racism are empirical in nature, there are also a number of conceptual and theoretical studies that grapple with these issues. Some of the more recent theoretical innovations include applying color-blind racial ideology to environmental justice struggles, exploring the racial state, and expanding the definition of environmental racism to include acts of racial violence occurring on the land.

Significant methodological progress has been made in empirical studies since the mid-2000s. Most of the early studies relied solely on data collected by the government, despite the fact that researchers have documented weaknesses in such data. In response to these problems, research teams, such as the Los Angeles Collaborative for Environmental Health and Justice (2010), began engaging in “ground truthing” with local community organizations to get a more accurate and robust understanding of local pollution sources and hazards. In this case, they trained local residents to identify potentially hazardous and vulnerable land uses in their communities that would otherwise be overlooked. Another related weakness in the data (and regulation) was an almost nonexistent ability to account for the cumulative effects of local pollutants and toxins, as most data are simply collected and counted by individual facilities. Once again, researchers have taken the first steps toward developing models that allow us to appreciate the cumulative impacts of pollution, in some cases creating “hotspots.” Hotspots refer to concentrations of pollution due to multiple sources and kinds of pollution. Researchers have long acknowledged that hotspots exist, but have not been able to map them rigorously. Building on this trajectory, and through continued innovations in GISciences, researchers have also begun to include vulnerability in such mappings, thereby portraying a more complete portrait of the hazardous landscape. Although we are only in the first generation of such work, this is one of the frontiers of environmental racism research (Pastor, Morello-Frosch, and Sadd 2013). Developing such a screening device can enable policymakers to better protect the most vulnerable communities before they are burdened by additional environmental problems and have to wage lengthy and costly battles against them.

The second pillar of environmental racism research centers on the environmental justice
movement itself. Scholars across the social sciences have studied the origins, motivations, identities, tactics, and challenges of the environmental justice movement. Early research was initially concerned with simply documenting its emergence. Its very existence was considered noteworthy because in the 1980s environmentalism was assumed to be a strictly middle-class, quality-of-life affair and not something in which the poor and people of color participated. Although most of the scholarship on the movement is rigorous, there is some work that tends toward the celebratory. This reflects the excitement of seeing historically marginalized people challenging the state and polluters, as well as the fact that researchers are often writing for dual audiences: scholars and activists. During the 1990s identity became an important topic of inquiry within social movement scholarship, and this is reflected in the literature on the environmental justice movement. Numerous scholars explored the kinds of organizations people of color created, how they understood and articulated environmental concerns, how they organized themselves, and how they interacted with the local state and polluters. While the vast majority of environmental racism research prioritizes race and class, there has been growing attention to the role of gender, in terms of both the gendered dynamics of the movement and vulnerability. Drawing on feminist and critical race theory, some scholars have begun employing intersectional analyses.

Research on the political demands, strategies, tactics, and philosophies underlying the environmental justice movement also falls into this category. One topic that both scholars and activists have discussed at length is the breadth and fluidity of the concept of environmental justice itself. On the one hand, activists deliberately challenged and broadened the conception of the environment as articulated by the mainstream movement. This expanded notion is embodied in the idea that the environment is “where we live, work, and play.” One of the strengths of this formulation is that it challenges us to never separate the environmental sphere from the social realm, so that we are always cognizant of the multiple forces constituting a subject or place. On the other hand, however, sympathetic critics have pointed out that the term is so expansive that any kind of injustice can theoretically be termed “environmental racism.” The question then becomes: Is such a broad definition helpful? Does an effective movement require a tighter point of intersection, or is it enhanced by such breadth?

Another important topic that both activists and scholars have addressed centers on the interrogation of “justice” itself. In his book *Defining Environmental Justice: Theories, Movements, and Nature* (2007), David Schlosberg identifies three forms of justice that run through the environmental justice movement: distribution, recognition, and participation. Distribution refers to the spatiality and proximity of pollution; recognition refers to the need for acknowledgment and respect; and participation is the degree to which affected communities can contribute meaningfully to the regulatory process. His work, along with that of scholars such as Ryan Holifield, has underscored that environmental justice is about much more than just the location of pollution. Equally important are the processes leading up to such patterns and the path(s) to resolution. This focus on ethics has greatly enriched the academic literature, the policy arena, and activists’ praxis.

Yet another strand of scholarship that has developed recently is cultural studies of environmental justice. This scholarship moves beyond typical social science analysis and is more rooted in the humanities. Examples of such research include analyses of toxic tours, the role of memory in environmental struggles, and the way in
which environmental problems are represented by writers and artists. This branch of work is linked to the larger world of the environmental humanities, which is currently undergoing rapid development.

As the movement has evolved, however, there have been a growing number of critiques of both the movement and its associated scholarship. As previously mentioned, some have chided the movement for becoming less oppositional. One arena where this can be seen is in terms of both capitalism and the state. One of the initial critiques of the environmental justice movement levied by corporations and others was that activists simply did not want locally undesirable land uses (LULUs) in their backyards. Activists countered that they sought to ensure that LULUs were not put in anyone's backyard. There have been, and continue to be, impressive examples of solidarity between communities to ensure that an objectionable project was not simply relocated to another vulnerable community. This was fairly radical, as activists were essentially challenging the private decision-making nature of capitalism. Accordingly, early writers saw within environmental justice the roots of a powerful critique. Some of this work has continued with a greater emphasis on the globalized nature of the economy, by highlighting economic and material flows, the uneven integration of places across the planet, and the dominance of corporate power (Faber 2008; Pellow 2007), although this research strand is not dominant. In fact, some have argued that the movement itself has lost touch with its more radical roots and is operating primarily within the space defined by the regulatory environment. There is growing evidence that, while activists spend enormous resources seeking relief from the state, and while the state has certainly acknowledged environmental racism, it has not assisted activists in a meaningful and significant way. A recent edited volume by David Konisky (2015) indicates that the federal government has failed to address environmental racism in a meaningful way. Indeed, researchers have even found racial disparities in how the Environmental Protection Agency (EPA) protects local communities. A pivotal ruling occurred in 2001 in Alexander v. Sandoval, where the court ruled that plaintiffs could no longer bring suits against entities using federal funds based on discriminatory outcomes; plaintiffs must now prove discriminatory intent, which is extremely difficult. One alternative idea that seeks to move beyond traditional remedies is the idea of environmental reparations districts. In this scenario, local communities would have powers comparable to those of historic preservation districts to ensure that vulnerable communities are protected.

Another critique stems from the fact that the environmental justice movement has not done an adequate job of connecting with labor. Despite the fact that movement activists and workers may come from similar communities and social positions, there have been relatively few times when community activists and workers were able to unite in demanding that a polluter clean up its act, while protecting workers' jobs. In many ways the classic “economic blackmail” dynamic still operates across the environmental justice landscape. This leads to yet another criticism that is actually related to, and pertains to, class. Observers have noted the movement's hesitance to take on class issues, particularly within communities of color themselves. Such tensions may stem from conflicts between workers and residents, the class position of organizers versus the larger community, and/or economic diversity within communities. The specific intersection of racial and class dynamics presents a range of challenges that require careful negotiation.

Partly as a response to these shortcomings, as well as other challenges, such as globalization,
Pellow and Brulle (2005) have called for the development of “critical environmental justice” studies, which tackle these issues directly. Such a call suggests the maturing nature of the field. Signs that the call is being heeded are evident in some of the most recent work, which not only draws on sophisticated theoretical insights but moves beyond hagiography and does not hesitate to critique the movement itself.

The third and last area of scholarship centers on the question of race and the environment more generally. Essentially, the environmental justice movement, by focusing on race and inequality, challenged dominant narratives of human–environment relations and essentially called for a rewriting of environmental history. This is a vast project that entails rethinking people’s historical and contemporary experiences with the environment in light of inequality and power. Although the term “environmental racism” only came into being in the 1980s, it does not mean that societal inequalities were not manifest in the environmental arena earlier. Indeed, one could argue that all indigenous history, as well as the history of slavery, for example, can be seen as environmental history (see, e.g., Carney 2002). While social inequality never characterized environmental studies in general, some scholars have acknowledged such social relations – but they lacked a systematic framework and scholarly context for discussing them. Increasingly, scholars are going back and reinterpretting such fields as environmental and urban history (Taylor 2009), in light of new understandings of the connection between race, inequality, and the environment. This project is still in its infancy.

One example of this kind of work is by sociologist Devon Peña, who has studied Chicana/o agricultural communities in southern Colorado. His focus on land encroachment, the commons, acequias (communally maintained water systems), and heirloom seeds has comprised an important stream of research that has not only challenged traditional assumptions about the nature of family farms, but also insisted that the environment be taken seriously by Chicana/o studies (Peña 1998). While Peña does not hesitate to show the structural challenges these farmers encounter, his research is extremely important in that not only does he discuss a community of color far beyond the realm of urban toxics, but he indicates the breadth and depth of environmental issues for all communities. Carolyn Finney (2014) has also pursued a distinctive path with her work on African Americans and the National Park Service. She has explored not only how African Americans have historically experienced parks, but also how they are represented within the larger context of wilderness. Like Peña, she extends her analysis back hundreds of years and compels us to reconsider what we think we know about social forms of domination and the environment.

One of the findings to emerge from this scholarship is that important differences exist between the relationship of various communities of color with the environment. While much of the environmental justice literature refers simply to “people of color,” this term overlooks important distinctions. For instance, while indigenous people are always included as a group facing environmental racism and have been extremely active within the environmental justice movement, they have not always embraced the term “environmental racism.” Some argue that native peoples are distinct from racial minority groups in that they are nations, and the concept of racism is not adequate to the task of describing or analyzing their situation. Accordingly, some have applied the concept of settler colonialism to better understand the environmental hardships and struggles that native peoples have experienced. Settler colonialism
not only elucidates the multiple injustices and power relations embedded, for example, in the proposed Tar Sands pipeline (Preston 2013), but also draws attention to the fact that the land on which most US national parks and wilderness sit once belonged to native peoples who were forcibly removed in order to make room for new owners and uses.

Asian/Pacific Islanders also have a very distinct relationship to the environmental justice movement. Almost all studies of environmental racism, that is, disparities, center on African Americans, Latinas/os, and indigenous peoples. Only rarely are Asian/Pacific Islanders included, and, consequently, there has been little evidence that they are impacted in a comparable way, primarily because of spatial and economic patterns; however, Julie Sze (2011) has argued that even though Asian/Pacific Islanders don’t register significantly in terms of distributitional justice, the story changes if we switch the lens and consider procedural justice, in which Asian and Pacific Islanders, especially immigrants, are routinely overlooked and excluded. Sze also reminds us that Asian/Pacific Islanders have been an essential part of the environmental justice movement, as individual activists, scholars, and policymakers, through the Asian Pacific Environmental Network (APEN), and in multiracial formations.

In contrast, the environmental disparities and challenges that both African Americans and Latinas/os face have been more thoroughly documented. As large, primarily urban groups, both populations have been studied in terms of their geographic proximity to pollution. Because these two groups are highly urbanized, disproportionately low-income, and residentially segregated, they register far more frequently as impacted communities. In addition, given their concentration as low-wage workers performing some of the most dangerous work, there has also been some attention given to the workplace hazards they encounter, especially Latinas/os.

A key event that enabled many people to see the deep and pervasive nature of environmental racism was Hurricane Katrina. When Katrina struck New Orleans in 2005, it became apparent to millions of people exactly how poverty, residential segregation, and racism operated to create a disaster resulting in the disproportionate deaths of African American residents, and also how racism has shaped the rebuilding of the city. Whereas previously many were willing to see racism as a hostile, discriminatory act, Katrina showed how systematic neglect and disinvestment could produce landscapes of environmental racism. Many scholars and activists took the opportunity to study Katrina and to use it as a symbol of environmental racism, with a particular focus on the structural disadvantage that characterizes much of African American life.

While there is no denying the tremendous impact that the environmental justice movement has had in producing a new paradigm centered on inequality and justice that has resonated far beyond narrow conceptions of the environment (e.g., climate justice, food justice, transit justice, energy justice, etc.), the future of environmental racism as a concept is uncertain. As previously discussed, given the political shift toward the right in the United States, it has become increasingly difficult to make claims based on race in the courts, and large swaths of environmental law and regulation have been seriously weakened. In response to this situation, some have suggested that a human rights framework may be more effective and that activists need to operate more in the international arena. Indeed, globalization presents both opportunities and challenges to environmental justice activists. On the one hand, the concept of environmental justice, broadly defined, has found a global audience and the term is frequently used to denote instances when
poor, vulnerable, and nonwhite communities are being exploited, killed, displaced, and polluted. For instance, the struggle of the Ogoni people of Nigeria against oil producers is generally recognized as an environmental justice struggle, as is the Union Carbide disaster in Bhopal, India, and its aftermath. While the injustice is obvious, these examples are not typically conceptualized as racial. Thus, there is a clear need for activists and scholars to work on reconceptualizing the key terms and structures of the movement. What is the relationship between environmental racism and environmental justice, given that the latter has expanded significantly? How do these various pieces function together? While US activists generated the concepts of environmental racism and environmental justice and offered them to the world, they have not been as open to learning and drawing from global experiences, despite the fact that environmental struggles on the part of the poor and dispossessed are rampant today. In many ways, the concept of environmental racism remains very much rooted in the US experience. Although there are many opportunities to open up a dialogue and to move toward a more global movement, it remains to be seen where the environment justice movement will go.

Defining environmental regulation

Environmental regulation refers to the means, mechanisms, and actions used to achieve behavioral control and influence over target groups in the field of environmental protection. Traditionally, environmental regulation has been interpreted to mean forms of regulatory authority promulgated by state actors through detailed, prescriptive, and legally binding rules. Yet this narrow perspective has increasingly given way to a much broader conception of environmental regulation which encompasses a wider range of regulatory actors, approaches, and forms of control (Gunningham 2009; Fiorino 2006). This expanded interpretation of environmental regulation reflects a more sophisticated scholarly understanding regarding the “who” and “how” of environmental regulatory influence – that is, the actors who promulgate regulatory control and the instruments through which they do so. Moreover, it reflects ongoing shifts in an underlying reality, most commonly associated with a growing role for nonstate actors in environmental regulation, and the adoption of so-called smart regulatory strategies by state ones.

Typologies of environmental regulation

Environmental regulation has been categorized in a number of ways. One common way is according to the actors and sources of authority. A distinction is therefore frequently drawn between state and nonstate forms of regulation – also framed as between public and private regulation. As its name suggests, public environmental regulation involves the promulgation of regulatory control, influence, and actions by governmental actors. Along similar lines, private regulation involves nonstate authority, wherein environmental standards, expectations, and activities are developed, implemented, and enforced by private actors. Private/nonstate actors, in turn, can be further subdivided into civil and market actors. Civil actors comprise individuals, community groups, and nongovernmental organizations (NGOs), while market actors include firms and business associations. Regulatory influence and control exercised by these three groups are referred to as government (state), civil, and market (self-) regulation, respectively.

More recently, attention has focused on so-called hybrid and co-regulatory forms of regulation. Underpinning this interest is the observation that environmental regulation may also be achieved by combinations (or “constellations”) of different actors who interact, cooperate and collaborate to realize collective goals (Steurer 2013). Three main co-regulatory arrangements exist: (i) public co-regulation between state and market actors, also variously
labeled government–business and public–private partnerships; (ii) public co-management involving state and civil actors; and (iii) private co-regulation, also known as private–social and business–NGO partnerships, involving joint action by market and civil actors.

A second way in which environmental regulation has been classified is in terms of regulatory instruments (Wurzel, Zito, and Jordan 2013). Instruments can be understood as the tools or techniques through which regulatory control is exercised and policy objectives are achieved. Although a number of competing typologies exist, four broad categories of instruments are commonly identified: (i) directive-based standards; (ii) market-based instruments; (iii) voluntary approaches; and (iv) information-based approaches. The last three categories are described as new environmental policy instruments (NEPIs).

Directive-based standards attempt to achieve regulatory goals through the promulgation of technical rules (or standards) by the state, backed up by various administrative or legal penalties to incentivize compliance. Also known as command and control (C&C) instruments, they comprise a command (i.e., what a particular regulatory target must achieve) and a control (i.e., a sanction for noncompliance). The actual command can take a wide range of forms from ambient and emission standards, technology-based standards, through to product- and process-based standards. In practice, C&C can be anticipatory in nature, requiring regulatory targets to achieve certain standards prior to the commencement of an activity (e.g., through permitting processes), as well as continuing to control activities once they are operational. To take one example, in order to receive clearance for sale in domestic markets, many countries require new motor vehicle types to meet prescribed tailpipe emission standards, measured in a test facility over a specific driving cycle (i.e., the anticipatory control). Once on the road, individual vehicles are invariably subject to further rules, obliging owners to obtain a test certificate on a periodic basis to demonstrate conformity with in-use emission standards (i.e., the continuing control).

Directive-based standards provide a transparent, familiar framework of environmental regulation which, assuming compliance by regulated parties, offers timeliness and certainty of outcomes. This makes C&C particularly well suited to regulating substances where an immediate, outright ban is required, such as in the case of highly toxic chemicals with potentially serious environmental or human health effects. However, a frequent criticism of standards is that they are overly detailed, inflexible, and ultimately expensive. All regulated parties are required to comply with the same standard, irrespective of their abatement costs or availability of alternative abatement options, meaning that C&C may not achieve environmental goals at the least overall cost for society. Directive standards have also been criticized for failing to offer incentives to abate beyond prescribed requirements and for discouraging ongoing innovation. Additionally, critics have pointed to the high monitoring and enforcement requirements of C&C standards (particularly in the case of multiple, distributed sources of degradation), and their potential to create adversarial relationships between government regulators and regulated parties.

Market-based instruments (MBIs) are a second set of regulatory instruments. MBIs use financial incentives (and disincentives) – as opposed to prescriptive standards – to influence environmentally relevant behavior. There are two main types. The first are so-called price-based instruments which can be further broken down into eco-taxes and subsidies. Eco-taxes seek to reduce environmental “bads” by internalizing the costs of environmental damage into market
users are required to pay a tax for the use of the environment (e.g., as a resource in production or as a sink for pollution) – thereby making environmentally damaging activities more expensive. Categories of eco-taxes include user charges (e.g., taxes on waste sent to landfill), emission charges (e.g., on NOx emissions), sales taxes (e.g., on pesticides used in agriculture), and deposit refund schemes (e.g., for drinks containers). The aim of subsidies is to increase the supply of environmental “goods” by paying actors for environmentally beneficial choices, activities, and investments. Residential feed-in tariffs, whereby households are paid a preferential rate for supplying electricity from small-scale renewables to the grid, are one contemporary example of an environmental subsidy.

Quantity-based instruments are a second type of MBI which, in the realm of environmental regulation, mainly comprise tradable permit (TP) schemes. These schemes involve the creation of a right – either to consume a particular resource (e.g., water) or to emit a pollutant (e.g., SO2) into the environment – which is subsequently traded within an administered market. Two subcategories of TPs exist: cap and trade and baseline and credit. Under cap and trade, a specific quantity of rights (also known as permits) equal to the overall cap are allocated to regulated parties through one of a number of possible mechanisms, for example given away for free based on historic usage/emissions or auctioned off. Individual parties are prohibited from using more resources/emitting more pollutants than the quantity of rights they currently hold, with penalties for noncompliance. However, rights can be bought and sold by parties, constituting the trade. Regulators can increase the stringency of environmental requirements by lowering the overall cap (e.g., on the total amount of pollutant releases permitted in a particular year) over time. Established cap and trade schemes include Australia’s Hunter River Salinity Trading Scheme (regulating saline water discharges), the European Union’s (EU) Emissions Trading System (regulating greenhouse gas emissions), and the United States’ Acid Rain Program (regulating SO2 emissions). In baseline and credit schemes, regulated parties are assigned a baseline, defining the maximum amount of emissions/resource usage permitted during a particular period. Actors who emit/consume less than this baseline can generate reduction credits which can be sold to actors who exceed their baseline.

According to their proponents, an important advantage of MBIs lies in their flexibility, in that they allow regulated parties to decide the actions they wish to take in order to contribute towards environmental goals. For example, a polluter faced with a carbon emissions tax could either pay the tax or chose to reduce emissions through one of a number of abatement channels (e.g., switching to a less carbon-intensive fuel or investing in more carbon-efficient process equipment), selecting whichever option is cheapest. Precisely because of this flexibility, and the ability of the “invisible hand” of the market to distribute environmental effort towards actors who can undertake environmentally beneficial actions most efficiently, it is suggested that MBIs are cost-minimizing for society as a whole. MBIs also create ongoing incentives for low-cost abatement and for cost- and environment-efficiency-enhancing technological innovation. Critics have countered this positive assessment. Amongst others, they have pointed to the difficulties of effectively administering, monitoring and enforcing MBIs; the possibility of market manipulation by more economically powerful parties; and problems of environmental “hot spots” inadvertently emerging where polluters with high abatement costs are concentrated in the same area.
ENVIRONMENTAL REGULATION

A third category of instrument, voluntary approaches (VAs), brackets a diversity of different regulatory techniques. What unites VAs, however, is the fact that they are not mandated by law, with participants voluntarily engaging in measures aimed at protecting the environment. Several different types of VA are identified in the literature: unilateral initiatives, codes of conduct, public voluntary challenges, and negotiated agreements. Unilateral initiatives are voluntary environmental actions taken by individual firms. A case in point is 3M’s Pollution Prevention Pays (3P) program comprising an “in-house” corporate initiative aimed at supporting projects which save money through reduced pollution at source and improved energy/resource efficiency. Codes of conduct, on the other hand, are institutionalized forms of collective action orchestrated by industry associations, NGOs, and standard-setting organizations (Eden and Bear 2010). Adopters commit themselves to a set of principles, policies, and practices governing their environmentally relevant behavior. Certification schemes are a particular type of code, where participants meeting predefined process and/or product-based requirements gain recognition in terms of an eco-label or publicly recognized environmental standard. Cashore (2002) has famously invoked the concept of nonstate market-driven (NSMD) governance systems to describe such schemes in which the institution of the market provides the necessary incentives for participation and compliance. The Forest Stewardship Council (which certifies wood sourced from sustainably managed forests) and ISO14001 (a standard for certifiable environmental management systems) are well-documented examples of NSMD schemes.

Two other types of VAs involve a more explicit role for the state. Under public voluntary schemes (PVSs), the government defines a set of voluntary standards or requirements, which participating firms pledge to follow. In return for compliance, private parties may receive public recognition in the form of a state-sponsored eco-label, or else be rewarded with other inducements (e.g., regulatory “relief” from reporting requirements or public subsidies). An example of a PVS is the Costa Rican Tourism Board’s Certification for Sustainable Tourism, which provides participating tourism businesses with a certified evaluation of their beyond-compliance sustainability-related practices and performance. A fourth type of voluntary approach is that of negotiated agreements (NAs), which are bilateral agreements struck between governments and private actors. The precise nature of particular agreements and their participants vary. However, they typically involve some form of environmental target (e.g., for pollution reduction), together with a timescale over which either individual firms or entire industry sectors agree to meet the target. The Netherlands has made extensive use of NAs, with the Dutch environmental ministry agreeing a series of covenants with different industry sectors and their organizational representatives as a key vehicle to realize public environmental goals.

Much like MBIs, the strengths of VAs are assumed to lie in their flexibility and creativity. VAs harness the self-regulatory and innovative capacities of private actors to foster cost-effective regulatory actions which go beyond the “one size fits all” of directive standards. Moreover, they appeal to the logic of self-interest, providing participants with positive market incentives (e.g., such as differentiation advantage for their products), and reducing the threat of potentially costly, state-imposed regulation. By relying on voluntarism, rather than on the legal sanction of government regulators, proponents have also suggested that VAs engender a sense of positive (shared) environmental responsibility which sustains ongoing commitment. Voluntary
ENVIRONMENTAL REGULATION

approaches have nevertheless been heavily criticized, first and foremost on the grounds of their limited substantive effectiveness. A common assertion is that many VAs are vehicles for corporate “greenwash.” That is, voluntary regulations allow firms to create the impression that they are contributing to environmental goals, without necessarily bringing about significant and corresponding improvements in underlying environmental performance. The empirical literature provides some support for this claim – at least for weaker codes or PVSs with limited substantive performance requirements and/or lacking monitoring and sanctioning mechanisms (Borck and Coglianese 2009).

A final set of instruments are premised on influencing behavior through the provision of information to various external parties (Mol 2008). The underlying logic is that actors lack sufficient information – about environmental quality, the environmental performance of firms and their products, or even their own environmental impacts. Information-based regulation addresses informational failures and, in doing so, empowers various stakeholders to take regulatory actions. As citizens, for example, communities can use information to put pressure on polluters, politicians, and/or environmental agencies. As consumers, individuals can use information to guide their purchasing decisions, providing firms in relevant product markets with an incentive to improve their performance. As investors, actors can penalize poorly performing firms (e.g., by selling their stock), and reward those with superior environmental performance (e.g., by lowering the cost of capital).

One of the most widely documented forms of informational regulation is public disclosure, of which there are two main types. Pollutant Release and Transfer Registers (PRTRs) make data available to the public on the volume of specific pollutants emitted and/or transferred off-site by particular firms. Two prominent cases are the United States’ Toxic Release Inventory and the EU’s European Pollutant Release and Transfer Register (formerly European Pollutant Emission Register). Performance evaluation and ratings programmes (PERPs) go one step further, in that regulators use data to produce publicly available environmental ratings of individual firms. Indonesia’s Program for Pollution Control Evaluation and Rating (PROPER) falls into this category, with public regulators assigning a graded color code to firms corresponding to their level of environmental performance. Disclosure-based initiatives have also increasingly been enacted by private actors, including business groups and NGOs, in areas such as climate change. A high-profile example of the latter is the CDP (formerly the Carbon Disclosure Project), a nongovernmental organization sponsored by major institutional investors, which collects and reports information on the greenhouse gas performances, policies, and practices of thousands of private companies across the globe.

Eco-labels constitute another type of information-based regulation. Eco-labels can be voluntary, yet labeling can be mandated by governments through regulations requiring producers to provide environmental information on their products to relevant stakeholders. A growing number of countries therefore require manufacturers of various electrical goods to provide standardized energy labels for their products. Governments can also empower citizens through freedom-of-information legislation, requiring public bodies to disclose environmental information that they hold in response to citizen requests.

Themes in environmental regulation

Underpinning much of the recent work on environmental regulation is the idea that it is undergoing significant change, characterized
ENIRONMENTAL REGULATION

by three ongoing dynamics: (i) the reform of public environmental regulation; (ii) a growing role for nonstate actors; and (iii) the rescaling of environmental regulation. The rest of this section outlines these dynamics.

Reform of public environmental regulation

A first key theme in the literature is the reform of public environmental regulation and the shift from a first to a second generation of regulation (Fiorino 2006). First-generation regulation, which came to the fore in countries such as Germany, the United States, and Japan during the 1960s and 1970s, is commonly described according to several distinguishing characteristics. One is that it was predominantly concerned with controlling local, visible, and point sources of environmental degradation (e.g., air pollution from power plants). Second, it was predicated on centralized, hierarchical regulatory power, exercised by state institutions. Hence first-generation regulation was largely achieved through media-specific C&C instruments, implemented and enforced by newly created environmental regulatory agencies. Third, it was technocratic, underpinned by a belief in expert science, and the idea that environmental problems could be solved through modern technological solutions. Many of these solutions involved end-of-pipe technologies (e.g., catalytic converters fitted to vehicle exhausts), which capture pollutants after they have been produced, rather than prevent their generation in the first place.

The reality of first-generation environmental regulation was – perhaps unsurprisingly – more complex and geographically variable than these stylized descriptions suggest. To take one example, important differences have been documented in the way that C&C was implemented by regulatory agencies across countries. An early contrast was made between the US approach, described as rigid, sanction-based, and adversarial, and the UK one, characterized as flexible, compliance-based, and cooperative (Gouldson 2004). Typically, such variations have been explained in terms of so-called policy or regulatory styles, indicative of underlying institutional traditions. Significant differences have also been noted in the degree to which public regulators made use of instruments other than C&C.

Notwithstanding these differences, observers have pointed to a shift towards a second generation of environmental regulation in many developed countries. This second generation seeks to address a new set of environmental challenges. Amongst others, these include forms of environmental degradation which are more diffuse in origin (e.g., agricultural runoff); lack the visibility of many first-generation pollutants (e.g., volatile organic compounds); are characterized by scientific uncertainty, ambiguity, and contestation (e.g., genetically modified organisms); and are closely bound up with the daily lifestyle choices of citizens (e.g., CO₂ emissions).

Another distinguishing characteristic of second-generation regulation is that it has attempted to move away from a predominant reliance on technical rules, legal coercion, and state monitoring systems. Instead, the emphasis has been on the development of more cooperative, less prescriptive forms of regulation which leverage the self- (and co-) regulatory capacities of nonstate actors. To this end, regulatory agencies have innovated, experimented, and applied a range of more flexible, collaborative forms of NEPI. The result is a policy instrument mix that includes not only C&C, but also a variety of MBIs, VAs, and informational approaches. The strategic use and orchestration (by government regulators) of different combinations of regulatory instruments which additionally
harness the regulatory capacities of nonstate actors is often described as smart regulation (Gunningham 2009).

A further characteristic of second-generation regulation is its emphasis on prevention. Inspiration for this preventive logic has come, in part, from the precautionary principle which has emerged as a key principle guiding environmental regulatory decision-making over recent decades. However, it also reflects growing recognition that first-generation C&C approaches did not always solve problems, but often simply transferred them across media. One practical example of this preventive thinking is the growth of integrated permitting whereby regulators issue a single permit for an entire plant, considering together all air, water, and waste issues so as to minimize overall environmental harm.

The shift from first- to second-generation regulation has formed part of a wider effort to reform – or literally reinvent – the way in which governments attempt to regulate environmental issues. Pressure to reform has been fueled by growing resentment towards C&C, both by regulated parties faced with escalating compliance costs, and by regulators themselves struggling to enforce rules. Yet, beyond these practical considerations, regulatory reform has been profoundly shaped by ideological considerations associated with the rise of neoliberalism in the 1980s and 1990s. The influence of neoliberal principles in environmental regulation – often framed as market environmentalism or neoliberal environmental governance – has been widely discussed in geography (Heynen et al. 2007). Crucial to this work is the notion that markets, market principles, and market actors are increasingly being deployed in natural resource and environmental governance. To take one example, TP schemes are predicated on processes of commodification whereby an environmental good or service (say, CO₂ or H₂O) is converted into a tradable commodity which can be exchanged for profit in a market setting.

Whilst public regulation has evolved, substantial variations have been observed in the way that second-generation environmental regulation has unfolded across space. Much of the comparative work in this area has focused on the EU, with studies revealing significant differences in the adoption of NEPIs across member states over the past two decades (Wurzel, Zito, and Jordan 2013). National contextual factors, which influence the costs, benefits, and feasibility of different choices, have figured significantly in explanations of these cross-national differences. Another related concern voiced by scholars has been the degree to which NEPIs have supplanted more conventional, directive-based approaches. A recurrent conclusion is that C&C remains a central component of the instrument mix in the majority of developed countries, although the way it is configured and implemented has become more flexible and responsive to regulatory realities (Fiorino 2006; Gouldson 2004).

Approaches by governments to environmental regulation have also been evolving in countries outside of the developed world. The literature in this regard largely examines the experience of emerging economies which, following in the footsteps of developed countries, have experimented with a range of NEPIs (Caffera 2011; Blackman 2008). A number of factors have been implicated in this trend, including: external support for new regulatory approaches from international organizations such as the World Bank; lesson-drawing and inspiration from, and emulation of, past adoptions in other countries; and the search for regulatory alternatives against a backdrop where the effectiveness of C&C has sometimes been undermined by low levels of enforcement and compliance.

A common observation – across developed, emerging, and developing countries – is that
new regulatory instruments are far from a panacea to the shortcomings of more traditional, directive-based approaches. In fact, despite their appeal (in terms of flexibility, cost-efficiency, etc.), the actual performance of NEPIs is heavily influenced by two fundamentals. One is the design of individual NEPIs in practice. There are multiple ways in which instruments such as TP schemes, codes of conduct, and disclosure schemes can be set up, configured, and put into operation. Evidence suggests that the actual effectiveness of NEPIs crucially depends on features such as the stringency, specificity, and bindingness of performance obligations together with the quality of monitoring and enforcement mechanisms (Borck and Coglianese 2009; Fiorino 2006).

Another fundamental which is known to significantly impact the performance of NEPIs is the capacity of actors to perform various regulatory functions. This includes administrative capacity, which is necessary in order for public regulators or private actors to devise appropriate regulatory schemes, effectively oversee their implementation, resolve any problems, and ensure compliance. Yet it also includes the capacity of actors to meaningfully and effectively participate in environmental regulatory schemes, systems, and programs. To take one example, the ability of civil stakeholders to act as environmentally effective surrogate regulators in the case of public disclosure schemes is known to depend on the existence of civil capacities, such as the technical knowledge and skills needed to effectively process disclosed information, as well as the resources, freedoms, and channels available to civil actors to exert regulatory pressure on firms (Mol 2008). The importance of capacity goes some way to explain why the performance of NEPIs has often fallen short of expectations in various emerging economies where they have been implemented (Caffera 2011).

The growing role of nonstate actors

A second major theme has been the growing regulatory role of nonstate actors. Within this context, an especially provocative thesis to emerge is that a transition is underway from an era of “environmental governance by government” towards one of “governance without government,” as private actors increasingly engage in the setting and implementation of regulation. The regulatory function of nonstate actors has been widely discussed in relation to market actors. Their enhanced role reflects the fact that firms are increasingly being enrolled by government regulators as part of ongoing regulatory reforms. However, market actors are also actively becoming regulators in their own right, orchestrating and participating in a wide variety of private voluntary initiatives.

A significant body of work, much of it couched within a framework of corporate environmentalism and corporate social responsibility (CSR), has documented the drivers underlying firms’ growing self-regulatory activities (Blowfield and Murray 2014). One is heightened stakeholder expectations regarding firms’ environmental performance and the fact that they can no longer simply rely on compliance with government regulation for social legitimacy. Another strand of literature emphasizes market benefits, focusing on how beyond-compliance strategies and investments can help firms to reduce their costs, increase their revenues, and mitigate business risks (Meckling 2011). Parallel to these developments, the growth of market self-regulation has frequently been associated with globalization, with voluntary schemes pursued by firms as a means to manage their cross-border environmental impacts and safeguard their reputations.

Civil actors and NGOs, in particular, have additionally played an increasingly important regulatory role over recent decades. They have been instrumental in defining and articulating
informal standards and norms of environmental responsibility. NGOs have performed a monitoring function, collecting information on governments’ and firms’ compliance with treaty obligations and public regulations, as well as the performance of firms in relation to their own commitments and societal norms of corporate responsibility. Allied to this role, they have acted as enforcement agents, using a range of tactics to bring regulatory targets into compliance with formal or informal standards. NGOs have assumed the role of private policymakers, participating in efforts to formulate, promulgate, and enforce voluntary initiatives, both by themselves and in conjunction with market actors (Eden and Bear 2010).

Recent work has also explored how individuals are being engaged in self-regulatory activities. One stream of literature has documented how governments have encouraged individual citizens to contribute towards public environmental goals through behavioral change. Amongst the domains of “pro-environmental behavior” (PEB) that have been discussed as objects of public policies are recycling, modes of travel, household energy use, and the purchase of environmentally friendly goods and services. Work has also examined the rise of ethical consumption and how individual citizens are demonstrating their normative commitment through consumption practices.

The growing involvement of private actors has been met with a mixed response. On the one hand, some have welcomed their expanded role as regulatory actors, particularly in areas where traditional forms of state-centric regulation have proved ineffective. Nonstate actors bring new resources, incentives, and regulatory architectures to the pursuit of collective environmental goals. Yet many others have been more critical. A recurrent focus of this critique has been on civil regulation and its representativeness, legitimacy, and accountability. Certain environmental NGOs have been accused of lacking a democratic mandate, articulating the interests of narrow publics through their regulatory actions, whilst proving inattentive to others. Questions have also been raised about the transparency and inclusivity of the (“closed door”) processes through which private codes of conduct have been made by NGOs and market actors.

Another oft-made charge is that, rather than a progressive response to evolving environmental demands, the growing involvement of market actors is a covert effort to manipulate those demands. The literature has therefore documented how certain firms (sometimes in collaboration with NGOs, as part of so-called bootlegger-and-Baptist coalitions) have lobbied for public environmental regulations as a means to disadvantage their competitors who face higher compliance costs. Critics have further suggested that market actors have purposely sought to narrowly enframe and shape environmental regulatory solutions in ways which do not threaten their interests and which prevent the emergence of more binding, stringent forms of regulation. As an example, advocacy by market actors has been implicated in the emergence of TP schemes in carbon. Carbon trading has allowed major polluters to accommodate growing demands for climate action, but to do so in a way which permits ongoing capital accumulation, and avoids costly carbon taxes (Meckling 2011).

Rescaling environmental regulation

A third important theme in environmental regulation has been rescaling. A core idea of this literature is that the traditional model of territorial environmental regulation is being reworked and reconfigured in multiple ways (Reed and Bruyneel 2010). More specifically, it is suggested
that regulatory authority no longer exclusively resides in a centralized state, which exercises hierarchical power vertically. Instead, authority in environmental regulation is increasingly being dispersed across a wider range of spatial scales, as well as to different actors within and between these scales. Rescaling is a consequence of a purposeful strategy of national governments to cede sovereignty – upwards to supranational bodies and downwards to governmental actors at the local level – in order to more effectively achieve their policy goals. Yet it also reflects attempts by actors to challenge the monopoly of the nation-state, to expand their regulatory competence, and to address real or assumed governance gaps in the area of the environment.

Earlier work tended to focus predominantly on the vertical aspects of rescaling. Scholars of global environmental politics have therefore examined the rescaling of regulatory authority in the intergovernmental realm. Particular attention has been paid to interstate cooperation, and the creation of international environmental agreements (IEAs), regulating issues ranging from whaling and hazardous waste through to climate change. A considerable body of work also exists on the upward rescaling of authority to supranational governmental bodies. By far the most significant of such bodies is the EU, which has emerged as an important regulatory actor over recent decades. The literature on vertical rescaling has additionally focused on the decentralization of regulatory authority to subnational governmental and non-governmental actors. Community-based natural resource management initiatives represent one example of vertical rescaling, realized through a partial transfer of regulatory authority from the state to local-level civil actors.

The past decade has further witnessed a flourishing of work on the horizontal rescaling of regulatory authority. Much of the focus has been on transnational (governance) networks which straddle national borders and, directly or indirectly, perform regulatory functions. By definition, these networks go beyond those exclusively constituted by national governments in the intergovernmental realm, in that they involve a prominent role for nonstate and/or subnational governmental actors. Within the private sphere, geographers have shown particular interest in transnational certification networks, through which market actors and/or NGOs seek to regulate environmental and social aspects of production processes and/or products across national borders (Eden and Bear 2010). Work on horizontal rescaling involving governmental actors has, amongst others, focused on transnational municipal networks comprising local authorities and municipalities (Bulkeley 2005).

**Continuity amidst change**

Although much of the recent literature on environmental regulation emphasizes change, caution should nevertheless be exercised not to overstate these dynamics. Certainly, new regulatory instruments are being deployed more widely, nonstate actors are assuming an expanded role, and regulatory authority is being spatially diffused. Yet the overall story is just as much about continuity as it is about change. Hence directive-based standards continue to play a prominent role within public environmental regulatory systems and, in the majority of countries, the state remains the single most important environmental regulatory actor. In fact, despite claims of environmental governance without government, a great many NEPIs are reliant on governments defining and enforcing rules, and even largely private forms of regulation can often be seen as operating “in the shadow of hierarchy” (Gunningham 2009). Recent dynamics are therefore best understood as a reconfiguration of state regulatory authority, with governments...
Performing regulatory functions in conjunction with a growing range of actors, and furthermore at and between a range of scales.

**Environmental restoration**

**Sally Eden**  
*University of Hull, UK*

“Environmental restoration” and “ecological restoration” refer to a range of methods that aim to repair human damage to ecosystems and landscapes. Like restoring a damaged painting or piece of furniture, the main idea is to remove traces of damage and put an area back to how it looked or functioned before humans changed it – what is often referred to as the “pre-disturbance” state. Methods used to do this include removing species, reintroducing species, recontouring and redirecting river channels, re-establishing flooding regimes on wetlands, replanting forests, and decontaminating land.

Sometimes restoration projects aim for a complete redesign of an ecosystem, including its ecological and hydrological functioning. More commonly, though, restoration projects aim only for a limited or partial improvement in a landscape or they focus on particular functions, for example, flooding, prey–predator relationships; in such cases, restoration is sometimes referred to as “environmental rehabilitation” instead. Where environmental restoration is implemented or studied by professional ecological scientists, it is sometimes referred to as “restoration ecology” or “ecological restoration,” because it is being used not only to try to repair environmental damage, but also to test scientific theories of environmental change and ecological development (e.g., Palmer *et al.* 2005).

So the term “restoration” may refer to any one of various levels of intended intervention, such as:

- creating new ecological functions or whole landscapes;
- restoring or (re)creating (some) pre-disturbance or historically defined functions or landscapes;
- reassembling (some) pre-disturbance functions;
- rehabilitating (some) functions, by repairing or reclaiming (parts of) landscapes;
- enhancing or improving functions or aspects or appearance, that is, very partial modification or minimal repair.

One example of restoration is at Wicken Fen, a national nature reserve in Cambridgeshire, England, that has been owned and run by the National Trust, a charity, since 1899. In recent years, the Trust has expanded the wetland area by digging out surrounding farmland (see Figure 1), aiming to restore it to its traditional state, that is, the type of reed wetland existing before the region was extensively drained in the 1940s. This example shows that restoration can sometimes involve *changing* one landscape (e.g., farmland) into another (e.g., wetland), using bulldozers and other earthmoving equipment or fire. This differs greatly from other forms of conservation which usually focus on maintaining a landscape in its current state and thus preventing change.

**Origins**

Restoration is the latest “wave” of environmental protection methods, following on from nineteenth century efforts at preservation...
(e.g., through designating national parks and nature reserves) and twentieth century efforts at conservation and sustainable development (see Sustainable development). Sometimes referred to as “creative conservation” (e.g., Adams 2003), restoration seeks not only to protect valued environments or features, as preservation or conservation methods also try to do, but also to repair damaged environments and, in the more extreme cases, to create new ecosystems and landscapes following human use and abandonment, such as restoring an old quarry pit into a lake for waterfowl.

One of the earliest and most famous examples of restoration began (and continues) at the University of Wisconsin-Madison’s Arboretum in the United States. Aldo Leopold, a major figure in environmental conservation and professor of game management at the University, began to restore prairie vegetation in the 1930s and 1940s by cutting, seeding, and setting fires to cultivated land. His aim was to restore the prairies to their ecological state in the 1840s, before Wisconsin was settled, cultivated, and therefore environmentally transformed by incoming Europeans.

But this pioneering effort was isolated and not promoted further after Leopold’s untimely death in 1948. It was not until the 1980s that restoration was more widely advocated and popularized as a solution for human-related environmental damage and loss of valued landscapes and ecosystems. A key figure was a successor to Leopold: William R. Jordan III arrived at the University of Wisconsin-Madison Arboretum in the late 1970s and began to practice and promote ecological restoration through his scientific and conservation activities. He helped to set up the journal Restoration and Management Notes (now Ecological Restoration), to promote the ideas and practices of restoration internationally. Through his writings and advocacy of what he has referred
to as “the restoration movement” (e.g., Jordan 2003), he encouraged environmental restoration not only as a way to improve environments and their ecological functioning, but also as a way to bring humans closer to nature through rehabilitating their local landscapes in a more “creative” form of conservation (Adams 2003) and one which Jordan (2003, 3) referred to as “a kind of gardening.” Jordan also explicitly linked “nature” and “culture” through the meanings and practices of ecological restoration and argued that this was a more positive, hopeful approach to conserving all manner of landscapes and ecologies. He also used this approach to criticize the emphasis on technical aspects of restoration in the literature and therefore to emphasize also the sociocultural performance and ritual involved in doing restoration work.

Reflecting growing interest in the 1980s, the Society for Ecological Restoration (SER) was set up in 1987 to bring together people and organizations interested in and actively practicing ecological restoration across the world. It now publishes two journals: Restoration Ecology – published by Wiley and including peer-reviewed papers on the scientific and technical aspects of restoration – and Ecological Restoration – published by the University of Wisconsin Press and including articles on the practical and professional issues facing restoration practitioners. SER also publishes an International Primer and Guidelines to encourage the normalization of restoration practice across the world. The Primer states that: “Ecological restoration is the process of assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed.” The Guidelines stated that:

Ecological restoration is the process of assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed. It is an intentional activity that initiates or accelerates ecosystem recovery with respect to its health (functional processes), integrity (species composition and community structure), and sustainability (resistance to disturbance and resilience).

SER considers that the acid test of a successful restoration is therefore that the restored ecosystem should continue to function ecologically, even after restoration projects have stopped and deliberate management has ceased.

There are many other organizations that now promote various methods for restoration. For example, in the UK, the River Restoration Network was set up to promote river restoration by acting as an information exchange for case studies and developing best practice and linking practitioners to share their experiences and expertise. Now called the River Restoration Centre, this brings together river restoration experiences across Europe and runs conferences for interdisciplinary learning between scientists and practitioners of river restoration specifically.

Ideas of restoration often challenge existing and institutionalized methods of environmental management and conservation. For example, river management by the state in the late twentieth century tended to focus on engineering-led approaches to securing water supply and preventing flooding through damming, deepening, straightening, and dredging rivers and removing wetlands. Rising interest in river restoration among practitioners in the 1990s directly challenged such traditions by arguing for more sinuous river channels (see Figure 2) and, most controversially, more flooding of river floodplains. This new paradigm did not completely replace the established ways of managing environments, as it continues to be contested, but it did expand the range of methods employed by state agencies and shifted thinking more toward “working with nature” in the interest of sustainability (e.g., Adams, Perrow, and Carpenter 2004).
Recently, restoration has increasingly been referred to as part of the notion of “rewilding” landscapes. Introduced in the 1990s, the idea of rewilding focuses specifically on restoring species and areal interrelationships, such as reintroducing predators to a landscape and connecting habitats through wildlife corridors. In the Netherlands, the organization Rewilding Europe was initially set up by four conservation organizations (WWF-Netherlands, ARK Nature, Wild Wonders of Europe, and Conservation Capital) to build a network of rewilding projects and

Figure 2  Meanders recreated on the River Skerne, northern England. With permission from AirFotos Ltd, Northumberland Water, and the River Restoration Centre.
promote the ideas and practices more widely. However, the idea of “rewilding” relies upon the contested concept of “wildness” and this makes the term both more immediately graspable in the popular imagination and also more controversial than the seemingly less provocative concept of “restoration” (see below).

So, the initial idea of restoration has taken various forms and different names in different times and circumstances, emphasizing that restoration is often based on an ideal, rather than a reality, and also that it is prey to the vagaries of both the politics of and the changing trends in environmental management.

Controversies

Since the 1980s, environmental restoration has become controversial for both practical and philosophical reasons. As noted above, proponents of environmental restoration have argued that it can have positive benefits through testing and increasing scientific knowledge and also through connecting people with nature. However, critics have argued that not only is environmental restoration impossible in practice, but also that it threatens more legitimate forms of conservation and even may be used to justify causing more environmental damage.

Is restoration possible?

There are several reasons why restoration of environments and landscapes is often regarded as impossible in practice. First, it is argued that no one can truly recreate lost ecosystems, because our knowledge of the environment and how it functions is simply not good enough to correctly design restoration and ensure that it will work. Consequently, mistakes will be made and the resulting landscape will not be what was intended; instead, greater problems and damage may occur, especially where species are being introduced or removed. Evidence of this comes from many ecological interventions in the past, for example, introducing predator species to solve an existing pest problem, only to find that the predator species itself grows to become a problem in turn. And although many examples of restoration have been implemented and studied by scientists, often this is short-term and few are monitored long-term to produce convincing evidence of the success or otherwise of restoration work on ecological functioning (Palmer et al. 2005).

Second, it is difficult to select appropriate and clearly defined historical benchmarks or reference ecosystems that restoration is trying to reproduce, especially when landscapes have changed in different ways across the centuries. In other words, defining the “pre-disturbance” state as the goal for restoration is very difficult and contentious in practice. In the United States, pre-disturbance is often taken to mean “pre-European settlement,” which immediately and problematically “naturalizes” the activities of people living in North America before the Europeans arrived, thus devaluing both their impact (e.g., through deliberate use of fire) and their status as humans. In Europe, such a historical benchmark, however controversial, is in any case unavailable, so restoration projects there tend to hark back to various historical periods of ecological functioning, including preindustrial (i.e., pre-nineteenth century), preclearance or pre-agricultural intensification (i.e., pre-nineteenth century), or even postglacial (i.e., 10,000 years ago).

Third, some valued landscapes have actually been caused or created by human “disturbance” historically, for example, through grazing, tree clearance, excavation, and so on, especially in Europe. In England, some landscapes partly created by human activity are not only distinctive
and valued, but also designated to be protected and preserved, for example, the North York Moors and the Norfolk Broads. Attempting to “repair” such landscapes under the rubric of restoration would thus change and possibly threaten environments that are currently valued and protected.

Is restoration authentic?

A fourth and very different reason why restoration is argued to be impossible in practice is philosophical: even if we do have sufficient knowledge to recreate an ecosystem in all its complex functioning, even after centuries of human damage, and even if the resulting landscape looks and works exactly the same as another such landscape that has never been damaged, the “restored” area can never be an authentic environment because it has been created by humans, not by nature. Critics argue that the value of a restored environment will always be less than the value of the naturally created (but now lost) environment, even if the two environments cannot be distinguished from each other in terms of how they look or how they function ecologically. Elliot (1997) referred to the idea of restoring natural value as the “replacement thesis,” to argue against it on exactly this point. This philosophical argument about how far restoration can truly restore “nature” is really about whether we understand “nature” to be essentially defined as “without human interference,” and this assumption itself is very questionable (see below).

Does restoration threaten conservation?

A second line of opposition to restoration is that it may threaten or undermine other forms of conservation. If we accept that landscapes and ecosystems can be restored after damage, the implication is that damage is less of a problem and this will undermine efforts to prevent damage in the first place. And if we accept that restored environments can replace value that has been destroyed elsewhere, then this could be used to justify further damage.

Restoration has been used controversially in planning cases in precisely this way. At Twyford Down, England, a new motorway bypass round Winchester was partly justified by proposing to relocate valued areas of grassland and its non-human inhabitants such as butterflies to adjacent sites before blasting open the underlying rock to create a new cutting for the road and to restore the old road (now redundant) to grassland. This was an example of what Elliot called the “replacement thesis” being used by the state to support development over environmental protection. A huge and well-publicized campaign against the new road objected both to the destruction of the grassland to dig the bypass in the first place, but also to the claim that the recreated habitats would be equivalent to those lost.

Under Section 106 of the UK’s Town and Country Planning Act 1990, “s106 agreements” can be used to make a development proposal acceptable to planners by mitigating (that is, preventing or softening) the most damaging aspects of a proposal. Referred to as “developer contributions,” these may include restoration payments or works, for example, to restore a development site to its original functioning and design after use, such as when quarrying has ended, or to create comparable landscapes or ecosystems elsewhere to compensate for the loss at the development site. Referred to also as “planning gain,” such habitat “creation” has been used to enable developers to justify new developments by arguing that restoration elsewhere will compensate for damage in situ (e.g., Cowell 2003).
Using restoration as “compensation” or “mitigation” is thus a highly political move. Another example of restoration being used to undermine other forms of environmental protection is where the UK regulatory body, the Environment Agency for England and Wales, used restoration ideas to justify its changing approach to sea defense. The rising cost of defending the coastline against encroachment and the threat of climate change was used by the agency to argue that instead of rebuilding and maintaining sea walls against rising water levels, tidal flooding should be allowed and intertidal wetlands (re)created. At Alkborough Flats in Lincolnshire, England, agricultural land was bought and sea walls deliberately breached by the agency to allow the sea to flood a low lying area delimited by higher ground. Referred to originally as “restoration,” the agency later referred to such works as coastal “retreat,” “managed realignment,” and “sustainable flood management,” reflecting how ideas of restoration are not neutral, but become politicized and are used to justify contentious decisions about environmental management and to represent potentially negative change or damage in a more positive light.

As well as being part of the state’s planning processes, restoration has also been used in the interests of private capital. In the United States, restoration ideas have been developed into a commercial industry of “mitigation banking” (Robertson 2006). In the 1990s, proposals to destroy or damage wetlands were required to include provision to create the equivalent amount of wetland functions (an “ecosystem service,” see Ecosystem services) elsewhere. Private sector interests developed a new industry by making wetlands, having them approved by regulatory agencies as providing those functions, and then selling them as “credits” to developers; rather than creating their own wetlands, developers could therefore simply buy such “credits” and refer to them in their proposals to meet the planning requirements.

Such transfers of equivalent value (monetary and ecological) are highly contentious and have been criticized by geographers and others for attempting to create habitat in the same way that commodities (such as food or cars) are created, by exposing how parcels of land, presence of species, or ecological functions are commodified and used to justify further development in the interests of capital. Drawing on political economy, such approaches focus upon the role played by restoration in creating and substituting forms of “natural capital” and critique the notion that “nature” can be detached, moved, and replaced elsewhere.

As well as these practical and philosophical questions, in many cases restoration is controversial because it threatens other interests, for example, agriculture and hunting. A good example is the reintroduction of wolves to Yellowstone National Park, USA, in the 1990s. Wolves had been almost entirely eradicated from the United States by the mid-twentieth century because they were considered to be a predatory threat to livestock and government provided incentives in the form of bounty payments per head. But changing ideas of ecology and conservation raised interest in using predators to control expanding populations of prey and led to calls to reintroduce wolves to Yellowstone to control the rising elk population by predation, rather than by human-led culling. Since wolves were released in Yellowstone in the late 1990s, a stable population has been established, despite some having been shot, probably by ranchers concerned that they were preying on livestock animals, rather than elk.

In Scotland, a plan to reintroduce beavers to the rivers and streams in Argyll was held up for years by arguments over the likely effects,
leading to some beavers which had been captured for later release then dying in their pens. After a five-year trial was agreed in 2009, a small number of beavers were released and have since begun breeding. Beavers are particularly good examples of restoration by nonhuman agency because not only do they interact with other species, but they literally rebuild environments through damming waterways.

As well as reintroducing species, some restoration projects also aim to remove species from a landscape. For example, gray squirrels were introduced to the UK in the late nineteenth century and have since outcompeted red squirrels, which have been in the UK since the end of the last ice age, ten thousand years ago. This has prompted campaigns to “restore” red squirrels by culling grays. There are also many examples of plant species that are targeted for removal in order to restore environments, often because they were deliberately introduced by humans for aesthetic or commercial reasons, but later expanded and outcompeted other species, for example, Himalayan Balsam, introduced to the UK in the mid-nineteenth century.

Both reintroducing and removing species are controversial because decisions about which species should be present in a particular area often fall back on problematic definitions of “native” species that need to be retained versus “alien,” “invading,” or “exotic” species that need to be removed. For example, red squirrels are classed as “native” to the UK, but grays are classed as “invasive non-native.”

From a geographical perspective, such arguments about “native” and “alien” are problematic. They would no longer be tolerated in a discussion about human migration across national borders and they are becoming increasingly untenable in discussion about nonhumans, as we learn more about how plant and animal species have evolved, moved across the globe and interacted with each other over time. Definitions are also highly time-dependent: for example, what is “native” in a landscape during an ice age may disappear from the same landscape during a warmer interglacial period, so defining “nativeness” as an essential quality of any species may be a rather pointless exercise. And the very idea of being able to clearly distinguish the “native” from the “alien” illustrates a problem with environmental knowledge underlying restoration: nature is not easily compartmentalized and often our taken-for-granted ways of thinking about the environment in such categories fall apart under academic scrutiny.

Should we restore “nature”? Finally, even if all these problems about knowledge, definitions, and competing interests are solved, an important ethical argument remains: do we have the right to experiment with landscapes in this way? Some have argued that any attempt to restore an environment is yet another example of human arrogance in assuming we can somehow “fix” the natural world, an arrogance that is even more pointed if we remember that the damage that restoration tries to repair was induced by human activities in the first place. The ethics of restoration and especially what this means for our understanding of nature (see Nature) is thus an important topic for research.

Environmental philosophers (e.g., Elliot 1997; Katz 1996; Light 2000) have debated the meanings of “restored” environments in terms of authenticity and fraud. If someone sees a “restored” environment but does not know that it has been deliberately restored by environmental managers following human-induced damage, does that mean that the person is deceived into thinking that it was produced solely by “nature”? And if they are deceived, does that matter? Some have argued that any restored environment is
fraudulent because attempting to erase human activity through human intervention renders that environment inauthentic, because it has been shaped by human agency.

Others have argued that this debate over authenticity is misguided because it falsely and unhelpfully separates humans out from “nature” and assumes a dualism between nature and (human) culture which separates the two and values nature over culture as a source of environmental transformation. Instead, it has been argued that we should appreciate that humans are also environmental agents, just as other species are; after all, beavers change the environment by building dams, herbivores change grasslands by grazing, and predators change the ecological balance of populations by catching prey.

In geography, the rise of research approaches variously called “cultures of nature,” “hybridity,” and “actor-network theory” have increasingly challenged the idea that nature can be defined or understood as nonhuman. For example, the recent idea that we now live in a geological era that can be called “the Anthropocene” emphasizes that all Earth’s systems have now been altered (even if only slightly) by human activity and that no “pure” nature, no “wilderness” strictly remains. Such discussions both emphasize how tightly humans, nonhumans, and inorganic environments are entwined but also reject the idea of trying to repurify this entanglement in order to “restore” a pure nature that has supposedly been lost. Here, restoration is in any case a coproduction of humans and nonhumans and thus no less or more “authentic” than any other such coproduction.

The other side of this argument is that geographers have also challenged the focus of most restoration projects on the nonhuman aspects of redesigning landscapes, to the neglect of human aspects. This is because the literature continues to be dominated by natural science perspectives and technical information, which argue that restoration needs to be strongly science-led to be successful and to counter opposition from (nonscientifically trained) critics, such as residents in areas surrounding restoration (e.g., Whalen et al. 2002). As a consequence of such arguments, there remains little social science research into how ideas of environmental and ecological restoration are understood and how far restoration projects are meeting the needs of local human stakeholders in practice. Human geographers (e.g., Adams, Perrow, and Carpenter 2005; Eden and Tunstall 2006; Petts 2007) have drawn attention to this problem and emphasized the importance of local community involvement in restoration projects.

Also, the literature on restoration and examples of restoration projects tend to be confined to areas in the Global North, giving a strong geographical bias to debates in restoration research and its practices. This is perhaps partly because of the longer history of dramatic environmental transformation in many northern countries but also because of the increasing budgets and attention given to conservation there, ironically only often after considerable species and habitat loss.

References

This entry charts the evolution of environmental risk analysis and management. Particular attention is given to the evolution of thinking and analysis, especially in the United States and Europe, and particularly to the role of geography in this evaluation. The entry begins with a discussion of early thinking in hazard analysis, and particularly the role of natural hazards. The discussion then goes on to the analysis of environmental risk, and particularly the structure of such risks and how they relate to the options in risk management. Particular attention is given to uncertainty, the social amplification of risks, the importance of place, and risk communication.

Natural hazards and disasters

The study of natural hazards internationally dates back to 1945 when Gilbert F. White (1945) in the United States published his PhD dissertation entitled Human Adjustment to Floods. This was followed several decades later by work in which White continued to explore how hazard management could be improved by the adoption of an enlarged range of options seeking to reduce the toll of natural hazards. But the first overall assessment of the incidence and effects of natural hazards occurred in 1975 with White and Haas’s (1975) Assessment of Research on Natural Hazards. In this work, they made a general argument that hazard management could employ better planning, land-use controls, and other mitigation measures (Mileti 1999). The work reflected the efforts of over 100 experts (mostly from the United States) to take stock of past, present, and future natural hazards and associated disasters. A decision model, linked with a human “adjustment” model, generated a five-step strategy for coping with natural hazards in the United States and abroad:

1. assess hazard vulnerability,
2. examine possible adjustments,
3. assess human perceptions and estimates,
4. analyze the decision process,
5. identify the best decisions and adjustments.

In particular, a broad approach was mandated, including a prominent role for the social sciences in North America. In short, there was not a new hazards paradigm, but a broader and more integrative and interdisciplinary approach emerged.

Gilbert White continued to spearhead many of these changes in the United States. During the 1960s and 1970s at the University of Chicago he trained a number of geographers who became leaders in hazards research, notably Robert Kates and Ian Burton. Subsequently, he moved to the University of Colorado where he founded the Center for Natural Hazards Research and Applications Information, whose annual meetings became a meeting ground for scholars and practitioners. Meanwhile, the US National Science Foundation established a natural hazards research program which provided stable funding for the evolution of natural hazard and disaster research during the 1970s, 1980s, and 1990s, and continues to this day.
ENVIRONMENTAL RISK ANALYSIS

In 1992, at a Boulder workshop, leaders of the field supported a second assessment which would review the burgeoning natural hazards research that had emerged since the first assessment was conducted. The result was *Disasters by Design: A Reassessment of Natural Hazards in the United States* (Mileti 1999). Not only did this assessment mark the notable developments in the field during this period, but it set forth six major principles by which natural hazards management could move from an adjustments approach to the realization of a sustainable hazards mitigation orientation.

1. Maintain and, if possible, enhance environmental quality.
2. Maintain and, if possible, enhance people’s quality of life.
3. Foster local resiliency to and responsibility for disasters.
4. Recognize that sustainable, vital local economics are essential.
5. Identify and ensure inter- and intragenerational equity.
6. Adopt a consensus-building approach, starting at the local level.

A somewhat different path for the development of natural hazards and natural disasters research was proposed by sociologists at the Disaster Research Center at the University of Delaware. (For an anthropological review of the emergence of this perspective and impact on social policy, see Quarantelli 1998.)

Risk analysis

Early risk analysis approaches

The early history of risk analysis focused on the probability of events and the magnitude of consequences and grew out of the expansion of nuclear power in the 1950s and 1960s – largely centered on reactor accidents. Critical to this was the so-called Rasmussen Report, the *Reactor Safety Study*, WASH-740, published by the US Nuclear Regulatory Commission in 1975, which examined the numerical estimates of the probabilities for different accident scenarios. In the years that followed, a deluge of plant-specific probabilistic analyses occurred. By early 1987, some 15–20 large-scale assessments had been conducted (Kasperson and Kasperson 1987). Similar studies were also conducted in Germany and Sweden. Over time, the function of risk assessment came to be understood as achieving sound risk characterization, understood as the final step in a process that involved hazard identification, exposure assessment, and dose-response assessment, culminating in risk characterization which provided the science needed for decision-making. Consideration of benefits was also recognized as important. The objective of risk assessment research over the early decades, then, was no less than to depict a particularly hazardous situation in as accurate, thorough, and scientifically objective a manner as possible. This process was enshrined in the United States in a National Research Council (1983) report which came to be known as the Red Book. Since that time, and despite its narrow view, it has become the bible of federal agencies and other risk managers in the United States and abroad.

World Commission on Environment and Development

An early departure from the world of the Red Book occurred when the World Commission on Environment and Development (1987) report appeared. The Commission set the goal as realizing sustainability rather than limiting itself to risk and disaster management. It defined
sustainability as “development that meets the needs of the present without compromising the ability of future generations to meet their own needs” (188). This definition has become widely used though sustainability has remained largely a philosophical principle that has not been comprehensively adopted in the environmental risk community.

Critique of the mainstream

Even in the latter part of the last century, not all environmental risk analysts espoused mainstream thinking and models emanating from the early work on natural hazards and nuclear technology. Geographers were prominent in this critique, including Hewitt (1983), who called attention to the vulnerability associated with poverty and social class. In At Risk: Natural Hazards, People’s Vulnerability, and Disasters (Blaikie et al. 1994; see also the second edition, Wisner et al. 2004) and earlier work on social erosion geographers who worked out of a neo-Marxist and development studies approach presented a different picture of the ongoing toll of hazards in the so-called third world.

Enlarging the environmental risk paradigm

Although it has received much less publicity, the National Research Council published a 1996 report entitled Understanding Risk: Informing Decisions in a Democratic Society (Stern and Fineberg 1996). Going beyond the Red Book, this report argues that the process used for characterizing risk must come from a combination of analysis and deliberation. In this context, deliberation involves such processes as discussion, reflection, and persuasion to communicate and consider issues, while increasing understanding and informing decisions. As such, the expanding framework for risk analysis and decisions involves such criteria as:

- getting the science right,
- getting the right science,
- getting the right participation,
- getting the participation right, and
- developing an accurate, balanced, and informative synthesis (Stern and Fineberg 1996, 6–7).

Ironically, although the report mostly enlarges the framework used in the Red Book, it has not been widely adopted by risk practitioners, principally, perhaps, because of the enlarged role given to deliberation as opposed to expert technical knowledge.

Uncertainty

Few issues are more perplexing for environmental risk analysts than uncertainty (Jager et al. 2001). Examples of uncertainty problems abound. If we take a familiar problem, such as the continuing toll of automobile accidents, the causality of collisions is generally well understood, even including how human behavior interacts with the physical system so that events (collisions) can be minimized through traffic regulations and highway and vehicle designs. Compare this with climate change where an array of changes in temperature, precipitation, sea level rise, and severe storms may extensively alter the nature of ecosystems, disrupt coastal systems, and threaten human health. As yet, the timing and spatial distribution of such changes remain beyond our assessment capabilities.

At the outset, it should be clarified what is meant by uncertainty and how it enters into environmental risk analysis and decisions. In cases of uncertainty, we usually mean that the direction of change is relatively well known but the probability of events and the magnitude of consequences, and perhaps even the receptors at risk, cannot be estimated with any precision.
ENVIRONMENTAL RISK ANALYSIS

Three major sources of uncertainty exist: where insufficient data exist to estimate probabilities and magnitude; where insufficient models exist to characterize risk genesis and consequences; and where basic processes in physical and human phenomena are not understood and even the direction and causes of change are not known to science, and thresholds and nonlinear relationships are present but not understood.

The most difficult source of uncertainty is what is typically termed “deep uncertainty,” or alternatively “ignorance” or “epistemic uncertainty.” These are uncertainty situations in which, typically, the phenomena posing potential threats to human societies are characterized by high levels of ignorance and are still only poorly understood scientifically, and modeling and subjective judgments must substitute extensively for estimates based upon experience with actual events and outcomes, or ethical rules must be formulated to substitute for risk-based judgments.

For those who must make decisions, deep uncertainty can be a major swamp – and, paradoxically, an opportunity as well. On the one hand, deep uncertainty is a field for creativity and experimentation. Well-established approaches may or may not be appropriate, and so arguments may well be made for initiatives that strike out in new directions. Timing is also uncertain, so one can wait for political “windows” of opportunity. On the other hand, escape from the imperative to come to decision is also abundantly there. In the political context, delay is a major resource and deep uncertainty provides wonderful cover. For those who seek to escape the exigencies of a decision whose outcome and political fallout remain highly uncertain, or to postpone to the next lucky incumbent, abundant rationale can be made to delay for further research and assessment with the admonition that “we will know better.”

It is important to note that whatever the political objective, delay itself further adds to uncertainty just as the science to narrow uncertainties proceeds. Exporting decisions to unknown future political environments inevitably adds new and often unforeseeable elements to the decision context.

While there is little question about how difficult the determination of risk uncertainty is for the scientific community, it is not an issue for the scientists alone. As Box 1 shows, principles have been identical to guide analysis. Uncertainty also has much to do with the differential pattern of people’s vulnerability, to nature and to human communities, and to the complexities involved in determining optimal management approaches and interventions. To take a prominent example, risk assessment assumes that sufficient knowledge and quantification can be achieved so that command-and-control strategies and regulation can be employed. Much depends on how large the residual uncertainties are and how they affect the acceptability of the risk. Where deep uncertainties exist, other management approaches may be called for, such as adaptive management.

A causal model of risk

Risk assessment is at least a four-step process involving risk identification, assignment of priorities, risk evaluation, and risk management.

Risk identification

Hazard managers do not like surprises. What is unacceptable, indeed downright dangerous, to the continued wellbeing of the manager is to miss the existence of a risk completely. Risk managers have available to them a variety of methods for identifying hazards, including research, engineering analysis, screening, monitoring, and diagnosis. Some of these sources of information are incidental to risk identification: thus, new carcinogens may be found as byproducts of
cancer research, product failure mechanisms may be recognized in engineering analysis performed for other reasons, and surprise hazards emerge as outbreaks or clusters. Other sources of information are the product of purposeful efforts: thus, screening of chemicals provides early warning of toxicity, and environmental monitoring of pollutants affords estimates of potential health effects.

Despite an enlarged capacity, some technological risks escape timely identification, of course, and become known through outbreaks or experienced consequences. Thus, the threat of buried chemical wastes at Love Canal in the United States was unrecognized until severe winter storms raised the water table and injected noxious chemicals into the basements of residences (Ember 1982).

Assigning priorities

Risk managers cannot, of course, deal simultaneously with all identified risks within their domains of responsibility. Somehow the risk domain must be ordered and priorities attached to the many candidates competing for managerial attention. There are choices to be made—choices between risks with better-known acute consequences and those with poorly understood chronic consequences, or choices between attending to serious risks with few available sources of control and attending to lesser risks with effective available means of control. The criteria for establishing priorities are laden with value considerations: Is it the aggregate risk or the distribution of risk that is more important? Should ecological risk receive lower priority than health risks? Should children enjoy a higher priority for protection than adults? Should present generations be valued higher than future generations? Inevitably, establishing priorities requires trading off some values to achieve others. Perhaps one of the most value-laden decisions a risk manager, or monitor for that matter, makes is the initial one of what to work on.

The message is clear. Effective risk management requires a well-ordered risk domain. Since creating such a structure is intrinsically normative as well as scientific, it should be rationalized openly and in close consultation with the various interested stakeholders (Renn, Webler, and Weidemann 1995).

Risk evaluation

Once a risk has been identified, the next steps in assessment are: (i) to estimate and characterize scientifically the probabilities of specific events and related consequences and (ii) to evaluate this characterization in social terms.

Unfortunately, there is no simple relation between scientifically estimated risks of death and injury and the social valuation of a given hazard. In fact, much to the chagrin of many scientific risk analysts, the public apparently does not respond equivalently to equal threats of mortality. A high-mortality hazard such as an auto accident sometimes provokes relatively little fear, whereas some low-mortality hazards (e.g., botulism or nuclear power) evoke great anxiety. A great deal of confusion and conflict in risk management arises from this conundrum.

Beyond the question of how best to characterize risks, risk evaluation presents other serious problems for the management process. There is the recurrent need to attend to secondary and tertiary effects, or, equivalently, to define the full range of possible consequences. A nuclear accident, for example, may produce fatalities, injuries, property damage, and a high level of anxiety. But it can also lead to regulatory change that result in subsequent shutdown of all similar plants, producing disruption, further anxiety, and possible power outages. Such secondary consequences are rarely predicted and infrequently
Box 1 Recommended principles for uncertainty and variability analysis.

1 Risk assessments should provide a quantitative, or at least qualitative, description of uncertainty and variability consistent with available data. The information required to conduct detailed uncertainty analyses may not be available in many situations.

2 In addition to characterizing the full population at risk, attention should be directed to vulnerable individuals and subpopulations that may be particularly susceptible or more highly exposed.

3 The depth, extent, and detail of the uncertainty and variability analyses should be commensurate with the importance and nature of the decision to be informed by the risk assessment and with what is valued in a decision. This may best be achieved by early engagement of assessors, managers, and stakeholders in the nature and objectives of the risk assessment and terms of reference (which must be clearly defined).

4 The risk assessment should compile or otherwise characterize the types, sources, extent, and magnitude of variability and substantial uncertainties associated with the assessment. To the extent feasible, there should be homologous treatment of uncertainties among the different components of a risk assessment and among different policy options being compared.

5 To maximize public understanding of and participation in risk-related decision-making, a risk assessment should explain the basis and results of the uncertainty analysis with sufficient clarity to be understood by the public and decision-makers. The uncertainty assessment should not be a significant source of delay in the release of an assessment.

6 Uncertainty and variability should be kept conceptually separate in the risk characterization.

Source: NRC 2009, 120

analyzed, even though in many cases they are the most important consequences of a particular event.

Following the risk assessment, control analysis judges the tolerability of the risk and rationalizes the effort that is made in preventing, reducing, and mitigating a risk. The key link between risk assessment and subsequent initiation of control actions is the judgment of whether a hazard is tolerable or not. One of the most perplexing issues facing hazard managers, it has been mislabeled the acceptable risk issue (Fischhoff et al. 1981). It is unlikely that any risk is “acceptable” if it is unaccompanied by benefits or is susceptible to easy reduction. Many risks are imposed upon individuals, often without warning or information. Such risks are better thought of as “tolerated”; they are suffered in practice, not accepted.

For identifying means of control, the causal structure of the hazard becomes the central concern. Complex cases require a full fault- or event-tree analysis. Whether simple or complex, an analysis of causal structure must be broadly based and include potential control actions that span the range from human needs and wants to exposure, consequences, and mitigation.
of consequences. To this end, it is useful to contemplate the control structure for the traditional technological risk, within the seven-stage model of causal structure. The potential control actions include: (i) modify wants; (ii) choose alternative technology; (iii) prevent initiating events; (iv) prevent releases; (v) restrict exposure; (vi) block consequences; and (vii) mitigate consequences.

In addition to identifying the technical means of control, each control action can be implemented in a number of different ways. There are three major modes of inducing society to undertake the control action. Society can: (i) mandate the action by law, administrative regulation, or court order and thereby ban or regulate the product or its use or distribution; (ii) encourage the action through persuasion or by providing incentives, penalties, or insurance; or (iii) inform those creating or suffering risk, allowing them voluntarily to reduce or tolerate the hazard. At any moment all of these modes may be utilized in connection with a specific hazard. Thus, the hazard of driving is controllable by 37 different “highway safety countermeasures” and a comparable number of vehicle safety standards, each involving one or more stages of the causal structure of the hazard. For any given case, a lively ideological debate may erupt over which implementation modes are the most desirable.

An important aspect of control analysis is to inquire into the relative cost of control interventions (be they technical, behavioral, or informational) and modes of implementation. Known as cost-effectiveness analysis, this approach permits the risk manager to select the most efficient actions available.

Risk management

Equipped with a risk assessment and a control analysis, and assuming the risk has been judged intolerable and thus requiring action, the manager next must design a risk by society management strategy, consisting of an overall management goal. Such a strategy needs to take into account the need for “thick analysis” of longer-term issues in sustainability (Adger et al. 2003). The control package will specifically include both control interventions (oriented toward the causal structure of hazards) and modes of implementation (oriented toward alternative institutional means for control).

Risk acceptance may be achieved by providing compensation, as through higher wages for riskier work, or by seeking informed consent, as in informational or warning labels on hazardous products. The purpose of the latter is to make the risk more voluntary by increasing information related to technology choice. It applies to a broad range of risks.

Risk spreading seeks to transform a maldistribution of risk into a more equitable one, through redistribution of the risk over social groups, regions, or generations. The new distribution may also seek to equalize experienced risk, to make risk concordant with benefits or with the ability to bear risk. An interesting example of risk spreading is the introduction of tall stacks to transform a local pollution problem into a regional one. Here, by all appearance, the principal regional hazard, acid rain, was initially unsuspected, and only at a later time became recognized as a serious ecological and health threat.

Risk reduction, in contrast to spreading and acceptance of risk, involves decisive intervention in the causal sequence of hazards. It is therefore a step that may in some circumstances curtail the benefits of technology. An extreme case of reduction is aversion, as exemplified by the total ban on a technology.

Risk mitigation includes a variety of ways of modifying hazard consequences once they
have occurred. Typical actions include disaster relief, medical intervention, family assistance, and compensation through insurance or other means. Risk mitigation is often an initial societal response when risks have not been anticipated or when the causal chain of the hazard is poorly understood, as exemplified by the thousands of court cases now pending against asbestos manufacturers.

Although presented here as an integrated managerial approach, strategies usually develop piecemeal, frequently lack internal logic, and may appear only through trial and error over time (Perrow 1984). However they develop, they must eventually strike a balance between reaping technological benefits and reducing unwanted risks. In addition, governance needs to be adaptive and to seek longer-term resilience (Folke et al. 2005). Control actions will range along the causal chains of hazards, reflecting optimal points of intervention. In contrast, for preventing the disruption of the ozone layer, a feared and intolerable consequence caused in part by a minor technology (aerosol cans), upstream intervention based on banning is both reasonable and acceptable. For most hazards, midstream and downstream strategies of intervention are appropriate. They interfere less with benefits and can be directed at specific targets. Typical of such interventions are the use of filters on cigarettes and the wearing of seatbelts in cars. Neither strongly affects the benefits, and each reduces hazard consequences. When the causal structure is poorly understood and unpredictable, society by necessity concentrates on mitigating consequences. An example of this is the case of environmentally caused cancer, where both agents and mechanisms are to a large extent unknown.

A mature hazard management strategy is one which over time seeks a preferred path between realizing technological benefits and reducing unwanted risks. It will normally employ a complex set of interventions along the hazard chain and utilize a variety of managerial modes of implementation, and includes both “normal” and “post-normal” risk assessment (Funtowicz and Ravetz 1992). Such a system evolves partly through improved knowledge and partly through trial and error.

Vulnerability

The concept of vulnerability, defined here as “the differential susceptibility to loss from a given event,” is a central but still incompletely developed concept (see Adger 2006). It is abundantly clear that the impacts of environmental change or stress lie partially with the character of the extent and exposure – and partially with human and social vulnerability systems, people, and social organizations affected. Sen (1982) has shown powerfully that food crises can occur even with food available, finding their roots instead in changing social and economic entitlements. Environmental risk, in short, is an interactive phenomenon involving both nature and society, particularly inequality and a lack of buffering against environmental threats.

Although the specific terms, concepts, and criteria used to address vulnerability differ, basic concepts are consistent: the ability to continue function within a normal range despite perturbation and the ability to overcome perturbations that substantially disrupt the normal functioning of the system. These two concepts address internal characteristics of the affected system. Economic, political, and biophysical changes may interact to alter the vulnerability or resilience of the system. Differing efforts at defining vulnerability reflect the character of the concept. Vulnerability is a useful general
concept that depends on the definition of event and social context to provide insight into specific key situations. Accordingly, the factors influencing vulnerability vary widely among scales of analysis, so that scale-sensitive analyses of environments remain a pressing need. Essential steps in assessment can nevertheless be defined (Schröter, Polsky, and Patt 2005).

The structure of environmental risk, then, reflects human driving forces, patterns of environmental change, the fragility of ecosystems, the vulnerability of social groups, and the adverse effects that result (Pelling 2011). The stages in the evolution of risk consequences are highly related and interactive. The magnitude of the impact will depend not only on the extent of the environmental change but also on the character of social institutions and relations contributing to the resilience or capacity of a group in the region to be harmed (i.e., its vulnerability).

Obviously, different attributes of an environment are highly relevant to analyses of human-induced environmental stresses. Fragile environments degrade more readily under mismanagement and exact higher societal costs for risk management or for substitution in production. More robust environments do not degrade so rapidly and respond to substitutes and mitigation interventions more economically. The projected rapid rate of change relative to the rate at which species reestablish themselves, the isolation and fragmentation of many ecosystems, the existence of multiple stresses, and limited adaptation options suggest that some ecosystems (e.g., forests, mountain systems, and coral reefs) are particularly vulnerable to climate change.

Economic marginality describes a situation in which the returns to an economic activity barely exceed the cost. Again, it may be that small changes in physical conditions affecting economically marginal practices will result in great changes. Uncertain changes in environmental patterns may remove some of the buffering offered by established coping strategies and institutions based upon “peasant science” and the local tradition of indigenous knowledge and experimentation (Watts 1987, 179). The concept of entitlements – access to resources and assistance – suggests a wide range of circumstances surrounding everyday life that may influence vulnerability (Sen 1982). Decisions about risk management also depend on the social context, such as information channels, types of entitlement available, psychological factors of risk heuristics and biases, and how decisions and risk problems are framed (Kahneman, Slovic, and Tversky 1982).

The nature of social and economic institutions is yet another factor that affects vulnerability. The infrastructure of social institutions pervasively shapes the breadth and depth of response capability. For institutions, the ability to benefit (or to avoid harm) rests largely with the ability to react rapidly to opportunities. The ability of social institutions to provide warnings, diagnosis, insurance, and planning support is a key element in shaping successful societal coping.

Demographic and health considerations among human populations represent an area of specific concern and investigative depth in relation to a number of hazards. Population growth in marginal areas – such as coasts, drylands, and degraded areas – may expose more people to additional stresses. Other demographic and social characteristics (such as age and occupation) of those populations will also be important in evaluating overall levels of vulnerability. Special needs populations (the elderly, those with disabilities, lactating women, children under five) are among the most vulnerable persons in natural disasters. Vulnerability, in short, leaves a fingerprint that becomes increasingly complex as more social relations and scale disaggregation are
integrated into the analysis. This is even more the case when ecological effects are included.

One of the most perplexing problems in risk analysis is why some relatively minor risks or risk events (as assessed by technical experts) often elicit strong public concerns and result in substantial impacts on society and the economy. Such concerns and impacts are typically the result of social amplification – changes in risk perception and response based on psychological, social, institutional, and cultural processes. Social amplification is most likely to flourish when the risks are serious and the situation is fraught with uncertainties.

Social amplification of risk

The social amplification of risk framework seeks to understand and account for public attitudes toward risk. The framework links the technical assessment of risk with psychological, sociological, and cultural perspectives of risk and risk-related behavior (Kasperson et al. 1988; Pidgeon, Kasperson, and Slovic 2003). The main thesis of the framework is that risks interact with these perspectives in ways that may amplify or attenuate public responses.

Risk amplification typically occurs at two stages in a risk scenario: in the transfer of information about risk and in social response mechanisms. Signals about risk are both transmitted and processed by individuals and social entities, called amplification stations. The individual might be a scientist, for example, who communicates the risk assessment; a social entity might be the news media, a cultural group, or an interpersonal network. The perceived amplified risk leads to behavioral responses that result in secondary impacts or ripples.

Social amplification may qualitatively and quantitatively increase not only the perception of risk but also the risk itself and its consequences. For this reason, social amplification of risk must be included in analyses of public and regulatory reactions to risk events.

The key amplification stages are listed below:

- filtering signals (only a fraction of all incoming information is actually processed),
- decoding and reframing signals,
- processing risk information (e.g., drawing inferences),
- attaching social values to information as a basis for drawing implications for management and policy,
- interacting with cultural and peer groups to interpret and assess the validity of signals,
- formulating behavioral intentions about whether to tolerate a risk or take action against the risk or risk manager,
- engaging in group or individual actions to accept, ignore, tolerate, or change the risk.

The starting point in the social amplification framework is a risk event, which might be an actual or hypothesized incident (or even a new report about a known risk) and which may be minimal, largely irrelevant, or localized in its impact, unless it is observed and communicated to others and thus amplified. The characteristics of the risk are then portrayed through communication signals that interact with psychological, social, institutional, and/or cultural processes in ways that intensify perceptions of the risk and its manageability. The experience of risk thus involves not only concern about potential physical harm but also interpretations of risk by groups and individuals. The social amplification of risk framework enables effective assessment of this multidimensional risk experience, secondary and tertiary consequences, and the actions of risk managers, stakeholders, and the public.

The term “amplification” refers to the process of various social agents generating, receiving,
ENVIRONMENTAL RISK ANALYSIS

interpreting, and passing along risk signals, which are always changed in the process. In fact, risk signals are subject to predictable transformations as they filter through social and individual amplification stations. The social amplification stations generate and transmit information via communication channels such as mass media, social media, letters, telephones, and face-to-face conversations. The transformations may increase or decrease the volume of information about an event, heighten the salience of certain aspects of a message, or reinterpret and elaborate available symbols and images, leading to particular interpretations and responses by those who next receive the information.

Individual amplification stations are affected by risk heuristics (i.e., qualitative aspects of the risk and context such as attitudes, blame, or trust). Individuals are also members of cultural groups and other social units (social stations of amplification) that codetermine their risk perception. Individuals in groups and institutions do not simply pursue their personal values and social interpretations; they perceive risks, those who manage them, and the risk problem through the lens of values of the organization or group and, perhaps, its cultural biases. Thus, there is often an “organizational amplification” of risk that must be considered.

Social amplification also accounts for the secondary and tertiary consequences, or ripples, of some events. Like ripples in a pond, they may spread far beyond the initial point of impact and may even affect previously unrelated groups or institutions. Imagining ripples in a pond is a good way to think about how impacts associated with the social amplification of risk spread outward from those directly affected (or first notified) to the next, institutional level (a company or an agency), and, in some cases, to other parts of an industry. For example, in the wake of the Deepwater Horizon explosion in April 2010, the effects spread from the drilling rig to the rest of the Gulf of Mexico, including the wetlands and beaches in all of the adjacent states, and then to politicians and petroleum industry representatives who were compelled to reconsider their plans to expand offshore drilling.

The concept of rippling impacts suggests processes that can extend (in risk amplification) or constrain (in risk attenuation) temporal, sectoral, and geographical impacts. It also illustrates that each order of impact, or ripple, may not only have social and political effects but also trigger (in risk amplification) or hinder (in risk attenuation) managerial interventions to reduce risk. Such secondary effects include market impacts (e.g., consumer avoidance of a product or related products), demands for regulatory constraints, litigation, community opposition, loss of credibility and trust, stigmatization of a facility or community, and investor flight. They may also include some or all of the following effects:

- enduring changes in perceptions, images, and attitudes (e.g., anti-technology attitudes, alienation from the physical environment, social apathy, stigmatization of an environment or risk manager),
- losses in local business sales, lower residential property values, and lower levels of economic activity,
- political and social pressure (e.g., political demands, changes in political climate and culture),
- changes in the nature of the risk (e.g., feedback mechanisms that heighten or lower the risk),
- changes in training, education, or required qualifications for operations and emergency response personnel,
- social disorder (e.g., protests, riots, sabotage, terrorism),
ENVIRONMENTAL RISK ANALYSIS

- changes in risk monitoring and regulation,
- higher liability and insurance costs,
- repercussions on other technologies (e.g., lower levels of public acceptance) and on social institutions (e.g., erosion of public trust), as when the 1984 explosion at the chemical plant in Bhopal, India, raised concerns about the possible failure of “fail-safe” systems at nuclear power plants.

Once secondary impacts are perceived by social groups and individuals, they may lead another stage of amplification and tertiary effects that may affect other parties, more distant locations, or future generations. Each order of impact may also trigger (in risk amplification) or hinder (in risk attenuation) positive changes for risk reduction. Examples of positive changes were apparent in the wake of the Fukushima nuclear accident of 2011 in Japan when Germany restructured its energy system and the United States (among other countries) launched a major review of all its nuclear plants.

Risk and place

Geographers have been particularly interested in how the nature of a particular place affects the risk experience. The hazardous facility siting literature illustrates how new facilities and technologies can change how people feel about a place because of worries about environmental contamination and health risks – people may feel the place is now unsafe (Slovic, Flynn, and Gregory 1994). Studies can show that places can be associated with fears about risks to health and valued amenities and the place can become stigmatized, affecting retirement plans and tourism. Places can be compared by their risk portfolios and by public concerns about risks (Boholm and Löfstedt 2004).

Facilities, as well as associated infrastructure such as electricity transmission lines, may also be perceived as changing the character of an area or of a community. For example, siting of new energy sources can be seen as a taking of public space or the industrialization of the seascape.

There are some, however, who caution against emphasizing visual (and noise) concerns too much, even when they are clearly salient, as there may be other reasons for the strength and direction of opinions (Firestone and Kempton 2007). They suggest that a broader set of reasons are often important to negative opinions, including potential impacts on tourism, recreation, and the environment, as well as factors such as perceived inadequacy of the decision process and prior experience with facilities and developers.

Social trust and risk

Trust is related to expectations about others and orientations toward an uncertain future. The “others” of whom individuals and groups have expectations include actors at various scales, such as individuals and institutions. In the context of risk communications and management, trust has been the subject of extensive research by geographers and others (Siegrist 2010). Discussions have focused variously on general trust, interpersonal trust, social trust, and institutional trust. Interpersonal trust refers to the expectations that individuals have about others, and it emerges primarily through direct interaction. On the other hand, social trust is a feature of more distant or indirect relations between people and others. In complex sociotechnical systems the focus of managing social trust (or distrust) often refers to the expectations that people have about institutions and the agents acting on their behalf. Kasperson, Kasperson, and Golding (1999, 37) argue that social trust is “onion-like”:
the deepest level, the core of the onion, involves trust in the political community that underlies the constitutional structure of politics and democratic institutions; next is a layer of trust in the political regime; then comes trust in governmental and other political institutions; and finally, there is the level of trust that relates to particular representatives of the institutions (Kasperson, Golding, and Tuler 1992). The importance of social trust for risk communication arises for a variety of reasons. First, social trust helps to create the conditions by which people with conflicting preferences or values can collaborate to manage risks – through dialogue, problem-solving, and negotiation.

While social trust can facilitate agreement, acceptance, and support, it cannot guarantee these outcomes, although this is often an implicit hope of those who seek it. Trust is particularly important for stable arrangements in contexts of unequal power. Risk-related controversies can be a function of ways that people think about the competence or fairness of risk managers (Kasperson, Golding, and Tuler 1992). Opposition to siting of hazardous facilities often grows from negative judgments about the competence or fairness of those seeking to place risks on a host community.

While there is considerable discussion of the nature of trust in the context of risk management and communication, the general conclusion is often that social trust is lacking. Also, it is clear that there are many tools for risk communication, but they carry a trust ingredient. Moreover, a long-term shortfall in public confidence in social institutions has been documented in numerous polls and surveys.

There is scant evidence that the rebuilding of trust can be accomplished in the near term, despite the view of some risk managers that they will quickly build trust where it is lacking. Actions that might increase social trust among some groups erode social trust in others. To the extent that social distrust is systemic in nature, system change is required for changes in the level and objects of social distrust. Thus, there is no simple answer as to how to rebuild social trust in many pluralistic (or even fragmented) societies.

A second reason is that changing negative views can be very difficult. The “affect heuristic” suggests that when people like an activity or technology, they tend to view it as having high benefit and low risk (Slovic 2012). On the other hand, if they dislike it, they see benefits as low and risk as high. Thus, information intended to educate or persuade is all too often impotent. In contexts of information complexity and uncertainty, the affect heuristic can be a powerful mechanism for making judgments about risks and those that managed them, in much the same way as trust is used to make judgments about those who manage risks in contexts of information complexity and uncertainty.

A third reason is that our understanding of which events and activities build social trust and which erode it is still limited. Slovic (1993) found that events and activities presumed to erode trust can have a stronger impact on overall levels of trust than do those thought to strengthen social trust. This is often referred to as the “asymmetry of trust,” and is the source of the aphorism that “trust is easy to lose but hard to gain.”

Although there are many challenges to rebuilding and maintaining social trust, there is evidence that institutions responsible for planning, operations, and risk communication can be designed to function in the presence of social distrust, rather than seeking trust before moving forward. Social distrust can serve as an important social and political factor in risk communication (Pidgeon, Kasperson, and Slovic 2003). Functional distrust, or “critical trust,” can ensure oversight and vigilance. Critical distrust can
ENVIRONMENTAL RISK ANALYSIS

hold in check the growing power of elites and technical expertise, generate alternative control mechanisms in democratic institutions to maintain social order, and encourage realistic appraisal of the operation of elites, and the actions of democratic institutions, without fostering the withdrawal of mandates. So, the pressing need is not to maximize trust, but to concoct the mixtures of trust and distrust that should prevail within a political risk management institution.

Risk communication

The appearance of Effective Risk Communication (Árvai and Rivers) in 2014 indicates how important risk communication is in environmental risk assessment and management. In 1986, the first National Conference on Risk Communication, attended by 500 experts, was held in Washington, DC. This review was intended to take stock of the burgeoning field of risk communication and the explosion in the early 1980s of books, scholarly articles, and handbooks purportedly providing guidance on “how to do it.” The conference dissected the level of thinking and practice.

A first major finding in risk communication is the importance of persistence. It is not unusual for either the public sector or the private sector to provide a modicum or token of support for risk communication at the end of a lengthy risk assessment process. The success of the anti-smoking campaign in the United States was due in no small part to its decade-long effort to convey a wide array of information and warnings of the risks of smoking. Effective risk communication requires sustained effort throughout the risk deliberation process, with learning along the way. This means that the resources that are needed are often far larger and the time required much longer than many risk managers anticipate or undertake.

Also, as Fischhoff, Bostrom, and Quadrel (1993) pointed out 20 years ago, the scope of the communication must be broad and comprehensive enough to embrace the issues of concern in the policy or decision arena. Part of the success in the anti-smoking effort was due in no small part to the fact that the communicators took head-on the notion that attractive women look so sophisticated with a cigarette dangling from their graceful fingers. The notion that smoking was a dirty habit may have been as important as pointing out the added cancer risk. Similarly, the failure in radioactive waste disposal to broaden the debate to include civil liberty and equity issues (such as the distributions of risks and benefits across generations and the location of waste generation versus the location of risk-bearers) has excluded important issues of public concern.

An indispensable element of risk assessment and management is characterizing and communicating uncertainty. Uncertainty comes in a wide variety of types and flavors. And neither decision-makers nor publics like it very much. Despite decades of work on communicating uncertainty, the track record is not encouraging. Variability, involving different risk exposures and sensitivities, is still often confused with uncertainty and the unknowns in the structure and experience of risk. And even risk experts often confound different sources of uncertainty which arise alternatively from data inadequacy, limitations in model parameters, and imperfect understanding of the scientific phenomenon in question. As a result, risk managers often see more data or “working harder” as the best answer to reducing uncertainty despite accumulated experience that points out that more scientific work often uncovers new uncertainties while reducing existing uncertainties, making management no easier. Then again, value issues often creep into the identification and assessment of uncertainty, making decisions no less
problematic. Accordingly, the issue of how to communicate uncertainties to decision-makers and publics remains problematic and risk experts often content themselves to say that society and decision-makers must learn to live with uncertainty, a stance that remains no less problematic than it was at the first national risk communication conference nearly 30 years ago.

So the question remains as to what can be learned from this record of grappling with uncertainty. First, it is clear that decision-makers and publics do not require the full catalogue of uncertainty that science can create. Indeed, sharing everything that experts know about risk uncertainty may be highly counterproductive for decision-makers and publics. Rather, they do need to know those uncertainties that really matter to the magnitude of the risk and its management. Equally important, uncertainties lodged in the value systems of those who will bear the risks need to be brought to the fore and integrated into the assessment and management processes. It is also clear from “mental models” research (Morgan et al. 2002) that understanding how perceptions are lodged in cognitive structures can be very helpful in risk communication. And there is a need to move to resilience and even beyond (Pelling 2011). Otherwise, important uncertainties will remain unknown but quietly sabotage decision-making.

**Conclusion**

While environmental risk analysis has attracted much attention from both scholars and decision-makers, the field is poised for yet new topics and directions. The pre- eminent role of the United States and the place of natural hazards are undergoing major transformations. Climate change is revealing the global scale of the issues that confront the next generation of geographers and environmental risk analysis. The speed of economic development and technological change poses new challenges for analysis and management, and above all for international governance and cooperation. Other sciences will be increasingly important and new theoretical and management integration will be required. The new emphasis upon building resilience will draw geographers and others into the theoretical developments and planning initiatives. Meanwhile, the scope of the analysis and those bearing future risks will inevitably shift to Asia, Africa, and South America. New thinking and analysis will be needed as the scale and importance of these changes become clearer and more salient.

Environmental risk analysis

The debate about environmental science and society refers to the social influences on knowledge about environmental changes and risks. Many orthodox analysts claim that scientific inquiry is a representative and trusted means of understanding environmental risks in a way that is free from social influence. Increasingly, however, various social scientists have argued that scientific knowledge can never be free of social influence, and that, consequently, it is difficult to identify natural processes and objects that are not in some way framed by social thinking. The differences between these perspectives have important implications for understanding the nature of environmental risk, and for how disagreements about risk should be settled. The debate has also influenced parallel discussions about the nature/society divide, and the politics and authority of expertise.

Environmental science and knowledge

Science is usually understood to be trusted and accurate knowledge that has been created using established methods by trained analysts. The term “scientific” is often used to denote knowledge that is different from individual opinion or political influence. The debate about environmental science and knowledge partly involves a criticism of scientific methods for complex social phenomena, as well as how scientific knowledge is a site of political contestation and power itself.

First, “science” itself is a varied and changing practice. Most scientific research employs the term “positivism” to describe a scientific method that seeks to make generalizations about trends or objects in rigorous and trusted ways, rather than on the basis of individual cases or personal opinions. Positivist science has been used with great success for various outcomes in human history, but social scientists have also questioned its appropriateness for explaining social phenomena. Positivism has changed over time. Early positivism, such as by the physicist Ernst Mach (1838–1916), looked for patterns in datasets. The Vienna Circle of logical positivists in the 1920s advanced this approach by seeking to verify observed patterns by looking at other datasets. Karl Popper (1902–1994) went further by arguing that theories should be considered true until empirical tests were able to falsify them. At each stage, the predictive potential of positivism has increased. But social scientists have argued that it simplifies how far generalizations can be made, or how far datasets can actually test assertions. Most analysts also believe that scientific progress does not always occur by empirical research, but by social factors driving new “paradigms.”

Second, social scientists also point out that much discussion of “science” in public and policy debates does not always reflect recent scientific research, but instead is better described as knowledge that maintains authority despite the existence of counter-evidence. This type of knowledge owes its authority to cultural,
political, and social factors that lie outside of scientific methods. A key concern here is the long-standing debate about the relationship between facts and norms. Commonly, many policymakers or scientific advisers seek to justify normative decisions by asking “What are the facts?” Social theorists, on the other hand, have often argued that social norms drive the generation of facts — and that existing facts, therefore, reflect historic norms, which in turn reflect unequal power relations in society.

Debates about environmental science have also shown these divisions. Many researchers adopt a so-called knowledge deficit model that argues there is a need to resolve uncertainty about environmental risk by seeking more facts and information. Sociologists of scientific knowledge, however, have argued that it is also important to note that certainty also implies the absence of contestation, and hence analysts should ask what social factors lead toward some questions being identified as certain and others as uncertain. Often, certainty also implies the creation of networks of expertise or arenas of debate that are not open to public participation (Funtowicz and Ravetz 1993).

A related debate also concerns the ability to label objects or scientific causality as either “natural” or “social.” Many discussions about environmental risks engage with biophysical hazards or environmental changes that are commonly labeled as natural, or as uncontrolled by human agency. Research about so-called natural hazards has indicated that many risks posed by events such as landslides or flooding can affect vulnerable social groups more than others, and hence society can influence risks. More generally, sociologists of science have also questioned the possibility of calling anything “natural” because all knowledge is generated through some kind of social gaze (Latour 1993).

Some physical scientists have expressed concern that these comments might reduce attention to natural concerns beyond human interests (Soulé and Lease 1995), or that “social constructivist” approaches to knowledge are culturally relativist because they reduce the ability to make truth claims to the predominance of different social positions. But, against this, social scientists have pointed out that the intention in discussing the social influences on environmental knowledge is to reach a more useful and inclusive understanding of environmental risks rather than to deny that they exist. Moreover, they argue that there is a need to develop new approaches to understanding environmental science that acknowledges the historically contextual nature of knowledge about the environment, and the political arenas in which knowledge is generated and used.

Indeed, social scientists have expressed concern that much currently accepted science might provide simplistic explanations or facts by which to measure or manage environmental problems. For example, analysts have argued that current debates about anthropocentric climate change tend to focus too exclusively on atmospheric greenhouse gas concentrations as the means by which to drive climate change policies. Global climate models focus on atmospheric changes such as in greenhouse gas concentrations or radiative forcing, and climate policies emphasize relative rates of fossil fuel use. Fossil fuels, or carbon, are an important part of the climate change problem, but focusing on these aspects alone might lead to the avoidance of questions about how and why climate change is considered a problem in different contexts or the means by which people can reduce social vulnerability to it (Demeritt 2006). Indeed, in many developing countries, climate change is a problem because of a lack of social resilience, which might be achieved through the appropriate use of fossil
fuels. Consequently, social scientists have argued that measurements of environmental changes per se, such as increasing greenhouse gas concentrations, should not be conflated with the risks and vulnerabilities of people who experience these changes, and that, hence, environmental science needs to seek more holistic and inclusive ways of measuring risk.

There is therefore a need to understand the social contexts within which both environmental changes are considered meaningful and some environmental facts are considered representative, and to find ways to generate new, and more representative, environmental facts. Some analysts use the term “coproduction” to indicate the mutual generation of knowledge and social order (Jasanoff 2005). Social science analyses of environmental science might therefore seek to understand which social outcomes are supported (cognitively or tacitly) by existing environmental knowledge, and what alternative outcomes might arise from new knowledge, and vice versa.

**Theorizing science and society**

Various approaches attempt to explain how social forces shape environmental science and facts. These approaches have developed over time. One early approach, known as cultural theory, held that the production of authoritative knowledge lay in the essential differences between different individuals in all societies (Thompson, Ellis, and Wildavsky 1990). They identified four key worldviews – individualism, egalitarianism, hierarchism, and fatalism – which could be associated respectively with the social positions usually adopted by businesses, environmental activists, governments, and powerless citizens and workers. Cultural theory argued that the common disagreements about environmental problems usually came down to the generation of knowledge and the respect given to knowledge by different worldviews, whose approaches to problems were very different from each other. This approach has been used to explain the differences between environmental skeptics and activists, as well as the widely diverging statistics generated on environmental problems such as deforestation.

Hence, cultural theorists argued that we should not ask “What are the facts?” but, instead, “What would you like the facts to be?” Successful environmental governance does not lie in asking which perspective is right but in acknowledging that they all contain elements of truth.

During the 1990s, analysts began to adopt the insights of more poststructuralist theorists such as Foucault and Latour. This kind of research analyzed the specific contexts where social forces have acted cumulatively to make science socially selective and unchallenged. For example, analysts have used the term “environmental narratives” to describe convenient explanations of environmental problems that are adopted in common discourse or by specific organizations, and which organize complex biophysical changes simultaneously with the creation of social roles of blame and responsibility (Hajer 1995; Forsyth 2003). For example, the problem of desertification in Africa has been defined, and redefined, over a period of years, often in ways that allow states to legitimate environmental policies that would otherwise be challenged, such as controlling pastoralists or smallholder agriculturalists. Narratives might be “stabilized,” or held in place, by a combination of alliances between different actors such as governments and environmental activists who might agree on certain environmental facts or framings for policy discussion. Narratives might be destabilized by demonstrating that smallholders might not threaten environments, or by proposing new framings for problems. Some development organizations have argued...
that the word “desertification” itself gives the wrong impression of land being permanently damaged by human action. Instead, a more useful and less discriminating form of policy for vulnerable people might result if it were called “drought-proofing.”

Reframing environmental science might also occur through active consultation of, and participation by, diverse social groups in the formation of environmental facts and norms. Feminist social movements, for example, have been partly responsible for diversifying the understanding and treatment of breast cancer during the 1970s and 1980s. Health activists in the United States have also persuaded scientists conducting research on HIV/AIDS (human immunodeficiency virus/acquired immune deficiency syndrome) to look at ways of enhancing the lives of people living with HIV as well as seeking to prevent its transmission. The generation of knowledge on environmental or health risks, therefore, reflects the social solidarities that perceive it to be important, or that are socially empowered to influence data collection or the objectives of research.

The growing field of science and technology studies (STS) is increasingly influencing the analysis of environmental science and society. STS scholars often study the “boundary work,” or means by which various actors might separate science (or knowledge that is publicly unquestioned) from nonscience (or knowledge that lacks social legitimacy). Boundary work is an important concept that explains how facts or narratives become stabilized, or how experts gain legitimacy. Actor-network theory (ANT) has also been used to analyze how the objectives and assumptions of scientific inquiry attribute agency to nonhuman items (Braun and Whatmore 2010). ANT reveals how scientific explanations can be upheld only if underlying framings of research are maintained, and hence how scientific explanations and models can be transported between different contexts if those same framings are maintained in each location.

**Governing expertise**

The debate about environmental science and society also implies that science gains authority according to the organization or individual that presents it. Much discussion about scientific authority in environmental policy adopts the concept of epistemic communities, which was originally defined to mean networks of scientists who had established authority, and who were also willing to communicate important scientific concerns to policymakers (Haas 1992). Perhaps the best-known example of an epistemic community is the Intergovernmental Panel on Climate Change (IPCC), which has published regular synthesis reports of climate science in order to explain priorities to policymakers since 1990.

STS scholars, however, have made various criticisms of this model of expertise. First, expert knowledge is rarely communicated without the influence of local experiences and cultural norms. Knowledge therefore does not travel cleanly to new locations but is consumed and respected according to pre-existing norms and concerns. Second, risk assessments and official communications are sites that build or destroy trust between citizens and officials. For example, research on government advice following the radioactive fallout from Chernobyl during the 1980s made simplistic assumptions about which people and activities were at risk, and resulted in local people rejecting formal advice. Other examples include the attempts of governments to reassure or warn citizens about mad-cow disease, HIV, or wearing car seat belts (Wynne 1996).

Third, epistemic communities themselves undertake various acts of boundary work to
define which problems are to be assessed, and by which kinds of expert. The IPCC, for example, generally defines risks arising from anthropocentric climate change as resulting from each unit of additional atmospheric greenhouse gas concentrations. It also seeks to define these risks by speaking with one voice through official summaries partly negotiated by national political representatives. Critics have suggested that this form of expertise tends to set itself up for rejection by reducing the range of risks experienced under climate change, and by its manner of communicating to diverse social actors (Hulme 2009).

And, fourth, the criteria for authoritative epistemic communities vary between different contexts. It is sometimes difficult to distinguish the epistemic authority of different organizations. In the case of genetically modified organisms, for example, there is no equivalent of the IPCC, and much public debate has been influenced—rightly or wrongly—by newspaper reports or non-governmental organizations. Some analysts have proposed the concept of *civic epistemologies* to indicate the specific national contexts by which knowledge or expertise is considered authoritative. In the United Kingdom, for example, debates about genetically modified organisms have been stabilized more through the influence of nominated experts and judiciary bodies than in the United States, where policy science and litigation have more influence (Jasanoff 2005).

Questioning the epistemic authority of expert organizations does not necessarily mean denying the existence of an environmental problem. Rather, it seeks to draw attention to which questions are being asked, or not asked, and which social outcomes are being achieved, or not. Pointing out how the IPCC, for example, defines climate risk, or seeks to define certainty, does not deny climate change but instead aims to improve how complex phenomena such as risks arising from climate change can be understood and to make scientific knowledge more relevant to a wider set of people. For example, the Research Program on Climate Change, Agriculture and Food Security (CCAFS) of the Consultative Group on International Agricultural Research (CGIAR) is devising ways of implementing climate change policy among low-income small-holders by integrating climate change mitigation and adaptation. Instead of framing climate change policy only in terms of reducing the risks posed by additional greenhouse gases, this network is trying to reduce emissions simultaneously with increasing food supply and social resilience.

A more decentralized form of expertise is *citizen science*, which seeks to harness the knowledge and concerns of local citizens. Citizen science also offers the opportunity to build social trust in risk assessments, as well as flexibility in identifying problems. In developing societies, this form of analysis has been used under frameworks such as *community-based adaptation to climate change*, which seeks to develop participatory responses to new and unexpected environmental risks in ways that address local concerns and knowledge. In other locations, forms of citizen science allow local people to feel included in the framing and implementation of research about environmental problems such as changes in wetlands, bird populations, or pollution. By being involved, citizens also are more likely to trust scientific expertise and to participate in resulting policies.

Environmental science

Sally Eden
University of Hull, UK

Environmental science is a wide field of research that examines all aspects of how environments develop, change, and are impacted by human activity. This includes work on the basic principles of environmental processes and change, considering both organic and inorganic elements of the natural environment. It also includes more applied work and research into policy-relevant environmental issues, such as climate change and pollution, as well as human–environment research into how human activity impacts on the environment and how this impact might be ameliorated.

Origins of environmental science

The origins of environmental science lie in the development of ecology, geology, and other sciences in the eighteenth and nineteenth centuries. At first they were driven by amateur naturalism in the “Arcadian tradition” (Worster 1994), where catching and classifying beetles or gathering fossils was enjoyed as a hobby by wealthy gentlemen (and some ladies) of leisure.

But scientists increasingly sought universal laws to explain how the environment worked, not merely to understand and enjoy nature, but also in order to use, manage, and exploit natural resources, to dominate and control environmental processes. Rather than looking in wonder, this approach often regarded environments pragmatically in terms of machine-like processes that, given sufficient knowledge, could be more effectively managed and exploited in the interests of industrialization and European imperialism in the nineteenth century (Bowler 1993; Worster 1994).

This mechanistic view of the environment supported the separation of processes for analysis, so that different aspects of Earth surface functions and ecosystems became the focus of different scientific disciplines: geology, ecology, geomorphology, atmospheric meteorology, and physical geography all developed their own disciplinary perspectives on aspects of environmental processes and change through the nineteenth century and into the twentieth century. These early efforts at understanding environments often focused on how they functioned in terms of natural cycles of carbon, water, and other nutrients, food chains/webs, weather patterns, stream evolution, and positioning of the continents. But the disciplinary diversification that facilitated such specialization later proved problematic when the search for more integrated and holistic understanding to tackle environmental problems in the twentieth century was hampered by the disciplinary boundaries that were by then entrenched.

Against the rising power of human technology and the dominant Enlightenment ideal of progress, more and more commentators began to argue that environments were being damaged by human exploitation. A key geographical work, Man and Nature by George Perkins Marsh, was published in 1864 in the United States and is sometimes cited as the first “modern” expression of such environmental concern. Marsh’s book
was pioneering in challenging the common assumption that environmental resources were inexhaustible and the environment was resilient to human impact, but the agenda it set was not pursued until the twentieth century.

Environmental science and environmental concerns

It was only in the mid-twentieth century that environmental science really began to address what we now think of as “environmental issues,” prompted especially by Rachel Carson’s (1962) *Silent Spring*, which used scientific evidence to argue that pesticide use was taking a huge toll on bird populations. The rise of ecology as a scientific discipline in the twentieth century, as well as computer modeling of environmental futures, also contributed to the rise in environmental concern and attempts to protect environments from further harm. Both *Silent Spring* and *The Population Bomb* (Ehrlich 1968) were politically influential books written by ecologists that prompted both high-profile debate over and more research into human–environmental futures. The environmental movement thus both contributed to and benefited from the expansion of environmental science since the 1960s, with environmentalism serving as “a midwife” in legitimating new scientific agendas and providing an audience eager to hear their results (Hart and Victor 1993).

So, by the 1960s, the label “environmental science” had come to mean scientific research into basic environmental processes, but also more applied research that sought to inform environmental protection by improving our understanding of how environments work and how they are changing. Geographers and historians of science have thus shown that environmental science is not neutral, but was shaped by the rise of the environmental movement, as well as by policy demands for environmental knowledge for decision-making. For example, scientific work on the carbon cycle in the 1960s was not connected with climate change until the 1970s, when this had become an issue (Hart and Victor 1993). In turn, emerging scientific results have shaped public awareness of, and policy agendas to tackle, environmental problems such as global climate change (Taylor and Buttel 1992).

Some environmental scientists embraced this policy relevance and usefulness; for example, British ecologists in the 1940s attempted to define nature “conservation” as their own scientific and professional remit, and thus to exclude amateur naturalists who were working instead on nature “preservation” (Bocking 1993). But others sought to maintain their scientific credentials as separate from policy demands; for example, the Ecological Society of America sought to present ecology “as an objective, value-free science,” rather than a political movement (Kinchy and Kleinman 2003, 891).

Geography as a discipline missed many of the benefits from the “rising tide” of environmental concern in the 1960s that underpinned the expansion of environmental science elsewhere, especially in ecology. This is remarkable given the potential of geography to combine insights from physical and human geography to advance research into the human–environment interactions. At the time, the discipline was undergoing divisions between physical geography and human geography, with the latter increasingly influenced by humanism and Marxism into the 1970s, with little attention paid to environments, and experiencing the rise of spatial science in physical geography in particular. By the 1990s, however, geography had begun to develop this area, so that “environmental geography” was recognized and defined as “the interface” between physical and human geography by the
United Kingdom’s Subject Benchmark Statement in 2000, which defined the discipline in higher education nationally.

The range of environmental science today

Today, “environmental science” is a widely recognized label for both basic and applied research into environmental processes and problems and encompasses a vast field of topics. For example, the subject category of “Environmental Sciences” in Thompson Reuters ISI Citation Reports included 223 journal titles (as of October 2015) including  

- Aerosol and Air Quality Research
- Arctic, Carbon Management, Conservation Biology, Ecotoxicology, Energy Policy

Currently topping the ranking in this category (as measured by Impact Factor) is Energy & Environmental Science, launched by the Royal Society of Chemistry in 2008, which is emblematic of the range of environmental science today, describing itself as a “forum for researchers investigating a more energy-sustainable planet.” The journal editors emphasize collaboration and cross-fertilization between disciplines such as chemistry, engineering, and global atmospheric science (Energy & Environmental Science 2015, 14). This reflects both the breadth of environmental science today and also its emphasis on addressing environmental problems through issue-oriented research and innovation.

Environmental science thus contributes to practical measures for redesigning environments through restoration, remediation, rehabilitation, reclamation, and species reintroductions. Bodies such as the Intergovernmental Panel on Climate Change have been established precisely in order to identify the best scientific knowledge (as defined through peer review) on the processes in, impacts of, and options for mitigating climate change, and to communicate this knowledge to global environmental policymakers under the auspices of the United Nations.

Is environmental science multidisciplinary, interdisciplinary, or transdisciplinary?

This breadth of scope means that, to address environmental issues fully, environmental science needs to draw on knowledge traditionally claimed by different disciplines and integrate diverse expertise. For example, to research ways to reduce waste pollution on land, a research team may need expertise in microbiology, to analyze how mixed waste decomposes after dumping, in hydrology, to understand how polluted waters from dumps move into and through groundwater systems, in engineering, to explore ways to tap gas released from the dump for energy recovery, and in economics, to analyze the costs and benefits of different technologies to address this.

The need for such integrated expertise has caused environmental science to be labeled multidisciplinary, interdisciplinary, or transdisciplinary by different commentators.

“Multidisciplinary” means that researchers work collaborate by pulling together knowledge and methods from different disciplines, and sharing expertise to address problems that
ENVIRONMENTAL SCIENCE

involve more than one discipline. For example, the journal *Science of the Total Environment* defines the total environment as the atmosphere, hydrosphere, biosphere, lithosphere, and anthroposphere, and only publishes “multidisciplinary” work which focuses on more than one of these spheres. The journal lists 19 relevant topic areas for articles, including agriculture, air pollution, ecosystem services, ecotoxicology, environmental management, groundwater hydrogeochemistry, human health, nanomaterials, noise, remote sensing, marine ecology, and waste and water treatment (*Science of the Total Environment* 2016). This again suggests the great breadth of environmental science today and that multidisciplinary collaboration can be as varied as engineering working with hydrology to address water management, or atmospheric science working with medicine to monitor the spread of air pollution and its effects on human health.

“Interdisciplinary” goes further and means that researchers from different disciplines work together by developing new knowledge and methods; that is, they do not simply combine expertise from multiple disciplines (as in multidisciplinary research), but collaborate more creatively to innovate and develop new ways of addressing problems that exist between and across disciplines. “Transdisciplinary” means a yet further move to a holistic approach to researching environmental problems that borrows freely from other disciplines, but works across disciplinary boundaries without being confined by disciplinary agendas.

These three terms are often used interchangeably and it is difficult to pin down the differences precisely, because they often function mainly as normative ideals of how research such as environmental science should progress, rather than as mutually exclusive descriptions. Moreover, achieving interdisciplinary and transdisciplinary research in practice remains difficult, because traditional disciplinary boundaries are still used to organize academic departments, training and recruitment of researchers into academia, and research funding and publishing regimes, for example, through the remits of funding bodies and peer-reviewed journals. This means that work that aims to go beyond disciplinary agendas is often pulled back into them when it comes to academic publishing or teaching, although it may have more success influencing practical work outside academia, which is less bound by such disciplinary “silos.”

And there is a further challenge: many environmental issues require analysis not only of myriad organic and inorganic environmental processes, but also of complex environment–society interactions, for example, for climate adaptation modeling. This requires the environmental natural/physical sciences to integrate with the social sciences addressing those same problems from very different perspectives, but is hampered especially because of deep divides in methodological expectations. Environmental social science has come to value qualitative methods recently, because they are seen as more able than quantitative methods to get beyond simple, post hoc rationalizations of environmental actions to reach more contextual, socially embedded reasons, especially to expose social norms and routinized practices. However, qualitative methods are often seen by environmental natural/physical scientists as woolly, anecdotal, and lacking in scientific rigor, thus hampering interdisciplinary working.

Some have argued that because of these problems of integration, what is needed is not merely environmental science but “sustainability science” (see Sustainability science), taking a transdisciplinary approach to fully integrating research from the natural, biological, social, and engineering sciences in order to use findings directly to shape policies and actions for sustainability.
Criticisms of environmental science

Although often presented as neutral, objective, and value-free, environmental science has also been shown to be irreducibly social and political (e.g., Taylor and Buttel 1992; Demeritt 2001). For example, analyses by social scientists of global warming science and climate change modeling suggest that scientific research is defined not solely by scientists but also through their interactions with other interests, especially policymaking (e.g., Shackley and Wynne 1995). But acknowledging this risks providing ammunition to those opposed to mitigating climate change, who then claim that scientific results are distorted and corrupted by political pressure or personal interests.

Environmental science has also been criticized for not being able to address the complex environmental problems of today, such as biodiversity loss and climate change, problems which have high uncertainty in terms of what we know, but also high risks in terms of their potential impact on human activities. Because of this uncertain but risky character, some argue that these problems require a new kind of science, a science that goes beyond the traditional approach of providing objective, certain knowledge to policymakers, a “post-normal science” (Funtowicz and Ravetz 1993; Ravetz 1999) that draws on scientific knowledge but also incorporates other ways of knowing, thus democratizing participation in decision-making through involving the “extended peer community” outside professionally accredited scientists.

This offers a normative analysis of what science should become, in order to tackle complex environmental problems where “facts are uncertain, values in dispute, stakes high, and decisions urgent” (Ravetz 1999, 649). This exhortation argues that, where there are few “hard,” objective scientific facts available to make decisions, “soft” subjective value-judgements become more important. But some scientists see this as threatening their scientific authority and professionalism by allowing nonscientists to be accepted as valid contributors of knowledge on the basis of experience or their position as a stakeholder affected by environmental change, rather than on the basis of research or training.

Environmental uncertainty

Simon J. Shackley
University of Edinburgh, UK

Environmental systems are typically complex making them difficult to understand and subject to high levels of variability and uncertainty. Predicting how such systems might change in the future is a precarious task, a classic example being the difficulty of weather forecasting beyond a week ahead due to the chaotic properties of weather (requiring great precision in establishing initial conditions, which in practice is currently not possible).

Types of environmental uncertainty

Understanding of scientific uncertainty has been revolutionized in the past half century through mathematical advances in understandings of nonlinear dynamic processes and systems, variously known as chaos, complexity, and indeterminacy (Smith 2007). But there remains vigorous debate about how best to analyze environmental uncertainty. Some scientists maintain belief in the capacity of classical scientific experiments, whereby underpinning mechanisms and processes are neatly parcelled up and investigated one by one through establishing dependent and independent variables. Those working in the complexity paradigm, meanwhile, point to the prevalence of interactions between multiple, simultaneous mechanisms/processes, requiring extensive use of surrogate and composite variables, parameterizations, analogs, and more holistic, system-wide investigation, involving inter alia statistics and simulation modeling tools but also recognition of the value of qualitative methods.

Uncertainty is often described in terms of “risk” but environmental uncertainty differs from risk in that risk is quantifiable in a probabilistic sense but uncertainty is not, because the probability of an event happening and the magnitude of its effects are unknown and therefore not quantifiable. An example of risk is a 1:10 chance of a flood happening. But in many real-world settings, such a flood risk is based on historical records, which are usually insufficiently long or accurate to generate quantitative predictions; furthermore, it assumes that other parameters influencing flooding are either not changing or are changing in known ways. Predicting flooding is therefore more about uncertainty than about risk.

As well as uncertainty, there is also indeterminacy (Wynne 1992), whereby further uncertainties are introduced when people and institutions attempt to apply knowledge of (and in) complex environmental systems. Indeterminacy usually arises where contingent sociotechnical practices and behavioral and collective responses brush up against the presumptions of scientific and engineering analysis. It is assumed, for instance, that agricultural workers who apply pesticides carefully read and understand the health, safety, and environmental instructions for appropriate application; hence the manufacturer and regulator can feel confident that due diligence is undertaken. Yet, the realities of real-world application of pesticides soon reveal a different story, one that requires regulators and
Environmental uncertainty

scientists to appreciate the sensitivity of their risk assessments to questionable assumptions and to perhaps ask a different kind of question – not so much “how safe is chemical X?” but rather “under realistic use conditions, what is the risk of overexposure by the operator, how certain is our understanding of the harmful impacts of chemical X, and is that risk acceptable to users and operators?”

As well as uncertainty, risk, and indeterminacy, understanding and predicting environmental change also involves ignorance, where processes, mechanisms, interactions, and feedbacks that are relevant to a given system are simply not known about at a given time (they are “unknown unknowns”). An example in climate modeling is the realization over the past 20 years that human-induced biomass burning (associated with deforestation and agriculture but also cooking) has impacts upon global climate change through the production of black and organic carbon particles. An example in the social sciences is the unexpectedly rapid pace of economic change in China over the past two decades. Even in 2000, the experts on greenhouse gas emission scenarios for the Intergovernmental Panel on Climate Change (IPCC) so underpredicted China’s growth that the IPCC’s highest emissions scenario was outpaced by real events in less than a decade.

Environmental uncertainty as a problem, resource, or construction?

Environmental uncertainty is still widely regarded as a “problem” by policymakers and by many scientists alike, the prevailing assumption being that reducing uncertainty will illuminate the correct policy pathway. This so-called linear model ties in closely with modernist assumptions of progress which have proven so controversial amongst social scientists. Yet, scientists also know only too well that science-in-practice generates new uncertainties at the same time as answering existing questions and, occasionally, paradigm shifts change the set of questions entirely. Environmental uncertainty is also used by researchers and other stakeholders to argue for more expenditure on research and development, and in policy debates to argue against implementing a policy or technology (e.g., via the Precautionary Principle, where the onus is on avoiding environmental harm, but also by climate change sceptics who continue a long tradition of proposing “more research” before major policy interventions are undertaken). Environmental uncertainty is rarely “neutral” but becomes embroiled in – and fuels – political and policy debates and controversies.

Douglas and Wildavsky (1982) reframed the entire domain of environmental risk and uncertainty as being far more about cultural and social constructions of what is regarded as an acceptable risk than about merely quantifying risk; the role of technical knowledge in that social process varies but is frequently minimal while the role of values is given greater prominence. Because of technical uncertainty, the same corpus of knowledge can readily support a number of distinctly different positions on complex environmental issues. Cultural theorists have therefore argued that values and associated commitments and preferences come to shape the way that uncertain knowledge is constructed and its consequences articulated. Some advocate a specific grid-group theory to account for the mutual reinforcement of patterns of social interaction and social construction of risk and uncertainty (e.g., Verweij et al. 2006). But this has proven controversial, in part because scholars have been unable to agree on a single theory of social construction, resulting in widely diverging
and incommensurable understandings of how environmental uncertainties are constructed.

**Coproduction of environmental knowledge and policy**

Underpinning notions of uncertainty is the *conditionality* of scientific knowledge. While scientific knowledge claims can be validated to some extent though use of controlled (usually laboratory) conditions, beyond such confines claims to knowledge are harder to validate. A classic example is the long-term fate of radioactive fallout from the Chernobyl nuclear power plant accident of 1986 within upland peaty soils in northern England (Wynne 1998). The soil scientists used models of soil dynamics which failed to take account of the particularities of peaty soils and of sheep grazing practices. This inappropriately extended the scope of their existing numerical tools into untested domains, including socioecological practices that were not incorporated into their soil models. Similar examples can be provided for many other types of models used in geography, for example in studying climate change, hydrology, geology, and infectious diseases.

In understanding why such extension work happens, scholars have developed the concept of the coproduction of science for policy. “Science” provides answers to technical questions faced by policymakers, while policy decisions help scientists by articulating technical questions, helping to bring closure on what issues they should address and how. Uncertainty for both science and policy is reduced by this coproduction – a self-reinforcing cycle which only comes unstuck when it bumps up against some disruptive event. A good example is the risk assessment surrounding “mad cow disease” (bovine spongiform encephalitis, or BSE) in the United Kingdom, whereby key scientific questions faced by the scientific advisory committee established to advise the government on the risks of BSE were answered in part on the basis of the implicit preferences of senior policymakers. In the pre-1996 period, this advice was that the risk of the infective agent responsible for BSE moving from cows to humans (hence the risk of eating BSE-infected meat) was negligible; that advice changed in March 1996 when the UK government stated that there was firm evidence that the infective agent causing BSE had moved from cows to humans. Politicians subsequently explained to the public that their pre-March 1996 decisions were taken on the advice of the scientific experts, ignoring or obscuring the political decisions in choosing which questions were (and were not) addressed (and how) in the first place (Van Zwanenberg and Millstone 2005).

**Responses to environmental uncertainty**

It has been proposed that policymakers shift focus away from “predicting” or “anticipating” the future because of endemic uncertainty (Collingridge 1980). Even if it is dressed up as “analysis of future scenarios,” the temptation to select more or less “likely” scenarios tends to prove irresistible to scientists and policymakers alike. An alternative is a “fallibilistic” approach (Collingridge 1980), based upon prudent “trial and error,” minimizing the error costs (that is the cost of an incorrect policy or business decision) and maximizing the rapidity and quality of feedback on the impacts of an intervention. The fallibilistic approach tends to encourage more flexibility and changeable options and responses, frequently implying smaller-scale interventions, at least initially until the complexity of the system and its sensitivities are better understood. This is because scale effects, nonlinearities, and
indeterminacies always limit the ability to predict the impact of an intervention going forwards.

Views based on the construction or the coproduction of environmental uncertainty have prompted arguments for greater transparency and openness in how values and environmental facts become intertwined. New institutions and processes for bringing together different perspectives to create policies which appeal across distinct value clusters have also been proposed. For example, participatory, dialogue, or deliberative democracy approaches are now widely researched and practiced in areas of environmental uncertainty. In development studies, uncertainty in the socioeconomic and cultural context of rapidly changing economic, environmental, and socioecological conditions has been better understood by using more qualitative, dialogue-focused methods such as interviews, focus groups, and ethnography – as opposed to traditional surveying. Still, the relative undercapacity of research institutions in many developing countries has hindered attempts to understand and interpret rapidly changing societies and their relationship with the environment, encouraging an opportunistic or “scattergun” approach by governments, nongovernmental organizations (NGOs), and donor organizations aiming to encourage more sustainable development pathways. All too frequently, interventions are poorly designed, are not integrated with other ongoing programs and developments (including commercially focused projects), and the outcomes are not properly or independently recorded. Nonetheless, new technologies for collecting and sharing information may assist the further development of progressive mutual learning participatory methods, in turn providing a better understanding of the uncertainty space within which interventions are proposed.

In industrialized countries, experience of participatory approaches with publics has revealed a greater awareness of the conditionality of scientific knowledge amongst the public than was perhaps initially presumed by the scientific community. Some skepticism of the motivation of scientists and engineers, of their funding sources and suspected “hidden agendas” has emerged during focus and in-depth discussion groups, while many participants have also found face-to-face interactions with practicing scientists to be highly rewarding due to the openness and transparency with which scientists tend to discuss uncertainty in such an intimate context. The problem is in scaling up such experiences beyond the very small samples in a focus group and also in embedding the outcomes of such processes in real-world policymaking, thinking, and practice. In reality, many senior policymakers are resistant to the premise behind deliberative democracy, limiting the potential opportunity for uncertainty to be viewed as a constructive source of dialogue and negotiation rather than as a “problem” that needs to be “fixed.”

Environmental valuation includes different methods for estimating the economic values associated with ecosystems. Monetary values for ecosystem “goods” (such as clean air, wildlife, biodiversity, and scenic views) and “services” (such as the carbon sequestered by forests or the habitat provided by wetlands) are, however, difficult to calculate because such goods and services are not normally traded on the market. There is, thus, much contention over the best method for deriving monetary values and debate about whether ecosystems can be responsibly represented by prices.

Origins of environmental valuation

Environmental valuation originates in the field of economics where there have been wide-ranging attempts to assign monetary values to ecosystems since the late 1940s. However, it was not until the 1990s that systematic valuation frameworks were devised in the discipline. Such valuation frameworks allowed the practice to be taken up outside of the academy by policymakers and public agencies. In the absence of actual markets for environmental goods and services that would determine prices based on demand and supply, economists now use two main approaches in order to arrive at monetary values. The first approach encompasses stated preference methods, including the most commonly used contingent valuation method in which respondents are surveyed about their willingness to pay for environmental improvements or to avoid environmental loss. For example, respondents might be surveyed about how much they are willing to pay for a specified reduction in air pollution or to conserve a particular species. The second approach encompasses revealed preference methods, whereby environmental prices are calculated using market information for similar market-traded goods and observed human behavior. In hedonic pricing, for example, holding constant other possible variables, the difference between the price of a house with a mountain view and one without is approximated as the environmental value of the view itself.

While the term “environmental valuation” most commonly refers to the practice of assigning monetary values to nature, the question of how nature should be understood, treated, and valued (i.e., what significance and importance it should be accorded) has been discussed by multiple disciplines through varied approaches. From Marxist perspectives, authors expose the poverty of capitalist economies that can only value nature in terms of its ability to circulate on markets, thus negating the cultural and moral values associated with all economic activity (see Eaton 2011). Other authors suggest that nature can and should be valued through nonmonetary approaches that focus on more pluralistic conceptions that account for cultural, moral, and ethical understandings of nature. For example, O’Neill, Holland, and Light (2008, 200) propose
that environments should not be understood as “mere bundles of resources” but, rather, as “places to which humans have a lived relation of struggle, wonder and dwelling.” For these authors there is no single value (such as dollars or pleasure) to which all others are reducible. There is thus no credibility to the idea of trading off environmental values, because value is specific to time, place, and positionality. Instead, these authors call for pluralistic conceptions of environmental values that are rooted in everyday encounters between humans and nonhumans, and privilege history and narrative in the valuation of the environment. Such an approach requires policymaking practices that see decisions not as discrete events but as historical patterns of choice that express the character of the institutions that make them. Certainly conceptions of value in relation to the environment are wide and diverse in geography and many have arisen precisely as criticisms of the process that has come to be known as environmental valuation.

Once environmental goods and services have been assigned monetary values, they can be incorporated into resource management and policy decisions, and traded on markets as commensurable quantitative amounts. For example, lost habitat, increased air pollution, and aesthetic changes are rendered as quantitative sums that allow them to be compared to the projected economic benefits of a proposed industrial project in a cost–benefit analysis. In the case of externalized costs associated with environmental degradation, policymakers can transfer the costs associated with a particular activity to the perpetrator through legislation, taxation, or levies. For example, the environmental costs associated with absorbing the waste products of a particular commodity can be internalized into the price of the good to be paid by consumers, or into the price of the inputs to be paid by producers. Payments for maintaining ecosystem services such as habitat can also be made by states wishing to promote environmental stewardship to private citizens and other organizations that manage private resources. Farmers, for example, have benefited from such payments to conserve habitat on their lands. Finally, environmental valuation enables practices of compensation for environmental losses and the offsetting of environmental impact in one location through investment in environmental goods and services in another. Once a price is determined for a wild lake bearing fish, for example, an industrial developer can be made to provide compensation to a local community for the impact of its development on the lake, or it can be asked to offset the environmental damage it will cause by investing in “equivalent” environmental goods and services in another location.

While academics have been developing methodologies of environmental valuation since the 1940s, its application in public policy and private markets has been more recent and limited. Environmental valuation techniques have been used in damage assessment and resource compensation in the United States, and in valuing the benefits to human health from changes in environmental quality in the United States, Canada, and Europe. Environmental valuation has also been used in cost–benefit analyses of water and forest resource planning and for state-run payments for ecosystem services (PES) programs, whereby farmers or other stewards are paid to preserve an ecological function like species habitat.

More recently, environmental valuation has been increasingly used to value ecosystem services with the aim of incorporating them into various programs of trading and offsetting. At the international level, since the 2000s the United Nations Environment Programme, the G7 environmental ministers, the Global Environmental
Facility, and the European Union have been involved in several initiatives to assess and document the costs and benefits of biodiversity. This international assessment of environmental benefits and costs is informed by multidisciplinary debates that surrounded Costanza et al.’s (1997) valuation of the entire Earth (its “natural capital” and environmental services) at $33 trillion (Figure 1). Especially contentious is the accuracy of calculating a total value of the Earth rather than a marginal value of a unit of nature. Further debate surrounds the best practices for the valuation, including the standardized classification of environments.

At national scales, trading and offsetting have been explored by Hillman and Instone (2010) in their analysis of Australia’s NSW Threatened Species Conservation Amendment (Biodiversity Banking) Act 2006, which allows landholders to establish values for the biodiversity of a site and offer the values as credits that developers can purchase in order to offset biodiversity losses caused by their actions elsewhere. Robertson (2007) has examined the US Environmental Protection Agency and the US Department of Agriculture’s creation of water quality and wetland credits. In these banking and offsetting schemes, environmental goods and services are brought into markets; their prices are, thus, forged through the practice of market trading rather than assigned on the basis of stated or revealed preferences or intrinsic biophysical worth.
Engagement in human geography

Human geographers have engaged with the practice of environmental valuation through both application and criticism. Some authors have adopted it as a mechanism through which to incorporate a concern for the environment into policymaking. For example, looking at China’s housing market, Jim and Chen (2007) compared stated and revealed valuation techniques in a study of environmental externalities, such as access to green space and views of water and parks in Guangzhou. They argue that municipalities could mobilize the positive economic values accorded to environmental attributes in order to encourage urban green spaces and nature conservation in the development of housing. Heidkamp (2008) argues that geographic factors such as scale and proximity should be incorporated into environmental valuation techniques, and thus into cost–benefit analyses. According to Heidkamp, spatial proximity should be factored into the relative scarcity of environmental goods and services. For example, trees may be plentiful globally, but their being scarce locally might make for a higher price in a particular market. Moreover, transaction and interaction costs increase over distance, which means that, in addition to temporal discount rates, spatial discount rates ought to be applied in valuation methods. Heidkamp suggests that spatial variables such as scale and proximity be integrated into cost–benefit analysis through the use of geographic information systems (GIS).

Geographers have also been investigating environmental valuation through the use of qualitative methods. In their study of a contingent valuation survey used by the Pevensey Levels Wildlife Enhancement Scheme in the United Kingdom, Burgess, Clark, and Harrison (2000) found that respondents’ answers to the survey questions were very context–dependent because respondents came to the surveys with different knowledge and experience of the environment they were asked to value. They also found that the presentation of information about the good that was to be valued significantly affected, indeed framed, the respondents’ willingness to pay. Finally, Burgess, Clark, and Harrison reported that once respondents had engaged in their in–depth discussion groups and learned more about contingent valuation, they felt deceived about the purpose of the survey and were resistant to the idea that a monetary value could even be associated with nature. In a second study Clark, Burgess, and Harrison (2000) used qualitative methods to assess whether the willingness–to–pay figures that survey respondents provided were valid. They found that respondents called into question both the bases and the relevance of their own willingness–to–pay figures when they were engaged through in–depth discussion after having taken the survey. These studies suggest that contingent valuation methods don’t simply reveal underlying and unchanging values, but rather that environmental values are constructed through interactions, that they are changing, and that they are specific to contexts like place and experience.

Criticisms of the practice of valuation can be grouped in two main categories. First, geographers have challenged the methods of valuation and questioned the commensurability of different bits of nature across space. Much of this criticism is focused on revealed and stated preference models for deriving prices for nature. As critics point out, such methods are focused on individuals’ willingness to pay, which says little about the value of the piece of nature in terms of its ecological, cultural, social, or even economic functions. In other words, just because individual consumers are willing to pay only a small amount to conserve water quality does not mean that water quality is of little value to a local economy.
When preference-based approaches are used for deriving value, only those bits of nature for which individuals are willing to pay receive investment for conservation. However, other methods for valuation exist. For example, Costanza et al.’s (1997) valuation of the Earth’s ecosystem services used a benefits transfer approach that priced the benefits of natural ecosystems to society by transferring calculations based on willingness to pay from one particular study region to various other regions and contexts. This allows the calculation of value regardless of whether there is a willing buyer of such services, and recognizes that ecosystems do not stop transferring valuable benefits to society if there are no willing buyers. However, at root, this approach is still based on calculations of willingness to pay.

Techniques rooted in biophysical approaches provide a quite different method for valuation. According to the Economics of Ecosystems and Biodiversity (TEEB) (Kumar 2010), a prominent global initiative focused on the economic benefits of biodiversity, biophysical approaches can be used to measure the value that flows from underlying physical parameters. For the TEEB, biophysical indicators such as diversity, quantity, condition, and pressures facing ecosystems should be the main factors in valuation. In the case of timber production, for example, dry matter productivity can be modeled and mapped using remote sensing imagery and meteorological data to measure the extent and quantity of dry matter. Here monetary values are attached to biophysical characteristics rather than to human preference.

Geographers have also questioned whether it is even possible in principle, and therefore desirable, to reduce complex ecosystems or bits of nature to quantitative prices and commensurable units. According to Robertson (2011), in order for ecosystem services to be incorporated into markets, and thus to circulate as value, a variety of “socially-necessary” abstractions must occur. For example, wetlands have to be classified into types that are described by relatively static and governable qualities, but these types can’t capture the kind of dynamism of natural landscapes whose qualities are constantly changing over time and space. Moreover categories of value related to ecosystem functions are created that can’t fully express the complexity of wetland functions. In other words, the removal of wetlands in one location may not be ecologically equal to the preservation of the same quantity of wetland in another location, even if they are classified and categorized as equals, and circulate on markets as the same quantitative sum of money.

Another example of the reduction and simplification processes at the heart of environmental valuation is the ways in which the removal of different parts of a particular habitat may have differential effects that valuation techniques will miss. For instance, if one hectare of wetland habitat is removed from a larger mass, the impacts will be less than the removal of one hectare of the same habitat that serves as a small connecting patch to a wider network. The removal of the latter endangers species capacity for migration and movement. Valuation techniques could be modified to explicitly value the connectivity function of habitat, but it is unlikely that valuation can ever account for all the various different functions that nature and ecosystems provide. At the very least, such functions have to be known, understood, and capable of fitting into categories constructed by the humans doing the valuation. Not only will some environmental functions be missed, but others may not fit into valuation frameworks at all. Noninstrumental values, that is, values that are not useful for other (often human) purposes, such as filtering water or pest control, are the most difficult subjects of valuation. Such values are often called intrinsic values because they are ends in themselves rather
ENVIRONMENTAL VALUATION

than useful functions. For example, it is difficult to figure out how a cultural attachment to place can be captured by valuation. Indeed, the conceptualization of ecosystems as bundles of discrete functions itself is a socially constructed and instrumentalist imposition that belies the interconnected and complex ways in which ecosystems work.

Typically, geographers have understood the process of valuation as a practice of social construction rather than as the quantification of objective biophysical processes and traits. Managers, scientists, and economists must first name, describe, and explain the functions and worth of bits of nature before they can be classified and categorized discretely and assigned monetary values. In this line of critique, it is not just that humans might miss the full complexity of ecosystems in their classification schemes and categorization projects, but that nature can only be understood through limited human conceptions that are constituted by prevailing social, economic, and political discourses. Such a social constructionist view of valuation recognizes that values are not given or objectively measured; they are, thus, open to contestation and prone to becoming sites of resistance over political–ecological relations.

The social practice of environmental valuation has also been criticized as Eurocentric because the simplifying practices outlined earlier can be understood as privileging certain knowledges, peoples, values, and landscapes over marginalized others. Gibbs (2010) examines values associated with water in central Australia and finds that resource managers’ reliance on environmental valuation practices marginalize Aboriginal values like the variability of water regimes and the interconnections between water and the rest of the world. According to Gibbs, concepts of diversity, change, complexity, and interconnection rather than separation, compartmentalization, and domination should be at the center of resource managers’ valuation practices. Both the spatial and the temporal variability of water regimes contribute to the diversity of values attached to these variable conditions. For example, pastoralists are dependent on the growth that is stimulated by the episodic flooding of floodplains. Similarly, patterns of rainfall and river flow affect how water resources are used; waterholes may be present for only three months of the year or they may be permanent features of the landscape. Even though economic valuation practices have attempted to price a diversity of values, such as recreation value, aesthetic value, and Aboriginal heritage value, among others, according to Gibbs, these interpretations are often oversimplified and rooted in Eurocentric assumptions. After all, whose practices of recreation, aesthetic, and Aboriginal heritage are valued, and what does this do to the diversity of understandings and uses of each?

Finally, geographers have been wary about the consequences of representing nature in monetary units; many authors see it as the first step in the commodification of nature and the incorporation of nature into neoliberal and capitalist logics. However, analytical distinction can be maintained between the framing of the environment in economic terms (for example, as costs and benefits, as providing services, or as natural capital), the monetization or pricing of nature, and the commodification of nature. According to advocates of environmental valuation, the assigning of monetary values to nature and its functions can be achieved without the circulation of that nature as a commodity on markets. For example, environmental valuation for the purposes of cost–benefit analyses does not necessitate commodification. In fact, environmental valuation as a practice was developed in order to assign values precisely to those bits of nature that did not have market prices because
they were not exchanged on markets. On the other hand, the economic framing of the environment and the monetization of nature and its functions are, indeed, necessary prerequisites for commodification. As Gomez-Baggethun and Ruiz-Perez (2011) argue, conceiving of human–nature relations as relations of utility and exchange invites the logics of capital and profit-making. Given an economic framing of the environment, decision-makers increasingly make choices within a narrative of scarcity, efficiency, and profit.

Although the economic framing, pricing, and commodification of nature can be held apart analytically, in practice monetary valuation has often been the first step in a process that ends with the incorporation of nature into capitalist processes. Since the rise of ecosystem service valuation in the 1990s, conservation has been practiced more and more through market instruments with the goal of realizing the monetary values calculated by practitioners of environmental valuation. As Robertson and Wainwright (2013) show, the state plays a prominent role in pricing nature and ensuring the expansion of capitalist value. According to these authors, it would be a mistake to prize apart the two processes of pricing nature and profiting off nature because the practice of environmental valuation only makes sense within a system that confronts nature in socially abstract value forms.

Environmental determinism

Tom Johnston
University of Lethbridge, Canada

Environmental determinism is an idea that occupied a central position in geography during the early part of the twentieth century. It holds that the physical environment shapes the course of human economic, cultural, and social development, and that this effect is independent of space and time. Many of the core ideas held by environmental determinists can therefore be linked to the theory of uniformitarianism and to Darwin’s conceptualization of evolutionary processes. Clearly, environmental determinism drew inspiration from outside geography and must be situated within several broader intellectual and scientific traditions.

It was an idea that was very much a product of its time. According to at least one prominent chronicler of the history of geographic thought, it represents the first attempt by geography to develop an overarching, unifying philosophical framework and fashion the subject as a science in search of theories and laws. Geography was a relatively new discipline at the time; it had only been formalized institutionally in the late 1880s and was thirsty for a focus that would provide an identity for its practitioners and would garner respect from other scholars. Further, through an explicit characterization of Europeans and North Americans as superior, owing in part to a more bracing climate, it provided a theoretical and moral justification for colonial expansion and exploitation. In addition environmental determinism was used in support of false claims about the existence of “different races” but more insidiously of the presumed moral superiority of some so-called races and of the potential for moral decay faced by members of the “white race” who spend extended periods of time between the tropics of Capricorn and Cancer.

Within geography, environmental determinism is closely associated with the German geographer Friedrich Ratzel (1844–1904), who summarized his ideas about environmental controls in a two-volume offering entitled Antropogeoghie published in 1882 (vol. I) and 1891 (vol. II). Ratzel, who is also credited with codifying the concept of “Lebensraum” (living space), an idea that formed the theoretical foundation for Nazi territorial expansionism, influenced a number of other scholars associated with this school of thought. Most notable among Ratzel’s followers were Americans Ellen Churchill Semple (1863–1932) and Ellsworth Huntington (1876–1947). Thomas Griffith Taylor (1880–1963), whose appointment to the University of Toronto in 1935 marks the formal establishment of the geography department there, was also a prominent voice for environmental determinism.

During an unquestionably important period in the historical development of geographic thought, the advocates of environmental determinism failed to cultivate universal acceptance for their ideas. In his Presidential Address to the 1922 Annual Meeting of the Association of American Geographers, for instance, published a year later in the association’s journal (Barrows 1923), Harlon Barrows advocated a vision of geography in which the aim was
to “to make clear the relationships between natural environments and the distribution and activities of man” and “to view this problem in general from the standpoint of man’s adjustment to environment, rather than from that of environmental influence” (p. 3). Barrows went on to urge geographers “to minimize the danger of assigning to the environmental factors a deterministic influence which they do not exert” (p. 3). Two years after Barrow’s address, Carl Sauer launched a less diplomatic attack on environmental determinism, referring to the search for geographic controls as “facile” and stating that “the geographer has taken the affirmative side in a debate on environment and has therefore failed to maintain the objective quality of the scientist” (Sauer 1924, 18).

In response to mounting criticism, geography witnessed the emergence of “possibilism,” which was really a form of modified determinism. Under possibilism the environment is viewed as offering a range of options from which humans select a preferred one based on cultural differences, available technology, and so forth. As Jones (1956, 369) notes, the options available to humans were “circumscribed” by the environment but not “fattily determined.” Possibilism failed to address adequately the central concerns surrounding environmental determinism and was eventually dismissed for many of the same reasons that environmental determinism was; it too was regarded as fundamentally deterministic, it ignored the role of what later came to be called “human agency” and the importance of locally constructed realities, and with the regional perspective gaining prominence, a non-nomothetic approach, many geographers of that time questioned the legitimacy of human geography searching for general theories and laws in the first place.

In the telling and retelling of the story of environmental determinism, the views of its advocates might have been characterized somewhat more rigidly than may have been the case. For instance, Spate (1952, 407) observed that while Ellsworth Huntington’s determinism was “avowed, and clearly based too much upon a part only of the immense complex of factors that which have gone into the making of history.” He added a qualification: “though it should be added that he is aware of this, and it is his disciples rather than himself who threw discretion to the winds.” And in a review of Semple’s (1911) *Influences of Geographic Environment: On the Basis of Ratzel’s System of Anthropo-Geography* Maret (1913, 282) noted that “Miss Semple possesses in a high degree the saving grace of moderation” and is “fully aware as she is of the fact that anthropogeographers in the past have occasionally brought more zeal than discretion to their task, she does not put her strengths into ventilating the larger and vaguer claims of her subject.”

The acceptance of environmental controls in the context of human development was not limited to geography nor was it limited to the period during which the idea occupied a position of prominence within the discipline. As noted by many commentators, discussion of the link between environment and humans can be traced to Greek scholars and to such works in particular as Aristotle’s *Politics* and *On Air, Water and Places* by Hippocrates. Environmental controls were also advocated by the Arabic scholar Ibn Khaldun (1332–1406), and according to Sommer (2007) a range of post-Medieval scholars, including Machiavelli (1469–1527), Montesquieu (1689–1755), Jean Bodin (1530–1596), and the German philosopher Johann Gottfried Herder (1809–1882) whose ideas about human adaptation to the environment are echoed today in the concept of cultural adaptation. During the modern era, environmental determinism has also enjoyed general acceptance within other disciplines, most
notably in anthropology, where the enthusiasm for environmental determinism may have been more deeply entrenched in theory and certainly lasted longer, but also within history, economics, and political science.

In recent decades, support for environmental circumstance as a nontrivial influence in the course of human activities and development has enjoyed in resurgence of sorts, especially in studies of regional economic development. This thinking can be seen, for instance, in Diamond’s Pulitzer Prize winning *Guns, Germs and Steel*. Such views have not been received with much enthusiasm in some quarters of contemporary geography, especially although not exclusively among critical theorists. And so environmental determinism has not enjoyed any kind of a renaissance within geography.

Once a core theory in geography, environmental determinism is today, much like William Morris Davis’s “Cycle of Erosion,” a subject covered in courses on the history of geographic thought rather than a functioning analytic framework. But geography has a long history of reinventing itself and the study of human–environment relationships remain a central part of the discipline’s focus. We see this interest manifested in many research initiatives, most notably in the contributions geographers continue to make to the study of natural hazards and global environmental change.

Grassroots environmentalism is that element of the wider environmental movement that engages in forms of contentious politics to develop knowledges about environmental issues, challenge cases of environmental destruction, and construct alternative visions and examples of ways of living that grassroots environmentalists argue are superior to contemporary unsustainable, unequal or oppressive ways of organizing society. Grassroots environmentalism involves ordinary people and activists who develop forms of contentious politics that they put into action themselves, using the resources and skills they have to-hand and guided by strategies they develop themselves. Grassroots environmentalism involves “contentious politics,” a feeling that something is not right, and that something must be done about it. This may be direct action, creating alternative visions and knowledge, or creating alternative institutions. Grassroots environmentalism does not limit itself to lobbying, to making demands or requests that others – businesses or the state – should take action to change policy. If demands are made, they are backed-up by action undertaken by activists, either to raise issues or to develop alternative models of how society should be organized. It is this focus on activists that makes grassroots environmentalism distinct.

Thus, grassroots environmentalism can be contrasted with other forms of environmentalism, such as conservation and community-based resource management, which do not have that element of contentious politics or the generation of alternatives. A focus on the grassroots excludes “elite activist” environmentalisms, such as that of Greenpeace, where the role of the grassroots is to provide money and/or resources to fund activities aimed at raising media awareness carried out by a small, select group of activists, perhaps in clandestine ways, or to fund lobbying. It can be contrasted with electoral politics through green parties. It can be contrasted with policy activism, aimed at changing government policy through lobbying alone. It must include some element of contentious politics.

Values

Grassroots environmentalism shares a number of value systems with the wider environmentalism, but tends to align itself with more fundamentalist or deep green, or ecocentric values (which see humans as just another species of equal value with other species) than with more pragmatic, cornucopian or human-centered values (which stress human primacy). Grassroots environmentalists share environmentalisms’ concerns about the questionable value of industrialization, centralism, and the big technological projects associated with contemporary capitalism but are also likely to be critical of the large scale, technological or market-based fixes to environmental problems, such as genetic modification, geoengineering or nuclear power, associated with cornucopian or promethean conceptions of...
ENVIRONMENTALISM, GRASSROOTS

environmentalism. Grassroots environmentalists are likely to be skeptical about the power of these “technological fixes” to solve pressing environmental problems, to question whether the resources needed to manufacture them on a large scale are are likely to continue to be available, and are concerned that these innovations are an attempt to maintain an unsustainable economy for one species – humanity – at the expense of others. Grassroots environmentalists are more likely to identify with the Luddites, those early opponents of capitalism who broke machinery that was putting them out of work, than with those who see technology as part of the solution. Some grassroots environmentalists are attracted to the primitivist preindustrial politics of green anarchism, arguing that given that humanity began to degrade its ecosystem when it first embraced settled agriculture, fossil fuel industrialization is unsustainability encapsulated.

Thus, grassroots environmentalists are more likely to take an ecocentric or deep green philosophical position, seeing humans as but one species amongst many others of equal value. Often attracted to anarchist thinking, they generally favor small scale and appropriate technological solutions because they argue that these enable humans to live within the wider ecosystems that nurture them, not attempt to dominate them. They are more likely to want to value local and indigenous knowledges, perhaps based on a deep understanding of the ecosystems in which indigenous people have lived for generations, and the knowledges that have grown up over time that have been constructed by a society adapted to that ecosystem. They look to value what Martinez Alier (2002) has called the environmentalisms of the poor and support an ethos of environmental justice, opposed to the destruction of environments inhabited by poor people and people of color. In cities, grassroots environmental struggles may take the form of urban social movements or community activism against, for example, a decision to site an incinerator next to a poor community.

Grassroots environmentalism may take the form of a political ecological struggle over the use of water resources or about land use. It may be a struggle over the industrialization of the countryside, over plans for, for example, a wind farm or fracking shale gas. In the latter case, grassroots environmentalisms can be dismissed by opponents as “nimby,” arguing that development should be somewhere else, “not in my back yard.” Grassroots environmental actors can, indeed, be relatively globally privileged actors defending their property values in an area of natural beauty valued for its recreational value. Or they can take a more ecocentric position, defending the rights of other species for their own sakes, opposed to development anywhere: not on Planet Earth (“nope,” not “nimby”). Here, disputes about the value of methodologies for valuing the services provided to humans from the natural world, so-called payments for ecosystem services, come into play. Some grassroots environmentalisms would welcome the chance to draw the value of the natural world into land-use decision-making. Others would oppose what they would see as the “commodification of nature.”

Grassroots activists may active in a number of social movement organizations at the same time, as well as in noncontentious environmentalisms, such as conservation societies, and vote for green parties. They are part of the wider environmental movement, not separate from it. Movement between the different elements of the wider movement is free and easy. They may be active in animal liberation politics, wishing to value other species in their own right. They are also likely to be engaged in women’s liberation, the peace movement, LGBT politics, and/or race-based movements, groups between which
again they would not wish to draw a wall. They see themselves as part of the wider movement for global social justice, with the proviso that theirs is a politics from the bottom up, from the grassroots, periodically coalescing into convergence spaces (Routledge 2003) in which they come together to act in concert, before dispersing.

**History**

Some would claim that grassroots environmentalism can be discerned in political actions going back to the Diggers of the English revolution tilling the land in common on St Georges Hill in Surrey, through direct action against industrialization from the Luddites to attempts to establish alternative or intentional communities in the United States and elsewhere in the nineteenth and twentieth centuries. Contemporary grassroots activism emerged in the 1960s as activists in the wider antiwar, countercultural, and student movements in the United States began to engage with the effects of environmental issues on people’s daily lives, and with wider debates about the environmental dangers of nuclear power and nuclear weapons in an era where nuclear weapons were still tested in the atmosphere in the South Pacific.

The issue of hazardous waste in poor communities was encapsulated in the struggles over Love Canal in Niagara Falls, New York, where hazardous chemicals had been dumped for decades in an abandoned canal that was later sold for a dollar for the construction of a school. The resulting health problems amongst local residents sparked grassroots mobilization to acknowledge the problem, close down the school, and relocate the community. The aptly named Love Canal became the first environmental cause celebre, inspiring many community protests against toxic chemicals that would have been tolerated before.

The environmental justice movement was born. Activists also pointed to the issue of environmental racism: the strong correlation between race and the location of toxic waste dumps.

Other grassroots environmentalists in the United States were inspired by Ed Abbey’s (1973) novel, *The Monkey Wrench Gang*, which popularized the tactic of “monkey wrenching,” the clandestine sabotage (ecotage) of industrial machinery that was engaged in ecological destruction of wilderness. The book inspired Earth First!, a loose network of activists who, adopting the slogan “do or die,” engaged in semilegal or illegal monkey wrenching, at times at great cost to their members (EF! member Judi Bari survived a car bomb). Others, inspired more by Gandhi than by Abbey, reacted against what they perceived as red neck misanthropy, rejecting a politics that seemed antihumanist. Some Earth Firsters, especially in the United States, argued strongly that humanity had become unsustainably populous and needed to die off: might AIDS be nature’s way of fighting back? Others identified a racist trope – were there not too many people but too many brown skinned people? Many were repelled by such antihuman views (Scarce 1990).

European and British grassroots environmentalism owes more to the peace and anti-nuclear movement and to feminism than to the preservation of wilderness given that it is almost impossible to find areas of Europe that have not in some way been altered by humanity. The Campaign for Nuclear Disarmament emerged in the late 1950s, and antinuclear activists opposed both civil and military applications of nuclear technologies. Large scale protests against nuclear power, especially in Germany, when allied to the threat to German forests from acid rain led to the formation of the German Green Party, which specifically saw itself as an antiparty party linked to grassroots environmental and peace activism. Friends of the Earth formed specifically
as a result of the failure of conservation groups to oppose nuclear technologies. Nuclear accidents at Sellafield (UK), Three Mile Island (USA), and, of course, later the catastrophic accident at Chernobyl in the USSR were huge mobilizers of protest against nuclear power. The decision by NATO to base ground-launched Cruise missiles in western Europe in the early 1980s was a similar mobilizing event, sparking mass marches and the long lasting peace camps at US bases in the United Kingdom.

The ideas and tactics of Earth First! crossed the Atlantic in the early 1990s as a result of the decision of the then UK government to engage in a major expansion of road building (Wall 1999). Protest camps were established to oppose a number of road building projects that activists claimed destroyed ecosystems and communities to promote unsustainable and antihuman “car culture.” “Reclaim the Streets” and “Critical Mass” organized occupations of road space for street parties and cycling festivals: large numbers of cyclists would congregate at rush hour and proceed through the city at a leisurely pace, arguing that they were not blocking traffic, they were traffic. This movement won a limited, if short term, victory in that a number of planned road schemes in the United Kingdom were cancelled. A new raft of innovative grassroots protest techniques such as “locking on” (activists using bicycle locks to attach themselves to machinery, property or trees scheduled for demolition) and constructing tree houses or sleeping platforms on stilts became a regular feature of grassroots environmental activism.

Other grassroots environmental activists experimented with the construction of localized economies. They established a number of local exchange trading schemes (LETS), networks sharing skills through the use of a community currency that members created and agreed to share between themselves. They established housing cooperatives and other forms of cohousing, and independent media. They set up bike repair workshops and social centers where activists could meet and exchange ideas, often in squatted buildings. These grassroots networks formed some of the currents from which emerged the anti-globalization and anti-capitalist movement that emerged at the turn of the last century until the events of September 11, 2001 and the resulting war on terror gave birth to a significant antiwar movement worldwide, but diverted attention away from environmental issues.

While long-term anthropogenic global warming had been identified in scholarly papers for many years, Al Gore’s (2006) film “An Inconvenient Truth” and a series of high temperature events and disasters like Hurricane Katrina contributed to a new form of grassroots environmental activism in the early years of the twenty-first century, climate activism (North 2011). Concerns about the implications of dangerous levels of climate change, “peak oil” (a time when easily extractable and cheap fossil fuels become more scarce), and other forms of resource constraint, and, after 2008, the global financial crisis intertwined to give a spur to a new wave of alternative institution building in the form of transition towns and low carbon communities. Activists met to educate themselves and their fellow community members about the implications of these three threats to continued global prosperity, and to take steps to create what they argued was the alternative: a community-run, convivial, localized grassroots economy. They established local currencies, community-owned ways of generating renewable energy, local food, local forms of production, and cooperative housing in order to bring these localized economies into being (Hopkins 2008).

Other grassroots climate activists, concerned that the transition movement was apolitical,
argued that more robust direct action was necessary to confront those entrenched powerful groups that, they argued, were responsible for global warming. Short duration protest camps were established outside power stations at which activists experimented with alternative ways of living in low carbon ways, and carried out direct action against polluters often in highly imaginative ways. For example, some climate activists formed the rebel clown army, using clowning as a way to communicate the politics of the movement and to disarm the states’ repressive apparatus: who would hit a clown? (Mason 2012). In the United States, high profile activism opposed the building of pipelines to carry oil from Canadian tar sands, and against coal-fired power stations. In the United Kingdom, communities opposed “fracking,” injecting fluids under high pressure to release natural gas from shale.

Drawing what they argue are the lessons of the failure of global elites to respond to the multimillion strong global protests against the forthcoming attack on Iraq in 2003, grassroots climate activists can be skeptical about the power of demonstrations to change policy, preferring direct action. They point to the success of the struggles of the suffragettes in early twentieth century Britain, which, they argue, forced the issue into the news and alerted an apathetic population about the nature of the problem. And, as was the case with Earth First! in the United States, climate direct action has drawn the attention of the security forces to the movement, with the high profile unmasking of police informers who had been embedded in the movement for many years, even fathering children with activists.

The response of the environmental movement to plans for a major expansion of nuclear power in the United Kingdom is unknown at the time of writing, although some high profile environmental activists have argued that given the danger of climate change and the need to keep the lights on, nuclear power should be embraced. Others, less convinced, continue to argue for grassroots, convivial, community-based local economies powered by renewable energies. They continue to be skeptical about high tech solutions to the climate crisis.

Current dilemmas

A number of questions face grassroots environmentalism in the early twenty-first century. Should the response to environmental and, more recently, climate crises work with or oppose the grain of currently hegemonic neoliberal conceptions of how to create prosperous economies, have faith in technological solutions (and in the human ingenuity capitalism unleashes), and see mass consumption lifestyles as inevitable? Who, some asked, ever rioted for austerity? Should the movement aim to convince large numbers of people to change their unsustainable practices, or concentrate on communicating the problem to the media and developing sustainable ways of living through what Seyfang and Smith (2007) call grassroots innovation niches? Transition towns activists are particularly critical of the likelihood of large numbers of people embracing the deeply ecological lifestyles pioneered in the protest camps.

Is grassroots environmentalism anti-capitalist or not, or, in the case of accusations of nimbyism, even progressive? Are radical environmentalists, as some neoliberal commentators and climate skeptics argue, “watermelons” (green on the outside, red on the inside), or wealthy people protecting their way of life in the face of what needs to be done to keep the lights on? For grassroots environmental activists associated with the peak oil movement, there is no point in actively confronting a system that is doomed to
collapse anyway as a result of resource constraint. Mass high consumption lifestyles, they argue, are unsustainable, have no future, and so the task for twenty-first century grassroots environmentalism is to use the same ingenuity that was used to build fossil fuel capitalism to build sustainable alternatives. While they would argue that, of course, it is necessary to oppose egregiously unsustainable practices like the construction of new fossil fuel power stations, they argue that too often direct action convinces few to change their livelihoods, and will be easily contained by the state – as the levels of police infiltration into the movement demonstrate. What is necessary is the patient work of construction of alternatives to unsustainable capitalism, which in many cases means recovering local knowledge about what food can be grown locally, how to reuse and repair what we have, and develop renewable energy projects, cooperatives, and local currency schemes. Anti-capitalist advocates of direct action counter that transition towns activists are naïve in expecting powerful elites to enable convivial and egalitarian grassroots localized economies to grow up as a viable alternative to the system from which they benefit.

Another question concerns the continuing nature of the grassroots environmental movement. It continues to be dogged by accusations that is white, globally privileged, and in danger of being seen as defending itself from developments that it still does not want in its back yard – an issue from fracking and opposition to wind farms especially. On the other hand, others argue that globally privileged actors engaging with the geographies of responsibility for their engagement with 200-year-old unsustainable fossil fuel capitalism is to be applauded. Those who accuse the western environmental movement as globally privileged ignore ways that networks of activists in the Global South and North can collaborate, or the rise of environmentalisms in the global south, especially in China (Watts 2011). Grassroots environmental activists continue to oppose the dumping of hazards on poor communities. But what has yet to be constructed is a global grassroots movement capable of opposing unsustainable practices, and bringing into being a sustainable economy that balances the right to development of all the world’s people in a climate constrained world where humanity has changed the planet to such an extent that real wilderness, untrammeled by humanity, cannot really be seen to exist. We now live in a period where humanity has changed the planet to such an extent that we are now living in a new geological age, the anthropocene. Grassroots environmental activists now need to develop an ecological and economic ethics for this new era (Gibson-Graham and Roelvink 2010).

In simple terms, environmentalism can be understood as the political and personal actions that are taken to justify and enable the protection and transformation of the environment in different ways. There is, however, a challenge associated with trying to develop an effective understanding of environmentalism. Environmentalism is associated with such a bewildering array of processes, ideas, and practices that its nature is difficult to grasp.

There are several different ways in which environmentalism can be defined. It can be understood in relation to that with which it is associated, namely, the environment. Environmentalism can thus be seen in the action of ecologically oriented protest groups, the electoral politics of green parties, the planning processes that seek to protect parts of the natural world, and the laws that seek to reduce the human impact on the global environment. Environmentalism is also evident in the energy company that fits pollution filters to its chimneys, the airlines that offset the impacts of flying by planting new forests, and the supermarkets that support organic food production. One can also define environmentalism by what it seeks to do. This might be protecting a piece of apparently unspoiled nature, reducing the amount of greenhouse gases that are entering the atmosphere, raising awareness of environmental change, opposing the damaging environmental activities of governments and large corporations, carefully monitoring the processes of ecological change, or providing education about how people can reduce their own impact on the environment.

But there is more to environmentalism than its goals. First, environmentalism often offers a form of metaphysical perspective. Metaphysics is concerned with the fundamental nature of being and seeks to highlight processes that may not be immediately obvious in any given moment. In this context, environmentalisms of different forms theorize the underlying processes that inform human–environmental relations in different ways. For eco-Marxists, environmental exploitation is connected to the broader processes of capitalism and its tendencies to externalize environmental costs (Burkett 2014). For deep green philosophers, human–environmental interactions are defined by an emerging disconnect between human consciousness and the natural wisdom (Luke 2002). Other branches of environmentalism emphasize the role of religion, technology, urbanization, gender relations, and race in shaping emerging human–environmental relations (Pepper 1996).

Second, environmentalism can be understood as an ethical standpoint that attempts to define what is just, right, and proper in environmental affairs (Fox 2006). This is not to suggest that there is necessarily any agreement on what is ethically good and bad within environmentalism. While certain thinkers and activists will argue...
that environmental justice is defined by limiting human interference in the biosphere and allowing ecological systems to return to a state of nature, others claim that such idealistic thinking is impossible and that humans have a collective duty to manage the global environment sustainably in order to balance the needs of economic growth, social welfare, and ecological protection.

Third, environmentalism marks out a form of political position and mode of representation. In the nineteenth century, this involved initial systematic attempts to protect nature from the harmful impacts of human development. The second key period in the development of environmental politics was the 1960s and 1970s, when environmentalism emerged as one of a series of radical movements (alongside feminism and antiwar campaigns) that sought to question the values, logics, and consequences of the Western military-industrial complex. As a political position, environmentalism is expressed in the treehouses of road campaigners and the meetings of the Intergovernmental Panel on Climate Change; antifracking camps and the electoral politics of green parties; animal rights campaigners and antinuclear power groups. What unites these diverse actors and interests is a desire to bring nature and the environment into political debates and consideration.

This entry explores environmentalism in three different forms and draws particular attention to the connections between environmentalism and geography. The Prussian geographer Alexander von Humboldt famously defined geography as the study of the Earth as the home of the human race. This deceptively simple definition reveals that geography finds its origins in the ways in which environmental and human systems interact. As a discipline that has brought together those keen to document changes in the planet’s environment (including hydrologists, glaciologists, pedologists, geomorphologists, meteorologists inter alia) with those who seek to understand the particular nature of the human condition (including anthropologists, urbanologists, behavioral scientists, and historians), geography has occupied very similar practical and conceptual spaces as environmentalism.

The connections between geography and environmentalism can be understood in three main ways. First, the research of environmental geographers into the processes of environmental change has actively contributed to scientific, public, and political awareness of environmental transformations that have inspired different forms of environmentalism to emerge. Second, the work of certain forms of critical geography (particularly in the context of Marxist, feminist, and various strands of poststructuralist geography) have helped to expose the broader processes that generate environmental change and prevent effective action being taken to prevent ecological harm. Third, geographers have been important chroniclers of environmentalism, and have explored the ways it has emerged in particular places, the specific spatial tactics it has deployed to pursue its political and ethical goals, and the impacts of different policy regimes and modes of socioecological practice.

Environmentalism in history

Environmentalism is now a mainstream phenomenon. This can be attested in governments, where environment ministries exist throughout the world; in the media, where broadsheet newspapers have dedicated environmental sections and TV channels employ environmental correspondents; and in politics, where green parties vie for our votes on a regular basis. As with many contemporary phenomena, however, there is a tendency to ascribe much too short a history to the notion of environmentalism. Given the
rapid rise of environmentalism over the last half century, there is a collective propensity to think of it as an invention of our time. In reality, environmentalism is much older than that. Although environmentalism as a formal political movement may have relatively recent points of origins (dating back to the late 1960s and 1970s) as both a metaphysical perspective on socioenvironmental affairs and an ethical standpoint with regard to human–ecological relations, environmentalism is tied into a much longer human past. While they may not have voted for a green party, or campaigned against the impacts of climate change, early human societies developed complex understandings of the relationships between people and their surrounding environment, and orchestrated sophisticated systems and rituals for controlling these relations. By briefly exploring the complex historical evolution of environmentalisms of different kinds, the next section reveals some of the historical ideas that continue to inform contemporary manifestations of environmental thought and practice.

Premodern environmentalisms

One of the most valuable insights into the history of environmentalism is provided by the geographer Clarence Glacken. A professor of geography at the University of California, Glacken is today most widely remembered for his book *Traces on the Rhodian Shore* (1967), which explored the history of Western thought concerning culture and nature. The notions of “designed Earth,” “environmental influence,” and humans as “geographic agents” have, according to Glacken, been characteristics of thought since at least the time of the ancient Greek world. These systems of thought echo the ethical dimensions of modern environmentalism to the extent that they raise the question of how humans impact on environmental systems (in relation to the notion of humans as agents of environmental change), and imply the existence of a natural environmental order in the world (environmental influence). They also reflect the metaphysical dimensions of later environmentalism in the ways they encourage a search for deeper, hidden meanings in the observation of environmental systems (in relation to the notion of a divinely designed Earth).

Recognizing the ancient history of environmentalism is helpful on at least two fronts. First, it enables us to see more clearly the evolutionary roots of our environmental concerns and to understand their place within the broader human condition. Second, being cognizant of the ancient history of environmentalism illustrates how environmental thought has changed over time, and that our own environmental assumptions may not be as solid as we believe. A closer look at the prehistory of environmentalism reveals the selective translations of certain ideas into different strands of contemporary environmentalism. In his celebrated discussion of the medieval roots of modern environmentalism, for example, David Pepper (1996) provides a captivating account of premodern visions of nature. According to Pepper, the medieval period exhibited forms of environmentalism that resonate strongly with the two dominant strands of modern environmental thinking: ecocentrism and technocentrism (1996, 37). For Pepper, ecocentric perspectives emphasize the rights of the environment and the importance of observing and learning from the natural world. Conversely, technocentrism suggests that human science and technology have the capacity to deal with environmental problems without the need for society to significantly limit its socioeconomic ambitions.

The medieval world was characterized by two ways of thinking about the environment:
anthropocentrism and organicism (Pepper 1996, 124–165). Anthropocentrism was a medieval worldview based on the assumption that the Earth was at the center of the universe and constituted a divinely created terrestrial dwelling for humans. Anthropocentrism led not only to the common belief that the environment’s purpose was primarily one of human use, but also to the common practice of explaining natural phenomena through human-centered modes of understanding. Consequently, in the medieval period it was common to hear accounts of the Earth and environmental systems that likened it to a human body (Pepper 1996, 130). The idea of anthropocentrism continues to inform technocentric versions of modern environmentalism. Technocentrism thus typically places human needs over those of the intrinsic rights of nature, and tends to project technological solutions onto environmental systems that fail to operate as social systems require.

While medieval cosmologies tended to place humans at the center of creation, they were also based on a firm belief in the organic unity of the total environment. In the medieval world recognition was constantly given to the mutual interdependencies of all living and nonliving matter (including humans). Organicism was associated with popular and scientific beliefs in a Great Chain of Being, within which all things, from the lowly truffle to the mighty whale, formed part of an integrated organic whole (Pepper 1996, 132). In certain versions of the Great Chain of Being, humans were located between monkeys and angels! Organic visions of the Earth continue to inform ecocentric environmentalisms today. In the defense of environmental rights and consistent attempts to recognize humanity as part of, and not separate from the environments on which they depend, ecocentrism supports an essentially organicist worldview.

Modern environmentalism

Although environmentalism has ancient points of origin, the environmentalism we are most familiar with today has a more recent point of origin. The immediate post–World War II period is associated with an unprecedented period of economic growth and prosperity for many living in more economically developed countries. This period witnessed the rise of mass consumption, the popularization of the motor car, the emergence of new forms of comfort in the home (particularly in relation to central heating, labor-saving devices, and refrigerators), the rising availability of fast and cheap food, and the broader rise of the suburbs. This period of economic growth has been described by some as the “Great Acceleration” (Whitehead 2014) and was associated with new forms of often unnoticed pollution that were products of the industry on which economic growth was based. It is in this context that a new generation of ecological scientists, operating both within and beyond the discipline of geography, played a critical role in alerting the world to the environmental impacts of the mass consumption society. The most celebrated of this new generation of scientists was undoubtedly Rachel Carson.

Carson was an American biologist, conservationist, and nature writer. She is now best known for her 1962 book *Silent Spring*, which explored the impacts of the expanded postwar use of artificial pesticides (such as DDT) on wildlife and broader environmental systems (Carson 2002/1962). While artificial pesticides had enabled harvests to increase greatly and had helped to keep the costs of food mercifully low, Carson revealed that many of the chemicals in circulation were in fact carcinogenic and were having a devastating impact on wildlife populations. *Silent Spring* led to outright bans on certain pesticides in many countries, and
laid the foundations of the modern environmental movement which arose in the 1960s. In many ways, Carson’s work was emblematic of a broader field of ecological science that had been emerging since the nineteenth century. This was a form of science that lent itself less to technocentric solutions to environmental problems and more to illustrating the complexity and fragility of environmental systems. Ecological science would ultimately offer a scientific basis to the forms of ecocentric environmentalism that had historically been based on myth and conjecture.

During the 1960s scientifically grounded, ecocentric forms of environmentalism flourished and grew. What is now described as modern environmentalism grew out of the connections that were forged in the 1960s between concerns over environmental destruction and broader currents of countercultural protest. Countercultural movements in the 1960s questioned the orthodoxies of mass production and consumption and persistent forms of conflicts (focusing specifically on the American war in Vietnam and the proliferation of nuclear weapons). This was a form of politics that resonated strongly with environmentalists’ concern over the forms of social values that were generating environmental degradation. By the late 1960s and early 1970s modern environmentalism was evident in the presence of the first green political parties, the rise of various governmental departments that were devoted to environmental protection, and various green nongovernmental organizations.

Nongovernmental organizations (NGOs) have been central to the emergence of modern forms of environmentalism. The first environmental NGOs can be traced back to the nineteenth century and the establishment of prominent nature protection organizations such as the Sierra Club in the United States and the Royal Society for the Protection of the Birds (RSPB) in the United Kingdom (which was established in 1889 as the Society for the Protection of Birds). The RSPB was formed in order to oppose the use of bird feathers as plumes on hats. As a society with a royal charter, many of whose members were from the upper and middle classes, the RSPB represents what is often termed a reformist environmental group. Reformist environmental groups emphasize gradual change within existing social and governmental structures as an effective route to addressing social problems. Since the 1960s and 1970s a new breed of environmental NGOs has emerged which have called for more fundamental changes in social relations with the natural world. So-called radical environmental groups such as Greenpeace and Earth First! argue that only significant changes in the nature of the capitalist industrial order will lead to the protection of the biosphere over the long term.

A defining moment in the history of modern environmentalism came in 1972 with the first international conference being convened to discuss emerging environmental problems: the United Nations Conference on the Human Environment, which was convened in Stockholm (Adams 2002). While in many ways it reflected the culmination of centuries of struggle and intellectual evolution within the field of environmentalism, it was also a key turning point in environmental debates. In Stockholm it quickly became apparent that addressing many of the most pressing environmental issues facing humanity could not be achieved in isolation from the pursuit of economic development in many of the poorest parts of the world (Adams 2002). During the 1970s and 1980s the tensions between the demands of environmentalists and the need for economic growth were tentatively reconciled in the now popular (if highly contested) concept of sustainable development (Whitehead 2007).

Drawing on the insights of sustainable yield science, sustainable development suggested
that it is possible to combine environmental protection with continued economic growth, so long as certain ecological systems on which humanity depends were managed in a sustainable way. In many ways, it was the idea of sustainable development that enabled the broader goals of environmentalism to enter the political mainstream, as national, regional, and local governments and corporations signed up to its core principles. But, rather than reflecting a new era for environmentalism, sustainable development appears to have provided new contexts within which the competing visions associated with environmentalism could be expressed and contested. Writers have, for example, observed that there are two broad forms of sustainable development: weak and strong (Neumayer 1999). While strong forms of sustainability suggest that there are natural limits within environmental systems that human development should observe, weaker versions of sustainability suggest that long-term sustainability can be achieved through the substitution of human capital (in the forms of new technological developments) for natural capital. It is clear that strong interpretations of sustainability are grounded in ecocentric thought, while weaker interpretations of sustainability are indebted to technocentric ideas.

In his celebrated analysis of the history of environmentalism, O’Riordan (1981, 5) claims that there are actually important subdivisions within ecocentric and technocentric forms of environmental politics. According to him, ecocentrism is composed of deep ecology and self-reliance movements. The deep ecology movement emphasizes the complex web of interconnections and mutual dependencies that characterize life on Earth, and advocates that nonhuman life should be given rights and protection in a similar way to human life. Self-reliance initiatives are less ecologically oriented but emphasize the importance of living at small scales in close proximity to the environmental resources on which a community depends. What deep ecology and self-reliance movements share is a suspicion of large-scale modern technologies and cultures of mass consumption (O’Riordan 1981).

O’Riordan argues that technocentric thinking can be divided into two main groups: environmental managers and cornucopians. What unites both of these perspectives is a belief that economic growth and environmental resource exploitation can continue without posing a significant long-term threat to the viability of the biosphere. The environmental managerial perspective recognizes that, in order to protect the environment, it is important that new laws, taxes, and restrictions are put in place and that there is careful scientific monitoring of environmental pollution. Cornucopians, however believe that humans will always find a way out of the difficulties that environmental change may precipitate and that the best way to release creative energies is to promote deregulated market systems (O’Riordan).

It is not difficult to find examples of the different forms of ecocentric and technocentric environmentalism identified by O’Riordan in the world around us. Geoengineering, for example, appears to take environmental management to new levels. Geoengineering involves the large-scale manipulation of environmental systems by humans in order to tackle problems such as climate change or nitrogen pollution in marine systems. In relation to tackling climate change, climate engineering could involve spraying the upper reaches of the Earth’s atmosphere with sulphur particles to produce an artificial cooling effect. Many have been critical of the idea of geoengineering, partly because it is claimed that it does not address the root causes of contemporary environmental problems, but also because of the often unknown nature of the environmental consequences of the geoengineering interventions themselves.
In opposition to geoengineering, groups have advocated more radical transformations in the nature of the relationship between humans and the environment. Prominent among these initiatives has been the degrowth movement, which exhibits many of the characteristics of O’Riordan’s self-reliant branch of environmentalism. The movement calls for a change in social attitudes toward economic growth. While the necessity of growth has been an axiomatic assumption within capitalism since its inception, advocates of degrowth claim that, in future, society must find a way to develop more stable and sustainable levels of economic development. The degrowth movement is based on the fact that there are biophysical limits to the total growth of the global economy and that economic growth does not necessarily lead to enhancements in human wellbeing. In this context, contemporary manifestations of ecocentric environmentalism are increasingly exploring the ways in which it may be possible to develop socioecological prosperity without having unregulated economic growth (Jackson 2011).

**Environmentalism across space**

As well as historical perspectives on environmentalism, spatial analyses of environmentalism are also important for two broad reasons. First, they draw attention to the in situ practices that characterized environmentalisms of different kinds. By focusing on what could be termed “actually existing environmentalisms” (the forms of environmentalism that are actually delivered on the ground rather than expressed in ideas and discourse), geographers have exposed the inevitable compromises that have to be sought between ecocentric and technocentric brands of environmentalism.

Second, a spatial perspective reveals the important role that space plays in the constitution of environmentalisms of different kinds. If space is taken to refer to various aspects of proximity, location, scale, and boundary, it can help to expose the ways in which environmental thought gets repeatedly expressed, realized, and contested in the world around us. As the rest of this section will show, these forms of spatial perspective on environmentalism can shed valuable light on its metaphysical, ethical, and political dimensions.

**Proximity, scale, and boundary**

There is something of a geographical paradox at the heart of ecocentric versions of environmentalism (see Sandbrook 2015). On the one hand, these environmentalisms emphasize the importance of being in close proximity to the natural world. Through proximity to nature, many in the environmental movement argue, people can both enhance their own wellbeing and develop a better understanding of, and respect for, the workings of environmental systems. The idea of the value of environmental proximity is often traced back to the nineteenth-century writings of the American author Henry David Thoreau, who famously spent two years conducting an experiment in simple environmental living on Walden Pond in Concord, Massachusetts (Thoreau 1996). The environmental proximity principle is also part of a much broader attempt to redefine ethics in relation to the land and landscape. In his celebrated book *A Sand Country Almanac* (1968), the American ecologist Aldo Leopold suggested that an environmental ethic should be based on the extension of the ethical community from people to the ecological systems they inhabit. The land ethic suggests that moral judgment about right or wrong actions can only be made with reference to understandings of the actual consequences of those actions for the social and biotic communities in which they are made.
ENVIRONMENTALISM

At the same time, many environmentalists believe that the key to protecting the environment is to ensure that it is kept separate from human activity and intervention (Sandbrook 2015). The separation of environmental spaces, landscapes, and ecosystems from human activity can be seen in a range of spatial designations including national parks, wildlife reserves, and the greenbelts that encircle many cities. Most recently it has been observed in attempts to “rewild” certain environmental areas. These spatial strategies put physical distance and functional separation between human and environment systems, and while they may help to protect nature they can serve to work against the development of forms of environmental understanding and appreciation that rely on human proximity to nature.

The practices of human environmental propinquity and separation find expression in two of the most common strategies in environmentalism: conservation and preservation. The conservationist movement has consistently emphasized the ways in which careful human management of the environment can enable natural and human systems (including agriculture, tourism, forestry, and fisheries) to coexist without compromising ecological sustainability. This type of thinking lay at the heart of the conservation ethic promoted by the American forester Gifford Pinchot. Pinchot suggested that it would be possible, through the careful accumulation of scientific knowledge of the forests (and broader environmental systems), to use timber resources without compromising ecological integrity of the woodland systems from which they were taken. Preservationists, however, argue that any form of human intervention in environmental systems represents a disruption to that system and that the best way to protect the ecological integrity of different environments is, where possible, to prohibit human activity within them.

Interestingly, questions of proximity and separation are important features within geographical and environmental debates around the issue of scale. Although scale has various meanings within contemporary geographical scholarship, the term is used here to refer to the spatial extent of social and environmental organization. Many in the environmental movement have been critical of the ways in which industrial capitalism has resulted in the globalization of human life. Globalization is seen as problematic in environmental (and more specifically ecocentric) terms for three reasons: (i) because it is associated with increasing demands for finite energy resources to facilitate the global transfers of goods and services; (ii) because the global transfer of goods and services contributes to the production of rising levels of pollutants, in particular greenhouse gases; and (iii) because it results in the increasing separation of people from the environmental systems on which their day-to-day life depends. Significantly, those who adopt a more technocentric approach to environmental matters tend to be less worried about globalization. To them the free movement of trade across international boundaries provides new incentives and opportunities to develop the economic efficiencies and technological advances that will enable more sustainable forms of environmental relations to emerge (see Kahn 2010).

In response to the concerns that ecocentric thinkers have with the environmental impacts of globalization, certain branches of the environmental movement have called for the rescaling of socioecological life. Two prominent initiatives within this field have been the relocalization and bioregionalist movements. The relocalization movement, such as transition culture initiatives (Mason and Whitehead 2012), work toward the principle of subsidiarity: the idea that social and economic processes should be carried out at as local a level as possible. Relocalization
movements thus claim that if energy, food, and water production and supply can be carried out at community levels, the impacts of these processes on the environment will be greatly diminished. **Bioregional** movements assert the same ethos of localization, but tend to focus less on the community and more on larger regional scales somewhere in between the local and the national. What is significant about bioregionalism is that its advocates suggest that it is nature and not humans that should set the boundaries within which bioregional communities work. So, while bioregionalists claim that regions should be self-sustaining in their use and reuse of environmental resources, they also hold that regional boundaries should make ecological sense. Bioregions thus tend to be defined by river catchment areas, mountain ranges, or other ecological and geomorphological markers. Echoing the principles of ecocentric environmental thought, bioregionalists claim that if society is organized in environmental spaces it is much more likely that humans will understand and respect the ecological systems on which they depend.

Technocentric critics of relocalization and bioregional movements claim that these geographical expressions of environmentalism tend to generate arbitrary spatial boundaries in social and economic life. It is further argued that these boundaries not only inhibit personal freedom, but also serve to stifle the creative energies and exchange of ideas that are vital in the pursuit of solutions to some of our most pressing environmental problems.

**Environmental sites and locations**

The previous section illustrated that environmentalism has implications for how we understand the spatial organization of human societies, and that the decisions we make about the scales at which society operates have important implications for our relations with the environment. But there are other spatial factors that are important in the constitution and practice of environmentalism. The changing sites and locations within which different forms of environmentalism are practiced can tell us a great deal about their ethical and political dimensions.

Historically, many ecocentric forms of environmentalism have been located on the margins of mainstream society. The establishment of environmental communes, eco-villages, and other forms of green utopianism has embodied an attempt to provide examples of how humans can forge different types of living arrangements with each other and with the environment. While often criticized for constituting easily ignored forms of environmentalism, eco-utopianism has used its metaphorical and literal position on the margins of industrial society to demonstrate the forms of community that can emerge when environmental values are aligned in more ecocentric directions.

While environmental protests take very different forms, they often involve the deliberate occupation and reuse of prominent spaces. For example, the direct action environmental movement, which became popular in the 1990s, strategically occupied spaces in order to delay or prevent the building of new roads and other environmentally damaging infrastructures. More recently the rise of climate camps has seen the establishment of large-scale but temporary communities, in protest against global inaction in the face of climate change.

Perhaps the greatest locational challenge faced by modern environmentalism has come in the form of the complex processes associated with urbanization. Historically, many branches of environmentalism have either ignored or actively opposed the processes of urbanization. In these contexts, urbanization was seen as either the geographical antithesis of where
environmentalism’s concerns were located (namely, in the exurban spaces of nature), or as a spatial threat (particularly in the forms of transboundary pollution and suburbanization) to the ecologies that environmentalism was dedicated to protecting (Gottlieb 1993). Since the early 1990s there have been significant challenges to the urban blind spot associated with environmentalism (Harvey 1996). Groups such as the Environmental Justice Movement and the Cittaslow initiative have sought to actively change the geographical focus of environmentalism from nature to the everyday places where people work, rest, and play (Gottlieb 1993). The Environmental Justice Movement emerged from concerns over the consistent location of communities of color and low income near to sites of environmental pollution production and toxic waste disposal. The movement has sought to shift the locational politics of environmentalism from exurban nature and toward urban living. The movement has also sought to fuse concerns over environmental degradation with those of social injustice, and to forge a common politics of radical ecological resistance.

Interestingly, the Environmental Justice Movement, and the varied forms of radical political ecology with which it is associated, has also challenged the metaphysical, ethical, and political dimensions of environmentalism. At a metaphysical level the Environmental Justice Movement asks new questions about the ways in which the often obscured spatial relations of racism, sexism, and class exploitation generate social and ecological injustice at a range of scales. In relation to ethics, the practices of environmental justice seek to extend the moral domains associated with environmentalism. While environmentalism, historically, sought to extend ethical concerns from human to environmental realms, the Environmental Justice Movement, and associated forms of radical ecology, seek to extend the political concerns of environmentalism to marginalized socioeconomic groups. What was once a movement devoted primarily to the protection of nature has become one that recognizes that the protection of the environment cannot be achieved without addressing the spatial relations of global economics, racial exploitation, and neocolonialism.

Environmentality and green governmentality

Stephanie Rutherford
Trent University, Canada

Environmentality, or green governmentality, is a neologism that offers an extension of Michel Foucault's concept of governmentality (Foucault 1991, 1997, 2003, 2007, 2010). Defined very broadly as “the art of government” (Foucault 1991) or “the conduct of conduct” (Gordon 1991), governmentality takes aim at the modalities of modern rule. More specifically, studies in governmentality examine how power is not only repressive but also productive, eliciting and promoting particular knowledge systems, techniques for regulation, and subject positions that work to the best end of a governing authority (for further explanation, see the entry on governmentality in this volume). As an elaboration on governmentality, environmentality seeks to understand the ways in which this analytic of power can be applied to how we understand and act upon questions of environmental management, from global climate change negotiations (Bäckstrand and Lövbrand 2006) to individual habits of recycling (Darier 1999). It has become a useful concept to help think through the ways that the environment is not only a biophysical reality, but also a site of power, where truths are made, circulated, and remade.

As originally articulated by Foucault, governmentality did not give any weight to the environment as a domain of rule, even though he wrote at a time of eco-cultural foment. Indeed, Foucault’s first articulations of governmentality were largely preoccupied with questions of the modern state and the birth of liberalism, considering how various political authorities worked to govern their human populations to achieve the best end of the state. This focus on the practices of the state has largely remained as Foucault’s interlocutors have applied his insights to a range of cases (Rutherford 2007). However, as one can see from the two broad definitions of governmentality given above, there is room to extend the terrain that governmentality considers. Recognizing this possibility, scholars began to think about how the kinds of questions that governmentality asks about the world might successfully be applied to the environment.

For example, in the late 1990s, American political scientist Timothy W. Luke (1995, 1999) wrote a series of articles and book chapters that used the terms environmentality and green governmentality to explore the ways in which the environment (and the study of it) can be a site of political calculation. He is the scholar most closely associated with the coining of the term. For example in 1995, Luke examined the Worldwatch Institute (www.worldwatch.org/), a nongovernmental research organization concerned with global environmental issues, from biodiversity loss to climate change. Through the organization’s efforts to collect the latest data about the state of the planet’s environment, it measures and forecasts environmental harm and provides solutions to avert environmental crises. In so doing, Luke argued that the Worldwatch Institute is at the forefront in generating “the eco-knowledge of modern governmentality” (1995, 70). In later writings he went beyond the Worldwatch Institute to assert that “most
environmentalist movements now operate as a basic manifestation of governmentality” (Luke 1999, 121). Around the same time, Eric Darier’s edited volume *Discourses of the Environment* (1999) was published, containing a series of chapters that expanded the relationship between governmentality and nature even more fully. This book offered an early (and still salient) assertion that we are witness to the biopolitical management of all life, where nature is rendered into populations of resources to be mapped, measured, and managed. Humans are also arranged in various populations through environmentality, and as such, their interactions with the environment are framed as in need of management.

From these initial articulations, environmentality, or green governmentality, has been tested in a wide variety of cases – from biodiversity protection (Youatt 2008) to the American Museum of Natural History (Rutherford 2011) – and places – from the rural Philippines (Dressler 2014) to Amazonia (Cepek 2011). Although there are myriad ways this analytic of power might be applied, there are three interrelated areas that are included in any effort to understand the workings of green governmentality.

First is the production of rationalities of rule. Foucault suggests, “… power produces; it produces reality; it produces domains of objects and rituals of truth” (Foucault 1995, 194). Hence, the rationalities that underpin green governmentality suggest the forms of knowledge/power that open up particular grids of intelligibility while foreclosing others. Dean (1999, 23) has talked about governmental rationality as operating through “characteristic forms of visibility, ways of seeing and perceiving” that coalesce into regimes of truth. Perhaps the most salient form of rationality or way of seeing and perceiving the environment is through the lens of science (Rutherford 2007). The supposed impartiality, objectivity, and dispassion of science lend it an authoritative voice to speak for the wellbeing of nature on a range of scales from the local to the planetary. Statistical measurement, graphic representation, modeling, and forecasts all work to generate a broad picture of nature to be managed. Demeritt (2001) offers a potent example of how this happened in the Progressive-era United States by sketching the emergence of the “normal forest” through scientific forestry. Demeritt shows how the visual representation of the nation’s forests as both under threat and in need of management worked to enframe nature, making what was once heterogeneous appear to be coherent and unified. In so doing, the forests of the United States were abstracted from their specificity and made into a single national and natural resource, one whose depletion marked both the progress and the cost of civilization. By representing nature in this way, new categories and means of assessment became possible – such as annual allowable cut and maximum sustainable yield – and new authorities became empowered to manage these categories. And so, in the case of the “normal forest,” power was productive: it generated new ways of seeing, invented categories of analysis, normalized particular strategies for environmental management, and authorized experts (foresters and conservationists alike) to act on that management.

Second is the question of strategies of intervention. As Demeritt’s example demonstrates, the rationalities at play in representing environmental problems generate specific ways of seeing and hence offer a particular range of solutions for their amelioration. In a broad sense, the calculations offered through power/knowledge regimes produce a domain of objects – the environment – that is then taken up by various authorities – nongovernmental organizations, scientists, corporations, institutions like the World Bank, all levels of government, and even celebrities – to propose solutions to environmental problems.
Particular strategies of intervention are elicited, from establishing biodiversity preserves to geoengineering to composting, as mechanisms to deal with the environmental problem in question. One approach to assessing potential environmental harm that has gained broad acceptance in Western liberal democracies is the environmental impact assessment (EIA) (see Doyle and McEachern 2008). As these authors demonstrate, the application of a cost–benefit analysis through government-mandated EIAs generates forms of rationality read through expertise that seeks to measure and weigh the environmental impacts of economic activity. EIAs also invite public participation in the decision-making process, bringing both proponents and critics under its normative banner, where the proceedings produce new kinds of knowledge, but within a delineated (and often neoliberal) framework. In the end, these environmentality strategies follow the logic of the rationalities that suggest them; put differently, the solution necessarily follows the discourse used to frame the problem.

The third dimension central to environmentality is generation of specific kinds of self-governing subjects. Technologies of the self, or those tactics and practices that allow subjects to constitute themselves as particular kinds of people in and through power, are important to the practice of rule. Various discourses have produced the conditions of possibility for us tell to the truth about ourselves in a range of circumstances: for example, voter, activist, parent, child, student, or teacher. The multiple identifications with and performances of these subject positions, in turn, work to regulate the ways in which people present themselves to the world. In the case of environmentality, the subject position most often taken up is that of green citizen. This can mean different things at different times, but at its core, the green citizen manages her or his behavior, and the behavior of others, to promote the health of the environment. For example, Agrawal explores the idea of “intimate government” (2005, 193), where villagers in Kumaon, Northern India, became environmental citizens through a process of devolution of power, becoming experts in the management of their own forests through conservation initiatives targeted at their own practices as well as the practices of others. In a different vein, Rutherford (2011) had examined how a documentary like Al Gore’s An Inconvenient Truth can work to produce a particular kind of environmental citizen: a subjectivity formed through the rites of green consumption. In any incarnation, the green citizen is an excellent example of governing at a distance, whereby the state (or any authority) can rely on subjects to regulate themselves.

The three dimensions of environmentality elaborated above might be made clearer with the help of a brief example, one that also points to an emerging field in environmentality: the issue of climate change or climate governmentality (Stripple and Buckley 2013). Increasingly, both the political context and discursive framing around climate change have moved towards emissions trading as the mechanism through which global climate change can be managed. For example, a global cap-and-trade system through the now defunct Kyoto Protocol was normalized as the appropriate means to ameliorate climate change, rather than a carbon tax, or perhaps more radically, the payment of an ecological debt. However, this approach (or any approach) requires experts and specific technologies to measure either failure or success and determine the optimal results of a strategy of intervention. In climate governmentality, an important knowledge/power nexus that shapes the terrain of debate is found within the profession of accountancy. One might wonder what accountants have to do with what many would consider primarily to be a problem of the
ENVIRONMENTALITY AND GREEN GOVERNMENTALITY

planetary ecosphere. But the framing of climate change has emerged in distinctly financial terms. As Lovell and MacKenzie (2011) point out, accountancy has become increasingly central to this normalized way of framing both the problems and the solutions to the climate crisis. As such, the example of climate accounting provides an important and specific articulation of the key aspects of green governmentality explored above. Climate accounting produces a particular mentality or rationale for intervening in climate politics. Lovell and MacKenzie show that the accounting profession offers a reading of the climate problem that both narrows the terrain of intervention while inserting their expertise as central to its solvability; for accountants, “climate change is seen as a corporate problem, which is solvable with careful application of existing accounting approaches and techniques” (2011, 725). Lovell and MacKenzie further contend that accounting, accelerating with the rise of the European Union Emissions Trading Scheme and other mechanisms to trade carbon, has intervened with very specific policy solutions in a political terrain that asserts that climate change is a problem of calculation, measurement, and trading of carbon rather than its production. These authors suggest that the epistemic community of accounting, which emphasizes their specific professional expertise and technical strategies of calculation, offers itself up as the logical body of knowledge to deal with climate mitigation. Calculation here is key as it defines the manner in which problems can be assessed and acted upon by, following Murray Li (2007), rendering the problem in strictly technical terms, a hallmark of governmentality. And, although Lovell and MacKenzie do not make this assertion, a subject position could be put forward – the climate accountant – whose expertise and practical skills allow them to engage in policy construction and implementation on this question. As such, accountants not only respond to the question of climate change within their professional frame, but actively produce the broader discourse and policy action on this environmental problem, through the application of accounting rationales, the practice of particular technologies, and via their epistemic community. In this way, the seemingly apolitical discipline of accountancy constitutes and shapes the responses that can be taken to climate change; it is a productive force for environmental management. Put another way, the accounting profession is a key actor in the production of green governmentality on the question of climate change.

Eolian erosional processes and landforms

Julie E. Laity
California State University, Northridge, USA

Wind erosion is an important geomorphic process in locations with abrasive sediment, strong winds, and sparse vegetation. The sediment, largely sand, is supplied from rivers, beaches, and alluvial fans. As a result, eolian erosion is principally confined to desert, coastal, and cold (periglacial and paraglacial) environments. In deserts, owing to the pervasive aridity, lack of vegetation, free sweep of the wind over large areas, and abundant sand, a complete suite of eolian landforms develops, including ventifacts (wind-eroded rocks), yardangs, inverted relief, and deflated depressions. These landforms are best expressed in the very arid deserts of South America, Asia, and Africa, with the smaller and more humid deserts of North America having fewer features (ventifacts, small yardangs, and pans), and Australia appearing largely free of abraded landforms, although pans are present. Similar landforms have been identified on Mars from both satellite and rover imagery. In terrestrial coastal and cold environments, ventifacts are recorded, but yardangs are generally absent. During the Pleistocene, widespread abrasion occurred at the fringes of ice sheets, with many reported localities in Europe and North America.

The landforms of wind erosion vary greatly in scale, from small pans to enormous depressions, and from individual yardangs to immense meso-scale ridge systems. Erosion of ventifacts and yardangs occurs as sand is transported from source areas towards sinks. These landforms thus mark the path of moving sand and can be used to reconstruct pathways and, by inference, contemporary or paleo-circulation patterns. Landforms of eolian erosion are largely stationary, unlike many depositional landforms, and thus represent a time-integrated record of wind direction and intensity. Larger landforms, such as yardangs, range in age from thousands to millions of years, and thereby experience periods of climatic change, during which time they are modified by water as well as wind. Indeed, fluvial processes are often important precursors to wind erosion, supplying sediment, affecting surface erosivity in pan and depression formation, and providing conduits for wind erosion in yardang fields. Furthermore, water modifies yardang surfaces through solution, rilling, gullying, and mass movement. Climate change also affects the biomass, the height of the water table, and the circulation of the atmosphere. Wind erosion is thus strongly interconnected with many other elements of the Earth system environment.

Relative to landforms of deposition, such as dunes, those of erosion have received less attention. In part, this stems from the relative remoteness of many of these landforms from major research institutions and the difficulty in traveling to such regions. Many questions remain to be answered concerning the mechanisms of micro-feature formation on ventifacts and yardangs, the physical interaction between landforms and the wind, and the evolutionary history and rates of formation of landforms of wind erosion.
Processes of eolian erosion

Two principle processes operate to erode a landscape: abrasion and deflation. **Deflation** involves the removal by the wind of noncoherent, fine material from the surface. The material has often been pre-weathered by salt weathering or other processes, facilitating erosion. This process is most significant in areas with poorly lithified rocks or unconsolidated sediments. **Abrasion** results from the mechanical wear of coherent sediments or rocks by the impact of particles in saltation, chipping away the underlying surface. The relative significance of these processes of erosion is not well understood. Abrasion appears to be the key player in the development of several important landforms, including ventifacts and yardangs, whereas deflation contributes to the development of surface depressions, both large and small.

The process of abrasion is often likened to sandblasting. It is affected by the properties of the particles and the rock, the nature of the environment, and the timescale. The effectiveness of abrasion is related to sand grain composition, size, and shape. In terms of composition, the density and hardness of the particle are significant. The density determines the mass contribution of kinetic energy. Hardness influences whether kinetic energy is transferred to the ventifact or the grains become deformed themselves. Quartz grains dominate on Earth, with basalt sand present in some areas. On Mars, most sand is basaltic. As particles become larger in diameter, their kinetic energy for a given velocity increases greatly. However, it becomes increasingly difficult for the wind to entrain large grains. Therefore, while large grains are more abrasive, smaller sand grains may do more of the work, because they are more easily entrained (Bridges and Laity 2013). Grain shape is generally less of a factor in erosion because most sand grains are well rounded. Nonetheless, recently formed angular grains have the potential to cut and gouge rocks more effectively, enhancing abrasion.

Environmental factors also influence wind erosion. These include wind speed and shear stress; wind direction; particle supply, wind frequency, and integrated flux; local topography; and local rock distribution. As noted earlier, abrasion requires that winds be strong and frequent and that there be an adequate supply of sand. Thus, a region that is windy, but lacks loose sand, will not show signs of abrasion. Furthermore, abrasion may lessen over time as sand supply becomes depleted (commonly the case in glacial environments) or as the winnowing of fine sand leaves behind a coarse, protective lag (common in desert river systems). A continuous supply of abrasive sand may require surface disturbance, such as flooding, to destroy surface lags and expose underlying sand. These disturbance events promote and sustain the abrasion process.

On level ground, the height of sandblasting is typically limited to 1–2 m above the surface. This value is sometimes exceeded on hillslopes or in locations where sand ramps or beveled ventifacts propel sand higher into the airstream, impacting downwind rocks at a higher level.

Fossil ventifacts and yardangs mark regions where the conditions for abrasion have ceased. Relict landforms may appear weathered, stained, varnish–covered, or veneered in lichens. The lithology of the landform affects weathering rates. Yardangs formed of weak sedimentary rocks can show signs of mass wasting and gullying, and solution modifies limestone yardangs or those with a significant salt component. Salt weathering of ventifacts adjacent to playas results in rapid physical changes that cause many rocks to disintegrate. In deserts, some rocks, such as granites, weather relatively rapidly and do not provide a long record of abrasion on ventifacts; others, notably basalts, preserve features in fresh
condition over thousands of years. The partial abrasion of varnish, as observed on some ventifacts, indicates that morphologic development may occur over multiple cycles.

The processes associated with deflation have received less attention than those of abrasion. Deflation involves the action of the wind alone. In order for fine particles to be picked up and removed, the rocks or sediments must be pre-weathered. This can occur through salt weathering or the action of grazing animals, which disturb the surface by trampling, rendering it more susceptible to wind erosion. Deflated material is transported as fine grains in atmospheric suspension.

Landforms of eolian erosion

Desert depressions and pans

The wind plays a role in excavating large-scale desert depressions and forming pans, small-scale features that are widely distributed in arid lands. Desert depressions frequently have a polygenetic origin, involving wind erosion, block faulting, broad shallow warping, stream erosion, karst activity, mass wasting, salt weathering, and zoogenic processes (Aref, El-Khoriby, and Hamdan 2002). They include the large enclosed basins of Africa: Siwa, Qattara, Baharia, Farafra, Dakhla, and Kargha.

Pans are widespread in southern Africa, on the High Plains of the United States, and in western and southern Australia (Goudie and Wells 1995). Several factors predispose a region to pans, including a dry climate, a vegetation-free surface, a low water table, and materials susceptible to deflation, such as poorly consolidated sediments, shales, and fine-grained sandstones. Feedback mechanisms play an important role in pan growth and enlargement. As water accumulates in depressions, salts are left behind, which retard future vegetation growth, weather sediments, and attract large animals, rendering the surface more susceptible to wind erosion. The position of the water table influences both depositional and erosional processes in pans through complex interactions with vegetation and sediments.

Yardangs

Yardangs are the most impressive landform of eolian erosion, being immediately visible on aerial or orbital images of Earth and Mars. They form vast arrays of parallel forms, as observed, for example, in the Dasht-e Lut Desert of Iran. Around the Tibesti Mountains of Africa, wind-eroded ridge systems are of such extent that they follow the deflection of the trade winds and cross ancient impact craters. In large systems, barchan dunes may occupy the swales between yardangs, abrading the yardang flanks and the inter-yardang corridors.

In their most classic form, yardangs appear as elongate, streamlined ridges, resembling an inverted ship’s hull. The windward face is typically blunt-ended as a result of direct abrasion, whereas the lee end may taper to a point. However, the yardang assumes many forms and may also appear flat topped or short and stubby in appearance. The length-to-width ratios of yardangs average 3:1 or greater, a form that minimizes wind resistance. However, this value is influenced by rock material, time of exposure to the wind, and wind direction. In Peru, streamlined yardangs range in length-to-width ratio from 3:1 to 10:1. The length of yardangs ranges from meters to kilometers; those developed in basaltic lava flows of Holocene age in Argentina are up to 10 km in length (Inbar and Risso 2001).

Yardangs occur in the most arid regions of Earth, where wind processes dominate. Their formation is assisted by a favorable material, weathering, and channels formed by rock fractures or fluvial processes that are exploited.
by unidirectional or seasonally reversing winds. Prominent fields in Africa and Asia include those in Egypt, Libya, Chad, Niger, the Arabian Peninsula, the Namib Desert, the Taklimakan Desert, the Qaidam Basin, and the Lut Desert. In South America, yardangs occur in Argentina and along the coastal desert of Peru. There are minor groups in North America. Paleo-yardangs, relict conditions that were possibly drier and colder, are recorded in Europe, both in Spain and in Hungary. Owing to the remote nature of most yardang fields, there has been little comprehensive study of the processes of yardang formation, and meteorological information is often lacking. The relative role of abrasion and deflation remains unstudied and probably varies according to the material and the weathering environment.

Yardangs form in a broad range of geologic materials. These include claystones, sandstones, limestones, dolomites, granites, schists, gneisses, and volcanic ignimbrites and basalts. Yardangs in the Qaidam Basin of China are covered in thick crusts of salt (Rohrmann et al. 2013). In layered rocks, the form of the yardang is influenced by differential erosion of materials that vary in their resistance. Steps, fins, and shelves may result.

Between the yardangs are spaces referred to as troughs, couloirs, corridors, swales, or boulevards. When the yardangs are close together, a U-shaped corridor is common; as the distance widens, the couloirs become flattened. Most of the geomorphic work creating yardangs appears to be concentrated within these corridors, where ripple trains or barchans migrate downwind, abrading longitudinal striations and creating shallow erosional basins.

In addition to abrasion and deflation, other geomorphic processes modify the windform. Fluvial erosion helps to initiate yardang fields by creating stream courses that are refashioned and enlarged by the wind. In weak materials, yardang slopes are often gullied by rainfall and the corridors eroded by fluvial action. Mass movement modifies yardangs and slump blocks are observed, particularly near the undercut noses of the form.

The rate of yardang formation is strongly affected by the relative hardness of the substrate. On playas, yardangs can develop within a few thousand years, sometimes facilitated by a drop in the water table, which forms a base level to wind erosion. In the Bodélé Depression, Chad, 4 m-high yardangs were estimated to form in playa sediments within 1200–2400 years. In Argentina, yardangs 2–3 m in height formed in basalt in less than 10000 years. However, large bedrock yardangs along the coast of Namibia may have taken millions of years to develop (Goudie 2007).

**Inverted topography**

Inverted topography develops where areas of the landscape that were previously low in elevation, such as river systems and deltaic distributary systems, are left standing in high relief owing to their relative resistance to wind erosion (Bristow, Drake, and Armitage 2009). The resistance of the channels may result from the induration of sediments by chemical precipitates. Inverted topography is most often evident in yardang fields, with the former point bars and meanders of channel systems now marked by remnant hills and ridges. Examples of inverted topography include raised channels in Oman, Egypt, and China, as well as on Mars.

**Ventifacts**

Whereas yardangs are predominantly found in highly arid climatic conditions, ventifacts occur in desert, coastal, and cold (periglacial and paraglacial) environments. Ventifacts are also widespread on Mars, where they were identified, first tentatively from Viking images, and
then unequivocally from the Pathfinder and Mars Exploration Rover (MER) images. The requisite environmental conditions for ventifact formation are strong winds, a supply of abrasive sediment (dry sand), vegetation cover that is absent or scant, and a relatively stable surface covered by boulders or bedrock. Ventifacts occur both as active and as fossil forms. The geological record indicates that ventifacts are extensive in Quaternary deposits and may preserve evidence of intense wind activity in even older rocks, including deposits of Permian to Triassic age where the facets, grooves, and polish that exemplify ventifacts remain remarkably well preserved.

Wind erosion is pervasive in cold environments and ventifacts are found from sea level to altitudes as high as the Qinghai–Tibet Plateau (5200–5600 m a.s.l.) and the Argentine Puna Plateau (4500–5000 m a.s.l.). Modern ventifacts are reported from Antarctica and ventifact sites relict of Pleistocene ice age conditions are found widely across Europe and North America. Ventifacts form near glaciers because of the high sediment yields associated with retreating ice and the strength of katabatic or other downslope winds. Development occurs close to the glacial margin and ceases within a few decades of deglaciation, reflecting the relative speed with which vegetation recolonizes surfaces and abrasive sediments are winnowed away by the wind.

Coastal ventifacts have been described from many localities, including New Zealand, the United States, and the United Kingdom. However, it is difficult to determine from the literature how widespread they are and whether they are more common in temperate climatic zones than elsewhere. Abrasion may be enhanced during periods of lower sea level, when sand is exposed on coastal plains.

Ventifacts appear to be relatively common in arid and semiarid environments, but there has been little comprehensive or basin-wide mapping of these features, and thus their distribution here is also poorly known. They have been recorded in most of the world’s deserts, with the exception of Australia. It is likely that ventifacts are more areally extensive in deserts than elsewhere owing to the greater supply of dry, transportable sand. In coastal and paraglacial environments, by contrast, ventifacts are often limited to narrow fringes. Periglacial ventifacts may be more widespread, but their distribution has not been effectively mapped.

As Mars is a dry and windy planet with abundant sand and widespread rocky surfaces, it is not surprising that ventifacts are commonly observed in surface images. The environmental conditions differ substantially from those on Earth, however. The atmosphere is thinner (≈1/100), the gravity is lower (about 1/3), and the abrasive particles are largely basalt, rather than the dominantly quartz–feldspathic terrestrial sands. Nonetheless, the morphology and surface textures of ventifacts on Mars are broadly similar to those on Earth (Bridges and Laity 2013) and these features have been used to infer paleo-wind directions.

Field evidence and theoretical considerations indicate that sand is the most effective agent of abrasion in all environments. The efficacy of dust, ice, and snow particles has not yet been demonstrated. The process of abrasion usually occurs within the lower 1–2 m of the atmosphere. Kinetic energy (KE) increases with distance from the ground, usually peaking at approximately 10–40 cm, and then declining. As a result, abraded rocks evolve with a ramped facet up to the height of maximum KE. In very tall rocks, a notch can develop where abrasion lessens with height above the maximum KE point. In the field, conditions are often complex, with several conditions impelling saltating grains to elevations >2 m. These include: (i) hard surfaces, which impart greater grain bounce, (ii) moat and ramp structures in front of ventifacts – sand
travels up the ramp to abrade the upper surfaces of rocks, and (iii) in distributed rock fields, sand which flows up beveled ventifact faces and is propelled into the airstream, hitting rocks down flow on their upper surfaces. The rate of abrasion is strongly dependent on wind speed and frequency, in addition to characteristics of the particle and the rock.

Ventifacts are recognized by their unique morphology, which is often characterized by (i) facets, (ii) polish, (iii) textural features (pits, grooves, flutes, helical scores), and (iv) textural changes (etching, fretting, and knobby texture). Each ventifact has a unique shape, a function of the lithology and size of the rock, the size and nature of abrasive material, the duration of abrasion, wind strength and frequency, wind direction, and rock exposure (influenced by burial by sand, sheltering effects of other rocks, and flow interactions within the boulder field) (Laity and Bridges 2009). Textural features are universal in nature, such that a flute may form on volcanic tuff, basalt, granite, or marble. Textural changes are more dependent on the initial lithology of the rock, with etching, for example, resulting from layered rocks of different hardness. The orientation of linear features such as flutes and grooves parallels the direction of the highest velocity winds in a region.

Many ventifacts show facets – planar surfaces that are largely perpendicular to the wind, formed on the windward face of a rock. More than one facet may form if there are bidirectional or multidirectional winds. For small rocks, new facets may form when the rock is subject to shifting or overturning associated with earthquakes, frost heave, undermining by wind or water action, and disturbance by animal movement or humans.

Local topography influences wind speed and direction, and hence the location of ventifacts, the intensity of their development, and the orientation of features such as flutes, grooves, and facets. Wind is commonly accelerated through topographic constrictions and up the windward flanks of hills. As a consequence of this increase in wind speed, sand transport is increased. As a result, ventifacts are commonly found near ridgecrests and on the upper slopes of hills, and in notches and structurally controlled valleys. The intensity of abrasion, as measured by factors such as groove width and length and pit diameter, often increases with elevation up a slope.

The relationship between the form and texture of a ventifact and the wind direction may be used to infer atmospheric circulation patterns at the surface. If the ventifacts are relict, they serve as a proxy for paleocirculation reconstruction. Efforts to map at a regional scale require many observations because, in small areas, the orientation of grooves and other features may be strongly influenced by local topography. The results of mapping over wide-ranging areas can be related to models of atmospheric circulation to infer changes in wind pattern or intensity over time.

Estonia: Eesti Geograafia Selts (EGS) (Estonian Geographical Society)

Founded: 1955
Location of headquarters: Tallinn
Website: www.egs.ee
Membership: 213
President: Mihkel Kangur
Contact: mihkel.kangur@tlu.ee

Description and purpose

The EGS is a nonprofit organization for geographers and enthusiasts of geography. Its principal goals are to develop the science of geography, to support education of geography, to popularize geography and concepts of sustainability, and to collaborate with scientific societies and institutions in Estonia and abroad.

The EGS provides a place where representatives of different divisions and groups of the geographical sciences can meet, providing favorable conditions for discussing wide-ranging geographical problems. To this end, an important role is played by conferences, seminars, and publications that report the results of scientific research conducted by its members.

Journals or major publication series

Eesti Geograafia Seltsi aastaraamat (Yearbook of the Estonian Geographical Society)
Estonia. Geographical Studies

Current activities or projects

The main field of activities by the EGS are: scientific research by members; publication of scientific and popular scientific works; organization of conferences, symposia, seminars and other scientific undertakings (expeditions and tours); and dissemination of geographical knowledge.

Brief history

Important in the founding of the Russian Geographical Society in 1845 were geographers from the Baltic province with close relations to Estonia, including academics K.E. von Baer, F.G.W. Struve, W. Dahl, and G. Helmersen; the ocean explorers A.J. von Krusenstern, F. von Wrangell, and F. Lütke; army leader F.R. Berg; and others. The idea of founding a geographical society in Estonia as a branch of the Geographical Society of the Soviet Union originated in the mid-1950s. By that time a considerable number of specialists had graduated from the Geographical Department of Tartu State University, a necessary requisite for establishing the organization. The resolution for the founding of the EGS was passed by the Scientific Council of the Geographical Society of the Soviet Union on November 15, 1955. The assembly elected Vello Tarmisto (Cand. Geogr., the originator of the idea for the EGS) as president.

Since 1992 and the 27th International Geographical Congress in Washington, the EGS has represented the Estonian National Committee in the International Geographical Union.

Ethics in geography fieldwork

Jenny Lunn
American Association of Geographers, USA

An examination of the ethical principles that apply to geography fieldwork, as well as their application in the past, present, and future, must be preceded by a brief discussion of what is meant by “the field” and “fieldwork,” and what is particular to “geography fieldwork.”

“The field” is both a physical and conceptual space. While the term itself is contested, a simple interpretation situates the field as a counterpoint to the classroom, the laboratory, and the library as a place where information exists that can be collected and studied. While the field is outside of these other places of learning, it is not necessarily a distant or unknown place.

In turn, “fieldwork” is an act of entering the field to gather information which then can be processed, mapped, cataloged and analyzed in order to understand places, people, and phenomena. In the context of education, fieldwork is also a pedagogic technique for offering a hands-on experience of the subject matter, as well as teaching and practicing different methods and skills. Thus fieldwork is an activity that is carried out by both individuals and groups, as well as by experienced professionals and school and university students.

The sheer breadth of geography as the study of Earth and everything in it makes fieldwork very varied, from collecting ice cores on a glacier to interviewing children in an African village. Fieldwork involves dealing with landscapes, landforms, and environments; people, communities, and organizations; and statistics, images, and documents.

Although fieldwork is a defining feature of geography and an important mode of learning for students, it is not unique to the discipline. Fieldwork is practiced in many closely allied disciplines including anthropology, archaeology, biology, ecology, geology, and sociology, all of which go outside the classroom, library, or laboratory to collect data about things in the world. The distinctive nature of geography fieldwork lies in the core concepts of geography – space, place, scale – which frame investigations.

Although the field can be defined as a place where a geographer goes to gather information about people, places, or phenomena, raw data does not actually exist per se, it is created by the intervention of the researcher putting value on something as being of investigative worth. For example, water will flow along a river channel at a particular speed whether or not it is being measured by a researcher’s instrument, and forest villagers will collect firewood for their needs whether or not a researcher asks questions about their community resource management strategies. Thus data is shaped by the interaction between the researcher and the research subject, including how this relationship is established, conducted, and sustained.

This leads us to the very heart of the ethical dimensions of geography fieldwork: it is in the way that the researcher seeks, collects, analyzes, presents, and disseminates data that creates ethical issues to be negotiated and resolved. Furthermore, ethics not only relates to data on a specific research topic, but also to the wider moral and
ETHICS IN GEOGRAPHY FIELDWORK

social responsibilities of being a researcher in the field. This makes fieldwork not just a pedagogical or professional undertaking, but also something personal and political.

Key principles for ethical research

The key principles of ethical research practice are respect, beneficence, and justice (after the 1979 Belmont Report), and there are a number of practical ways in which these can be applied. It is important to note that these principles emerged in relation to research on human subjects but are also applicable to research on nonhuman subjects. The focus in the literature and in training tends to be how ethical principles relate to the relationship between the researcher and the research participants but there is also an ethical dimension to the relationship between the researcher and co-researchers or other professionals, the institutions that support and fund the research, the government of the home nation of the researcher, and the government of the nation where the research is carried out (if different).

“Respect” refers to the general attitude that the researcher should have toward the research subject and its wider context, thus it encompasses respect for people (both individuals and groups) and the organizations and structures set up by people, as well as respect for landforms, ecosystems, biodiversity, and natural resources.

A key aspect of practicing respect with human subjects is “informed consent,” which involves giving adequate information about the research aims, methods, and outcomes to potential participants, ensuring that they understand the implications of their involvement and gaining their voluntary consent to take part. Additional attention needs to be given to people from vulnerable groups or those with diminished autonomy (such as children or those with disabilities) to ensure that they or their proxy fully understand. Informed consent is also ongoing: participants have the right to withdraw at any time. Informed consent is a fairly uniform requirement with the exception of some covert research. In the case of nonhuman subject research in realms such as ecology, environmental science, and geomorphology, informed consent may involve dealing with the people who inhabit, own, or manage the habitats, resources, or landscapes being studied.

Another aspect of respect is the protection of privacy, which includes maintaining confidentiality (i.e., not sharing information about the research subjects), anonymization (i.e., removing names and other identifiers), and safe management and storage of data. Again, there are some exceptions; for example, some participants may not want to be anonymous and can be offered the choice if they understand the implications of being identified, and confidentiality can be breached if someone (especially a child) is at risk of physical harm. Privacy is just as relevant to the physical environment; for example, a study to map the location of a rare species should protect its location from public knowledge.

A further aspect of respect is cultural sensitivity, which means being aware of cultural codes, religious norms, and local beliefs so that the researcher is less likely to cause offense or distress by their behavior or attitude. While particularly pertinent for research carried out in a foreign country, this can be equally significant much closer to home.

The concept of “beneficence” refers to the welfare of the research subject being paramount. This means protecting them from any harm or distress that may be caused by participating in the research. Beneficence is usually considered in reference to the research subject, but protecting the welfare of the researcher themselves can be
just as important, particularly when the research involves dangerous locations, vulnerable people, or emotive matters. Beneficence is also relevant to protecting landscapes, environments, and nonhuman organisms.

Researchers seek to ensure beneficence through systematically assessing the nature and scope of both risks and benefits, and implementing measures to maximize possible benefits and minimize possible harms. Harm encompasses both the physical (e.g., physical injury, threat of violence) and psychological (e.g., stress, risk to reputation, loss of dignity, loss of self-esteem), and it is vitally important to consider the potential for harm both during the research and afterwards when the researcher may no longer be present.

The principle of “justice” means an equitable distribution of both the benefits and risks of research. This applies to all stages of the fieldwork process from fair procedures in the selection of research subjects, to ensuring that voices and perspectives are equally heard and represented, and the sharing of research results with individuals and communities affected by the research in a way that is appropriate and accessible.

Justice also involves reciprocity. What may finally result in a single-authored scholarly work may have been impossible without support and participation from funders, supervisors, gatekeepers, informants, interpreters, and many others. All such contributions to the research should be duly acknowledged and they should receive compensation of an appropriate kind.

In addition to these three core principles, ethical research practice also means complying with appropriate laws and policies (which vary by country and context) on issues such as data protection, environmental protection, land rights, criminal disclosure, and conflicts of interest.

Conducting research in another country can add further ethical considerations and requirements. For example, researchers should show respect for the host nation by complying with any legislation and procedures for outsiders conducting research (e.g., research permits) and seek to ensure that the research benefits the host country as much as themselves once they return home.

The key principles of ethical research practice—respect for people and places, maximization of benefits and minimization of possible harms, equity in the benefits and risks, and compliance with laws and policies—are pertinent to all geography fieldwork. However, there is little to suggest that ethics affect geographers any differently to anthropologists, ecologists, or geologists conducting fieldwork. Perhaps what makes geography distinctive is the sheer diversity of contexts in which geographers carry out fieldwork and the complex webs of social and physical interactions to which ethical principles should be applied. In addition, many geographers are engaged with contemporary issues—such as social justice to environmental protection—and may feel a moral conscience to use their work to make the world a better place; this blurring between professional and personal interests creates further ethical considerations.

Historical overview of ethics in geography fieldwork

During the eighteenth and nineteenth centuries, a diverse range of travelers, explorers, soldiers, scholars, missionaries, surveyors, social reformers, imperial diplomats, writers, traders, naturalists, journalists, and others observed, mapped, and collected information about different places, people, and phenomena. This can be loosely categorized as early geography fieldwork.

The dominant paradigm was a detachment between the researcher and the field. The field was “out there,” somewhere else. It was
often overseas and the public “at home” reve-
eled in reports of the distant and the exotic. When the field was domestic it was also pre-
sented as an “other place,” as exemplified by nineteenth-century social reformers who cat-
aloged and mapped conditions of poverty in industrial cities such as London.

Instruction manuals for travelers had been in circulation since the sixteenth century but proliferated during the nineteenth century. The Royal Geographical Society added to the assem-
blage with “Hints to Travellers,” first published in 1854 and with many subsequent revised and expanded editions. Contents included suggested equipment that a traveler should take and how it should be packaged; instructions for taking accurate measurements and drawing maps; and advice on appropriate clothing and medical care in the field. A more populist handbook called The Art of Travel was published by RGS Fellow, Francis Galton, in 1855. It contained practical advice on expeditions (such as making camp and purifying water) and suggested what equipment to take. The content of both publications focused on practical and methodological issues with simply no reference to suggested behavior in the field in relation to the local environment or people.

While motivations for fieldwork varied – from adventurous exploration to scientific investigation and from military surveying to religious crusade – the common thread in each was a utilitarian ethic, collecting whatever was useful for the particular purpose. Public interest in, and respect for, these endeavors lent legitimacy to further expeditions and field trips. The unquestioned right to do whatever they wanted and wherever they wanted was based on the assumed supremacy of Western civilization and the unshakable belief in science and progress. However, built into the relationship between fieldworkers and the field were power and hierarchy, prejudice and racism, that is clear in the language used to describe “other” people and places (e.g., uncivilized, savages, cannibals).

Analysis and reflection of (un)ethical practice in the field during this period has only been car-
rried out more recently, particularly in the context of postcolonial critiques. Today the behavior of these “early geographers” would be classified as gross malpractice. There are plenty of examples of taking local people as slaves, plundering vil-
lages, sexual exploitation of native women, and excessive violence. For example, on one of Stanley’s expeditions in Africa, the theft of a few items from his field camp was countered by shooting dozens of locals dead. With widespread demand from museums and anthropological institutes for human specimens and cultural artifacts, naturalists and ethnologists dug up skeletons from graves and took material objects without permission. It was also popular practice to take one or two “natives” back home to be publically displayed at exhibitions and circuses as live specimens of exotic and savage peoples.

While some showed utter contempt for the subjects of their investigation, others displayed some cultural sensitivity and respect in the field. Many were driven by a moral, sometimes religious, imperative to bring “civilization” and “progress.” The goal of some fieldwork and the publication of findings was to improve condi-
tions (e.g., urban poverty) or campaign against mistreatment (e.g., slavery). However, there sometimes seems to be a contradiction between the humanitarian mission and the imposition of power and authority.

Overall, it is difficult to make generalizations due to the sheer diversity of people conduct-
ing fieldwork, and their different motivations and attitudes. In the field there is a lack of evidence of ethical principles such as gaining the consent of participants, protecting them from harm, and fair representation of different views. Likewise, the majority of post-fieldwork
publications – whether formal reports, scholarly papers, or populist articles – describe methodology and findings but do not demonstrate ethical considerations or engage in critical self-reflection. However, all of this must be seen within the context of the times when there was a complete separation of science and ethics.

From the establishment of the academic discipline of geography in the nineteenth century through to the first half of the twentieth century, there were a succession of major trends – environmental determinism, regional geography, and the quantitative revolution. In each case the methodology of fieldwork and data collection was influenced by the prevailing epistemology, but a lack of reference to ethical principles continued indicating that it was just not part of research practice. For example, early guides for practitioners such as the “Outline for Field Work in Geography” (Jones and Sauer 1915) focused on practical issues and data collection methods with no reference at all to ethical principles or behavior. This does not necessarily mean that all fieldworkers were unethical in their practices but neither can it be claimed that they were ethical.

From the 1970s onwards new trends and topics in geography created a context for ethical issues to be considered. The emergence of critical geography and the humanistic turn, increased awareness of environmental problems and global issues, feminist critiques and postcolonial discourses, postmodern ideas, and participatory methodologies have all in some way challenged assumptions about Western hegemony in science and the production of knowledge, particularly contesting the ability of geographical investigations to be objective. In this context a considerable amount of reflexive writing has emerged by geographers questioning issues such as identity and positionality, politics and power-relations, voice and representation. These socially and politically situated understandings of research and knowledge production provided the context for a more ethical approach to geography fieldwork.

Geography was slow compared to other disciplines to develop ethical guidelines for research practice. It was seen as the responsibility of the individual researcher or teacher to ensure that ethical principles were upheld in fieldwork. Some learned societies and professional bodies produced codes of good practice but these were nonbinding. Among the ethical guidelines available to geographers are the Association of American Geographers’ “Statement on Professional Ethics” (2009), the American Geographical Society’s “Guidelines for Ethical Conduct of Foreign Field Research” (2009), and the Royal Geographical Society’s “Code of Practice for the Grant Programmes” (2006). Depending on their subdiscipline, geographers can also refer to guidance from the bodies of allied disciplines, such as the Geologists’ Association’s “Code for Geological Field Work” (1975), the British Sociological Association’s “Statement of Ethical Practice” (2002), or the British Ecological Society and Young Explorers’ Trust’s “Environmental Responsibility for Expeditions” (2002).

In addition to voluntary ethics codes, mechanisms such as research training, student supervision, and peer review provided a framework for research ethics to be taught and monitored, but, by and large, ethics in geography fieldwork was still self-defined and self-regulated until its more recent formalization in the ethics review process.

**Formalization of ethics in geography fieldwork**

The recent introduction of a system of external accountability for ethics in geography fieldwork needs to be contextualized in the emergence of research ethics in wider academic
ETHICS IN GEOGRAPHY FIELDWORK

and professional practice since World War II. While the ancient civilizations of Egypt, Greece, and Rome set down some ethical principles in relation to medical science, there were some appalling examples across the centuries of some very unethical medical practice.

The history of medical science is littered with examples of testing on people, often marginalized or vulnerable groups whose lives were perceived as having less value. For example, physicians developing vaccines in the late seventeenth and eighteenth centuries used slaves as their test subjects. During World War II Nazi scientists conducted medical experiments on thousands of concentration camp prisoners, inflicting wounds, transmitting infections, and administering experimental drugs so that the effects could be observed. Likewise, the Japanese used captured prisoners of war for testing biological and chemical weapons. In the United States, the twentieth century saw government-sponsored research into the effects of untreated syphilis in African American men and the effects of radiation on human beings using cancer patients, pregnant women, and military personnel as test subjects. In each of these cases the research was carried out either without the knowledge or without the consent of the participants.

The war crimes tribunal that charged 23 of the abovementioned Nazi physicians led to the establishment of the Nuremberg Code in 1948 which set out guidelines on the ethical conduct of research, emphasizing that human participants should give voluntary consent and that the benefits of research must outweigh the risks. This was followed by the 1964 Helsinki Declaration on Ethical Principles for Medical Research Involving Human Subjects. Under these codes, the responsibility for carrying out research in an ethical manner lay with the individual researcher and it was not obligatory until governments stepped in to establish regulations.

The United States was the first, in response to a series of scandals including the Thalidomide tragedy and the Tuskegee experiments. The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was established and published a set of ethical principles and guidelines in 1979 known as the Belmont Report, which became the standard for ethical review in the United States of America and beyond. The 1970s and 1980s also saw Canada, Australia, the United Kingdom, and other countries adopt the practice of ethical review of medical research by independent committee. This served to standardize various voluntary codes and provide a mechanism for peer and public accountability.

By the turn of the twenty-first century, the process of ethics review had expanded from the medical and behavioral sciences to human subject research across the social sciences including human geography. Many geographers are now required to undertake an ethics review prior to fieldwork. Formats and requirements vary by institution and country, but usually an Institutional Review Board or Ethics Committee will consider a researcher’s proposal and the measures put in place to ensure ethical practice. In some cases they may request a revision of methodology before giving permission for the fieldwork to go ahead. Some institutions also require an end of project ethics report which details whether ethical considerations changed during the research process, how they were addressed, and how this affected the research.

Some critiques of ethical codes and the ethical review process for geography fieldwork

The improvement of ethical standards in fieldwork should be lauded. Voluntary ethics codes
set by disciplinary bodies and funding organizations, as well as compulsory ethics reviews imposed by academic departments and educational institutions, have been implemented largely with good intentions. The professional practice of today’s geographers in the field is far removed from the invasive, exploitative, insensitive, patronizing, racist, and selfish behavior seen in previous centuries. Hopefully it has also improved the quality of scholarship and the reputation of the discipline. However, ethics codes, the teaching of ethics, and the ethics review process have not been without criticism for a number of reasons.

First, voluntary codes are seen as too vague while the ethics review process is too restrictive. Given the nature of the discipline, geography fieldwork is tremendously diverse in terms of subject matter, location, and methodology thus any ethics code applying to all members of the discipline will have to be broad in scope. However, reducing core principles to the lowest common denominator can have the effect of distilling their value and leaving them so open to interpretation that almost anything goes. Furthermore, concepts such as “integrity,” “justice,” and “transparency” are abstract ideals and not readily translated into practice in the field. On the contrary, the ethics review process can be very prescriptive but the principles and practices developed to govern medical research are not necessarily suitable for geographical research whose aims, methodologies, relationships, and risks are quite different. For example, informed consent is not always morally appropriate or practically possible for geographers conducting fieldwork in some settings, such as ethnographic studies, yet ethics review committees may insist upon it. This may be partly caused by the cross-disciplinary composition of ethics review committees where most of the members are not geographers and do not necessarily understand epistemologies or methodologies specific to geography.

Second, ethics is compartmentalized and presented as a discrete aspect of fieldwork. The process of ethics review is one aspect of preparing for fieldwork, a task to be ticked off the to-do list along with a risk assessment, testing equipment, booking travel, and so on. Similarly, in most fieldwork guides ethics is a single chapter among other issues to be considered such as research design and data collection methods. Likewise in student training, ethics tends to be one self-standing lecture or workshop in a series on research methodology. However, the reality is that ethics are integrated into every aspect of the fieldwork, before, during, and after. The literature, training process, and formal procedure for ethics approval should better reflect the integrated, cross-cutting, and enduring nature of ethics in practice.

Third, codes of good practice and the ethics review process tend to present ethical principles as a series of issues each with an attendant list of solutions, but the reality is not so clear-cut. The field is a constantly shifting environment where the researcher is interacting with the research subject and location. Ethics are messy, contested, and negotiable, requiring ongoing reflection and responsiveness. Even the most carefully prepared researcher can face ethical issues in the field that were not anticipated in the ethics review processes and which may require decisions not covered by ethical codes. To resolve an ethical dilemma often involves violating one ethical principle in order to preserve another. Thus the fieldwork process is a minefield of ethical “gray areas,” some of which may never be fully resolved. As every fieldwork situation is unique, ethics codes should be used as tools rather than rules.

Finally, while ethics codes and ethics reviews are now widely adopted, they are no guarantee
of ethical research. It is possible for researchers to meet all the standards on paper but to flout them in practice, and there is very little real punishment if this is discovered. Despite much talk about “accountability,” there is a lack of clarity in terms of accountability to whom. This stands in contrast to health and safety aspects of fieldwork which are now taken very seriously, with maleficence holding real consequences. Critics may say that the ethics review process provides a buffer for educational institutions and funding bodies in the case of misconduct, but while medical science, business, law, and other fields have faced cases of misconduct and malpractice, geography has been largely free from scandal and enjoys the public trust (perhaps apart from the recent criticisms of the American Geographical Society’s Bowman Expeditions). At the end of the day, without a system of guaranteed checks and punishments, the responsibility for ensuring ethical practice in fieldwork lies with the researcher’s own integrity and conscience.

Despite great advances in improving ethics in geography fieldwork, an endpoint has not been reached. As geography and geography fieldwork continues to evolve, new ethical issues will emerge. For example, new technologies such as remote sensing, GIS, and three-dimensional geo-visualization have opened up different ways of looking at, measuring, monitoring, and understanding the Earth and geographical processes; the insertion of a computer screen between the researcher and the field does not remove the ethical dimension but rather changes it. Likewise, the emergence of Web 2.0, social media, and mobile technology has enabled the use of citizen science to collect spatial data; but opening up of the category of “researcher” to anyone with access to the Internet poses difficulties of enforcing ethical practice. Meanwhile, virtual field trips now available to geography students via digital technologies also change traditional methods of real-life interaction between the researcher and the field, thus altering ethical dynamics.

Considering that the possibilities of geographic information systems (GIS)/GIScience as an enabling science and technology of human endeavor are limitless, ethical issues do and will often arise in their development and use. Actual developments and uses, and potential developments and uses, lead to significant responsibilities and choices that involve considerations of values. Ethical issues connected to GIS/GIScience are inseparable from science and technology and involve considerations of scientific and technological as well as philosophical and practical aspects. Reflecting this range of issues, a high degree of intellectual and cultural diversity characterizes both academically published and unpublished work aimed at professionals and specific audiences on GIS/GIScience ethical issues. Throughout all engagements with ethical issues three questions repeatedly come to the fore:

1. What can I/we do?
2. What could I/we do?
3. What should I/we do?

By way of introduction, this entry turns to an underlying question in GIS/GIScience ethical discussions and interventions: the question about the scope of ethics and determinations of the philosophical degree deemed necessary for meaningful ethical engagement. Taken in reverse order, since the understood meaning of ethics defines its scope, the observation that philosophy is too important to be left to the philosophers offers a relevant starting point. Paralleling the range of philosophical enquiry, the issues that ethics encompasses can touch all imaginable pursuits of humankind. The question arises as to where one can start to consider these issues. This vast number of theoretical developments and uses, as well as applications, suggest that starting from a field of science and engineering can delineate a scientific and professional scope and result in a useful framework for organizing ethical engagements. While “meaning of life,” “moral rigor,” and even many “right and wrong” ethical and moral questions may lie beyond the resulting scope, the development of disciplinary ethical enquiry to study ethical issues develops helpful guidance for thinking about scientific and professional issues involving conduct, value-connected choices and responsibilities in one’s work, and responsibilities arising in scientific and professional contributions.

We can start from a primary question, and perhaps the most essential ethical question for scientists and professionals working with GIS/GIScience, of what I/we should do with my/our skills, knowledge, and technology. Our lives and the world are increasingly shaped by computer-based information technologies. But these technologies do not come from another planet or mysterious network of laboratories,
but are infused with human values. Still it often seems that information technologies lead to situations in which common moral rules and principles don’t seem to apply or are unhelpful in assessing what should be done. Spatial IT scenarios have rich ethical dimensions, as illustrated, for example, in such questions as whether retailers should be able to track store visitors using the unique code associated with their mobile phones; whether data collected by laypeople for a scientific project should be used for research and distributed without assessment of its positional and attribute accuracy; or whether GIS professionals should redistribute data from an analysis that relies on copyrighted data. The ethical aspects of imaginary and real GIS/GIScience scenarios provide practical references for what otherwise can become very abstract questions about what to do with skills, knowledge, and technology.

In other words, GIS/GIScience ethics emphasizes engagements with practices and draws only in limited degrees on theoretical ethics. This reflects the central importance in GIS/GIScience of assessing and analyzing the values that impact research and professional activities (Calkins and Obermeyer 1991). Going beyond the “rights versus wrongs” canard, applied approaches to ethics emphasize practical thinking about the consequences of what GIS professionals and/or GIScientists are doing, could do, or should do. These questions have an ethical component related to the value-based choices individuals and groups make when developing, using, and applying GIS/GIScience. The outcome and orientation of the questions and discussion, and later their actions, are often connected to an activity they individually face or could face. The degree to which people take up philosophical theories varies – approaches of practical ethics most often proceed from an implicit theoretical engagement and take up the practical challenges without theorization but can be very significant in improving scientific and/or professional activities.

The remainder of this entry on GIS/GIScience ethics proceeds by reviewing important academic and professional work on ethics associated with GIS, GIScience, geography, and computers. This is the basis for a summary of current issues in the following section and some concluding observations in the last section of the entry about developments of GIS/GIScience ethics. It aims to complement entries in the Encyclopedia on privacy, surveillance, and other issues with ethical dimensions.

Previous academic and professional work

Ethics offers powerful means to approach the roles of values in the developments and uses of GIS/GIScience. Previous academic and professional work has thoughtfully engaged the limitless breadth of ethical approaches and provides important touchstones for considering the ethical dimensions of GIS/GIScience.

A very good entry point in contemporary scholarship to consider GIS/GIScience ethics is the essay by James Proctor, “Ethics in Geography: Giving Moral Form to the Geographical Imagination” (1998). Proctor situates ethics in science and philosophy, suggesting that geography’s contributions to the study of ethics lie in the twofold consideration of geography’s ontology and epistemology. Distinguishing practical scientific questions arising in the conduct of science from moral questions about the justification behind different emphases in scientific fields and their role in the development of Western societies, Proctor accepted widely followed distinctions and separates theoretical ethics, systemic individual reflection on normative concerns, from applied ethics which focuses on specific moral
concerns. Since a major concern of ethics over the millennia has been the alignment of intellectual endeavors with the goals and ideologies of the regime, much work on moral philosophy deals with abstract means and ends questions and formulation of normative positions. Since the enlightenment and the rise of the modern state, the theoretical frameworks for philosophical ethics moved from teleological (ultimate purpose) to deontological (duty and obligation) approaches. With socioeconomic developments of the nineteenth century, work on ethical issues burgeoned and continued to do so through the twentieth century into the contemporary era. Proctor summarizes the ecumenical shift in ethical philosophy which includes the establishment of intellectual queries into gender, modernity, development, and community that connect to work in geography. Ethical enquiry in geography itself has largely taken the form of “thick descriptive ethics” (Proctor 1998, 10), which can be the foundation for much ethical enquiry in geography and bridge professional and substantive concerns. Proctor points to the importance of querying the ontological and epistemological dimensions and making sense of the central space, place, and nature metaphors in geographical knowledge-building. These queries become more focused in studying the technical implementation from the geographical concept. Because ethical issues pervade geography, Proctor concludes that considerations of geographical knowledge-building can offer valuable benefits for the discipline (Proctor 1998, 15). The questions, “What is the place of ethics in geography?” and “What is the place of geography in ethics?” point to important ways in which such endeavors can enrich the fields. Michael Curry’s contributions offer significant insights along these lines into the limits of GIS, questions for GIScience, and the reflections on the developments that come with the widespread use of spatial technologies and development of digital places and individuals (Curry 1998).

Jeremy Crampton provides helpful engagements with these ethical concepts and brings them to bear on important practical aspects. In “The Ethics of GIS” (1995) he points to a lack of substantial discussion of ethical issues in geography, which has led to the dominance of conduct standards and simplified normative concepts of good behavior. In response, Crampton develops a contextualized approach to GIS ethics that relates internal practices to external contexts. While resting on a normative concept of ethics, his dialectic approach to considering local relations and wider forces interactions helps to move past the local/global duality. Drawing on Brian Harley’s work, he refers to the different perspectives as internal and external, following Harley’s perception that cartographers were unwilling to accept that maps can follow an external and ideological agenda (Crampton 1995). Crampton in later work suggests turning to the question, “Under what circumstances is a map authored?” (Crampton 2001, 243). While more hermeneutic in emphasis than Blomley’s invocation of critical geography’s Marxist mission (Blomley 2006), Crampton’s later work develops and applies a Foucauldian concept of power to assess how maps align heterogeneous perspectives and thus offer the state enhanced means of control over its now calculable territory (Crampton 2010).

During this period, GIS was a rapidly growing field and going through a process of professionalization (Obermeyer 1994) which included addressing ethical issues (Huxhold and Craig 2003). Professional work on ethics had of course started earlier, but in parallel to academic discussions and with only limited exchange and interests in crossing between the two fields during this period. The creation of a Code of Ethics and Rules of Conduct (URISA 2003).
culminated in some senses the professional discussions of that time with a normative formulation of conduct standards (Craig 2003; Huxhold and Craig 2003). Neither code nor rules of conduct meant the end of professional discussion and refinements. For instance, a 2004 workshop convened by the Association for Geographic Information (AGI) in the United Kingdom sought ways to go beyond an implicit emphasis in codes and rules on sanctions and focus on guidance for professionals (Blakemore and Longhorn 2004).

Such events point to the ongoing discussion of ethical issues in formal professional and scientific associations and at professional and scientific meetings. As GIS has become an important information technology in other fields, the discussion of ethical issues has expanded into specific domains, yet in the context of changing societal values. All academic disciplines reflect larger societal values. Ethical issues in GIS/GIScience necessarily consider and refer to values created outside of GIS/GIScience.

One significant uptake of ethical issues for GIS and GIScience led to the creation of case study materials and guidance for using those materials in both education and professional development (DiBiase et al. 2012). Case studies offer scenarios for teaching that challenge students or participants to analyze ethical problems and to develop solutions. Case studies make it possible for professionals to connect didactic materials to practical experiences. The well-known “case method” is a common pedagogical technique for strengthening the moral reasoning skills of students in business, medicine, law, engineering, and computer and information science (Davis 1999; Keefer and Ashley 2001; Quinn 2006). Discovery and deliberation of case studies draws heavily on Davis’s (1999) “seven-step guide to ethical decision making” (outlined in Box 1). Similar ethical analysis models have been suggested by Keefer and Ashley (2001) and others.

While case studies provide an important didactic instrument for engaging GIS and GIScience ethical issues at a variety of levels, work from computing ethics offers numerous other pedagogical concepts and discussions of ethical issues that have relevance for GIS/GIScience engagements with ethical issues. The virtue approach, which involves considering concepts and testimonials from professionals who exemplify virtuous values in their work, offers students material with which to engage with the complexity of professional and scientific activities in their field and professionals ways to reflect on values and consider theoretical situations (Huff and Martin 1995; Huff, Barnard, and Frey 2008). It also offers practitioners ways to connect ethical concepts to their experiences and hypothetical scenarios (Huff 2008) and move beyond the relativism and sublimation that often stymie people engaging with theoretical ethics (Critchley 2007). The rich discussion of computing ethics offered by Deborah Johnson in Computer Ethics (2009) covers a gamut of issues arising in the development of new technologies in the vacuum of policies and amid the conceptual muddles that so often dominates our knowledge and understanding of GIS and GIScience.

In particular, the distinction she makes between the “standard account” and “socio-technical systems” approaches to engagements with computing ethics offers a number of highly relevant starting points to consider the development of engagements with ethical issues in GIS and GIScience. Perhaps the most important starting point is recognizing that technology and society co-shape each other. That is, ethical engagements with information technologies have to consider the complex and multidimensional relationships between technology and society. Indeed, while the use of computing technologies raises many ethical issues, including a good number of unique issues, many of these
Box 1 Seven-steps approach.

Step 1 State problem. For example, “There’s something about this decision that makes me uncomfortable” or “Do I have a conflict of interest?”

Step 2 Check facts. Many problems disappear upon closer examination of the situation, while others change radically.

Step 3 Identify relevant factors. For example, persons involved, laws, professional code, other practical constraints.

Step 4 Develop list of options. Be imaginative, try to avoid “dilemma”; not “yes” or “no” but whom to go to, what to say.

Step 5 Test options. Use such tests as the following. Harm test: does this option do less harm than alternatives? Publicity test: would I want my choice of this option published in the newspaper? Defensibility test: could I defend choice of option before Congres- sional committee or committee of peers? Reversibility test: would I still think choice of this option good if I were adversely affected by it? Colleague test: what do my colleagues say when I describe my problem and suggest this option as my solution? Professional test: what might my profession’s governing body or ethics committee say about this option? Organization test: what does the company’s ethics officer or legal counsel say about this?

Step 6 Make a choice based on steps 1–5.

Step 7 Review steps 1–6. What could you do to make it less likely that you would have to make such a decision again? Are there any precautions you can take as an individual (announce your personal attitude on such questions, change job, etc.)? Is there any way to have more support next time? Is there any way to change the organization (for example, suggest policy change at next departmental meeting)?

Source: Davis 1999.

issues cannot be separated from complex ethical issues arising in the use of all technologies that have ever “stirred fear and apprehension as well as fascination and hope” (Johnson 2009, 6).

In what she refers to as the “standard account,” IT creates new possibilities for individual action and new forms of interactions. The focus of work on ethical issues is on these new possibilities through questions about who, what, how, and when. Ethical analysis can consider questions of what should be done and help evaluate how the possibility fits practices, values, cultural concepts, and so on. Computer ethics thus focuses on filling policy vacuums, for example in copyright laws that proceed from an assumption that all copyright material is provided on physical media, thus creating a vacuum for streamed movies and downloaded spatial data.
ETHICS IN GISCIENCE

In contrast, the “socio-technical systems” approach focuses on the co-shaping of technology, people, and society and rejects technological determinism. Strongly influenced by science and technology studies (STS), this approach’s rejection of technological determinism means connecting technological developments to societies and ideologies and looking at how technology, people, and society co-constitute each other. Thus, instead of a “standard account” analysis that may look for parallels arising in the adoption of Internet-based communications in each country that implements Internet technology, the “socio-technical systems” approach considers how societal influences alter the design, implementation, and use of Internet-based communications. For instance, the concerns about location privacies expressed by many people in Germany reflect a cultural history of state surveillance. In Brazil, in contrast, tracking is felt by many to offer a new level of security for individuals and families. Perhaps the biggest difference between the two approaches is that “socio-technical systems” avoid focusing on material technological objects and resulting impacts and instead consider how technological artifacts are embedded and created by intentional social activity as a social product that is also part of a social system. For example, a cell phone is not just the phone, but a combination of artifact and a network of people and other technologies.

This aspect of the “socio-technical systems” approach leads to significant consequences for engagements with ethical issues. Traditionally, ethicists have focused on human behavior and action and left out technology. Technology was largely understood to be neutral and its use depended solely on decisions of a person, group, or institution. The resulting emphasis on the material creates obstacles to understanding how artifacts and people interact, how people influence artifacts, and how artifacts influence people. Values are infused in the technology. The social practices that Crampton points to (2001) are integral to ethical engagements of GIS and GIScience.

An example of the “socio-technical systems” approach to this can be found in applied ethics (Harvey 2012). Applied ethics is an area of philosophy that approaches ethics with the idea that philosophy has to be relevant and engage actual issues for an audience that includes the public. Among philosophers, the public, scientists, and professionals, applied ethics has received considerable attention in recent years. Applied ethics echoes the principles of the “socio-technical systems” approach in its emphasis on engaging actual issues and being relevant to a larger public. Reflecting a scientific emphasis on moving past intellectual reflection, the emphasis of applied ethics is on developing an empirical foundation for ethics. Instead of looking for ethical theories and principles to explain choices, applied ethics involves considering both ethical concepts and the actual situations with actual consequences. In other words, ethical engagement involves clear connection to facts. For example, a GIS analyst working on a mapping project using census data needs to consider requirements of the project but also the larger situation.

Applied ethics involves considering the situation and internal and external relations and facts. Beyond these considerations applied ethical deliberation also reflects on the perspective and assumptions of different actors and ourselves in analyzing a situation – what many feminists refer to as standpoint theory (Walker 1998).

Persistent issues for GIS/GIScience ethics

GIS and GIScience have introduced, developed, and refined powerful technologies, skills, and
knowledge for the representation of geographic processes and patterns observed or measured in the world. Both professionals and scientists draw on ethics to help make decisions arising in the plethora of issues complicated by the vacuum of policies and the conceptual muddles that accompany the increasing ubiquity of location technologies (Sui 2004; Wilson 2012). These involve new applied ethical challenges.

While a particular application involves the specific concerns raised in other entries in this encyclopedia, several ethical issues of GIS and GIScience are of broad significance. Four such issues that deserve consideration here are:

1. the question of place and the geographical dimensions of ethical issues
2. ethical concerns with representation
3. spatial analysis and ethical responsibility
4. consideration of values in professional and scientific activities.

Place has been a central metaphor for geographic knowledge production. Informing the ontological scope of geography, it is used to organize geographical knowledge and make connections between materialist concepts of space and the places people live in and experience. Ethical issues arise in living and conceptualizing places. In geographic interventions of Bunge, Olsson, Wood, and others, whether ethics are place-bound or fundamentally universalist is questioned. The ethical issues arising in GIS and GIScience involve a great diversity of places and leave much latitude in interpreting this question.

Likewise, ethical concerns with representation arise frequently in making decisions in the design, implementation, and use of GIS and in advancing GIScience. The spread of GIS and its growing accessibility mean more people are thinking about representations of territory and questioning the canonical representations produced by state agencies and other actors. Issues of accuracy also reflect ethical concerns with representation and the need to assess whether spatial data is sufficient – the fitness for use criteria (Chrisman 1984; Comber, Fisher, and Wadsworth 2004; Goodchild 1998).

Similarly, the broadening use of spatial analysis leads to concerns with the ethical responsibility arising in the use of GIS and GIScience developments. It increasingly behooves GIS professionals and GIScientists to understand how data are collected, avoid the pitfalls of objectivism, and account for related ethical risks. Marc Armstrong draws on deontological ethics and the legal concept of malpractice which arises in the failure to follow accepted professional standards through negligence when the professional is required to act (Armstrong and Ruggles 2005). While GIS misuse rarely results in grievous consequences that directly endanger people, the consequences of slapdash work or unquestioning use of data can result in analysis results and information that lead to negative consequences and risks.

Accordingly, Armstrong and others argue for training and continuing education focus on consequences that arise from choices that can change results and thus sway conclusions. These issues are of course diverse yet also specific, making them a key focus of more recent attempts to advance ethics training (DiBiase et al. 2012). Case studies of various lengths and the seven-step method provide ways to learn how to incorporate values into GIS/GIScience activities and also provide a method for addressing ethical dimensions.

Conclusions

As the enabling science and technology in geography and many other fields, a primary, and perhaps the most essential ethical question about GIS/GIScience for professionals and scientists working with it is that of what
ETHICS IN GISCIENCE

I/we should do with our skills, knowledge, and technology. Given the limitless potential of GIS/GIScience’s support for human endeavors, opening the underlying issues, assessing and developing different pedagogical approaches for students and continuing professional development, and providing counsel have been the significant contributions of GIS/GIScience ethical engagements.

This entry provides an overview of these issues and approaches to engage ethical issues that GIS professionals and GIScientists have developed. Given actual and potential uses of these skills, knowledge, and technology, the more widespread distinction of theoretical ethics that deals with systemic and abstract reflections and applied ethical engagements with specific moral concerns degenerates into conduct standards and simplified normative concepts associated with maxims that become challenges to realize in the real-world complexity of science and technology. Instead, considering the geography of knowledge-building (Proctor) facilitates the engagement with actual situations and the co-shaping of GIS/GIScience socio-technical systems.

The ethical issues connected to GIS/GIScience accompany the developments in these domains. And they may even, from time to time, become the center of interest. The scientific, professional, technological, philosophical, and practical aspects of these ethical issues are ever present in a complexity matching the potential uses of GIS/GIScience. Considering the ethical dimensions of scientific and professional conduct, values in work-related choices, and responsibilities for the use of outcomes and products moves potentially abstract discussions into three questions:

1. What can I/we do?
2. What could I/we do?
3. What should I/we do?

Engagements with these questions and the situations, internal relations, external relations, and facts make up a common thread in GIS/GIScience ethics discussions and will continue to be a part of these fields.

Ethnicity

Emily Skop
University of Colorado Colorado Springs, USA
Wei Li
Arizona State University, USA

Ethnicity is a social construct that divides people into varying groups based on characteristics such as ancestral geographic and religious links, a shared sense of belonging, cultural traditions, values, political and economic interests, and historical ties. At the center of ethnic identities are the building blocks of language, dialect, faith, literature, folklore, music, food preferences, and clothing, along with kinship, neighborhood, community, and territorial links, and/or migratory status. These identifiers can serve as important referents to self–other identification, and ethnicity may influence both individual and group behavior in various areas of social life. This is especially true in multiethnic societies where the ethnic tie can be significant in shaping both primary social relationships, including one’s choice of close friends, marital partner, and residence, as well as broader collective political relationships, whereby a strong group consciousness can result in benefits and privileges within prevailing social systems.

While ethnicity can be a key source of social–psychological attachment, ethnicity is not the only way in which individuals see themselves and how others view them. Ethnicity typically interacts and intersects with other social constructs such as race, gender, class, social status, sexual orientation, age, and disability to form mutually constituted identities that cannot be examined in isolation from one another. At any time, an individual has multiple identifiers; for example, a Somali immigrant, mother-in-law, friend, and Christian may also be an office manager. Each one of these identifiers may be more personally relevant depending on the situation, but when they intersect they can profoundly affect individual lives.

Most scholars argue that certain identifiers are more dominant and powerful in society, and that these identities need to be studied together to fully understand how intensely they impact everyday life. Studying race and ethnicity in concert, for instance, is a key way forward to understanding how whole systems of privilege are granted to particular sectors of the population at the expense of other sectors. Since racial identification obscures ethnic group identification and vice versa, individuals and groups are placed in multiple social positions, which in turn become institutionalized in systems of inequality. In the United States, for instance, focusing only on race would hide the important differences between and within Chinese, Asian Indians, Filipinos, Koreans, or Japanese – all of which are Asian American ethnic groups. Then again, identifying individuals or groups solely by their ethnic identities would also obscure the relevancy of race in society. Thus, the mutual construction and intersection of these identities demonstrates how different people relate to one another based on varying social interactions.

Indeed, when varying social identities intersect, they form matrices of privilege and oppression whereby different social locations, based on ethnicity, race, gender, class, sexual orientation, age, disability, and other identifiers, combine
to shape individual lives and create systems of inequality. Experiences of oppression and privilege create social differentiation, whereby people come to be identified and ranked against one another based on physical and social characteristics. The combined aspects of one’s identity can either intensify (through multiple oppression) or buffer (via privilege) the full force of oppression that individuals and groups of people experience.

Because of the costs and benefits that can result, ethnic identities will be displayed to a varying degree by individuals and groups based on both in-group and out-group responses, and reflected at both individual and group levels. Ethnic identities can be self-claimed or externally imposed, depending on circumstances. Individuals typically self-identify as a member of a particular ethnic group to assert their sense of belonging, to maximize the benefits associated with this identity, to retreat from a group to minimize the disadvantages, or to disavow an ethnic identity for fear of persecution. However, it is the externally imposed ethnic identity that reflects broader societal impacts. For instance, using “Asian American” as the basis for categorization may result in “racial lumping” by the dominant society. In turn, population groups caught in this system of ascriptive racial categorization may react by rallying together to (re)create emotional links and form alliances based on their ethnic ties. In other words, ethnic identity formation may be the result of a group’s attempts to withstand structural disparities or to gain privileges that might otherwise be denied to them based on other social identifiers.

The end result of social differentiation is social stratification, which creates unequal access to valued resources, services, and positions in society. Discrimination, residential and occupational segregation, and economic isolation, as well as educational and health disparities, are the result of social differentiation. Indeed, matrices of privilege and oppression based on particular identifiers dictate the allocation of justice, the distribution of societal benefits, indeed the entire spectrum of life chances. In extreme cases, differential ethnicity is used to justify ethnic cleansing or wars against humanity. Ethnicity is one of the key elements used in social stratification, and thus it has very real consequences in people’s everyday lives.

While in the past essentialism was the theoretical model that dominated discourse surrounding ethnicity, the social constructionist model is currently the chief theoretical framework that structures the idea of “ethnicity.” Essentialism boiled ethnicity down to hereditary, biological, and primordial ties but social constructivism illustrates how individual and broader societal action and inaction institutionalize ethnic identities in particular places and situations. In the social constructionist model, individuals typically have multiple social identities which they use to define themselves, at the same time as dominant societal values play a critical role in the construction and classification of social groups. In other words, societal notions of what is considered normative, normal, or accepted frame personal identities at the same time as personal identities can reshape dominant ideologies through reframing stereotypes.

Indeed, social constructivism argues that differentiation and stratification vary across cultures and through time, so that the treatment of individuals and groups at both the individual and the institutional level changes, depending on context. In other words, it is possible to tell if some identifier like ethnicity is socially constructed if that same identifier is framed differently in another time frame or culture. In the United States, for instance, many groups that are now defined as ethnic groups, including most European immigrant groups, were in previous historical periods defined as races. The Irish,
Jews, and many other European groups came to be known as “ethnics” only in the early twentieth century and were thus identified by those of the dominant Anglo-Saxon ancestry groups, who often used the term pejoratively to distinguish and separate those groups from them. In fact the term “ethnicity,” or the condition of belonging to an ethnic group, did not even appear in scholarship until the early twentieth century, thus illustrating the socially constructed nature of this particular identifier.

Within geography, studies of ethnicity have reflected scholarly paradigm shifts over time. Earlier geographic research on ethnicity was strongly influenced by the Chicago School of sociology, with a focus on (i) the “race relations” cycle whereby all groups eventually assimilate to Anglo-Saxon Protestant American norms; and (ii) the “invasion–succession” model whereby a newly arrived ethnic group invades an inner city neighborhood and ultimately succeeds the group living there as that group moves outward toward the suburbs.

In recent decades, geographers have increasingly analyzed ethnicity from the perspective of dynamic structural opportunities and restraints, with a focus on antiracist and racialization theory, instead of the previous essentialist angles of the ascribed linguistic and cultural traditions alone. The retheorizing of ethnicity, in addition to the multiscalar analysis of individuals, families, groups, neighborhoods, city-regions, nations, and supranations, have reinvigorated the field of ethnic geography and made such research increasingly influential.

The early twenty-first century brings a new complexity to the scholarship surrounding ethnicity. As the cross-national movement and connections of people, goods, information, and financial capital becomes more prevalent, the idea of transnationalism has come to the fore. Transnationalism, the process by which migrants forge and sustain multistranded social relations that link together societies of origin and settlement, provides an alternative mechanism through which migrants forge their identities. If in fact individuals have multiple matrices of privilege and oppression to navigate, what will be the result for ethnic identities? One might argue that, in a world of globalization and diminishing spatial barriers to communication, movement, exchange, originality, exoticism, and authenticity will become prized possessions, and thus ethnic identities will become even more important and salient in the coming years. Yet others might contend that the entire process of social differentiation will become unhinged and that current mappings of ethnicity will be destabilized.

Whatever the outcome, the consequences of future ethnic geographies are likely to be remarkable. Indeed, the study of ethnicity may advance the goal of building toward more just and peaceful societies in the world. Therefore, future research on ethnicity should be multifaceted and multiscalar, including but not limited to change over time and across space, considering variations as a result of class, gender, age, generation, or migration status, and analyzing different subnational, national, supranational, and transnational contexts.

Ethnobotany

Robert Voeks
California State University, Fullerton, USA

Ethnobotany is the study of the dynamic relationship between plants and people. It traces its early history to the colonial quest for precious spices – cinnamon, clove, nutmeg, and other tropical treasures. As colonial merchants and settlers unwittingly spread tropical microbes to the far corners of the Earth, the search expanded to botanical remedies for the flotilla of new and geographically expanding diseases. Entrepreneurs and men of science sought fame and profit as they scoured these newfound lands for “green gold,” and so was born the ethnobotanical enterprise.

Ethnobotanists continue to search for novel botanical products, especially drug plants. These bioprospecting efforts have yielded considerable pharmaceutical success, but often at the expense of indigenous intellectual property. Beginning in the 1960s, the primary objectives of ethnobotanical research became more conceptual and problem oriented, as researchers shifted away from useful plant inventories to explore the complex relationship between people and plants. Ethnobotanical inquiry likewise became more interdisciplinary, involving especially anthropologists, archaeologists, botanists, chemists, and geographers. Laboratory and field methods were adopted from cognate disciplines, while data analysis became increasingly quantitative. The time frame of inquiry ranges from the late Pleistocene to the present, while the scale of investigation ranges from genes to landscapes.

Ethnobotanical research involves any dimension of people–plant relationships, but most current research focuses on several “projects.” Ethnobotanists seek to understand the process of domestication and diffusion of crop plants. They study the strategies employed by traditional societies to manage plant species, and the degree to which these actions are environmentally sustainable. They investigate how species are cognitively categorized, ranked, named, and assigned meaning. And they explore the impact of globalization on knowledge and use of plant resources.

The origin and spread of agricultural crops had long been a focus of interest, but in recent years there has been an expansion of inquiry beyond the big commercial staples – rice, maize, wheat, and potatoes – and toward understanding the patterns and processes of lesser known “wild” and semidomesticated species. Management involves selective wild harvest, sparing of perennials, pruning, weeding and fertilizing wild populations, burning competing vegetation, distributing seeds, and protecting important taxa through community regulation. Species managed by these strategies often exhibit significant differences in seed size, seed number, and other morphological features compared with unmanaged populations. In Mesoamerica, for example, 5000–7000 plant species are exploited by people, most are in some way managed, and roughly 200 are in some stage of incipient domestication (Casas et al. 2007). When wild species are introduced to home gardens, even more intense management occurs. Home
gardens are crucial resources for rural people, especially women, who use them for food, medicine, fuelwood, fiber, and shade, as well as for ornamental and ceremonial purposes. They are important repositories of rare wild species, particularly as their natural habitats disappear, and they are hotbeds of incipient domestication. These studies suggest increasingly that plant domestication should be seen not as a binary beginning and endpoint, but rather as a continuum, from totally wild species to highly modified modern cultivars.

Species management is often associated with intense manipulation of nature, and so investigation of species domestication often segues into the question of the “pristine myth.” Due to long-term encouragement or sparing of useful tree species, many so-called natural landscapes are better termed “cultural landscapes” or “domesticated landscapes.” The ancient Mesoamerican Maya, for example, planted old-growth fruit trees in fallows and created orchard gardens (*pet kotoob*) in the forest. Consequently, many of the otherwise pristine forests of Guatemala, Belize, and Mexico’s Yucatan today are dominated by useful wild trees that were planted and tended by people over a thousand years ago (Ross 2011). Amazonian forests likewise exhibit significant species distribution and composition features that are consistent with human management. To this day, indigenous people clearly distinguish between the varying utility of forest stands that are more or less anthropogenic. Even the distribution of the endemic Brazil nut tree (*Bertholletia excelsa*), which for many is iconic for the Amazonian forest primeval, is the result of centuries of movement and likely planting by forest folk.

As pointed out early by Carl Sauer, the use of fire to manage species and vegetation was widespread in temperate latitudes. Recent ethnobotanical research has confirmed many of these observations. In California, large expanses of oak woodlands were burned by native peoples to reduce insect predation on acorns and to reduce competition from invading conifers. In the southern Andes, monkey puzzle (*Araucaria araucaria*) was managed by fire to enhance its growth and productivity. Aboriginal peoples of southeastern Australia employed burning to enhance the growth of edible herbaceous plants at the expense of trees. And Canada’s First Peoples used fire liberally to enhance the quality and quantity of edible berry and tuberous species.

Rural subsistence farmers often maintain huge lexicons of plant names. But while they universally name and classify familiar species, all taxa are not treated equally. Staple crops, such as corn (*Zea mays*) and potatoes (*Solanum tuberosum*), are specified by dozens of subspecific epithets – the blue type of corn, the red type of corn, and so on. But less useful species often receive simply a nondescript gloss – it’s a weed, or it’s a liana. Species salience appears to be the primary naming feature; manioc (*Manihot esculenta*), for instance, is more salient to Amazonian subsistence horticulturalists than a rare vine that invades the swidden. Traditional societies organize their ethnofloras into ranks, often including kingdom, life form, genus, species, and variety; ranks tend to be similar across cultures, regardless of cultural significance (Berlin 1992). The genus in particular represents the most recognizable rank of plant perception among humans, and in most classification schemes finds its parallel in the Linnaean system.

The field of ethnobotany developed around understanding the relationship between indigenous people and native floras in rural, often isolated settings; the more sedentary and the more natural, the better. Yet in spite of preconceptions that people lose their ethnobotanical skills in the process of migration, it is clear that immigrants go to extreme lengths to continue using their traditional foods and healing
floras. This is particularly true when these plants represent distinctive cultural markers for oppressed diaspora communities. In the case of enslaved Africans, for example, there was a powerful impulse to recreate a semblance of their ancestral flora in the Americas. And in spite of the enormous barriers, significant elements of their useful flora arrived in the New World as part of the Columbian Exchange. This botanical homogenization facilitated continuity of African plant-based culinary and healing traditions among their New World descendents, thus providing avenues of cultural resistance to Euro-American hegemony (Voeks and Rashford 2013). Migrant people today likewise encounter considerable obstacles to international transfer of useful plants. Many avoid customs restrictions by surreptitiously bringing plants or seeds with them. In some instances, particularly with medicinal plants, the homeland species are weedy and cosmopolitan, and so often precede the arrival of immigrants. When other strategies fail, immigrants either learn the identities of replacement species in their new home, or simply abandon the use of useful plants in favor of supermarkets and pharmacies.

Subsistence harvest of traditional plant products in many cases has shifted to commercial extraction. Exotic foods, fiber, medicines, latex, and sundry other plant and fungal products – termed non-timber forest products (NTFPs) – are finding ready markets in the more developed world. By the 1990s, many nongovernmental organizations (NGOs) and government agencies began to view NTFPs as a potential rural development-resource conservation win-win. NTFPs can open routes to livelihood improvement among marginalized, rural communities, and, unlike alternative destructive forms of land use, the effects of petty extraction on the structure and function of forests is much less than other uses. Research on this subject is ongoing, and the results are mixed. In Latin America and Africa, earnings represent an economically justifiable use of gatherer time, but this is not the case in the poorest countries of Southeast Asia. Regarding ecological sustainability, most studies report that current levels and intensities of harvest are not threatening the biological replacement of individuals and populations, nor is the ecological integrity of the relevant ecosystems threatened. Regardless, commodification of previously subsistence plant products is dramatically changing many aspects of people–plant relations. Young people abandon all but commercially valuable species, gendered relations with nature change as women and men redefine their roles in the community, and the cultural significance of plants shift as botanical products are increasingly defined by their monetary value (Shackleton and Pandey 2014).

If you were to snap a picture of the stereotype of the ethnographer, it would be a landscape of his or her “field site”: perhaps a jungle clearing with thatched huts, and the lone field worker, writing inside a journal in the tent. Specifically relevant to the geographer-ethnographer, I think also about the image of a boat reaching ashore, the explorer discovering a “new” land. If not a jungle, then the boat is arriving on windswept rocky shores – or slides through an icy landscape of the polar regions. Sometimes those scenes have other, “local” people in them – but more often those landscapes are empty of everything but non-human biota. Ethnographers write the world in text and visual imagery, not without extensive field work – while also referencing the geographical imagination of the culture who will consume the ethnography. All knowledge is partial. By the stereotype’s definition, this means an ethnographer studies places and phenomena that are not within the researcher’s own home. There is a Far Side cartoon in which the viewer is privy to the living room conversation of a tribal family – who, upon seeing a canoe with people disembarking, cry “Anthropologists! Anthropologists!” And rush about the room, hiding their television and high-tech video equipment. The joke is of course playing on these stereotypes, and implies that the researcher is hoodwinked by their own fetishization of the “primitive.” I think of these stereotypes in my current research situation, in a small village of Athabascans in Nulato, Alaska. I hoped that my tent, situated for the summer outside the Chief’s front door, was merely repeating the placement and not the position and practice of the ethnographer in this community. In the first place, I told the Chief that what I hoped was to collaborate on a project as equals, that he as tribal leader could direct the purpose of the ethnographic research. Now I have left to wonder what sort of cartoon could be crafted about me. (Memo 3 on positionality, July 2, 2011)

Ethnography is both a method of data gathering and a representational practice of the qualitative scholar. Within geography it is often used as an inductive approach to empirical and emotional data, especially fieldwork data. Its attention to holism is perhaps a reason why geograph-ers, who literally “write the world,” are attracted to using ethnographic methods. Described by anthropologists as a practice of “thick description,” ethnography has been used to elucidate phenomena and causal relationships at scales such as a “culture” or “community,” particular places, or a particular event. Within geography, ethnography has been used to understand how humans create and relate to their material environments, as well as how power relations create and sustain social spaces, networks, and the literal movement of material bodies. Current trends in geographic theory, including critical geography and the “postmodern turn” across the social sciences, have influenced the topics, scope, and practice of ethnographic work. This entry outlines both the continuities and the changes in how ethnographic methods are employed by geographers.

The data used in ethnography comes from primary data gathering, often taking the form of field notes or visual and/or audio records of their fieldwork and/or participant observations. Ethnographers also generate data via interviews, surveys, photographs and other visual data, archival research, mapping, or other qualitative...
methods. An ethnographer’s primary sources are often complemented by secondary sources, such as census or geographic information systems (GIS) data. Nonspatial data is often analyzed discursively or via a coding scheme, with this textual analysis shaping the final ethnographic narrative – the “results” of the inductive study. There are a multitude of sources and analytical approaches available to ethnographers; many of these sources and approaches are helpfully explained through texts such as Crang and Cook (2007), Watson and Till (2010), and Herbert, Gallagher, and Myers (2005). As shown through their and other examples, this means that ethnographies can take a variety of forms, from a variety of research practices.

Via fieldwork, Herbert (2000) writes that ethnographers are able to understand what people do, because people cannot always consciously describe their actions and beliefs. Ethnographic research can also access the lived realities of populations and places that cannot be well understood simply by looking at aggregate quantitative social data. Aggregate survey data measuring the efficacy of public transportation, for example, may erase the problems experienced by minority groups, such as the specific transportation difficulties faced by poor women in urban areas. There are many kinds of experiences that are better accessed via ethnography than through other (quantitative or qualitative) methods; through the use of ethnography geographers can make sense of their literal “field” of inquiry, and generate new research questions that can be pursued through further qualitative or quantitative research.

Importantly, while there is no single way to conduct an ethnography, it is nevertheless possible to ascertain a good- from a poor-quality ethnography. For researchers do not merely “collect” data; as with every research methodology, ethnographers have developed rigorous approaches to analyzing their data and representing results. In the first place, ethnographers engage theory in their fieldwork differently from physical geographers; an instructive comparison is found in the chapter by Herbert, Gallagher, and Myers (2005), where geographers of different subfields describe their use of theory in the conduct of fieldwork. The physical geographer continually measures the “field” (via formal or informal hypothesis testing) against a larger body of theory of physical systems – often called an “objective” approach to the empirical world. In contrast, the ethnographers in Herbert, Gallagher, and Myers (2005) and elsewhere describe a process of using theory to inform their field practices as well as to make sense of their data, and they also describe their iterative approaches to analyze field experience while it was happening.

In this way, ethnography can be said to be both iterative and “intersubjective” – and thus the process of memo-writing and field note taking at large is a key way ethnographers maintain rigor in their work. As shown in the example memo at the beginning of this entry, and explained elsewhere (Crang and Cook 2007; Watson and Till 2010), a memo does not have to be a direct observation with the five senses, but more importantly it is a reflection on theory, method, and/or the researcher’s own participation in gathering data. A memo may record some ideas or observations quickly, or discuss at length the issue under focus and develop preliminary analyses. Memos, like all field notes, may be coded for patterns of thought and/or developed into a discourse analysis. They may be quoted in a finished piece of writing, like the aforementioned memo, as a sample of ethnographic data. Quoting memos and field notes is also a way to communicate or explain an issue in ways that are more accessible to multiple readerships, given that well-written (and first-person) field notes can at times read like a novel.
Rigor in field note practices includes constantly examining the researcher’s role in the collection of empirical data – called an exercise in “reflexivity.” One example of ethnographic reflexivity in geography is the collection of feminist research edited by Nast (1994) in the *Professional Geographer*. As demonstrated in that collection, to be reflexive a researcher must examine how they are sometimes “outsiders” or “insiders” in relation to a particular phenomenon under study – often their positionalities remain *in between* the “field” and “home.” The assumption is that researchers have an effect on the data regardless of the method, whether qualitative or quantitative, inductive or deductive. Thus writing about positionality provides rigor to an ethnographer’s empirical representation of the world; both the researcher and the reader would be made aware of the perspective through which the researcher has recorded and analyzed the empirical data. But, to be clear, these reflections are not mere personal opinions or journalistic observations. Rather, to be reflexive involves not only assessing the researcher’s emotions and personal experiences in relation to the issue/object being observed, but also engaging with theories of research ethics and positionality. Therefore, the actual act of being reflexive in the act of taking field notes allows a researcher to perhaps change their practices to more successfully collect data throughout the remaining time on a given project. It is a method for the ethnographer to check their own assumptions and to forge ways to build trust with the communities within which they work. The modern ethnographer does not want to be duped by his/her own desires, as the researchers in the cartoon were.

Reflections on positionality evolved to respond to what is called the “crisis of representation,” which greatly affected work across social sciences. As noted in Nast (1994), researchers began to recognize the “politics of representation”: where the *etic*, or “objective,” perspective was revered as the ideal of all Enlightenment-based sciences, ethnographers especially had to confront how such a practice can erase local expertise, called the *emic* perspective. The Western scholar, in accruing expertise on a community as an object of knowledge, thereby also disenfranchised that community from speaking for themselves in political life.

Watson and Till (2010) describe how geographers thereby became concerned with “decolonizing” their methods. To be seen as legitimate experts, ethnographers have traditionally emphasized the long-term nature of their projects – long periods of time to gather and interpret data, to immerse themselves in the lives of those they work with, and to reinterpret data. Important to this practice is an assumption that the ethnographer was studying an *other* society – via a more *etic* perspective – and thus required the time to immerse themselves in their new milieu. While the time of immersion is still of key import to the rigor of ethnographic work, today’s theory and practice of ethnography does not always require extensive temporal commitment in the field. In fact, a rigorous ethnographic practice today may emphasize less time spent in the field observing, and more time instead *collaborating* with those who hold an *emic* perspective – regardless of whether the ethnographer is “from” that context.

Because of the “crisis of representation,” geographers began to use traditional ethnographic methods instead to “study up” in elite Western societies. For example, some ethnographers studied practices of the state in its administration, in its policing, or in creating museums. Rather than focusing exclusively on other or minority populations who had less ability to represent themselves, many ethnographers studied up to access the lived experience of the “dominant” culture of which these researchers were often a part.
Meanwhile, geographers have also contributed to changing ethnographic practices of representation to continue to work with those people once constituted as “subjects” of research. Based on the assumption of the partiality of all knowledge, critical researchers from the fields of feminist and indigenous geography began to develop more deeply collaborative methods (Benson and Nagar 2006), and publish ethnographic accounts co-authored with those heretofore subjects (Watson and Huntington 2008). In this and other ways, the practice of ethnography has evolved in relation to the spread of postmodern and critical ideology and the evolution of participatory methods of research.

The practice of collaborative ethnography emerged also in response to traditional limits of participant observation. Instead of being limited from studying large-scale events (like a global environmental conference), ethnographers can create a model of team-based research similar to that of their physical geography counterparts. For a team of ethnographers who carefully coordinate their observations not only provides more data for a project, but the team model also provides structured checks on the data.

The ethnographers’ objects of knowledge have thus changed in tandem with changes in geographers’ objects of knowledge. Anderson (2012) describes how recent ethnographic works by geographers do not have to treat categories such as culture or community as static. Both informed by and informing geographic theories of globalization, Anderson (2012) writes that ethnographers understand communities as made or remade through uneven “spatial-social processes,” and that process-centered approaches can better understand and represent the lived experiences of globalization. Thus, not just cultures, places, and small events, but processes have also become the objects of knowledge of the geographer using ethnography. For example, multisited ethnographic studies (studying events located in different places) allow researchers to study the processes of globalization and the literal movement of material life.

Like the study of globalization, the new technology of the Internet and emergent digital communities have similarly created a challenge to traditional ethnographies of place, with carefully circumscribed boundaries. But, as noted in recent nonrepresentational theory, it is not just a place, but how we are in a place that constitutes that place. Thus an ethnography of cycling up a mountain, for example, demonstrates how movements in a place create meanings of that place.

Ethnography has been an important methodology for geographers whose objects of knowledge have included emotional experience. Via the exercise of reflexivity, some of this emotional data can contribute to understanding the role of subjectivity in the creation of knowledge. But, in other cases, access to emotional worlds is relevant to policy purposes – such as an ethnographic study of the experience of transnational migrants, or other groups whose life experience is not directly informing policy, but whose lives are nevertheless the topic of policymaking.

Geographers have also explored the connections between ethnography and the arts to engage the emotional world, many projects being visual in nature but some textual – such as those marrying ethnography with creative fiction. Unlike realist ethnographies, ethnographic fiction engages humanistic and nonrepresentational geography to create narratives whose emotional content is communicable to nonacademic audiences. What is to be gained ultimately by accessing emotional worlds is an understanding of the human values that motivate human action – data that are often not obtainable via other methods. Ethnography remains an important method to access information for which people are less immediately conscious.
As another visual method of representing the world, GIS and other spatial technologies and analytical methods are increasingly a part of the ethnographer’s methodological toolbox (e.g., Matthews, Detwiler, and Burton 2005). A growing number of realist ethnographers are conducting participatory mapping projects or cataloguing spatial data from field notes to process in a GIS. These projects are happening both with indigenous peoples, over large areas of territory, and in urban areas at small spatial scales. Such projects set apart the contributions of geographer-ethnographers from ethnographers in other disciplines.

It has been four summers since I first set up my tent in the Chief’s front yard. We developed this work iteratively … One day I was shocked to hear the Chief call me a “modern Christopher Columbus.” Shocked, and at the same time pleased – because as a critical geographer, I never wanted to deny my roots as an explorer … So this inductive, exploratory approach allowed me to include the Chief steering this ethnographic research: not describing “Nulato” or “Koyukon” as objects of knowledge … To do critical ethnography means to sacrifice one’s ego – to be humble – and to make room for voices besides my own in the ethnographic narrative. The effort has variable “success” – whatever that means. Four years into this current project, I am feeling success without even having yet published one word on this work. (Memo 1 on the use of critical ethnography, November 11, 2014)

Both the continuities and changes – and the challenges – in the practices of ethnography are referenced in this memo. Ethnography is most utilized within geography in fields such as cultural ecology, development studies, feminist studies, and social, political, cultural, and nature–society geography. Yet ethnographic methods need to be better understood across the discipline of geography; fieldwork, being a large component of ethnographic data, is also constitutive of geography as a discipline. In this way the inductive practices of ethnography may be usefully studied by any geographer wanting to explore a terrain that is unfamiliar or to better inform the research question. While ethnography is not applicable to all research questions, perhaps in future ethnography in geography will be more formally recognized as used by geographers everyday.

Andrew G. Turk  
*Murdoch University, Australia*

**Ethnophysiography: definition and scope**

**Definition**

Ethnophysiography studies how people conceptualize the natural landscape, especially landforms and water bodies. David Mark and Andrew Turk coined the term in 2003 to refer to an ethnoscience of natural landscape features. Ethnophysiography relies heavily on ethnography as a method for obtaining information through language community participation in interviews and discussion. Ethnophysiography focuses on kinds of things in the landscape, such as hills, rivers, and vegetation assemblages and aims to document in detail the terms in a language that refer to the landscape and its parts. It also examines how landscape plays a role in oral history and culture and how people are cognitively and spiritually attached to landscape. By documenting landscape concepts, ethnophysiography also may provide foundations for culturally appropriate indigenous GISs.

The Ethnophysiography Hypothesis proposes that people from different places and cultures use different conceptual categories for features of the landscape, as reflected in the generic terms in their languages for features and in their toponyms.

The meaning of the term *landscape* is contested. Sometimes the term “geographic” is used for the domain of ethnophysiography. The term “ethnophysiography” was chosen to reflect a focus on the world of physical geography, and so far, ethnophysiography excludes the built environment and administrative units at landscape scale. However, it does include toponyms and cultural and spiritual associations with landscape (Turk, Mark, and Stea 2011).

**Motivations**

Is GIS culturally biased? In the 1960s and 1970s most GISs were automated versions of analog practices in cartography, transportation, urban planning, and related fields. By the late 1980s, however, the GIS research community began to seek more comprehensive theories of spatial relations and geographic data models. This new research drew on formal mathematics and on artificial intelligence models of spatial phenomena. Several publications in the late 1980s and early 1990s raised questions of universality and possible linguistic or cultural biases in GIS software (Frank and Mark 1991; Turk and Mackaness 1995). If people in different cultures or languages conceptualize geographic or landscape phenomena differently, then GIS software is likely to be biased toward the languages and cultures that produce it, namely an Anglo-Germanic European worldview. An ontological turn in geographic information science (GIScience) directed further attention toward these issues.

Is this a language issue? Do cross-cultural differences in landscape terms and their meanings indicate differences in *thinking* about landscape,
ETHNOPHYSIOGRAPHY

or do they only reflect language use at a surface level? The well-known yet controversial Sapir-Whorf hypothesis, or Sapir-Whorf conjecture, claims that people think and reason using language, and thus predicts that if terms divide up a domain differently, this may lead to different reasoning and decision-making. An extreme version of this hypothesis implies that it may be impossible to fully transmit meaning from speakers of one language to speakers of another. A more probabilistic version of Sapir-Whorf would predict that terms will not “line up” across languages in a one-to-one fashion, but their meaning can still be expressed in other languages by using longer compound expressions.

Language, culture, cognition, environment, and history all play a role in the terms and categories that are used to communicate the conceptualization of a domain. The deeper structure of a language may influence the nature of categories and their labels and may constrain the nature of terms for landscape entities.

Interestingly, it was a geographic information (GI) and society research thrust, rather than cognitive and linguistic research themes, that brought issues of language-specific concepts to the forefront. A workshop on GI and society held in Friday Harbor, Washington, in 1993 led to a special issue of a journal that included the seminal paper by Robert Rundstrom (1995), entitled “GIS, indigenous peoples, and epistemological diversity.” Land rights and land management are particularly important to indigenous peoples, so if GIS is used in land disputes or land management, it is crucial to assess whether cross-cultural differences in conceptualization of landscape lead to conceptual biases in GIS. So far, the authors know of no serious efforts to redesign GIS software to accommodate such differences, although some practical GIS have attempted to include cultural information through their ontology and/or via multimedia elements, for example, the work of Wellen and Sieber (2013) with the Wemindji Cree in Northern Quebec. Research results from ethnophysiography should enable further advances in culturally appropriate indigenous GIS.

Components of ethnophysiography

Ethnophysiography differs from fields such as ethnobiology in more than just subject matter. In ethnobiology, scientific categories often are used to form a baseline or etic grid for the study of emic (within culture) categories across languages. A critical issue for ethnophysiography is that natural inorganic domains are not organized by nature into kinds to the same degree as for biological entities. Thus scientific geomorphology and hydrology do not provide ethnophysiographic researchers with an adequate etic grid of categories in the same way that biology often does for ethnobiology. People may cut the continuous landscape into different spatial parts, and then classify the parts differently as well. This provides a methodological challenge for ethnophysiography due to the lack of an independently defined baseline of categories. It also explains why languages, cultures, and individuals appear to differ much more in their categorization of very similar landscape elements than they do for plant and animal categories. Thus ethnophysiography may extend ethnoscience by more than just adding another domain.

Landscape terms and their associated concepts form a key component of the ethnophysiography of a language or culture. Most ethnophysiography or landscape-in-language projects have restricted the domain of study to terms for “natural” landscape features, including landforms, water features, and vegetation assemblages.

One issue is whether the “primary” denotation of a particular term is a feature at landscape scale. For example, the Yindjibarndi people
of northwestern Australia have a term “yirra,” which is used at landscape scale to denote the sharp edge above a cliff, where there is a particular risk of falling. However, the same word is also used to refer to other sharp edges, including the edge of a tooth or of a knife blade. A similar pattern is observed in Yindjibarndi for several other terms whose primary meaning seems to designate shapes, but which also denote objects or features having that shape. Research could determine whether landscape is the primary denotation of such terms, but to understand how language subdivides landscape phenomena into types or kinds, it makes sense to include terms that are frequently used for landscape even if their primary denotation lies elsewhere.

Toponyms (place names) are linguistic or symbolic labels for particular places or landscape features (including linear features, such as trails, and groups of features). Toponyms are one of the important subclasses of proper nouns and form an important area of ethnophysiography research. As symbolic references for particular places, toponyms may be a human universal. However, linguistic systems for toponyms vary widely across languages and cultures. To some extent, toponyms are “encapsulated,” by which it is meant that the terms (vocabulary) and constructions used within individual toponyms may differ from how the same concepts are expressed in that language more generally. In many, but not all, languages toponyms for some classes of features contain a generic component that indicates the kind of feature being named (e.g., Richmond Hill). In English and many other Indo-European languages, names of populated places often lack such a generic term while most other feature types do include generics.

Traditional Environmental Knowledge (TEK) is a term that is often used to focus on the value of traditional knowledge that is not captured by “scientific” or first-world knowledge. For example, TEK applies to types of plants and their uses, as food or medicine. Traditional geographic knowledge, on the other hand, seems mostly to be knowledge about places, which are instances or particulars, such as knowledge of what is where, and of how to travel from one place to another. Because geographic knowledge emphasizes instances, applying the TEK approach to geographic phenomena may be difficult, however, it is critical to include such investigation in ethnophysiography. People’s dwelling relationships with landscape are triggered predominantly by their temporal patterns of regular activities concerning utilitarian and social needs within what social anthropologist Tim Ingold (1993) calls a “taskscape.”

Landscape ethnoecology provides an approach to generalized places as containers for useful types of plants or animals (Johnson and Hunn 2010). Landscape ethnoecology focuses on relatively homogenous patches of vegetation. The approach is similar to land use and land-cover mapping via remote sensing within conventional science, but is based on traditional (“ethno-”) concepts of habitat types or kinds of places. The patch approach allows knowledge of plants and animals to be “scaled up” to the landscape scale.

Ethnophysiography recognizes that the landscape conceptualizations of a speech community extend beyond physical aspects of land and encompass their cultural and spiritual dimensions: memories, beliefs, fears, and so forth. Such considerations may be most evident for indigenous peoples but apply everywhere. A landscape term may incorporate spiritual aspects; for example, a permanent pool (yinda) in Yindjibarndi always includes a spirit (warlu). Basso’s (1996) book is a seminal publication on this topic and work by philosophers of place, such as Jeff Malpas (2006) and Ed Casey (1996), are reviewed in Turk (2011).
ETHNOPHYSIOGRAPHY

Tuan (1974, 4) discussed environmental perception, attitudes, and values about place and coined the term “Topophilia” to refer to “the affective bond between people and place or setting.” Within ethnophysiology, people’s emotional relationships with landscape can be considered via “intentionality” (phenomenology) or through the recent turn to “affect” in geography, literature, social sciences, and cultural studies.

What is excluded from ethnophysiology?

The current notion of the domain of ethnophysiology concentrates on “natural” environments and on terms for entity types, toponyms, and beliefs about landscape in general. Thus it does not include terms or linguistic constructs for spatial relations or for directional terms, nor choices and priorities for spatial reference frames, which are scale-dependent in some cultures. Also excluded are terms for artifacts (constructed entities) at landscape scale, such as buildings, settlements, roads, dams, canals, bridges, and geopolitical regions and administrative units. Separation of “constructions” and “nature” is itself somewhat artificial and the methods of ethnophysiology could usefully be brought to bear on geographic-scale artifacts. Perhaps this will demand a new term for the field or a broadened definition of ethnophysiology.

History of ethnophysiology

Research topics and collaborations

David Mark and Andrew Turk initiated the field named “ethnophysiology” in 2002; David Stea joined the project the following year. Seeds for the ethnophysiology topic were sown in their earlier work (summarized in Turk and Stea 2014) and germinated when Turk and Mark participated in a workshop on geographical ontology held in France in 2000. In 2002 Mark began a sabbatical with a month at the Max Planck Institute for Psycholinguistics (MPI) in Nijmegen, where he interacted with researchers examining space in cross-cultural context. Then Mark joined Turk in Western Australia where fieldwork with Yindjibarndi speakers launched the project; a description of that first case study was published (Mark and Turk 2003) and that paper introduced the term “ethnophysiology.”

Collaboration by ethnophysiology researchers with MPI linguists in their preparation of a special issue of Language Sciences (Burenhult 2008a; Burenhult and Levinson 2008) led to an international transdisciplinary workshop (on the Navajo Reservation) on “Landscape in Language” in 2008 (Mark et al. 2011) and a European Science Foundation Exploratory Workshop in Spain in 2012. Burenhult established the Language, Cognition and Landscape: Understanding Cross-Cultural and Individual Variation in Geographical Ontology (LACOLA) research group in Lund (Sweden). Turk is assisting linguist Clair Hill with one (regarding the Manyjilyjarra language) of about eight LACOLA case studies of landscape in language in different parts of the world.

Highlights of some case studies in ethnophysiology

By now, at least thirty detailed ethnophysiology-related studies of landscape in language have been published. These include the nine articles in Burenhult (2008a), several chapters in Johnson and Hunn (2010), and 14 case studies reported in Mark et al. (2011). These studies provide very strong support for the ethnophysiology hypothesis stated above and indicate that factors motivating landscape
ETHNOGRAPHY

categorization are perceptual salience, human affordance and use, and culture and social organization. Brief summaries of several of the case studies follow.

The first ethnophysiography case study was of Yindjibarndi, a Pama–Nyungan language (Turk, Mark, and Stea 2011, 26–31). Yindjibarndi country in northwestern Australia includes tablelands, broad valleys, ranges, rolling hills, extensive flats, and some cliffs and rock outcrops. The climate is hot and dry. There are no permanent rivers or creeks, with water only running after major rainfall events (cyclones), however, there are some permanent pools, springs, and soaks. The vegetation is grass, spinifex, low scrub, and scattered trees. Yindjibarndi people traditionally lived a seminomadic hunter-gatherer lifestyle, but have been progressively displaced by European colonization. Most Yindjibarndi people now live outside their traditional territory but retain strong cultural links to their land, visiting for hunting, gathering, and ceremonies. Many Yindjibarndi terms subdivide and classify landscape features differently than English. For example, the term marnda covers a range of features that in English would be called mountain, hill, ridge, rock, and so forth; related terms (bargu, burbaa) do not simply equate to hill or rise. Some Yindjibarndi terms effectively refer to shape rather than topographic objects, for example, burbaa, and may also refer to non-geographic entities of that shape. Compound phrases are used to denote kinds of marnda, some of which would be denoted by single words in English, for example, marnda marlirri for mesa. Yindjibarndi hydrologic terms refer separately to water, lying in pools, flowing, or flooding (bawa, yijirdi, mankurdu) and longitudinal depressions, small and large (gaga, wundu), along which water sometimes flows, and thus contrast with English and other European languages where terms such as “river” and “creek” incorporate both water and channel. Similarly, thardarr is a place where water sometimes falls down a cliff; if water is present it is referred to by the flow magnitude words above, so there is no Yindjibarndi term for a waterfall per se.

Turk, Mark, and Stea (2011, 31–36) conducted a study with Navajo, a Native American language in Arizona, New Mexico, and Utah in the United States. Navajo (or Diné Bizaad) is an Athabaskan language, having many verbs, few nouns, and no word-class corresponding to adjectives in English. Until recently, the Navajo people led a hunter-gatherer lifestyle, but then adopted corn growing and sheep rearing. Their land is semi-arid with a few permanent rivers and streams crossing or bounding Navajo country, but most watercourses are usually dry. Physiography is basin-and-range with flat-lying rocks and volcanic necks forming buttes, mesas, and plateaus. Some Navajo landscape terms encode the material of which the feature is composed, for example, bikooh is the term for a canyon or gully through soil and tsékooh for similar features cut into rock. Navajo toponyms often are descriptive, sometimes making it difficult to distinguish toponyms from mere landscape descriptions.

O’Meara and Bohnemeyer (2008) reported on landscape terms in Seri, a language isolate spoken in the Sonora region on the Pacific Coast of Mexico. Seri territory includes an arid coastal plain, some large islands, and the sea. The Seri were traditionally seminomadic hunter-gatherers and their primary food resource was the green sea turtle, but some terrestrial animals, such as deer, and also wild plants were eaten. Seri classify landscape in terms of material consistency and spatial properties such as shape, orientation, and mereological relations. Complex landscape terms are the rule rather than the exception and are based on one of four Earth substance terms:
ETHNOGRAPHY

hast (stone), hax (fresh water), xepe (seawater), and hant (ground, land), in combination with a definite article with posture semantics, a nominalized form of an intransitive verb, an adjective, or a relational noun.

Levinson (2008) discussed landscape terms in Yéli Dnye, from Rossel Island in Papua New Guinea. The island is mountainous with tropical rainforest, beaches, barrier reef, lagoon, rocks, and so forth. Speakers’ lifestyle includes gathering nuts and game, growing taro and coconuts (via swidden cultivation), and fishing. Terms are for seascape as well as landscape. To the Yéli Dnye, a watercourse consists of three segments: an upstream part in the mountains, a middle segment on lower land, and a third part being the stream of river water across the sea lagoon to a reef opening. The two upstream portions, taken together, would be termed a “river” in English. Parts of the lagoon have terms but not the whole. Toponomy seems to follow terms for landscape features (rather than being a complementary system) and toponyms form a syntactically distinct word (or phrase) class.

Burenhult (2008b) reported on language and landscape for the Jahai people from Peninsula Malaysia and adjacent parts of Thailand. Jahai belongs to the northern Aslian branch of the Mon-Khmer language family. Speakers are hunter-gatherers (and occasional swidden cultivators). The landscape is dominated by mountains drained by swift-flowing streams in steep-sided valleys. Rainforest covers foothills and lower mountains with occasional bare rock outcrops, some of mythological significance. Metaphor from animate domains, mainly human, is used in landscape terms; body parts (creating partonomy) and kinship terms (creating size taxonomy) are used to refer to streams and valleys. Toponyms seem exclusively linked to notions of drainage with permanence of water being crucial.

Enfield (2008) summarized research on landscape terms in Lao, a Southwestern Tai language. The landscape is flat, well-watered land with mountains (adjacent and distant). Vegetation is thick and tropical, and low land is cultivated. There is a general term for water – and rivers can be just referred to by that term – or if large by another term meaning “water mother.” Lao has a basic word phuu2 often translated as “mountain,” but is more accurately glossed as “mountain terrain.” Thus, phuu2 muaj1 nii4 (mountainous_terrain clf_unit this) means “this unit of mountainous terrain.” (The numbers denote tones, and “clf” indicates a “classifier.”) There is no Lao word for valley.

Holton (2011) compared landscape terms from two unrelated North American indigenous language groups, Athabaskan and Eskimo, living in adjacent areas of western Alaska, a landscape of large rivers, taiga woodlands, and broad valleys. This study demonstrates clearly that Tanacross Athabaskan and Central Yup’ik Eskimo speakers conceptualize landscape in different ways, such as different systems for categorizing elevated features. Living near the coast, Eskimo marine and coastal terminology is naturally much more elaborate than that of the inland Athabaskan. Conversely, hydrological terminology is more developed in Athabaskan with differences reflected in toponymy.

These case studies, and more than twenty others, clearly demonstrate the variability between language/cultural groups in the way that continuous landscape is broken into features and the sorts of cultural and spiritual associations with place. Concepts of landscape features may be expressed in generic nonlandscape terms, such as those for shapes. Also, nonspatial metaphors may be utilized to organize and represent aspects of landscape. There are also considerable differences in ways of forming and using place names.

Based on the published landscape-in-language case studies, Turk defined the ethnophysiography
ETHNOPHYSIOGRAPHY
descriptive model (Turk, Mark, and Stea 2011).
It lists key differences in the way landscape is
treated in different languages and cultures and
possible factors that might lead to these differ-
ences, although not suggesting that deterministic
causation is necessarily involved.

Methods

Ethnographic methods

Ethnophysiography case-study methods (Turk,
Mark, O’Meara and Stea 2012) vary according
to the physical and social environment, for
example, remoteness, vehicle access, vegeta-
tion, weather, availability of consultants, and
organizations to assist (especially representing
indigenous consultants). However, case-study
research in ethnophysiography usually includes
the following stages:

1 dictionary work and representative photo
collection;
2 field interviews with consultants;
3 photo interpretation sessions;
4 semi-structured follow-up to clarify confu-
sions, and so forth; and
5 reporting initial results back to community
members and getting feedback.

Case-study circumstances and pragmatic con-
siderations may mean particular techniques may
be used in a different order and/or iteratively.
All ethnographic procedures should be used
in a “reflective” manner with the fieldworkers
continually questioning the validity of their
results and ensuring ethical practice.

Other specific techniques that can be used
include:

• questionnaire for eliciting landscape terms
  and toponyms;

• consultants narrating a video (or animation)
  presentation featuring a person (or animal)
  moving through the landscape; and

• “director/matcher” technique – two speak-
ers are separated by a visual barrier, with one
describing a landscape image well enough for
the other to choose the correct image from a
duplicate set.

Some of the most valuable results have been
obtained by showing landscape photographs to
speakers. One can ask the participants simply to
report what they first notice in the photographs.
Of course, the result will depend on the partic-
ular photographs shown. Alternatively, partici-
pants can be asked to arrange photographs into
groups and perhaps describe each group verbally.

Surveys, questionnaires, and experiments

For some languages and cultures, information
about landscape categories and other concep-
tualizations can be obtained from surveys and
experiments. Surveys can provide valuable infor-
mation for larger groups especially in literate
majority cultures. Of course, for indigenous
populations, elders, and other marginalized
groups such experiments or surveys might not
be appropriate and ethnographic methods may
be preferred.

A valuable early survey approach can be to ask
participants to list terms of types of landscape
features. The exact wording of the question may
have significant influence on the results. The
superordinate category might be “landscape” or
“geographic” or perhaps “environment.” The
noun might be “object,” “feature,” or similar
words. Questionnaires and surveys can be used
to ask for typical terms of various superordinate
categories or to elicit definitions or distinctions
between neighboring categories. These different
types of data might be collected in writing or by
ETHNOPHYSIOGRAPHY

audio recording. If a large number of speakers can be surveyed, statistical methods of analysis can be used to determine, for instance, the frequency of subjects listing each term.

Ethical issues

When working with indigenous groups, language preservation often is a key consideration, however, there is also some element of “appropriation,” of “taking away” from the culture, so asking permission and involving communities in ethnophysioigraphy studies is required. It is also essential to understand the worldview of a specific indigenous group before attempting to interpret linguistic data.

The rights of collaborators and language communities must be respected by:

• ensuring permission is obtained for all fieldwork;
• making appropriate payments to collaborators;
• using both male and female researchers to handle gender-sensitive issues;
• not eliciting, recording, storing, or publishing secret/sacred information; and
• acknowledging collaborator contributions in publications.

Threats to validity

When designing or evaluating ethnophysioigraphy case studies one must consider threats to validity arising from methods of data collection and/or interpretation (Turk et al. 2012), which include but are not limited to:

• terms may relate to fairly equivalent concepts between languages, but landscape feature examples fitting the concepts may differ;
• the physical extent of a feature covered by a term may vary;
• different whole-part concepts may apply, for example, river water/channel;
• terms may refer primarily to shape rather than landscape features as entities;
• the physical point of view may influence feature conceptualization;
• terms may refer to spatial areas (places) rather than features (objects);
• participants responding to landscape photographs may misinterpret the scale, focus of attention, or content of the photographs;
• cultural and spiritual aspects of place may be misinterpreted, or not discussed;
• rare or exceptional features may be referred to only by proper names and not by generic terms; and
• generic parts of toponyms and landscape terms may have different meanings in more general contexts.

Such threats to validity of interpretation of landscape terms can be reduced through: use of multiple methods (“triangulation”) and iterative procedures; using a diverse range of collaborators; not “leading the witness”; being open to alternative interpretations; and becoming as intimate as possible with lifestyle and social structures of the language community.

Implications for geographic information systems and science

GIS software

As noted above, GIS may be biased toward the culture and society that produced the software systems. Languages of spatial relations show differences in the verbal expression of relative locations and spatial relations, but the relations as expressed in language seem largely to be based on common underlying topological and geometric principles. Ethnophysioigraphy research
has assisted in understanding this problem and providing solutions, potentially via contingent feature classification, leading to culturally specific GIS.

Bias in spatial data infrastructures?

Results from ethnophysiography clearly demonstrate that terms for categories of geographic entities do not “line up.” Spatial data infrastructures (SDIs) are usually produced by national mapping agencies or large corporations and are largely based on standard sets of entity types (feature codes). It is not surprising that the categories recognized by SDI developers are usually based on the primary languages of the countries or companies producing the databases. Mark and Turk (2003) showed that Australian government landscape categories for hydrographic features (from AUSLIG) had limitations for GIS for indigenous land management in Western Australia due to the mismatch of categories. Ethnophysiography results from other languages suggest that similar limitations will be the rule rather than the exception.

Information retrieval and natural language

Much of information retrieval in current search engines such as Google is based on text, words, and languages. If the meanings of terms from language to language do not “line up” or have a word-for-word translation then there will be impediments to users from one natural language trying to retrieve information on the web that is described in another natural language. This issue is broader than ethnophysiography, but there are probably unique issues of category correspondence for the landscape domain. The Semantic Web is intended to overcome such interoperability issues but may have just the same difficulties.

Implications for geography

Geography as a discipline has struggled for centuries with the relative importance of the “geography of the particular” (instances) and the “geography of the general.” In 1650, through *Geographia generalis*, Bernhardus Varenius launched a scientific geography. Findings from ethnophysiography remind geographers and those from related disciplines that attention must be paid to the particular and that cultural differences and some aspects of “general geography” are not universal. Ethnophysiography exposes a more subtle point – what is general within one culture may not be general within another. This recognition reminds the discipline of the importance of a cross-cultural and cross-linguistic perspective and raises some skepticism about truly general findings and human universals for the landscape domain.

Summary and conclusions

Ethnophysiography is an emerging field that can make important contributions to geography and to geographic information science as well as to linguistics, anthropology, cognitive science, philosophy, and other fields. The topic occupies a promising overlap between three main areas of contemporary geography: human geography, Earth systems science, and geographic information science. Ethnophysiography is positioned to provide answers to some of the questions of bias raised by critical social theorists. Results can form the basis of culturally specific information systems that would allow indigenous groups and others to address geographic problems from within the conceptualizations of their own cultures.

Given all this, it is somewhat surprising that cultural differences in geographic concepts have
ETHNOPHYSIOGRAPHY

received little attention until recently. Cultural studies were an important part of geography before the so-called Quantitative Revolution. Critical scholars reacted against the quantitative approach but did not restore cultural studies to their former prominence within the discipline. Ethnophysiography is a step in that direction.

Everyday life is all around us. We engage with it and construct it every day of our lives. We inhabit everyday spaces and do everyday things—repetitively, routinely, continually, rhythmically. Everyday life has been defined and described as banal, the taken-for-granted stuff of life, the “leftover” or remaineder, the unnoticed, the unremarkable spatial-temporal practices of ordinary people taking place in everyday spaces. At the same time, everyday life is fascinatingly rich and varied; it can be punctuated by the extraordinary. Aspects of everyday life can be rendered remarkable and exceptional by some kind of change in our social environments: a freaky day of weather; a dramatic frightening event; a chance meeting with a good friend; an accident; news of a baby’s birth; being fired; a first kiss. These events or instances make the day, time, and place memorable for either negative or positive reasons. They can be interruptions that are triggered by global processes (climate change, economic collapse, war) or intimate, localized processes (a car accident in the neighborhood, a stranger’s kindness). Hence everyday life is a conundrum, at once humdrum but also with the potential for drama. As Ben Highmore states, “the everyday offers itself up as a problem, a contradiction, a paradox: both ordinary or extraordinary, self-evident and opaque, known and unknown, obvious and enigmatic” (2002, 16).

Everyday life, described as the “landscape closest to us, the world most immediately met” (Highmore 2002, 1), is made up of repeated actions, recurrent journeys, and inhabited spaces that constitute the day-to-day stuff of living and being. The notion of “everydayness” is interpreted often as ordinariness, boredom, monotony, tediousness, involving dull routines, and lacking excitement. Such social ennui around the everyday is frequently exploited for commercial ends through the advertising of products that offer excitement, newness, and difference. However, even without the advertiser’s hype, a key feature of everyday life that philosophers and geographers alike emphasize is that the exceptional can be found within the everyday and that everydayness has the potential for the spectacular. We even articulate this in the uttered expression when something unusual, bizarre, or shocking is witnessed: “Now there’s something you don’t see every day.” This surprise element is considered to have a political and critical potential for social change. Feminists, in particular, have focused on the everyday (particularly the domestic everyday) and captured this in the pithy slogan “The personal is political” to demonstrate the potential of, and possibility for, the everyday to generate new political forms.

Everyday life as an entity has been with us as long as there has been human life; yet, as a concept, it did not appear as an analytical construct until the 1920s but it became increasingly significant post-World War II. Key Western philosophers who have developed analytical approaches to the everyday include Georg Lukács and Georg Simmel, both of whom have been particularly important in sociology and cultural studies, although less so in geography. Henri Lefebvre’s and Michel de Certeau’s theorizations have been more significant in geographical work.
EVERYDAY GEOGRAPHIES

on the everyday because they developed more critical insights of the everyday as problematic, bringing “the everyday into awkward focus” (Highmore 2002, viii), and for their analyses of the spaces and places of everyday life.

Lefebvre made the critique of the everyday a lifelong project, publishing three volumes on Critique of Everyday Life in 1947, 1962, and 1981, only the first of which has been translated into English (1991/1947). He was influenced by Marxism and surrealism, and driven by a desire to challenge the modernization processes at play in France and its colonies. Through observations of social formation, Lefebvre developed an analysis of the everyday that contained a critique of the US-driven processes of modernity and the continued colonial projects of the French state which were rapidly changing postwar life and creating states of alienation for ordinary people. For him everyday life was being produced according to the rhythm of capital, which penetrated every detail of everyday life. He identified urban space as a site of the intensification of everyday life but believed that everyday life held the possibility of its own transformation through processes of dealienation. For Lefebvre such processes would push toward the achievement of a politics rooted in the modification of the everyday. Lefebvre thus identified the everyday as a site of resistance, revolution, and transformation. As he worked with the concept of everyday life, Lefebvre also developed a critique of modernity and its negative impact on social differences alongside an analysis of the spatial forms that modernity creates. Despite his valuable insights, he openly acknowledged that his critique constantly lagged behind the persistent dynamism of the reality of everyday life.

Michel de Certeau’s key work, The Practice of Everyday Life (1984/1980), is located in a different intellectual and social climate. De Certeau was interested in the imaginative and inventive practices of everyday life while recognizing that these cultures were submerged below a level of textual and social authority. He argued that, while everyday practices and cultures remained invisible and unrepresentable, they performed resistive practices against these authorities. De Certeau was particularly interested in the metaphor and materiality of journeying and its notion of becoming rather than being, one of the ways in which he understood and analyzed everyday life. He wanted to capture the ways in which people operated and practiced everyday life, and recognized that, while people make do with ready-made culture (akin to Lefebvre’s culture of modernity) they also made with such a culture and demonstrated inventiveness and ingenuity. De Certeau wrote of this as a creative arrangement and rearrangement and so focused on the “creativity of appropriation, a poetics of experiences and a style of everyday life” (Highmore 2002, 148). It has been recognized that de Certeau’s is the most wholehearted attempt to develop an approach to the everyday from the material provided by the everyday itself. Critics have argued that his arguments roam and are unsystematic; however, that is the patterning of everyday life he worked to capture and present as a kind of poetics. For him it was essential to make the everyday visible, to be seen as more than remaineddered, because only after the everyday is allowed to surface can a politics of the everyday become possible.

Despite the framing insights and conceptual toolkits provided by these social theorists, contemporary scholars in the social sciences and humanities continue to grapple with definitions of everyday life. Geographers have found it a tricky concept to define – slippery and dynamic at the same time as it is routinized and predictable – but have nevertheless worked with the everyday for decades (particularly within a spatial-temporal context) with different
EVERYDAY GEOGRAPHIES

philosophical framings and methodological techniques that have proven valuable in the study of “geographies of everyday life” (Jarvis 2010). In an essay on the geography of everyday life, John Eyles (1989) provided an early argument as to why geographers should examine the everyday. He proposed that understanding and being aware of the commonplace were important for the development of a geography that was human-centered. It was seen as an essential way to explore the relationships between people and their environments at a time of rapid change (in his case time–space compression, but we might now name globalization, neoliberalism, terrorism and conflict, or climate change). Feminist geographers have made important contributions to furthering and stretching analysis of the everyday through researching women’s lives and articulating place- and space-based knowledge production. A key political aspect of feminist geographical work about the everyday is the goal of keeping women visible despite the processes of rapid global change, which tend to hide their social, economic, and political contributions. Holloway and Hubbard (2001) have drawn together a comprehensive analysis of what they call “the extraordinary geographies of everyday life” in order to examine the fundamental elements of human geography, people, and place. Most recently, Horton and Krafṭl (2014) have dedicated a whole chapter to “Everyday Geographies” in their Cultural Geographies: An Introduction. In a section working through the complexities of how to define the everyday, they conclude: “so whereas ‘everyday life’ refers to life as it is lived and experienced, ‘the everyday’ might be understood as the form that life takes after it is captured and transformed by a system of representation” (Horton and Krafṭl 2014, 183).

What is certain about the complexities and unpredictability of everyday life is that they will always be with us and, as human geographers, we will continue to try and understand and analyze it.

Evolutionary economic geography

Eike W. Schamp
Goethe University Frankfurt am Main, Germany

Evolutionary economic geography has emerged fairly recently as an alternative approach to explaining change in spatial and regional structures through endogenous technological innovation. Thinking about economic dynamics “from within” gave rise to a renewed debate in heterodox economics concerned with understanding the emergence of novelties that compete with each other and with incumbent structures as the main drivers of change. Charles Darwin’s theory of the evolution of species has been acknowledged as a generic concept here. There is considerable disagreement, however, on how far the analogy should go for socio-economic processes, particularly as Darwin’s “broad” concept has stimulated further refinements both in biology and in the social sciences. Much imprecision still prevails in economics about what “evolution” means. It is fair to say that the same applies to the current debate in evolutionary economic geography.

Evolutionary thinking has been discussed by economists since the end of the nineteenth century, for instance by Thorstein Veblen and Joseph Schumpeter. The debate gained momentum with Richard R. Nelson and Sidney G. Winter’s seminal book *An Evolutionary Theory of Economic Change* (1982). Evolutionary thinking in economic geography started in the late 1990s and achieved much attention when Ron Boschma and Koen Frenken (2006) picked up a question similar to the one asked by Thorstein Veblen 100 years earlier in economics: “Why is economic geography not an evolutionary science?” Currently, the perspective is predominantly oriented to evolution in economic geography as a competing or complementary conceptual approach to the study of regional change. A considerable proportion of scholarly debate in economic geography still draws its basic ideas from Nelson and Winter’s book. However, Richard Nelson considered evolutionary economics to be at an embryonic stage of development in the mid-1990s. Although very lively in recent years, evolutionary economic geography has not yet passed beyond that initial stage.

Some basic dimensions of evolutionary theory

Two questions arise when transferring a theory from the natural to the social sciences. First, how are the focal concepts translated and interpreted in accordance with the understanding of deliberate human agency in social sciences? Second, in what sense is the theory of evolution different from “competing” approaches relating to similar empirical problems in social sciences in general and in economic geography in particular? These questions will be answered briefly before turning to specific aspects of evolutionary economic geography.

The principal analogy draws on the question of how a new population of species emerges from the variation and replication of its “genes,” how a given population copes with environmental change by adaptation, and how it survives under
EVOLUTIONARY ECONOMIC GEOGRAPHY

selection pressures from environmental change. While variation and retention refer to genes, their carriers are the species of a given population, so-called phenotypes, interacting with and being selected by the environment. More recently, phenotypes have been termed “interactors,” whose capacity to adapt and survive in changing environments depends on the variation and replication of genes, hence the term “replicators.” This basic reasoning offers fascinating perspectives on the explanation of change and restructuring in economies if one translates the interactor into “organization or firm,” the replicator into “routines and technologies,” and the population into “sectors or industries.” This was the seminal step taken by Nelson and Winter (1982) in their book. Since then, however, a continuing debate has run as to whether the use of Darwin’s theory and terminology in economic and economic geography thinking involves analogies, metaphors, or mere “lip service.” Thus there is no clear-cut theoretical base for evolutionary economic geography but much diversity in the approach.

According to Witt (2008), at least three different interpretations can be identified in evolutionary economics, two of them relevant to economic geography. First, the most popular seems to be to use Darwin’s theory in a metaphorical way as a heuristic device in empirical research. This applies to the neo-Schumpeterian approach to evolution in economics, with Nelson and Winter’s (1982) book as its main proponent. Herein, entrepreneurial innovative activities at the firm level create variety in new technologies which, if successful (surviving), drive economic change. Many geographers of what could be called the Utrecht school of evolutionary economic geography around Ron Boschma and Koen Frenken followed this interpretation. Second, the naturalistic Darwinian view has been more or less rejected in economics. Third, universal or generalized Darwinism has been suggested as an abstract generic base for any empirical evolutionary research in the social sciences. In economic geography, Jürgen Essletzbichler and David Rigby (2007) have repeatedly discussed generalized Darwinism as a principal approach to evolution.

There is, nevertheless, some common understanding of basic dimensions in evolutionary thinking in economic geography. First, the trinity of variation, selection, and retention of technologies and organizations forms the starting point of dynamics in economic evolution. Second, the basic mechanisms of these dynamics are creativity and competition in particular environments. In the Schumpeterian sense of creative destruction, competition on innovation is the main driver of the emergence and creation of new “routines” within and among firms, where new routines, including the use of new technologies, enfold new organizational forms of both firms and sectors that have to persist on markets. Evolution then is the outcome of selection processes where the capability to persist depends on the diversity of innovations generated by the purposive agency of firms and the capability of actors to alter the rules that decide what is selected. This interpretation can obviously and easily be related to other theoretical strands in heterodox economics, in particular to neo-Schumpeterian innovation theory, Penrosian theory of the resource-based firm, and Simon’s concept of bounded and procedural rationality. In a wider sense, each consideration of knowledge creation and learning as purposeful action in trial and error that starts from heterogeneity of resources and finalizes in heterogeneity of results can be incorporated into evolutionary economic geography thinking. Altogether, the continuing mutation of routines and technologies through creation (and finally innovation) and imitation explains the extant
heterogeneity and variety of products, processes, and their firms.

Third, changes in a firm’s environment may stimulate novelties and contribute to their selection, that is, co-determine the survival chance of some competing routines and technologies and firms. While markets fundamentally form the firm’s selection environment in economic thinking, both upstream and downstream, geographers highlight place and region as important parts of the selecting environment. However, this brings several problems to the fore because markets as well as place and region are constructed (sometimes not deliberately) through the purposeful actions of competing firms, state regulators, and civil society and often do not exist in advance but may coevolve simultaneously with new technologies and sectors. As will be discussed later, this opens the debate to the concept of coevolution and to the need for incorporating institutional and political economic approaches into evolutionary economic geography.

Fourth, the emergence of new technologies, new firms, and new sectors is considered to take “historical” time. Current processes are irreversible, therefore, and embedded in or dependent on past processes. The perspective is of years if not decades in the practice of empirical research in evolutionary economic geography. Although historical events and contexts are unique, from this perspective, evolutionary thinking in economic geography looks for generic mechanisms that steer spatial and regional evolution.

Fifth, the evolutionary economic approach suggests building a bridge between the micro-foundations of variety creation, selection, and retention at the level of the individual or organization and the macro-perspective on (regional and national) economic change. While it is acknowledged that agency at the micro level (individuals, firms) is the main driver, evolutionary thinking wishes to use a meso analytic lens when explaining macro processes of economic change. This meso-level perspective refers to the emergence and survival of “populations” in their (changing) environment, be it organizational or technological routines, firms and sectors, or complex organizational forms such as clusters or regions.

Taking all these dimensions together, the second question about competing approaches can be answered quite quickly. Evolutionary thinking refuses the fundamental assumptions of neoclassical economic theory, such as the presumed rationality of human agents, the timeless and abstract market model as selection environment, and the search for a state of economic equilibrium, which for a long time formed the basis for spatial analysis and many regional growth theories in economic geography. Nor is evolutionary economic thinking similar to idiosyncratic thinking in economic history or older landscape approaches in geography. Evolutionary economic geography focuses on exploring generic spatial principles in the emergence of novelties and the dynamics of economic life.

Evolution in regions, an exercise in population thinking

Broadly speaking, evolutionary economic geography suggests different interpretations of Darwin’s theory and tackles a variety of problems with a variety of methods in practice. On various occasions, Jürgen Essletzbichler has convincingly differentiated between evolution (of technologies, firms, and sectors) in regions and evolution of regions. The first relates to evolving populations of technologies and firms in their respective local or regional environment, a perspective that is predominantly chosen in
the neo-Schumpeterian approach to evolution and realized in the majority of empirical studies in evolutionary economic geography (Boschma and Frenken 2011). These studies focused almost exclusively on the evolution of firms and sectors in a spatial and regional context. The evolution of regions has been much less approached empirically, and is considered a more complex problem that may call for the systemic perspective of generalized Darwinism (Essletzbichler and Rigby 2007).

Often implicitly, both the neo-Schumpeterian and the generalized Darwinist approach take up earlier concepts for analysis of the dynamics of economic evolution, in particular Gunnar Myrdal’s cumulative causation and Raymond Vernon’s product life cycle model. The development of novelties, firms, and sectors is said to pass through several life cycle stages in a seemingly well-defined order, that is, from birth or creation to growth, then maturation and, if there are no opportunities for life extension, decline. The same applies to higher-order arrangements of industries, basically to clusters which generally emerge around a focal industry, and networks (Glückler 2007). With reference to the basic geographical perspective on spatial unevenness and its reproduction in the world, the crucial questions concern, first, in what sense location has a diversifying impact on the emergence of novelties and, second, how far the evolution of novelties results in spatially uneven geographies. Hence the focus is on the interplay between the evolving population and its geographically defined environment.

Being less interested in the diffusion of novelties to extant firms by imitation and adaptation, the emergence of firm populations in an uneven spatial environment and the subsequent uneven spatial development of the population are at the heart of empirical research in evolutionary economic geography. Interestingly, empirical research has mainly focused on the spatial evolution of manufacturing industries either in “old” sectors such as the automobile and dairy industries taking a long-term perspective or in the recent formation of “high-tech” sectors such as laser, optoelectronics, video game, and software industries. Early studies of the evolution of industrial sectors such as the automobile industry have clearly revealed spatial unevenness in the formation stage of the sector, in the likelihood of firm entry and survival, and changing geographies of the sector during its life cycle. As the emergent spatial pattern in these industries is mostly in clusters, economic geographers have also turned to understand clustering as an evolutionary process (Boschma and Frenken 2011). The transfer mechanisms of new routines from an incubator firm to others mainly highlight the role of local spin-offs and labor mobility in evolutionary cluster models.

Over time, more detailed concepts have been introduced in order to explain the uneven geography of the evolution of firms and sectors and the role that local externalities play therein. Michael Storper and Richard Walker (1989) introduced the concept of a window of locational opportunity that was favorable to the emergence of novelties. Favorable environments seemed to be characterized by the lack of obstructive regional institutions – often caused by incumbent sectors in old industrialized regions – and the diversity of urban agglomeration externalities of the so-called Jacobs type. While this may be the case for disruptive technologies and sectors, in the Schumpeterian sense, recent research in economic geography has turned to more incremental technical change in looking for the roots of new technologies, with the concept of technological relatedness among firms and sectors (Boschma and Frenken 2009). In line with the literature on proximities in learning and knowledge development, it is claimed that the
evolution of new technologies and firms at a specific location is often related to previously accumulated knowledge there. As a result, the likelihood of the creation and survival of firms in a new sector may depend on local relatedness. It is a matter of empirical research, however, to depict that part of existing knowledge in incumbent sectors which generates opportunities for further knowledge creation and the formation of new firms and sectors. There certainly is a research frontier for the moment. Geographers have recently termed the local formation process of new industries that are technologically related to older ones “regional branching.” Branching may occur as a process of outsourcing new technologies from an old industrial sector or as a process of recombining competences from different sectors at a location in new firms. Current empirical research in evolutionary economic geography uses indirect measures of knowledge flows between industries that are assumed to be technologically related, such as patent use, proximity in industrial classification, and co-location. It seems evident that branching at certain locations may happen while it is at the same time truncated at other locations. Less is known in detail about knowledge communication resulting in the emergence of a new sector in situations in which the knowledge-base of different firms is related but nevertheless different. The crucial question then is when and how does heterogeneity among firms in variety creation lead to a new sector, hence heterogeneity between sectors. Another issue concerns the context in which bifurcation of sectors (or the emergence of a new variety of sectors) occurs. As the formation of new sectors is seen as both place dependent and place forming, further research is needed to understand the mechanisms of “lock-in” of the emergent firms and sectors and their local conditions.

EDITIONARY ECONOMIC GEOGRAPHY

The role of institutions in evolutionary economic geography

Since the beginnings of evolutionary thinking in economics and economic geography, there has been a controversy about the meaning of institutions for economic evolution. In the neo-Schumpeterian perspective, institutional change can be seen as another explanatory approach to economic change, separate from and supplementary to evolution. This is how Ron Boschma and Koen Frenken (2006) pointed to ontological differences and looked for “interfaces” between the institutional and evolutionary perspectives. These authors understand the (spatial) evolution of routines and firms as an outcome of industrial dynamics, and claim that territorial institutions do not sufficiently explain the evolution of both. However, they acknowledge a higher significance of sectoral institutions as part of sectoral and technological systems of innovation approaches. In contrast, critics claim that evolution of technologies, firms, and sectors cannot be fully explained by the economic assumptions underlying industrial dynamics alone but that agency embedded in institutions and local institutional settings as a selecting environment must also be considered. There is, however, also much controversy about the precise meaning of the term “institution.” Discussants generally apply an “old” understanding of institutions, as promulgated by Douglass C. North as the “rules of the game,” although concepts of new institutional economics such as transaction costs can also be used to explain evolutionary processes such as branching.

In fact, many concepts dealing with the evolution of firms and sectors in the neo-Schumpeterian interpretation of evolutionary thinking at least implicitly refer to the presence or absence of institutions related to technology. This is the case with places where windows of
locational opportunity open up when hampering institutions of old industries are absent or weak, or places favorable to the emergence of new firms such as urban agglomerations and certain clusters where institutions are present in knowledge communication between diverse (Jacobs externalities) and related technologies and sectors, enabling local relatedness of industries and branching.

The emergence of or changes in institutions can also be seen as an indispensable part in the explanation of evolution when adopting perspectives on the coevolution of two populations in mutual symbiosis, that is, an industry and related institutions. Here, a bidirectional causality through various self-reinforcing feedbacks brings about simultaneous growth in the evolution of two (or more) populations, for instance the co-emergence of an industrial sector and its related institutions of knowledge creation (as in the case of the rise of technical universities and interpersonal relationships between firms and universities in nineteenth-century Germany). Coevolution has become an important notion and issue in evolutionary research. But again there is often fuzzy use of the concept, despite the quest for a clear definition of bidirectional causality in empirical research.

The development of evolutionary paths

Mutations of routines, technologies, firms, and sectors – and regions – are assumed to happen continuously in the capitalist world of competition through innovation, steadily producing heterogeneity. For a long time, social scientists focused on trajectories or development paths of these units in order to explain the dynamics of uneven spatial development, widely adopting the concept of path dependence and lock-in in a life cycle model. From the evolutionary perspective, selection and retention of the selected variety are necessary for an evolutionary path to emerge, not least because this limits the kind and number of competing varieties that emerge. A path can be considered dependent when past occurrences and given specific social mechanisms condition future choices and the direction of future change, a process called “positive” lock-in of a specific technological, sectoral, and regional trajectory. Interestingly, economic geographers have based the concept of lock-in on arguments both from heterodox economics, such as increasing returns to scale, sunk costs, agglomeration, and network externalities, and from social sciences, such as institutions or other untraded interdependencies (Michael Storper). Path creation in technologies, firms, and sectors – in competition with incumbent structures and nearby alternative novelties – has largely been considered a local process, partly due to an enhancement by powerful actors such as policy agents, risk-taking entrepreneurs, customers, and institutions or certain regulations. Evolutionary economic geography claims that proximities and institutions in some places work in favor of the creation of specific sectors. As mentioned before, some evolutionary geographers have introduced concepts such as technological relatedness and regional branching based thereon.

Once a path has been locked in, questions arise as to how and how far retention of this path really is fixed. Time and again caveats have been expressed related to path dependence being overdetermined, and to possible degrees of freedom in path creation, path bifurcation, and path contingencies. More open concepts of development such as path diversity and path plasticity have been repeatedly suggested. The notion of lock-in has been more fundamentally blamed for referring to mechanisms of continuity rather than change, for failing to differentiate analytically between exogenous and endogenous pressures, and for favoring an understanding of strong
inertia and unexpected disruption/destruction instead of incremental change (Martin 2010). Furthermore, queries arose about the idea of inevitability in the life cycle concept as paths may be subject to rejuvenation or ongoing change. As a result, Ron Martin and others called for a rethinking of the concept and a closer theoretical social scientific underpinning that includes institutions and political economy.

While regional path creation in technologies was a major subject in early evolutionary economic geography with the example of emerging high-tech regions, the decline of technological, sectoral, and regional paths has been less analyzed. At the end of a life cycle, lock-in mechanisms may become a negative factor that protects the old and hampers the emergence of something new. For example, Gernot Grabher (1993) pointed to cognitive, functional, and political lock-ins through strong ties quite early on when explaining resistance to structural change in the Ruhr area. It is, however, far from clear what a life cycle means for a complex system such as a region. From an evolutionary perspective, the mechanisms of path decline or path rejuvenation (Martin 2010) and resilience still remain underexplored in empirical research.

Evolution of regions in a generalized Darwinist approach

Much recent criticism from an institutional or political economy perspective has focused on regional development as an evolutionary process. Generalized Darwinism has been suggested as another evolutionary approach for explaining the evolution of complex systems in the social sciences. The idea seems obvious for economic geography as well, as regions can be seen as complex adaptive systems of multiple populations in variegated environments.

Generalized Darwinism considers variety, selection, and retention as generic principles applicable to any evolutionary analysis of any (social) scientific issue. In this very abstract sense, complex systems may evolve similarly to populations of species through endogenous mechanisms (such as self-organization). However, approaching a specific issue with generalized Darwinism requires a careful translation of abstract principles into operational dimensions such as corresponding replicators, and of the interactors involved. “Higher-level groups” such as regions and cities or other groups such as class or gender may be considered as interacting complex populations in social sciences (Essletzbichler 2012). For these complex systems, individual agency is no longer relevant; instead cooperative and collective agency based on shared visions matters, and therefore the mechanisms of group selection are different. Jürgen Essletzbichler (2012), for example, suggests customs and conventions, routines and institutions, and regional policy as “component replicators” for the analysis of regions as social interactors.

Understanding regions as complex systems touches upon an important query in evolutionary economic thinking, namely the relationship between the micro, meso, and macro levels of analysis in the explanation of economic and regional change. While the neo-Schumpeterian perspective on evolution, as exemplified by Nelson and Winter (1982), has sometimes been mistakenly blamed for its focus on the micro level of the firm only – which nevertheless was intended to explain meso level change in sectors – the generalized Darwinism approach promises to emphasize the meso level, simultaneously respecting its interlinkages with the micro and macro levels. Naturally, these levels can be conceptualized as different geographical scales in economic geography. Hence the argument is for a multiscalar geographical perspective that
ECONOMIC GEOGRAPHY

also integrates institutional change at various levels into evolutionary analysis. This focus calls for careful reflection on social mechanisms that connect the different scales to each other.

The generalized Darwinist approach in evolutionary economic geography is a challenging endeavor that so far is mainly only a desideratum. Empirical evidence is urgently needed. In terms of methodology, generalized Darwinism demands a quite sophisticated systemic approach to evolution. However, generalized Darwinism is also a somewhat contested concept, both in the social sciences in general (Levit, Hossfeld, and Witt 2011) and in economic geography in particular. On the one hand, other partly competing partly overlapping concepts of the evolution of complex systems have been recently suggested, such as path dependency, complexity theory, and even panarchy. On the other hand, in the current debate on the dynamics of regions, “mid-range” issues such as regional adaptation and adaptability, regional resilience, and the development paths of regions do not seem to require generalized Darwinism as a basic concept (Simmie and Martin 2010).

Evolutionary economic geography: an ongoing construction site

Evolutionary economic geographers have presented substantial new insights into the dynamics of economic change and uneven spatial development within quite a short period of time. However, evolutionary economic geography is still a rather heterogeneous approach that calls for much further refinement. As a result, some evolutionary economic geographers conceive evolutionary economic geography as a metatheoretical framework for empirical analyses. Specifications are required for various dimensions. First, there is much overlap with other heterodox approaches such as industrial dynamics, firm demography analysis, innovation systems theory, or general systems theory. Subjects such as knowledge creation, innovation, learning, absorptive and adaptive capacity, life cycle, path creation, path dependence, path decline, lock-in, regional innovation system, learning cluster, and, more recently, resilience, can all be seen in very different perspectives, so that it seems easy to simply use the term “evolution” in a metaphorical sense. Suffice it to repeat, however, that the basics of evolutionary theory are emerging varieties, selection between competing varieties, and retention of the selected varieties, terms that lead to considering and analyzing related social mechanisms and processes of change.

Second, there is much scope for further refinement of arguments, both in the neo-Schumpeterian and the generalized Darwinian perspective on evolution. In the neo-Schumpeterian interpretation of the evolution of firms in a region, queries arose about the appropriate unit of analysis. While some researchers seem to take the firm as interactor theoretically for granted others just see this as a deliberate choice for empirical research. However, the firm is an ambiguous unit, in particular in the form of the “one plant one product” company often implicitly considered in evolutionary economic geography. Taking the multilocational and multiproduct firm into account would require a multiscalar perspective on firm agency that cannot be linked easily to economic evolution in and of regions. Furthermore, coexisting and co-emerging technological paths and their interrelatedness within the firm would require another perspective on time, more on simultaneous than on sequential processes. In analyzing the evolution of technologies at the plant level in regions, some authors avoided these pitfalls (Rigby and Essletzbichler 1997), but this choice
may often be limited by data availability. Moreover, most evolutionary microanalyses focus on the interactors (firms) but neglect to analyze the emergence of replicators (routines and technologies) per se. Technical novelty is generally taken as occurring between firms, not within firms. Consequently, mechanisms of replication and diffusion of routines and technologies take place between firms, in the general understanding, through labor mobility, spin-offs, and – less analyzed – supplier–customer relationships in value chains or mediated by intermediaries such as consultancy and training services or the media. In fact, there is ample evidence in the recent global value chains literature on local economic change driven by technological upgrading through top-down diffusion as opposed to bottom-up creative processes. Having said this, the specific definition of interactors and indicators of replicated variety (as, for example, the incidence of spin-offs, patent use, etc.) in the neo-Schumpeterian view of evolution in economic geography has paved the way to quantitative analysis and model building in empirical research (Boschma and Frenken 2011).

Generalized Darwinism requires higher complexity in empirical research and even stimulates further queries. Obviously, the definition of higher-level groups as the target of empirical analysis calls for an appropriate definition of the micro, meso, and macro scales, which in turn influences the kind of multiscalarity and interscalar interactions involved. For instance, firms simultaneously form part of regions, clusters, sectors, and networks, that is, groups at a meso scale which are not independent of each other. These groups may emerge differently, may be subject to different institutional settings, and may develop routines differently. As a result, mechanisms of variety creation, selection, and retention must be considered to be much more complex. This poses a problem for the methodology of empirical research, in favor of a qualitative approach to nested systems. Much criticism has evolved of generalized Darwinism as a workable approach in economics, blaming it for its imprecision in defining the core terms and explaining economic mechanisms in detail, and for being generally too abstract and imposing its concepts in a top-down manner onto reality in social sciences (Levit, Hossfeld, and Witt 2011). Recent discussions in biological sciences have also put a question mark over the current understanding of the fundamental principles of variety, selection, and retention and the use of generalized Darwinism, making the practice of a generalized Darwinist approach in evolutionary economic geography even more challenging.

Such claims for further development of the evolutionary approaches in economic geography are not exhaustive. Conceptual debate on evolutionary economic geography (or geographies, as some authors prefer to say) is lively. One of the most recent suggestions attempts to avoid fundamental debate about neo-Schumpeterianism “against” generalized Darwinism and prefers a practically oriented approach to subjects of evolutionary dynamism. Referring to Trevor Barnes’s plea for engaged pluralism in economic geography, Robert Hassink (Hassink, Klaerding, and Marques 2014) proposes the incorporation of institutional as well as relational economic geography concepts into evolutionary approaches to strengthen the role of agency and institutions in evolutionary explanation. Some weaknesses in the current empirics of the neo-Schumpeterian approach could be avoided, such as understanding the firm as an isolated actor and the coevolution of institutions as merely occurring intraregionally. While analysis of micro processes would benefit from a relational perspective, the institutional perspective would support the meso level in evolutionary analysis and help to clarify its interlinkages to the macro level of the economy.

Existentialism

Tom Mels

Uppsala University – Campus Gotland, Sweden

Existentialism is a diverse, anti-essentialist tradition of thought and engagement, incessantly seeking full immersion in everyday life. It claims that any effort to grasp existence entails a concern with the human being in its multifaceted bodily, emotional, cultural, and societal situation. Existentialism therefore insists that human experience, practical life, personal awareness, and the study of life from the inside need to be a fundamental part of scholarly engagement. A wide-ranging, yet distinct conceptual and categorical repertoire is commonly associated with existentialism’s approach to human existence. Notable among these are the intimately related notions of alienation, anguished responsibility, authenticity, commitment, irrationality, boredom, and situatedness. These motifs are recognized as descriptive of the human condition and the complexities of freedom.

Existentialist concerns were developed historically as a critical response to various kinds of deterministic thought. It thus provided an oppositional vocabulary challenging varieties of cultural, economic, religious, and racist essentialisms prevailing in European society and political life of the nineteenth and twentieth centuries. Within geography, the chief interpretation of existentialism has occurred in conversation with versions of phenomenology and various postpositivist currents. Although a heterodox existentialist allure can arguably be felt throughout the discipline’s research on place as a repository of meaning and experience, it remains most frequently associated with the advent of humanistic scholarship in the 1970s. By that time, existentialism and its multiple intellectual and cultural ramifications in visual art, literature, and cinema, had already enjoyed widespread popular acclaim in Europe for several decades.

The emergence of an extended associative community and intense scholarly conversation with Marxism and phenomenology help explain the reputation of existentialism as a loosely defined intellectual movement, presenting nevertheless a passionate sensibility of revolt against social and scientific categorizations and structures. While nineteenth-century philosophers Søren Kierkegaard and Friedrich Nietzsche have been identified as precursors of the movement, and Martin Heidegger and Maurice Merleau-Ponty (both of whom incidentally disavowed the term) pioneered some of its core themes, it was during the 1940s and 1950s that classic contributions to existentialism were made in the philosophical and literary work of Jean-Paul Sartre and his coeals Simone de Beauvoir and Albert Camus. Martin Buber, Karl Jaspers, Gabriel Marcel, José Ortega y Gasset, and Lev Shestov are some of the major figures staking out different varieties of twentieth-century existentialism internationally.

Existentialists typically insist on the deeply social and conventional ground of values, keeping at arm’s length mainstream philosophical positions in which disinterested science and moral claims to what is good and right take center stage. This may best be clarified by taking a brief look at the distinctive ways in which the aforementioned conceptual repertoire of existentialism has been construed.
EXISTENTIALISM

For existentialists, conventional appeals to pre-existing essences (divine will or abstract reason) deny that human existence is always in the making, a constant embodied being-in-the-world, rather than the result of a deterministically fixed framework. Meaning and value rather emanate from life itself, from personal engagement in the world. This prioritization of existence over any pregiven essence confronts us with a kind of historically, socially, and bodily situated freedom. Existentialists think of the committed personal affirmation of these conditions of existence as central to the notion of authenticity.

Although authenticity and freedom remain contentious terms in existential deliberation, they are usually not seen as human faculties or powers, but as processes or achievements. In various ways, they describe pathways by which one appropriates the possibilities of one’s social, historical, and spatial situatedness, achieving authentic, owned existence and freedom or fails to do so. For that reason the terms certainly do not hold any triumphant promise of liberty, let alone any easy justification of existing structures of oppression and domination. Rather to the contrary, for they mark out the burden, anguish, and anxiety of having to be free, of taking responsibility for our self-formation (Sartre 1943). Through engagement and identification with the projects conducted in our lives – rather than the “bad faith” of acting as interchangeable figures in roles dictated by the world – we have a means of starting to recover ourselves from alienation. Since this is always a recovery and self-making in situation, it is necessary to acknowledge how freedom, authenticity, and commitment are at all times entangled in various kinds of circumstances, ranging from the space of the body to geographical and historical context, the conditions of human sociality and forms of collectivity. Heidegger’s famous term for Being, Dasein (to-be-there), not only presupposes a self-interpretation, but also connotes an understanding of the contextual spatial and social situatedness of Being-in-the-world (Heidegger 1927). The possibility of freedom and authenticity, bound to such situations, includes a tight relation to the formation of others. Existence as a form of seeing beyond oneself achieved in actual human experience thus opens the prospect of authentic existential commitment in the world and of bringing into being a human community.

Authentic existence and recovery from alienation also raises the question of history (the temporalities of past, present, and future), and an empirical diagnosis of everyday life in the modern world. By extension, this question more immediately immerses existentialism in the practical matter of politics. Existentialist writing tends to diagnose existence in the face of the modern world as steeped in apprehension, confronting freedom and authenticity with instrumental reason, faceless technocratic rule, religious dogma, capitalist ideology, specialization and fragmentation, and the division of labor. Under such circumstances, genuine individuality will be substituted with what in various ways is described as the inauthentic herd mentality of humanity. Not unlike the Frankfurt School’s critical theory, Sartre was drawn to Marx’s critical analysis of alienation and capitalism as offering a singularly compelling understanding of the lived experience of unfreedom, oppression, and conflict under capitalism. Heidegger, meanwhile, for some time supported the Nazi movement that he thought of as announcing the advent of authentic selfhood, a genuine manifestation of an inner essence of Being in actual history, to later abandon politics for a more spiritual and poetic mood.

Despite the demise of the existentialist cultural movement, its core motifs continue to have prominence in contemporary philosophy and social science, ranging from poststructuralism to
humanist Marxism. Simultaneously, existentialism has been caught with an unclear position in crossfire between structuralist, phenomenologic, and positivist thought. Critics have taken existentialism to task for what is seen as its bleak image of alienated despair and moral defeat. They argue that as long as these conditions of existence are seen as universal rather than as the historically specific condition of capitalist modernity, existentialism naturalizes the very existence it sets out to condemn. Any vision of solidarity with other human beings then gets necessarily thwarted. Another strain of discontent concerns the adoption of phenomenological methods. This resulted in a narrowing of the existential to a notion of nontransferable, unique selfhood, and human consciousness. From a Marxist point of view, existentialism has been found to fetishize freedom and to mystify the construction of reality behind a jargon of authenticity that insufficiently addresses the class-based structural oppressions of capitalism (Adorno 1964).

Notwithstanding such concerns, clear traces of existential philosophy were concurrently bequeathed by existentialism to Marxian scholarship. Moreover, the bulk of this critique can be traced more particularly to the development of existential phenomenology. This is also crucial for what remains a partial reception of existential philosophy within geography.

Although the origins of its philosophical venture emanated from the European contexts and languages of French and German intellectual debate, the first interpretations within geography were made in the Anglo-American context. In the early 1970s, existentialism was partially absorbed in the undogmatic eclecticism of the humanistic turn within geography, joining an increasingly forceful critique by Marxists and other radicals against the prevailing positivism within the discipline. Not unlike the early and mid-century existentialist movement, humanist geography was an existential response born of discontent with the various determinisms it identified in modern geography. With the positivism and abstractions of spatial analysis, the essentialist approaches within cultural geography and the determinism of structural Marxism were seen as drifting further and further away from the complexities of human agency.

According to the proponents of humanism in geography, these explanatory methods, models, and law-finding ideals were a far cry from the complex lived experiences and relationships between people and their environment. They claimed that positivism had unduly limited geographical research to quantitatively measurable, material spaces. It had reduced the wealth of place to the diagrammatic simplicities of abstract space and reduced human complexity to the robotic schematics of economic man. As a corollary, many humanistic geographers also rejected the avowed neutrality of scientists with their ideals of distant objectivity and elitist views of scientific knowledge. Instead, combining elements of existentialism with a philosophical and methodological menagerie of hermeneutics, idealism, and phenomenology, they brought out a fuller spectrum of subjectivity in knowledge production. Meaning, values, experiences, and the imagination became keywords in their vocabulary and tools for the qualitative exploration of the sense of place, everyday life, the lifeworld, home, rhythms, and existential insideness and outsideness.

Existential phenomenology was most commonly used to explore the experiential depth of practically living in places: the sense of place shaped through our immersion in the everyday geographies of houses, offices, schools, and parks. For instance, Yi-Fu Tuan (1974) explored an array of human awareness of, affective and bodily ties with, and responses to the environment. Merleau-Ponty’s approach to embodied presence
Existentialism

and Heidegger’s example informed his method to uncover meaning and values associated with place. Embodied experience and the pre-reflective body-subject were treated with considerable detail in David Seamon’s work (e.g., 1979). Anne Buttimer’s existentially aware geography drew inspiration from architectural theorist Christian Norberg-Schultz and Alfred Schütz’s phenomenology of the social world, but also from the French geographical tradition on social space. Her work addressed, among other things, questions of place, rhythms (temporal and spatial zones of reach), and ideas of dealing with the everyday lifeworld and embodied knowledge. Buttimer’s work (e.g., 1993) pioneered bringing out the humanity of the researching geographer, with meditations on values, dialog and responsibility, meaning construction, and other epistemic and ethical questions. A strong sense of sociality was also negotiated by David Ley (1974), whose urban social geography opened windows on the interpersonal and intersubjective values and meanings were instilled into and distilled from existential space. In the late 1970s, Marwyn Samuels developed an explicitly existential geography influenced by Martin Buber’s spatial thinking about existential nearness and detachment, measured not in actual physical distance, but in terms of the perceived distance of human relationships. Existential geography would be about the interpenetration of people’s subjective attachments and historical relationships with the landscape.

Meanwhile, such empirical and theoretical exertions were not infrequently coupled to the ambition of developing a sustained critique of technocratic societies and their urban planning ideals and alienating practices. Edward Relph (1976) developed the argument that in advanced industrial society, authentic senses of place have by and large been replaced by inauthentic modes of existence. The result is an alienating placelessness in which a burgeoning existential outsideness – espoused by the dominant values of modern technologies, the mass media, commerce, state authority, and a space of uniformity – takes precedence over erstwhile conditions of existential insideness, which was felt through rich symbolic meaning, identity, and belonging to place. Existential critique is also prominent in Gunnar Olsson’s long-standing critique of taken-for-granted meanings and power imbuing positivist knowledge, modern planning, and the bureaucratic state. His enduring engagement with art and literature provided sources for critical inquiry into the interstices between individual and collectivity, mind and materiality, and notions of marginality, the body, alienation, and the absurd (Olsson 2007).

These existential forays into the geographical embeddedness of human subjects were derived from an array of philosophical sources – ranging from structuralism to phenomenology – and occasionally also from the intellectual heartland of existentialism. Although it hardly came to represent an agreed-upon approach, Edmund Husserl’s phenomenology may be singled out because it attracted considerable approval from existentialist quarters. Within the social sciences and humanistic geography the idea of consciousness as an immediate, meaningful openness to the world proved attractive. Conversely, Husserl’s bifurcated image of cognitive consciousness (the transcendental ego) standing outside the active, lived world of embodied, human existence remained unacceptable for many. Roughly along the lines of such a digestion of Husserl, existential phenomenology within geography redirected attention to the meaning and concrete reality of the human lifeworld. It prioritized intuitive methods and phenomenological description (devoid of the preconceptions of scientific understanding or common sense) over observable sense data and scientific explanation.
Unsurprisingly, in its often contrasting searches for the rethinking of key geographical methods and concepts such as place, space, and landscape, the existential response within human geography has been subjected to critique. The first line of critique is leveled on existential phenomenology’s methods. The bifurcated staging of, on the one hand, phenomenological description and intuition, and, on the other hand, scientific observation and explanation has been questioned. This critique often blends with the perennial philosophical controversy around the viability of a return to original experience and direct description of the world, devoid of preconceptions. By extension, the intuitive aspects of existential phenomenology’s method have been rejected as excessively subjective and relativist.

A second line of critique is related to these questions of method, but also reaches considerably beyond them. In particular from Marxian and feminist vantage points, the privilege given to everyday experiences, intentionality, and subjective interpretations has been questioned. Such privileging tends to underestimate the degree to which unequal and unjust social, political, and economic circumstances and structures – the capitalist mode of production, ingrained gendered inequalities – guide everyday life, self-understanding, and the like. According to this appraisal, the focus on place experience in existential phenomenology rested on an essentialist view of the human subject that in turn diverted attention away from structuring forces of class, gender, ethnicity, and other unevenly reproduced power relations. What transpires is not a critical geography of place and the exposure of various kinds of marginalization and oppression, but a romanticized, idealistic, and nostalgic view of place (often in the form of “dwelling”) contrasted with an alienating present. In this context, the contrasting pairings of place – space, insider – outsider, authentic – inauthentic in some existentialist writings have been perceived as expressions of a dualistic worldview. Equally, scholars identifying their work with existential phenomenology have rebuffed many of these issues as misconceptions of the existentialist intent.

Both genres of critique have implications for the awareness of values in geography. On the one hand, the humanist preoccupation with values in research processes has been accused of ignoring how societal pressures shape research agendas. But on the other hand, these disputes over method, values, and epistemology were of seminal importance to subsequent attention to the partiality and situatedness of scientific knowledge production and representation within geography. With its interest in the complexities of emotional response, and how feelings and values imbue experience and human agency, existential geography shared important traits with early feminist geographies.

Today, existentialism within geography remains primarily associated with the existential phenomenology of the 1970s humanistic turn. It is important, however, to recognize that the selectivity of this particular embrace easily underestimates the alternative routes through which the existentialist movement has entered geography. Although shared themes need not entail shared diagnosis, fascination with modernity, alienation, freedom, and situatedness all bear testimony to the circuitous influence of some of its core insights and analyses into the plethora of positions within postpositivist geography and during the 1980s and beyond. In recent years, the development of qualitative methods for a wide variety of human experiences has attracted renewed attention. Existentialist heritage can arguably be identified in the increasing amount of scholarship that is now being devoted to Heidegger’s work and Merleau-Ponty’s thorough reinterpretation of embodied experience, under

Exploitation

Jim Glassman  
*University of British Columbia, Canada*

Exploitation is a term that owes much of its importance to the varied and sometimes incompatible ways in which it is used, ranging from highly charged moral claims about human conduct to technical claims about the labor process. The range of these claims ensures that exploitation is a performatively significant term within political debates.

In its broadest and most morally charged uses, exploitation implies abuse of another, taking more from another than is normally considered socially acceptable. Frequently, this notion is applied to the use of another person’s labor without adequate compensation being given. Thus, wages that are extremely low compared to what many would find adequate are referred to as exploitative, as sometimes is the disproportionate performance by women of unpaid household labor. In this broad moral sense, the abuse of nonhuman nature by humans can also be seen as exploitative.

Within Marxist theories, the term “exploitation” takes on a more technical meaning. Marx did not regard the extraction of surplus value from wage labor to be abnormal under capitalist conditions of production, and in this sense exploitation was for Marx an analytical category, not a moral one (Heinrichs 2004; Harvey 2010). His argument was based on the notion that labor is the sole producer of value in capitalist economies, and that the surplus controlled by capitalists in the form of profit must be derived, ultimately, from wage labor. Exploitation thus refers to the difference between the total amount of time workers labor and the socially necessary labor time required for workers to reproduce themselves at a historically determined subsistence wage, which Marx assumed to be what workers normally received (Marx 1977). That difference is the surplus labor time appropriated by capitalists, or surplus value, and any increase in the amount of surplus labor time relative to the labor time necessary for reproduction is an increase in exploitation, independently of whether or not the historical subsistence wages paid workers are considered by some observers to be morally acceptable or unacceptable.

While this notion of exploitation within the labor process has been central to most Marxist analyses, the geographies of labor and surplus-value production associated with globalizing capitalism complicate estimates of who is being exploited and to what degree. If all labor took place within one capitalist firm and one location, it would be relatively straightforward to estimate a rate of exploitation. But if capitalists produce in different places around the world, if they pay workers differentially for the same amount of labor and similar levels of productivity, and if they can shift the surplus from one location to another while potentially paying more to workers in certain locations, the possibility arises that geographic transfer of surplus will allow workers in one location to reduce their levels of exploitation at the expense of other workers (Emmanuel 1972; Sheppard and Barnes 1990). This possibility of some workers benefiting from exploitation of other workers underpins notions of imperialism through unequal exchange, championed by certain neo-Marxists, such as world systems theorists (Taylor and Flint 2000).

Exploration can be broadly conceived as a process of building new knowledges through searching for and encountering new environments, people, and places. Although processes of exploration are integral to other disciplines as well, exploration has been most closely connected to geography through time; however, exploration does not begin with the discipline of geography, nor does it even necessarily begin with modern humans. The earliest forms of hominid exploration central to the migration and settlement of the human species took place at least 90,000 years ago when early hominids (*Homo erectus*) left East Africa. Taking into consideration the fact that every continent except Antarctica was settled over a 75,000-year span from those initial migrations, our ancestors were undoubtedly ambitious explorers. The methods of prehistoric migration, whether by land or sea, are still a subject of some dispute—indeed, some have argued that Australia was populated by ocean voyagers as early as 45,000 years ago, though early archaeological remains that could bolster this claim are unlikely extant. What is clear is that many of the earliest recorded historic voyages were undertaken at sea. As early as 670 BCE, the Egyptian Pharaoh Necho II dispatched a Phoenician expedition to circumnavigate Africa over three years.

The enduring relationship between geography, exploration, and science began forming early in the “Age of Discovery” from the fifteenth to the seventeenth centuries. This period of exploration may not have been any more ambitious than earlier eras, but manifested in large-scale public displays of power through financial investment, deployment of new technology, and, perhaps most importantly, a machine of publicity to document it all. The age of exploration and empire, perhaps most closely associated with the scientific voyages of Captain James Cook, relied not just on embodied exploration and encounter but on systems of documentation such as writing, painting, and mapmaking to establish colonial territories, filling in knowledges on what Europeans perceived as *terra incognita*. Geographers were complicit in contributing to European military expansion as part of the larger Enlightenment cultural project. Over this time, military and religious conquests installed European nation-states over much of the world, including the Americas, the Pacific, and Asia.

In the late nineteenth century, increasing pressure through competition to colonize more of the globe led to what has been termed “the Scramble for Africa”: the invasion, colonization, and annexation of the African continent from 1881 to 1914 (Driver 2001). Many of these African expeditions were sponsored by the Royal Geographical Society (RGS) in the United Kingdom (founded in 1830). Similar expeditions have been sponsored by the National Geographic Society in the United States of America (founded in 1888). Both institutions, as a result, have been embroiled in debates over the ethics of their involvement in imperial projects. It became clear to many in the
EXPLORATION
twentieth century that the tools of geographic exploration were the tools of empire. Because of these associations with governments, military, and spectacular cultural tourism, exploration as a concept became increasingly stripped from academic geography, seen as anti-intellectual endeavor. This view was reinforced by explorers themselves, who accused geographers attempting to theorize practice of being “armchair” academics, lacking the experiential credibility to guide narratives of exploration. Whatever the politics behind such expeditions, they were certainly successful from the point of view of European powers, leading to suggestions by the early twentieth century that there was nothing left to explore in the world; that humankind had entered the age of Geography Triumphant (Driver 2001, discussing a 1924 article in National Geographic magazine by Joseph Conrad).

Inevitably, however, a second land scramble of a slightly different nature began in the twentieth century and geographers were once again at the forefront of exploration under the guise of objective science. James Cook’s second expedition from 1772 to 1775 had fueled curiosity about Terra Australis, a new continent in the Southern Ocean. Between 1898 and 1910, seven major expeditions by European powers were launched onto the Antarctic landmass, the only continent on Earth without an indigenous population (Dodds 2012); however, this did not mean these explorations were without conflict. As with explorations in earlier ages, these expeditions were heavily financed by governments with political motivations leading to serious disputes over territorial claims. As with the scramble for Africa, in this period, the claims of nations were often pinned on “heroic” explorers. Norwegian Roald Amundsen was the first to reach the South Pole in 1911, to the dismay of British explorers who arrived just a few weeks later. Amundsen may have also been the first person to reach the North Pole in 1926 via airship. With both poles then mapped, the “final” pole sought was the highest. Mount Everest (the highest mountain from sea level but not the tallest from the sea floor) was summited by Tenzing Norgay and Edmund Hillary in 1953, who captured photos as evidence of their accomplishment. As with the mapping of Africa, many once again declared the “end” of exploration by the 1950s.

Debates and issues around exploration

As on Everest, visual representations have always been important to exploration. Many prehistoric cave paintings may have been depictions, or visual maps, of explorations into new territory. In the age of discovery, representations took the form of resident artists (painters) hired to depict journeys. With the invention of photography in 1839, the medium was recognized almost immediately, in the context of the expansion of European overseas empires, as an asset to explorers seeking to document their journeys and achievements (Ryan 1998). From the mid-nineteenth century to today, exploration photography has become ubiquitous and expected. Photographs were thought to capture something of an objective “truth” of an expedition, event, or encounter, perhaps more accurately than painting where the painter’s subjective interpretation of events comes through more clearly in the framing, textures, rendering of expression and gesture, and choice of color. Indeed, from the mid-nineteenth century, it was difficult to conceive of an exploration expedition without a photographer, or at least a camera (still or later video) as part of the field kit, a relationship that remains to this day. And although many still consider images “proof of achievement,” more contemporary geographic work has considered overlooked accounts of
images, the neglected home archives, and potential for additional mining of known archives to tell stories of individuals not foregrounded or those just out of frame.

These stories of exploration, while inspiring, are also stories of exclusion. The history of exploration until the twentieth century is a story largely told from a Eurocentric, androcentric, and science-centric point of view. Sustained critique followed from within geography to celebrate indigenous accounts of exploration and accounts of European exploration from indigenous perspectives. These narratives, many scholars argued, had been written from perspectives that failed to articulate the meanings and logics of non-Western peoples. Demands were also made to recognize the active exclusion of women from these expeditions and to rewrite history where women were involved and subsequently written out of history. In the history of Victorian exploration, for instance, as Mona Domosh (1991) convincingly argues, there were a number of women explorers written out of history because their explorations were not “goal oriented” or because their views and activities did not accord with geographic and scientific standards outlined by institutions such as the RGS. The RGS actively excluded women from membership and decision-making; women like Mary Kingsley, Mary Gaunt, and Isabella Bird were accused of being “travelers” rather than “explorers,” a gendered language divide still evident today. Interestingly, in the act of privileging process over goals, as many women who explored were accused of doing, these explorers often contributed more deeply to ethnographic and cultural understanding through their “subjective goals” than their male counterparts. The traveler/explorer divide highlights the always-present truth that exploration is as much internal as external, that exploration of the world is always an exploration of the self.

New themes in exploration

As a result of these sustained and important critiques, exploration fell even more deeply out of favor within geography. Few geographers embedded themselves on expeditions and even fewer labeled themselves “explorers” for fear of being perceived as anti-intellectual or, even worse, racist, sexist, or neocolonial. However, an American geographer called William Bunge disrupted this view in the 1950s; in short, Bunge argued that exploration could once again be a positive force, turned on ourselves. In the midst of stark racial and spatial division in 1969 Detroit, Bunge began undertaking what he called “expeditions” into low-income parts of the city under the auspices of the Detroit Geographical Expedition and Institute (DGEI). He argued that complete and full exploration of the urban environment would lead to democratization of space and a cultivation of deeper senses of community. Bunge offered tuition-free urban geography classes to low-income African-Americans and bused middle class white students into poorer areas of Detroit so that they could see how urban segregation was shaping their worldview and reinforcing inequality. A radical explorer for his time, Bunge was dismissed from multiple academic posts for his explorations. However, his message, that geographers should actively participate in the communities they are studying and strive to enact positive social change, has had lasting effect on the discipline and our considerations of the role exploration can once again play in geography.

The related philosophies of the Situationist International (SI), active in the 1950s and 1960s in Paris, were founded on the notion that due to the relentlessness and pervasiveness of commodity and administration under late capitalism, urban citizens had become passive spectators in a world presented to them as a
EXPLORATION

spectacle (Pinder 2005). Their solution to this problem was to reinstate active participation through explorations of the city in a process that might be considered a “counter-mapping” of place. Explorers were encouraged to undertake dérives or drifts through the city in the spirit of nineteenth-century flâneurs who refused to adhere to notions of “proper” places. The dérive opens out, in the spirit of exploration, chance for happenstance, which may lead to unexpected spatial discoveries and social encounters. Importantly, these explorations seek to redress earlier problems in exploration stemming from perceived overly objective and scientific goals by embracing the subjective process of exploration. And importantly, like Bunge’s expeditions, these were explorations not of distant lands or “foreign” people, but of the “home” and the “everyday.” The maps of the SI, drawn up from exploration of the exceptional in the everyday, were meant not to document and rationalize space but to disrupt social ordering, to draw up hypotheses for new constitutions of place that prefigured the social before the economic (see Bunge 1969).

The SI praxis was further drawn out through urban exploration, a globally recognized and socially significant practice from about the year 2000 to today (Garrett 2013). Urban explorers appropriated the language and imagery of colonial exploration and applied it to contemporary metropoli, which they claimed had become colonized by forces of capitalism, surveillance, and health and safety to the point of existential threat. Urban explorers called for subversion of dominant narratives of spatial regulation by undertaking explorations in cities without permission, sneaking into abandoned buildings, under construction skyscrapers, and subterranean tunnel systems, photographing the “discoveries” and distributing those photos publically online. The emulation of the colonial “explorer” ethos in the culture extended into the declaration of “Golden Ages of Exploration” (some lasting only months), the naming of locations by explorers of “virgin territory,” and the aesthetic coding of the photography used to “document” their explorations. The appropriation of these languages and aesthetics is both a serious political statement about access to and control over space and a flippant sapping of colonial practices. It is in this collapse of binaries that urban exploration finds its form, being both an objective technique of observation that reveals and comments on the “hidden” in the tradition of exploration and an inclusive, internal subjective search for meaning. Urban exploration is closely allied with practices such as skateboarding, graffiti and parkour (free running), which also constitute modern forms of exploration of cities. These practices similarly colonize and occupy spaces in the context of popular practice rather than colonial exploitation, being undertaken by local groups and individuals without state or institutional support. Ironically, the state and connected institutions, who clearly sponsored (and continue to sponsor) far more militant and violent forms of exploration, often condemn these exploratory practices “at home,” as being inappropriate, illicit, and even illegal. It would appear that not much has changed since Bunge’s time – exploration is still meant to remain “Out There,” among “The Other.”

Within geography there has been a preoccupation with mapping, Cartesian coordinate systems and “accurate” photographic depictions of places and landscapes that amounts to, in essence, a two-dimensional imagination, which is being challenged as geographers explore the vertical world through practices such as caving, scuba diving, tunneling, mining, air travel, ballooning, and vertical architecture. Ambitious as these studies may be, attachment to the “geo” has meant geographers often still remain remiss in
their attention to exploration of the deep sea and outer space, indications that perhaps vertical imaginaries have not stretched far enough. With the boundaries of deep-sea exploration continuously advancing through the use of robotics, there remains vast work to be undertaken on oceanic and maritime exploration. And beyond soil and sea, decades of concerted space exploration have also opened out new possibilities for discovery beyond Earth’s exosphere. Overwhelming public interest in the photographs taken by the Mars Rovers, life aboard the International Space Station, and the possible colonization of Mars in the next decade should have geographers working overtime to consider the geopolitics of space exploration and the importance of the current political moment in the galaxy, where control over and exploration of outer space is being handed over from governments to private companies. Given the discipline’s relationship with historic precedent, and the particular sensitivities that has engendered, geographers are well poised to critically comment on such activities. Additionally, attention to new spaces of exploration such as these, in the context of work by people like Bunge and the SI, should be seen as an opportunity for researchers to embed themselves on such missions and tell new ethnographic tales of exploration, critically filtered through our fraught past with exploratory practices (Naylor and Ryan 2010).

We might also consider the limits of exploration in a more (or less) phenomenological sense. For the endless accumulation and storage of information, again another proclivity of living under scientific frameworks emphasizing collection and retention, have also created new realms for exploration in the archive. It may be easy to imagine the physical archive or library as a place of exploration, a “great indoors,” digging through old manuscripts, maps, and photographs; indeed, many have written evocatively about the process of “delving” for material and having unexpected encounters with fragments of the past (Lorimer 2009). Further interrogation of the relationship between fieldwork and archives or what Felix Driver termed the field and “the cabinet” (Driver 2001) leads to a suggestion of a particular hybridity at work. Exploration of the archive rehabilitates archival fragments and lends itself to performance of landscape, place, and memory that might also be considered a form of activism. Archival exploration can answer the call of Domosh (1991) to recall the hidden histories of those who have been inadvertently or purposefully written out.

Archives can be “delved” beyond the obvious in a number of ways. First, one might consider, as Lorimer (2009) suggests, how Internet-based shopping on sites like eBay allows for collection of archives we may have never had access to previously and may encourage people to explore in an effort to find saleable cultural remains such as family photograph collections (another area of heated ethical debate). Second, the Internet most of us know and use, which is essentially an infinite archive, is only 0.03% of what is on the web. Behind, under, and entangled within this archive is a “deep web” where information accumulates without being categorized, tagged, organized, listed, and publically distributed. The daring virtual explorer or hacker may make forays into this zone, sometimes at great personal risk, to recover social and cultural data. Digging even deeper, one may find oneself in the “dark web,” an ethically and legally murky landscape where important social research can and should be undertaken. Consideration is also due to increasingly multisensory inhabitations of virtual avatars and virtual environments. Virtual “sandbox” environments in games, for instance, many of which take months or years to explore, may soon become boundless. Within the next few decades, it may become increasingly difficult
to distinguish between “real” and “virtual” experiences as our “second life” online becomes indistinguishable from the first, changing our notion of exploration indelibly.

Finally, we might consider new research into processes of nonhuman exploration. Now that machine capacity is outstripping human capacity to explore, and humans increasingly embody machines to explore inhospitable environments, the boundaries of exploration will inevitably change. But this is nothing new, for as we have seen, if anything defines exploration, it is its constantly changing nature. If we knew what was going to happen, it wouldn’t be exploration.

Exploratory spatial data analysis

Diansheng Guo
*University of South Carolina, USA*

Geographers acquire new knowledge by analyzing observation data, searching for patterns, testing hypotheses and formulating theories with insights from data. Spatial data analysis methods can be divided into two general groups: confirmatory analysis methods and exploratory analysis methods. Confirmatory methods normally require an a priori model, a statistical measure or an hypothesis, and use observational data to configure the parameters of the chosen model or statistically test the hypothesis. For example, it is possible to configure the coefficients of a linear regression model or statistically test a specific measure, for example, Moran’s I statistics, to detect the presence of a certain type of patterns in the input data. One shortcoming of confirmatory analyses is that they depend on the user to choose a model based on domain knowledge and the analysis cannot suggest alternative models if the chosen model does not correctly represent the phenomenon being analyzed. In practice, however, it is often not known what the true model is or which hypothesis should be tested. Therefore, it is more challenging and important to find the appropriate hypothesis or model (Tukey 1977, 1980).

Exploratory spatial data analysis (ESDA) uses visual graphics (including maps), exploratory statistics, and computational algorithms to enable the analyst to interact with the data, identify patterns, search for hypotheses and discover unknown or unexpected information. Exploratory analysis is often an iterative process, as preliminary findings may prompt the analyst to change data input, perform new analyses, and revise hypotheses or models. The importance of exploratory spatial data analysis is rooted in the complexity of geographic problems. Geography concerns the understanding of the dynamics and interactions of the Earth’s landscapes, peoples, and environments, which form a highly complex system. Therefore, geography heavily relies on the analysis of observational data to acquire new knowledge and to understand geographic processes, which inevitably involve many known and unknown factors and may also change over space and time. Spatial analysis by nature is an exploratory process that incorporates domain knowledge and analysis methods to comprehend the complexity of geographic phenomena with limited (although big) observational data.

In statistics, exploratory data analysis (EDA) was promoted by John Tukey to explore data and formulate hypotheses that could lead to new findings and experiments (Tukey 1977). Commonly used statistical graphics and methods include, for example, box plot, histogram, scatter plot, stem-and-leaf plot, and parallel coordinate plot, and multidimensional scaling. ESDA is an extension of EDA for the detection of spatial patterns and formulation of hypotheses based on the geographic distribution and relationship of the data. Traditional exploratory spatial data analyses are primarily visual and centered on a map. One classic example is John Snow’s study on cholera, in which he mapped the locations of deaths related to cholera during an epidemic in London in 1854 and found a high concentration...
of deaths near the water pump at the intersection of Cambridge and Broad Streets. Following Snow’s suggestion, the officials removed the handle of the Broad Street pump that supplied water to this neighborhood and the epidemic was contained. Today, the literature of exploratory spatial data analysis has become very broad and diverse, with methods developed in a variety of domains including geography, statistics, computer science, data mining, information visualization, human–computer interaction, and a wide range of related spatial sciences such as biology and geology.

Spatial data types

Before introducing various exploratory spatial analysis methods, it is important to understand spatial data, which can be classified into four major types from the analysis perspective: lattice data, geostatistical data, point event data, and spatial interaction data. Different data types require different methods for analysis.

Spatial lattice data are counts or averages of a measurement for a finite set of spatial units within a geographic area. Examples of spatial lattice data include remote sensing images (i.e., a set of pixels with observation values), cancer mortality rates for states in the United States, the presence or absence of a plant species in square blocks laid out in a forest, or the population of each block in a city. The spatial units in lattice data are fixed and represent a non-overlapping partition of the study area. The analysis of lattice data focuses on the attribute values, multivariate relationships, and their spatial distribution patterns.

Geostatistical data in theory can be observed at any location (thus form a surface), although the data are usually available for a set of selected locations, such as weather stations. The analysis of geostatistical data include, for example, the interpolation of the continuous surface and the prediction of values at unknown locations based on the limited observations.

Point event data are a collection of events that occurred at a discrete location and time, such as crimes, trees of certain species, and disease cases. The spatial locations of point events are often the most important piece of information and the focus of analysis, such as point pattern analysis or spatial clustering. Point event data may be aggregated to lattice data given a set of spatial units (such as the number of disease cases for each county) or be transformed to a surface (e.g., crime density surface).

Spatial interaction and mobility data represent the movements and flows from among a set of locations, such as migration, commodity flows, animal movements, vehicle trajectories, and human daily activities. With the ubiquitous location-aware technologies, such as smart phone and GPS, big data on geographic mobility become increasingly available, which present both unprecedented opportunities and challenges for spatial data analysis.

Challenges for spatial data analysis

Spatial data have a number of unique characteristics that pose problems and challenges for analysis, which nonspatial analysis methods often fail to address. A brief introduction is provided here to several of the main problems and challenges that spatial data analysis often attempts to address.

The spatial dependency or autocorrelation problem refers to the fact that spatial data often
EXPLORATORY SPATIAL DATA ANALYSIS

exhibit a certain degree of spatial autocorrelation, where the measurement at one location is similar to that of nearby locations. On one hand, the existence of spatial autocorrelation violates the data independence assumption (i.e., observation data at different locations are independent of each other) that many nonspatial analysis methods assume. For example, regression analyses that do not take into account spatial dependency can produce unstable parameter estimates and biased models. On the other hand, the detection of spatial autocorrelation by itself can be an important finding for applications that look for spatial distribution patterns such as disease clusters or crime hotspots. A number of spatial statistics and analysis methods have been developed to detect the existence of spatial autocorrelation or to carry out analysis that exploits spatial autocorrelation as a source of information, such as spatial regression methods and spatial interpolation methods.

The second challenge is the spatial heterogeneity or nonstationarity problem, which means that a relationship, model, or pattern may change over the geographic space. For example, the parameters for a regression model may change from place to place, or the values of a statistical measure (e.g., Moran’s I) may be different in different areas. To address the spatial nonstationarity problem, various local spatial analysis methods have been developed, such as local point pattern analysis, local spatial statistics, and local regression analysis, for example the geographically weighted regression (GWR).

The small-area problem in spatial data analysis is also well known. The term “small area” refers to a geographical area of either small size (e.g., area) or a small demographic count (e.g., population). For example, disease rates (i.e., the number of disease cases divided by the population at risk) estimated for units with a small population are usually unstable and exhibit much higher variance than those of larger units, which consequently cause difficulties for discovering true spatial patterns and relationships. The fundamental question is how to produce reliable estimate measures for smaller areas, such as means, counts, and rates, based on very small samples taken from these areas. The general solution to the problem is to borrow information of related data from spatial neighbors. Confirmatory approaches to small area estimation include various model-based methods such as multilevel regression models and Bayesian methods (Pfeffermann 2002). Exploratory spatial methods that address the small area problem include, for example, spatial smoothing, spatial interpolation, and kernel density estimation.

The modifiable areal unit problem (MAUP) has long been acknowledged in the literature of spatial analysis (Openshaw 1984). For example, for confidentiality reasons, spatial data are often aggregated to high levels based on administrative boundaries (e.g., counties) or other spatial tessellations. MAUP refers to the fact that spatially aggregated measurements (e.g., median income or racial percentage) and their spatial distribution patterns may change dramatically if different aggregation boundaries are used, which is caused by both scale and aggregation effects. The scale effect relates to the size of the spatial units being used (e.g., county vs state) and the aggregation effect arises from how the boundaries are drawn. Changes in either scale or unit boundaries will lead to changes in the data distribution and, thus, may lead to different analysis results. MAUP can be considered as a special case of the ecological fallacy, which concerns the potential problem for making inference about individuals based on aggregated data, for example, by ethnic groups, socio-economic classes, or geographic regions (Robinson 1950; Greenland and Morgenstern 1989).
In addition to the above well-known problems, there are also a number of major challenges that exploratory spatial data analysis can help address in analyzing the fast-growing complexity and volume of spatial data. First, spatial datasets are often of high dimensionality (i.e., having a large number of attributes or variables), which can cause serious problems for most analysis methods. For example, there are dozens or hundreds of variables in the census data and/or other data sources, which, for example, can be analyzed to examine how socioeconomic factors affect health outcomes. However, including too many irrelevant variables in a model will lead to unsatisfactory results and miss the true patterns. Most confirmatory analysis methods depend on the user to select factors for model construction or hypothesis testing. Since it is not often known beforehand which factors are important, exploratory spatial data analysis can be used to help identify important factors through: (i) visual approaches, such as univariate, mapping, multivariate mapping, and interactive feature selection assisted by statistical measures; and (ii) computational analysis, such as automatic feature selection methods, to search and evaluate subsets of variables. Feature selection methods are traditionally used to select a subset of variables for supervised classification problems (Liu and Motoda 1998).

The second general challenge in spatial data analysis concerns the complexity of potential patterns and various forms that they may take. For example, lung cancer incidence rates may be related to the interaction of behavior choices (e.g., smoking), local climate (e.g., temperature and humidity), socioeconomic status, access to health care, and other factors. Moreover, the relationship among these factors may be linear or nonlinear and may also change over the geographic space. All possible relationships or patterns form a hypothesis space. Ideally, it would be possible to identify the best model in the hypothesis space and then configure the model with appropriate observational data. Of course, this is practically infeasible and most (if not all) analysis methods limit or compress the potential hypothesis space by assuming a simple form of model, which can be configured with several parameters. For example, a linear regression analysis assumes that the relationship is of a linear form, that the observations are independent from each other, and that the relationship does not change over the geographic space. Exploratory spatial data analyses attempt to search in the hypothesis space without imposing an a priori hypothesis and assess a large number of hypotheses or patterns simultaneously.

The third challenge for spatial data analyses is the massive volume of today’s data with (i) details at a fine spatiotemporal scale, (ii) a large number of observation variables, and (iii) dynamic connections among locations and multiple attributes. Moreover, many research problems and tasks demand near real-time insights, such as for emergency response and decision-making. To achieve the capability of processing large data volumes efficiently and detecting complex patterns accurately, exploratory spatial analysis methods often integrate computational algorithms with visualization approaches. Such integration leverages the computing power and accuracy of algorithms with the inference and problem-solving capability of human expertise to addressing complex problems.

**Smoothing, density estimation, and interpolation**

**Spatial smoothing**

Spatial smoothing can be applied to spatial lattice data, such as area-based attribute data and
pixel-based images, to re-estimate observation values of small areas by considering the values in their neighborhood. For example, smoothing can be used to obtain a more reliable disease rate for each area by recalculating the rate using the total number of disease cases and the total population at risk in its neighborhood, which should be sufficiently large in terms of population or the number of cases. Broadly defined, spatial smoothing also covers various image filters, such as low-pass and high-pass filters, which are commonly used to extract different features from images. In general, a smoothing method involves three components: a neighborhood (e.g., defined by a bandwidth, first-order neighbors, or k-nearest neighbors), a weighting kernel (e.g., uniform, triangular, or Gaussian kernel) (Figure 1), and a filter operation (e.g., weighted average, mode, or other transformations).

Spatial smoothing can help remove spurious data variation, improve the signal-to-noise ratio, and thus help discover true patterns or important features in data. This benefit is maximized when the neighborhood size and shape is the same as the scale and shape of the true patterns. The bandwidth of the kernel can exhibit a strong influence on the smoothing result and, thus, should be configured carefully. Since the true scale of patterns is usually unknown, a sequence of different bandwidths may be tried to examine how patterns change across a scale. A larger bandwidth can help discover generalized high-level patterns at the sacrifice of spatial resolution and the risk of missing local patterns.

There are two main types of bandwidth: fixed and adaptive. With a fixed bandwidth, the radius is normally a geographic distance that is assumed to be the same throughout the dataset. An adaptive bandwidth allows the radius to vary from one data point to another. It is widely acknowledged that a fixed bandwidth causes biased estimations for most spatial datasets, as the underlying data density often exhibits significant spatial heterogeneity. Various adaptive bandwidth selection approaches have been developed to help configure bandwidth, which can be categorized into model-based and domain-based approaches. With the model-based bandwidth selection, a statistical model or criterion is often used to provide guidance on selecting an appropriate bandwidth value. Cross-validation (CV), Akaike information criterion (AICc) and Bayesian information criterion (BIC) are among the commonly used criteria. Domain-based bandwidth selection approaches usually rely on domain knowledge to choose a relevant attribute (e.g., population) to determine the bandwidth. For example, to adapt with the underlying population distribution, a population threshold can be used to determine the adaptive bandwidth, which stops expanding when the threshold is reached.

**Figure 1** Three kernel functions. (a) Uniform: \( W_{si} = 1 \text{ if } d_{si} \leq B_s \), else 0, where \( B_s \) is the bandwidth at location \( s \) and \( d_{si} \) is the distance between \( s \) and its neighbor \( i \). (b) Triangular: \( W_{si} = 1 - | d_{si} / B_s | \), if \( d_{si} \leq B_s \), else 0. (c) Gaussian: \( W_{si} = \exp \left( -(d_{si} / B_s)^2 \right) \) if \( d_{si} \leq B_s \), else 0.
Although in most smoothing applications the neighborhood is defined as a circular shape (where the bandwidth is the radius), it can be extended to accommodate different contexts. For example, the neighborhood can be defined as the area within a travel distance on a network or the first-order (or higher-order) neighbors based on contiguity. Spatial smoothing mostly uses the weighted average of neighboring values (including the observation value to be smoothed), where the weights are determined according to the kernel and the bandwidth. This can be customized for different applications to extract a surface of patterns and features, such as the low-pass and high-pass transformations in image processing.

**Spatial kernel density estimation**

Spatial kernel density estimation (SKDE) is often applied to point event data, such as geocoded crimes and disease incidences, to estimate a density surface of events and help identify the spatial structure of event distribution. Originated in statistics, kernel density estimation (KDE) is a nonparametric way to estimate the probability density function of a random variable based on a finite set of data samples. The simplest approach to density estimation is through a histogram (for 1-D data) or quadrat counts (for 2-D data). To obtain a more robust and smoothed density surface, kernel-based approaches are preferred. Let \( S = \{s_1, \ldots, s_n\} \) be a set of point events, where \( s_i = (x_i, y_i) \) is the location of an event. The kernel density surface \( f(s) \) over the geographic space can be estimated with equation 1:

\[
   f_h(s) = \frac{1}{n} \sum_{i=1}^{n} K_h(|s - s_i|) \quad (1)
\]

where \( f(s) \) is the probability of event occurring at location \( s \), \( h \) is the kernel bandwidth, \( |s - s_i| \) is the distance between the event location and \( s \), and \( K \) is a kernel function that is symmetric, non-negative, and integrates to one. \( K_h \) is called the scaled kernel and defined as \( K_h(|s - s_i|) = 1/h \cdot K(|s - s_i|/h) \). The kernel density estimation constructs a kernel centered at each event and the probability of observing an event at a location \( s \) is the average probability of all events in the data at that location.

Similar to spatial smoothing, a range of kernel functions are commonly used in kernel density estimation, including uniform, triangular, Gaussian, Epanechnikov, and others. While the choice of the kernel function \( K \) is not crucial, the choice of the bandwidth can have a strong influence on the estimated surface since it controls the amount of smoothing effect. A variety of automatic and data-based methods have been developed for selecting the bandwidth (Park and Marron 1990). The bandwidth may also be chosen with domain knowledge and empirical considerations.

**Spatial interpolation**

Spatial interpolation predicts the attribute value at a location based on a limited number of observed data points at other locations, such as estimating the temperature at one place (where there is no temperature measurement) using observed temperature values at nearby weather stations. Spatial interpolation is suitable for exploring the trend surface in geostatistical data where the observations are limited samples of an unknown continuous surface over the geographic space, such as rainfall, chemical concentration, noise level, and so on. Essentially, spatial interpolation methods assume that nearby locations are more likely to have similar observation values than distant locations. One of the common methods for spatial interpolation is inverse distance weighting (IDW), which calculates a weighted average of nearby values as
the estimation for a given point. To estimate the value at location $S_0$, the weight (or contribution) for data at $S_i$ is:

$$w_{i0} = \left(\frac{1}{d_{i0}^k}\right) / \sum_{i=1}^{n} \left(\frac{1}{d_{i0}^k}\right)$$

where $d_{i0}$ is the distance between $S_i$ and $S_0$, $n$ is the number of observed data points, $k$ is power parameter, and

$$\sum_{i=1}^{n} w_{i0} = 1$$

The interpolated value at $S_0$ is

$$x_0 = \sum_{i=1}^{n} w_{i0} x_i$$

A larger value for the power $k$ will introduce a stronger distance-decay effect, meaning that distant locations have much less contribution (weight) for the interpolated value.

While it is theoretically possible to interpolate values at any location, the estimation is more reliable for locations that have observed data points nearby and in different directions. If all observation points are all far away or on one side of the interpolation location, the result will be less accurate. Therefore, the interpolation is usually constrained within the bounding box of the input data. One common method to evaluate interpolation results is cross-validation, which withholds a sampled observation one at a time, performs the interpolation to obtain its estimation, and compares it to the true value. This approach may also help configure the power parameter $k$.

One of the major limitations of IDW is that it does not consider how sample data points are spatially distributed and correlated. Alternatively, geostatistical approaches (known as kriging methods) use variograms to evaluate the structure of spatial autocorrelation in the sample data, construct a formal function to describe the structure, and calculate the weights of observation points for interpolation. Since kriging methods take into account the spatial distribution and autocorrelation structure of observation data, they usually produce better interpolation results than the IDW method. For more information on spatial interpolation, see related entries Interpolation: areal, Interpolation: kriging, and Interpolation: inverse-distance weighting.

### Local spatial statistics

As introduced earlier, the existence (or nonexistence) of spatial autocorrelation by itself can be an important finding when the goal is to identify spatial distribution patterns. A number of spatial statistics have been developed to quantify spatial autocorrelation, that is, the degree to which a random variable at a specific location is dependent on the values at its neighboring locations. Such spatial statistics can be classified into two types: global statistics and local statistics. Global statistics calculate only one statistical value, the whole dataset, which can be tested to indicate whether the data have significant spatial autocorrelation or not. Local statistics focus more on the local variation of spatial autocorrelation and, therefore, calculate a local statistical measure for each location, which can be used to identify pockets of spatial association, such as unusually high concentration of disease cases. Therefore, global spatial statistics are considered confirmatory approaches that only test a single hypothesis while local statistics are more exploratory and search for significant local patterns within a hypothesis space.

### Global statistics

Moran’s I and Geary’s C are the most commonly used statistical indices for global autocorrelation.
EXPLORATORY SPATIAL DATA ANALYSIS

analysis, which calculate one statistical value for the entire dataset to measure how nearby locations are similar or dissimilar for a given attribute. The statistics value is then tested to determine whether the data exhibit significant spatial autocorrelation (or spatial clustering). The Moran’s I statistic is calculated using equation 2:

$$I = \frac{n \sum_i \sum_j w_{ij}(x_i - \bar{x})(x_j - \bar{x})}{\left( \sum_i \sum_j w_{ij} \right) \sum_i (x_i - \bar{x})^2}$$

(2)

where $n$ is the total number of locations, $x_i$ and $x_j$ are the attribute values for area $i$ and $j$, $\bar{x}$ is the mean of the attribute values, and $w_{ij}$ is the weight for the pair of areas. The weights $w_{ij}$ are normally set as 1 if $i$ and $j$ are spatial neighbors and 0 otherwise. The neighborhood can be defined as data points within a fixed distance, first-order neighbors, or according to other definitions. Moran’s I values range between $-1$ and 1, where 1 indicates the strongest positive spatial autocorrelation (with high values near high values and low values near low values) and $-1$ represents the strongest negative spatial autocorrelation (with high values near low values). If the observed Moran’s I is close to 0, it indicates spatial randomness, that is, absence of spatial autocorrelation.

Similar to Moran’s I, Geary’s C measures spatial autocorrelation by directly examining the differences in attribute values among observation points:

$$C = \frac{(n - 1) \sum_i \sum_j w_{ij}(x_i - x_j)^2}{2 \left( \sum_i \sum_j w_{ij} \right) \sum_i (x_i - \bar{x})^2}$$

(3)

Geary’s C values range between 0 and 2 with $C = 1$ indicating spatial randomness (i.e., no spatial autocorrelation), $C = 0$ represent the strongest positive spatial autocorrelation, and values above 1 shows increasingly negative spatial autocorrelation.

Local statistics

Local spatial statistics are exploratory approaches that focus on the identification of local patterns of spatial association.

The local $G$ statistics (Getis and Ord 1992; Ord and Getis 1995) measures the degree of association that results from the concentration of high or low values of a given variable. Given an area with $n$ spatial units, where each unit $i$ has a value $x_i$ for a variable, the $G_i(d)$ statistic tests hypotheses about the spatial concentration of the sum of $x_j$ values within the neighborhood of location $i$. The neighborhood is defined as the points within a distance $d$ to the unit $i$. The $G_i$ statistic is calculated as:

$$G_i(d) = \frac{\sum_{j \neq i} w_{ij}(d)x_j}{\sum_{j \neq i} x_j}$$

(4)

The summations over $j$ may or may not include $i$; $w_{ij}$ is one if unit $j$ is within distance $d$ to unit $i$. The $G_i(d)$ statistics detects whether high values or low values cluster in the neighborhood surrounding unit $i$. A high $G_i$ value indicates that high values tend to be near each other and a low $G_i$ value indicates that low values tend to be near each other. Note that the variable must have a natural origin and is positive, and that transformations of the variable values will result in different values for the test statistic. For example, it is inappropriate to use $G_i(d)$ to study residuals from a regression analysis.

Local versions of Moran’s I and Geary’s C, and a more generalized class of local indicators of spatial association (LISA), are developed to measure
the association between the value at \( i \) and values of its nearby areas (Anselin 1995). With the same notation for Moran’s I (equation 5), a local Moran’s I statistic for spatial unit \( i \) is defined as

\[
I_i = (x_i - \bar{x}) \sum_j w_{ij} (x_j - \bar{x})
\]

where the summation over \( j \) only includes values in the neighborhood through the configuration \( w_{ij}, w_{ii} = 0 \). A positive \( I_i \) means positive spatial autocorrelation at location \( i \), while a negative \( I_i \) means either a low value surrounded by high values or a high value surrounded by low values. Local Moran (and local Geary C) cannot distinguish high–high clusters from low–low clusters, unless values across clusters are compared after calculating the indices.

Local spatial clusters, sometimes referred to as hotspots, are those locations that have significant local statistics values. To test the significance of local statistics values, a Monte Carlo permutation approach is commonly used, especially when the theoretical distribution curve of the statistics is hard to obtain. The permutation process holds the value at a location \( i \) fixed and randomly permutes the remaining data values over the locations in the dataset. Each permutation creates a resampled dataset for location \( i \) as a realization of the null hypothesis (i.e., no spatial association at \( i \)). Repeating this process many (e.g., 999) times and calculating the statistics for each repetition creates an empirical distribution curve for the statistics, which provides the basis for significance testing of the actual local statistics value at \( i \). This will be repeated for every location in the dataset to obtain a map of local statistics values and their associated \( p \)-values.

However, when a large number of significance tests is carried out, there is a multiple-testing problem. It refers to the fact that the probability of incorrectly rejecting a null hypothesis is much higher than the confidence interval \( \alpha \) indicates when many tests are performed at the same time. For example, if a test rejects a null hypothesis at a confidence level of 0.05, it means that there is a 5% possibility that the null hypothesis is incorrectly rejected. If 100 such tests (which, for simplicity, are assumed to be independent from each other) are performed at the same time, then it is almost certain that one or more (actually the expected number is 5) null hypotheses will be incorrectly rejected even if there is no significant pattern in the data. In this case, it is difficult to tell whether the rejected hypotheses are merely out of chance or indeed significant. Various approaches for addressing the multiple-testing problem are introduced in the next section.

**Multiple-testing problem and correction**

In the literature of statistics, a number of methods have been proposed to control the multiple-testing problem. Two groups of methods are commonly used: (i) controlling the family-wise error rate (FWER) or (ii) controlling the false-discovery rate (FDR).

The family-wise error rate (FWER) is the probability of erroneously rejecting even one of the true null hypotheses among \( m \) independent tests. If the FWER is to be controlled at some level \( \alpha \), then each of the \( m \) tests has to be carried out at much lower levels. The simplest FWER approach is the Bonferroni method, which simply sets the level for each test at \( \alpha / m \) and is the most conservative correction approach for the multiple testing problem. Holm (1979) proposed a step-down procedure to control FWER. Consider \( m \) hypotheses \( H_1, H_2, \ldots, H_m \), with corresponding \( p \)-values \( P_1, P_2, \ldots, P_m \). Let \( P_{(1)} \leq P_{(2)} \leq \ldots \leq P_{(m)} \) be the ordered \( p \)-values and denote their corresponding hypotheses by \( H_{(1)}, H_{(2)}, \ldots, H_{(m)} \). Holm’s method starts testing from the smallest \( p \)-value \( P_{(1)} \). Let \( k \) be the smallest \( i \) for which \( P_{(i)} > \alpha \/(m - I + 1) \), then reject all \( H_{(i)}, i < k \).
Benjamini and Hochberg (1995) proposed an alternative approach that controls the false discovery rate (FDR), which is the proportion of rejected hypotheses that are incorrectly rejected. Consider testing $H_1, H_2, \ldots, H_m$, based on the corresponding $p$-values $P_1, P_2, \ldots, P_m$. Let $P_{(1)} \leq P_{(2)} \leq \ldots \leq P_{(m)}$ be the ordered $p$-values and their corresponding hypotheses be $H_{(1)}, H_{(2)}, \ldots, H_{(m)}$. To control the FDR at a level $\alpha$, and let $k$ be the largest $i$ for which $P_{(i)} \leq \alpha(i/m)$, then reject all $H_{(i)}, i < k$. FDR-based correction is less conservative and may reject more null hypotheses than an FWER-based method does as long as the proportion of incorrect rejections is controlled.

Both of the above correction procedures (FWER or FDR) assume that the hypotheses are independent from each other. When dependence exist among the hypotheses to be tested, which is the case for most local statistics as their neighborhoods overlap and spatial autocorrelation may exist, the above procedures may need further adjustments (Getis and Ord 2000; Benjamini and Yekutieli 2001). To correct the Bonferroni method for the overlapping problem, Getis and Ord (2000) use $\alpha/v$ (instead of $\alpha/m$) as the control level, where $v$ is the estimated number of nonoverlapping local regions.

**Spatial and space–time scan statistics**

Spatial scan statistics is a special type of local spatial statistics that is applicable for point event analysis to detect significant spatial clusters of events, such as hotspots of crimes or unusual concentration of disease cases. Spatial scan statistics uses both computational algorithms and statistical assessments to find areas with a significant excess of observed event points, for example, disease incidents.

There are three major differences between a spatial scan statistics and the local spatial statistics (e.g., Moran’s I and Geary’s C) introduced earlier. First, spatial scan statistics is mainly applied to point event data while local spatial statistics is mostly for spatial lattice data. Point event data can be aggregated to lattice data, for which spatial scan statistics is still applicable. Second, spatial scan statistics compares the total number of events in a neighborhood with its expected count, while local statistics examines the similarity of attribute values within the neighborhood. In other words, spatial scan statistics treats a neighborhood as a new and single unit. Third, spatial scan statistics attempts to enumerate all possible neighborhoods at different scales (i.e., with different bandwidth values), while local spatial statistics primarily focus on one scale (which is determined by the given units and the bandwidth selection). Theoretically, spatial scan statistics avoids the MAUP problem to a large extent and is able to find the appropriate scale for the strongest pattern.

A spatial scan statistic usually consists of the following steps:

1. Define a computational strategy to enumerate a large set of local neighborhoods (areas) that are candidates for spatial clusters. For example, a neighborhood can be defined as the area within a distance to a location. By varying the distance threshold, neighborhoods of different sizes can be created. Theoretically, all possible neighborhoods can be created and tested. However, to achieve computational tractability and statistical test power, circular or eclipse-shaped neighborhoods are most commonly used.

2. Calculate a test statistic for each local area based on the number of events and (optionally) the background population (such as population at risk for a disease). As such, the test statistics takes into account the
neighborhood size so that statistics values of different neighborhoods can be compared.

3 Test the significance level of the test statistic values, one for each neighborhood. For most applications, the theoretical distribution of the test statistics under the null hypothesis is not known and, therefore, a Monte Carlo permutation approach is often used. The multiple-testing problem should be addressed in the testing process.

An earlier example of such spatial scan statistics is the geographic analysis machine (GAM) by Openshaw (Openshaw et al. 1987; Openshaw, Cross, and Charlton 1990), which follows the above general steps and uses a Monte Carlo approach to perform significance test for each local statistics. The GAM defines 2-D grids covering the study area, sets a minimum and a maximum circle radius, and a size increment. For each grid point and a specific radius, compute the test statistic value (which is the count of events in the circle). To obtain a significant level, the test statistic value is then compared with the statistic values from a large number (e.g., 500) of permutation datasets, each of which is generated separately under the null hypothesis. To generate a permutation dataset, the events (e.g., disease cases) in the data are randomly re-assigned to the population at risk. A potential problem with the GAM is that it is difficult to adjust for the multiple-testing problem (Rogerson and Yamada 2009).

The spatial scan statistics developed by (Kulldorff 1997) calculates a likelihood ratio for each neighborhood. Let $p$ be the risk within a neighborhood $Z$ and $q$ the risk outside the neighborhood $Z$ in the study area. The null hypothesis is that $H_0$: $p = q$, and the alternative hypothesis is $H_A$: $p > q$ (or $p < q$). With the Poisson model, the test statistic, likelihood ratio ($\lambda$), for neighborhood $Z$ is defined as:

$$\lambda = \frac{\binom{O_Z}{P_Z} \binom{O_W - O_Z}{P_W - P_Z}^{O_W - O_Z}}{\binom{O_W}{P_W}^{O_W}} I \left( \frac{O_Z}{P_Z} > \frac{O_W - O_Z}{P_W - P_Z} \right)$$

(5)

where $O_Z$ and $P_Z$ denote the count of observations (e.g., disease cases) and the population within $Z$, respectively; $O_W$ and $P_W$ are the counts of observations and population for the whole study area. The likelihood ratio calculation based on the Bernoulli model is also provided in Kulldorff (1997). Different from the GAM, the spatial scan statistic by Kulldorff uses the maximum likelihood ratio of all enumerated neighborhoods as the test statistic. Therefore, the method only reports the most likely cluster, although a set of secondary clusters is also provided (but not declared significant). This can effectively avoid the multiple-testing problem, at the sacrifice of missing additional clusters. To derive the significance level, a Monte Carlo procedure is used to generate a large number (e.g., 999) of permutation datasets under the null hypothesis. For each permutation dataset, the test statistic (i.e., the maximum likelihood ratio) is found over all enumerated neighborhoods. Then the actual test statistic value is compared to the test values of all permutation datasets to derive the significance level for the most likely cluster. A significance level can also be attached to secondary clusters but they will not be declared significant even if their $p$-values are less than the critical level (e.g., 0.05). Later Kulldorff et al. (2006) extended the circular scan statistic by using ellipses as scanning windows; this has more varying parameters, including major axis, minor axis, and angle. The new likelihood ratio also considers a noncompactness penalty. Readers are referred Kulldorff (1997) and Kulldorff et al. (2006) for a detailed methodology explanation.
The spatial scan statistics can be extended to space–time event data with an added temporal dimension. Space–time scan statistics analyzes the incidents using both spatial and temporal information, in which the scan “window” (or neighborhood) is a cylinder with three dimensions (Figure 2). The base of a cylinder represents a 2-D circular window in the geographic space, while the height of the cylinder represents a time range. Similar to space scan statistics, the radius of the base and the height of the cylinder vary systematically, so that the cylindrical windows cover each possible combination of location and time. There are two types of space–time scan statistics: prospective space–time scan statistics and space–time permutation scan statistics. The prospective analyses only evaluate the cylinders that the ending time is “current,” that is, each cylinder (potential cluster) is still active (Kulldorff 2001). Prospective space–time statistics can be used to monitor and detect disease outbreaks early by comparing current pattern with historical trends. Alternatively, space–time permutation statistics primarily examines the space–time interaction without using population at risk, which is often unavailable, such as the population at risk for patients visiting a hospital with flu symptom (Kulldorff et al. 2005).

### Geographically weighted regression

Different from the above methods that detect univariate or point event clusters in space, regression analysis is commonly used to detect multivariate relationships among spatially referenced variables. However, there are a number of assumptions underlying the basic regression model that spatial data may not satisfy. One is that the observations should be independent of one another, which is often not true with spatial data due to the existence of spatial autocorrelation. This means that the regression model’s residuals might exhibit spatial dependence and lead to biased parameter estimates, which are either too high or too low as an estimate of the unknown true value. To address this issue, a number of spatial regression models have been developed, such as the spatial error model and the spatial lag model, which incorporate dependent variable values or residual values in each location’s neighborhood to explicitly model and use spatial autocorrelation for prediction. These models are considered model-based and confirmatory methods, and thus are not covered here. Details on spatial regression models are given in Cressie (1993) and other related papers.

Spatial heterogeneity is another challenge for regression analysis of spatial data. Generally, a single regression model is configured with all input data, which thus assumes that the relationship being modeled is the same everywhere within the study area. However, this is often not the case with spatial data, as the relationship might vary across space, which is referred to as spatial heterogeneity or spatial nonstationarity, as explained earlier. An early example of a regression model that attempts to deal with spatial
heterogeneity is the spatial expansion method (Casetti 1972), in which the model parameters are functions of location. Geographically weighted regression (GWR) is a more recent method for addressing spatial nonstationarity in regression analysis. GWR extends traditional regression analysis by allowing local rather than global parameters to be estimated (Brunsdon, Fotheringham, and Charlton 1996; Fotheringham, Brunsdon, and Charlton 2002). For each point in the geographic space, a regression analysis is performed on the data in the neighborhood around that point, where the neighborhood (or bandwidth) can be defined in several different ways, similar to the neighborhood model used previously in spatial smoothing and kernel density estimation methods. In estimating the regression model at a location \( u \), the observations that are closer to \( u \) will have a greater weight in the estimation than observations further away from \( u \). The equation for GWR is:

\[
y_i = \beta_0(u_i, v_i) + \sum_k \beta_k(u_i, v_i)x_{ik} + \varepsilon_i
\]

where \( y_i \) is the prediction for the dependent variable at location \( (u_i, v_i) \) and \( \beta_k(u_i, v_i) \) is the parameter for the \( k \)th independent variable at the location. The bandwidth in the kernel determines the number of observations and their weights being used in estimating the regression parameters.

As an exploratory spatial analysis method, GWR outputs a surface of estimates for each parameter and diagnostic (e.g., standard error and residual), which can help understand how the parameters change over space. With the kernel-based weighting and smoothing, nearby locations will have similar parameter estimates. As with other kernel-based approaches, the choice of kernel does not substantially affect the result while the selection of bandwidth can affect the outcome significantly. Therefore, it is important to choose an “optimal” bandwidth. When the spatial units are not evenly distributed in space, an adaptive bandwidth should be used, where each neighborhood will have the same number of spatial units and, thus, the same number of sample points. To find an optimal value for the bandwidth (i.e., number of sample points), GWR uses the corrected akaike information criterion (AICc), which compares different models considering the estimate of the standard deviation of the residuals and a penalty for the model complexity. The bandwidth with the lowest AICc is used in the estimation of the model parameters. The user may also choose a different bandwidth based on practical reasons or prior knowledge.

GWR provides an effective approach for examining spatially varying regression models and explores how independent variables affect the dependent variable in different ways from place to place. In the application of GWR, there are a number of aspects that need careful attention. First, to test the significance of parameter estimates in each local regression model, the multiple-testing problem should be taken care of according to the discussion in the section on Local statistics. Second, while examining the surface of parameter estimation is useful, it is also important to distinguish whether such variation in space is significant or not, that is, does GWR make a significant improvement in prediction over the global regression model for the specific analysis task? The AICc measure can be used for this purpose (Fotheringham, Brunsdon, and Charlton 2002). Third, GWR addresses the spatial nonstationarity problem by constructing local regression models. However, each local model may still suffer the spatial autocorrelation problem, that is, observation data are not independent from each other. Fourth, GWR allows parameter estimates of a regression model change over space while assuming that the model form does not change, that is, a linear
relationship for every neighborhood. Practically this is reasonable as nonlinear relationships are more difficult to model within a local neighborhood. Variable transformations, such as a logarithmic transformation, may be applied before the application of GWR to better model nonlinear relationship if there is prior knowledge of the relationship form.

Clustering, spatial clustering, and regionalization

General-purpose clustering

The previously introduced methods of local spatial statistics and scan statistics are to detect spatial areas (clusters) with excessive concentrations of point events or high (or low) attribute values, where the clusters only represent a portion of the input data. This section introduces another type of clustering analysis, which is to organize or partition the input data into a number of clusters based on the similarity among data items. Data items in the same group (cluster) are more similar to each other than those belong to different groups. The clusters together cover all data items, that is, every item in the data belongs to a cluster. Clustering analysis is also called unsupervised learning or numerical taxonomy, which is to discover the inherent structure (grouping) of observed items and group them accordingly to extract high-level labels and descriptions. Clustering has been studied extensively in many disciplines, such as statistics, computer science, biology, psychiatry, psychology, archaeology, geology, geography, and marketing. General clustering methods can be broadly classified into two groups: hierarchical clustering and partitioning clustering. Figure 3 shows an overview of different types of clustering methods, some of which are briefly introduced below.

Hierarchical clustering organizes observations into a hierarchy with a sequence of nested partitions or groupings. Commonly used hierarchical clustering methods include the Ward’s method, single-linkage clustering, average-linkage clustering, complete-linkage clustering, and model-based clustering (Fraley 1998; Jain, Murty, and Flynn 1999). Hierarchical clustering results are normally visualized with dendrograms, which are useful to help users examine patterns (clusters) at different scales and determine how many clusters should be obtained. To build the cluster hierarchy, a method often follows one of two general strategies: (i) a bottom-up agglomerative process – each observation starts in its own cluster and the most similar pair of clusters is merged as the hierarchy moves up; or (ii) a top-down divisive approach – all observations start in one cluster and splits are performed recursively when moving down the hierarchy. During the merge (or division) process, an objective function or a heuristic can be used to determine the best merge (or split). Figure 4 shows the clustering results of two hierarchical clustering methods: single linkage and complete linkage. The two methods are both agglomerative methods and only differ in their definition of “distance” between two clusters. The single-linkage method uses the distance between the nearest pair of points that connect two clusters as the distance between the two clusters, while the complete linkage method uses the distance between the farthest pair of points. This difference leads to the different results shown in Figure 4.

Partitioning clustering methods divide the input set of observations into a number of nonoverlapping clusters. A data item is assigned to the “closest” cluster based on a proximity or other dissimilarity measure. Commonly used partitioning clustering methods include the k-means and the expectation maximization (EM) methods. For example, k-means clustering
Partitioning clustering
- Distance-based methods (e.g., k-means)
- Model-based methods (e.g., expectation maximization)
- Density-based methods (e.g., DBSCAN)
- Neighborhood-based methods (e.g., OPTICS)
- Grid-based methods (e.g., CLIQUE)

Hierarchical clustering
- Distance-based methods (e.g., single linkage, average linkage, and complete linkage)
- Model-based methods (e.g., Fraley 1998)
- Density-based methods (e.g., expectation maximization)
- Neighborhood-based methods (e.g., OPTICS)
- Grid-based methods (e.g., grid clustering)

**Figure 3** A classification of clustering methods. Adapted from GeoInformatica, ICEAGE: Interactive Clustering and Exploration of Large and High-dimensional Geodata, 7(3), 2003, 229–253, Guo, D., D. Peuquet and M. Gahegan © With permission of Springer.

**Figure 4** Hierarchical clustering results of the single-linkage method (left) and the complete-linkage method (right), using the same 1-D dataset of 10 data points.

is an optimization problem that tries to find \( k \) cluster centers in the data and assign each data item to the nearest cluster center such that the total squared distances from data points to their corresponding cluster center are minimized. However, to be able to process large data in practice, the k-means algorithm uses a heuristic-based and iterative procedure to find a local optimum. Most partitioning clustering methods require that the number of clusters \( k \) be given, which is one of the disadvantage of these methods. Self-organizing map is a special partitioning clustering method, which not only segments data into clusters but also orders the clusters in a 2-D layout so that nearby clusters are similar to each other, which partially avoids the need for specifying an exact number of clusters beforehand. A comprehensive review of different clustering methods can be found in Jain, Murty, and Flynn (1999).

**Spatial clustering and regionalization**

There are three main strategies to incorporate spatial information in a spatial clustering process.
The first strategy derives clusters based on multivariate data with nonspatial clustering methods and then maps the clusters in the geographic space to understand the spatial meaning and distribution of clusters. This strategy is straightforward and requires minimum modification to the clustering method. However, it cannot capture spatial patterns in the clustering process and can only rely on user interpretation to link clusters to their spatial context.

The second strategy is to directly use spatial coordinates or spatial distance definition in the clustering process, which may solely be based on geographic coordinates (e.g., clustering of spatial point events) or a combination of spatial and nonspatial information (e.g., clustering spatial objects with multivariate information and spatial locations). This type of approach represents the majority of spatial clustering applications, as it can incorporate various context-dependent geographic metrics, such as network distance, travel time, barrier and impedance factors, into the clustering process. The challenge with these approaches, particularly when spatial and nonspatial information are both considered, is how to determine an appropriate way to weigh and combine spatial similarity with nonspatial (attribute) similarity, which subsequently may cause difficulties in interpreting the clusters. Similar to general-purpose clustering methods summarized in Figure 3, spatial clustering methods can also be partitioning, hierarchical, density-based, or grid-based. Readers are referred to Han, Kamber, and Tung (2001) for a comprehensive review of various spatial clustering methods.

The third type of approach imposes geographic constraints (such as geographic contiguity) in the clustering process. Regionalization is a special form of spatial clustering that seeks to group spatial objects into spatially contiguous clusters (based on a contiguity definition) while optimizing an objective function. Regionalization has been widely used in many application problems, such as the delineation of climatic regions, defining eco-regions, and map generalization. Existing regionalization methods that are based on a clustering concept can be classified into three groups: (i) multivariate (nonspatial) clustering followed by spatial processing to rearrange clusters into regions; (ii) clustering with a spatially-weighted dissimilarity measure, which can consider spatial distance as a factor in forming clusters but cannot guarantee that each cluster is contiguous in space; and (iii) contiguity-constrained clustering that enforces spatial contiguity during the clustering process. Recent reviews of different regionalization can be found in Duque, Ramos, and Surinach (2007) and Guo (2008). Regionalization methods are often extensions of a general-purpose clustering method by explicitly enforcing a spatial contiguity constraint in the process. Therefore, regionalization methods can be grouped into partitioning and hierarchical methods as well, which also allows the use of multiple variables to define cluster similarities and the incorporation of different contiguity definitions (such as contiguity on a road network).

Challenges in clustering analysis

As evident in the introduction above, there are a large number of clustering algorithms in the literature. Actually, an existing clustering method can easily be customized or a new clustering method designed by modifying one or more components in the clustering process, such as data representation, distance measure, and clustering procedure. As such, it becomes a major challenge for the user to choose (or design) an appropriate clustering method suitable for the problem at hand. Each method can be unique in a number of aspects:
the input data type, which may be numerical, categorical, network, spatial, image, or a mix of different types;
• the definition of “cluster,” which can be hierarchical, density-based, connection-based, distance-based, distribution-based, or a combination of them;
• the definition of distance (i.e., dissimilarity), which should effectively enable the construction of clusters;
• the strategy to group or divide data into clusters based on the above definitions;
• the number of parameters in controlling the above definitions and clustering process.

Different methods may produce dramatically different results. Even for the same method, different data inputs, data transformation or parameter setting can lead to quite different clusters. Therefore, it is critical in clustering analysis to carefully address the following questions:

• What data attributes should be included and how should the data be normalized and weighted?
• What is considered a cluster and what similarity (distance) measure is appropriate for the given situation?
• How to construct clusters given the data and definitions? How to balance efficiency in processing the data and the accuracy in finding clusters?
• How should domain knowledge be integrated in a particular clustering problem?
• How many clusters should be obtained and how to validate the clusters?
• Application-specific requirements, constraints, interpretation, and validation.

Given a data input, all clustering algorithms will produce clusters regardless of whether the data contain inherent clusters or not. Therefore, it is important to assess the output clusters, which may take one of two types of validation approaches: internal evaluation and external evaluation. Internal evaluation examines the clustering result based on the input data, which assign the best score to the algorithm that produces clusters with high similarity within a cluster and low similarity between clusters. Commonly used measures or indices for internal evaluation include the Davies–Bouldin index, Dunn index, and the silhouette coefficient. On the other hand, external evaluation assesses the clustering result based on external benchmark datasets with known cluster labels, which measure how close the clustering outcome is to the predetermined benchmark classes. This type of evaluation, however, should consider the fact that the performance not only depends on the clustering algorithm but also on the input data. If the input data do not contain the needed attributes to distinguish the clusters, then, no matter which method is used, the clustering result will not be very useful. Commonly used external evaluation measures or indices include the Rand measure, F-measure, Jaccard index, and the Fowlkes–Mallows index.

Geovisualization and visual analytics

Geovisualization concerns the development of theories and methods to facilitate knowledge construction through visual exploration and analysis of geospatial data, and the implementation of visual tools for subsequent knowledge retrieval, synthesis, communication, and use (MacEachren and Kraak 2001). Mapping is essential in geographic data visualization, which is often coupled with other information graphics, such as tables, histograms, scatter plots, charts, and more sophisticated multidimensional visualization techniques. The main difference between
traditional cartography and geovisualization is that the former focuses more on the design and use of maps for the communication of known information while geovisualization emphasizes the discovery of unknown information with highly interactive maps and computational algorithms for data exploration, hypothesis generation, and knowledge construction. For example, there are many geovisualization methods for multidimensional spatial data analysis, for example, scatterplot matrices, pixel-oriented approaches, parallel coordinates plots (PCP), and the dynamic linking between one or more of these nonspatial multivariate representations and geographic mapping. With linked representations (i.e., multiple views), users can construct a complex and comprehensive understanding of multivariate, spatial, and spatiotemporal patterns.

To cope with today’s big and complex spatial datasets, geovisualization involves active research to address several major challenges: (i) processing big datasets efficiently; (ii) handling multiple perspectives and many variables simultaneously to discover complex patterns; and (iii) designing effective user interface and interactive strategies to facilitate a user-centered discovery process. Due to limited visual space (e.g., monitor screens), large data volume can cause cluttered visual displays (e.g., points overlapping in a scatter plot) and make it difficult (if possible at all) for the analyst to visually perceive patterns. Large amounts of data also require a considerable amount of time to process, which is a huge challenge for interactive analysis. One solution is to rely on the user to dynamically filter, select, zoom, and adjust detail levels in the visualization, meaning that only a small subset of data is visualized at one time. Another type of solution is to combine efficient computational methods, such as clustering, classification, and association rule mining, with geovisualization, with the former finding patterns quickly and the latter helping users explore and understand the patterns.

To visualize multiple perspectives, such as space, time, and multivariate dimensions, it is often necessary to couple multiple visualization components (one for each perspective), integrate with dimension reduction techniques (to help compress high-dimensional data to a low-dimensional representation), and allow user interactions to seek patterns across perspectives. Different visual components are chosen according to the specific type of data or perspective to be visualized. For example, a map is needed for presenting spatial distribution and location patterns; a trend plot is needed for temporal patterns; and multidimensional visualization techniques are needed for understanding multivariate patterns. These components have to be linked to allow a holistic understanding of patterns across different perspectives; this is often referred to as multiple linked views. The “linking” among different views can be achieved through two main strategies: linking through visual identifiers such as color (e.g., the same object is assigned the same color in different views) and linking through user interaction (e.g., when a user selects a data object in one view, the same object will be highlighted in all other views). Each strategy has its advantages and limitations. Visual linking allows a quick overview of holistic patterns without user interaction but it relies on a small set of a clearly defined identifier (such as different colors or labels), thus is unable to simultaneously support linking too many patterns. Therefore, dimension reduction and computational grouping are often needed to extract major patterns and skip details, using methods such as multidimensional scaling, principal components analysis (PCA), self-organizing maps, or clustering methods. Interactive linking, on the other hand, can allow more details to be presented upon request but
cannot support a quick overview. In practice, these two strategies are often used together, following the well-known visual information seeking mantra: “overview first, zoom and filter, then details on demand” (Shneiderman 1996).

Research efforts for the third challenge have emerged as an active field called visual analytics, which is “the science of analytical reasoning facilitated by interactive visual interfaces” (Thomas and Cook 2005). Visual analytics is an interdisciplinary field that involves computer science, information visualization, cognitive and perceptual sciences, interactive design, graphic design, and different application domains such as social sciences. The design of the visual analytics tools and techniques is based on cognitive and perceptual principles, with a goal of supporting analytical reasoning and engaging human judgments in analyzing data and addressing complex tasks. Related to, but different from, scientific visualization and information visualization, visual analytics is especially concerned with coupling interactive visual representations with underlying analytical processes to address high-level and complex tasks, such as sense making, reasoning, and decision-making. Geo-visual analytics specifically focus on geographical data and problems, with strong involvement of methodologies and research advancement in the geographic information and spatial sciences, such as geovisualization, geospatial semantics and knowledge management, geocomputation, spatial data mining, and various spatial domains such as emergency management, public health, and citizen participatory decision-making.

Geovisualization methodologies may also be highly specialized for different data types, such as multivariate spatial lattice data (such as climate data), space–time event data (such as crimes, traffic accidents and jams), spatial interaction data (i.e., origin–destination data such as migration), trajectory data (such as human daily activities, vehicle trajectories), and georeferenced documents and social media data (such as web documents and tweets). The methodologies may also differ for different analysis tasks, such as real-time monitoring, spatiotemporal pattern discovery, participatory decision-making, or emergency response support. Two examples of geovisualization methodology are briefly introduced here; one is multivariate mapping for climate data analysis, the other is flow mapping for migration data analysis.

### Multivariate mapping

Methods for multivariate mapping can be classified into three main types. The first type, such as composite glyphs, depicts each variable with a certain visual attribute (such as color, shape, size, or orientation) and then integrates all variable depictions into one symbol to plot on a map. For example, the Chernoff face approach maps multivariate data by relating variables to different facial features (such as mouth, eye, and eyebrow) to create a face icon for each data object and then draws each face icon on a map at the location of the data object. However, this type of approach can only work with small datasets, as too many icons on a map will make the map cluttered and ineffective to allow pattern discovery. The second type uses multiple linked views (including maps) that show one (or more) variables per view and different views. The third type summarizes the multivariate data to a lower-dimensional space through clustering analysis and then visualizes the clusters with maps, plots, and other visual forms.

Figure 5 shows an example of the SOMVIS multivariate mapping (Guo et al. 2005, 2006), which couples a self-organizing map, multidimensional visualization (a parallel coordinate plot), and a map component. The method is a combination of the second and third types introduced above. Using the the monthly mean
surface air temperature for 60 years (January 1948–December 2007), an anomaly value, that is, the difference between the 40-year average (1948–1987) and the latest 10-year average (1998–2007), is calculated for each month and each grid cell in order to analyze temperature change patterns globally. The self-organizing map groups all grid cells into 49 clusters based on their twelve anomaly values (one for each month). The clusters are then colored with a systematic coloring scheme to support visual linking among multiple views. The parallel coordinate plot and the map visualize the multivariate meaning and spatial distribution of these clusters, respectively. For example, the red/reddish clusters, primarily located in the Arctic area, have high positive values for winter months (November, December, January, and February) and around zero (i.e., no change) for summer months (June, July, and August). This means that during the past decade, the Arctic area was much warmer than before in winter.
but relatively stable during summer. In contrast, the green/light-green clusters, mainly located in the Antarctic area, have high positive values for its winter months (April–September) and negative values for its summer months (January, February, November, and December). This means that during the past decade, the Antarctic area was much warmer in winter but cooler during summer. These patterns involve space (i.e., place-to-place differences in climate change patterns) and time (which is treated as multivariate information, i.e., 12 months as 12 variables), which cannot be easily discovered without the combination of clustering, multidimensional visualization, and mapping. The three views also support interactive linking; a grid cell or a cluster can be selected in any view and the selection will be highlighted in other views.

### Flow mapping

Flow mapping has long been used in a wide range of applications, such as human migration, transportation, commodity flow, and commuting (Tobler 1981, 1987). Two of the major challenges for flow mapping are: the visual cluttering problem – maps become illegible with too many flows plotted on top of each other; and the modifiable area unit (MAUP) and unit size problem – flow volumes are highly correlated with unit sizes, for example, population.

To address the visual cluttering problem, a number of approaches have been proposed based on: location aggregation, surface generation, or edge rerouting. A review of aggregation methods for movement data can be found in Andrienko and Andrienko (2002). However, aggregation will inevitably cause a significant loss of information, skip flow patterns at local scales, and suffer from the modifiable areal unit problem. Surface generation approaches produce a vector flow surface that only maps flows between geographically adjacent places (Tobler 1987), where a long-range flow is decomposed to a sequence of short flows. The limitation is that the origin and destination information of each particular flow is lost. The third group of approaches focuses on minimizing edge crossing (and thus reduce cluttering) in flow maps through edge rerouting (Phan et al. 2005) or edge bundling (Cui et al. 2008; Holten and van Wijk 2009; Verbeek, Buchin, and Speckmann 2011), which reroute or bundle edges to improve the visual clarity of flow maps. These methods are effective in producing aesthetic representation of flow data, especially for small datasets. On the other hand, the main limitation of this type of approach is that bundled edges make it difficult to perceive the actual connection between specific pairs of origin and destination.

There is also a variety of methods for flow visualization based on nonspatial views, such as ordered matrices, combinations of maps and matrices, interactive OD maps, and exploratory visualization. Normally, interactive visualization systems do not intend to summarize the entire dataset in a single flow map. Instead, they provide a nonspatial view (such as a matrix) and rely on user interactions to select data to map and explore flow patterns through an iterative process. These nonspatial approaches avoid, to a certain degree, the visual cluttering problem but they cannot provide a clear overview of spatial flow patterns. There are also methods for summarizing flow properties for each location using graph measures such as net migration ratio, centrality, and flow density (the number of flows passing a pixel) (Rae 2009). The kernel-based smoothing and density estimation methods introduced earlier can be extended or customized for mapping locational characteristics of flows (but not the actual flows) (Scheepens et al. 2012).
Different from the above location-based summary measures, a flow density estimation and flow mapping method has recently been developed to map flow patterns; it can address both the cluttering problem and the modifiable unit problem (Guo and Zhu 2014). This approach first estimates a normalized flow volume (or density) between each pair of origin and destination; then selects major representative flows to filter out less-important details and produce a flow map of overall flow patterns. For example, the United States county-to-county migration data collected by the Census Bureau contains migration flows among over 3000 counties, with more than a million flow paths. The flow volumes are not comparable to each other since county populations vary dramatically. Moreover, when focusing a specific age group (e.g., senior migrants of age 65–69), the flow from one county to another county can be very low or even none. Therefore, it is necessary to go beyond the default geographic units and examine flows between meaningful and comparable areas. Figure 6 shows the smoothed migration map for senior migrants of age 65–69; it shows that senior migrants in the east had a strong preference for Florida (particularly West and South Florida) while those in the west were more likely to move to Arizona or its surrounding area. For the metropolitan areas in the north (such as Minneapolis, Detroit, and Boston) there is also a senior migration trend towards the areas further

Spatial data mining and geographic knowledge discovery

Nowadays the availability of big and high-resolution spatial and spatiotemporal data provides opportunities for gaining new knowledge and better understanding of complex geographic phenomena and addressing urgent real-world problems, such as human–environment interaction, geosocial dynamics, global climate change, and pandemic flu spread. However, most traditional spatial analysis methods were developed in an era when data were relatively scarce and computational power was not as powerful as it is today (Miller and Han 2009). Existing methods often focus on a limited perspective or a specific type of model. With newly emerged data types, such as mobility, trajectories, social media, and volunteered geographic information on the web, there is a strong need for new approaches to analyze big and heterogeneous data sources and discover complex structures and new types of patterns (Guo and Mennis 2009).

To address these challenges, spatial data mining and geographic knowledge discovery has emerged as an active research field, focusing on the development of theory, methodology, and practice for the extraction of useful information and knowledge from big and complex spatial databases. Spatial data mining has deep roots in traditional spatial analysis fields (such as spatial statistics, analytical cartography, and exploratory spatial data analysis) and various data mining areas in statistics and computer science, such as clustering, classification, association rule mining, information visualization, and visual analytics. As an expansion of traditional exploratory spatial data analysis, spatial data mining and geographic knowledge discovery has several new perspectives. It tends to focus on much larger and more complex datasets and research problems. Data mining and knowledge discovery emphasize an iterative process that involves multiple steps, including data preprocessing, incorporation of prior knowledge, computational analysis, visual exploration, formulation of hypotheses, evaluation of results, and feedback on next iteration (Fayyad, Piatetsky-Shapiro, and Smyth 1996). It is exploratory in nature but more inductive and data-driven than traditional methods. For more information, readers are referred to the entry on Geographic data mining.

EXPLORATORY SPATIAL DATA ANALYSIS

Export processing zones

Dennis Arnold
University of Amsterdam, Netherlands

In the past half-century major transformations have occurred in the global economy as production networks originating in “core” capitalist economies have expanded their sourcing networks into new frontier regions of production across Asia, Latin America, Eastern Europe, and Africa. Foreign direct investment (FDI) has been the most important vehicle for bringing goods and services to foreign markets and for integrating national and subregional production systems. Assembly-based export processing zones (EPZ) and more recently special economic zones (SEZ) have remained a central means to attract and contain FDI in developing and emerging market economies. While the global trade and investment context from which assembly-based EPZs emerged has changed significantly in recent years, so too has zone development and administration.

SEZs are defined as geographically delimited areas, frequently physically secured, that are usually, but not always, outside the customs territory of the host country. SEZs are generally implemented to meet fiscal, social, and infrastructure policy rationales. The most important fiscal goal of an SEZ is to facilitate economic growth through the use of reduced tariffs and more efficient customs controls. They are also tools for companies seeking to cut costs and improve inventory efficiency, and they often address developing nations’ inefficient trade policies and physical infrastructure. They range in size from single factories to large cities. SEZs are under single management, either government or private sector. Businesses located within SEZs are normally eligible for benefits such as duty and tax exemptions on goods based on the fact that they are physically located within the zone. SEZ has become the generic term encompassing a broad range of economic zones, including free ports, free zones, foreign trade zones, industrial processing zones, science and industrial parks, logistics hubs, and EPZs, the focus of this entry. Many countries employ their own variations of these special enclaves, and use their own terminology. For example, Mexico refers to its SEZs as *maquiladoras*, Ghana, Cameroon, and Jordan have industrial free zones, and the Philippines calls its economic zones special export processing zones.

EPZ and SEZ definitions are, for the most part, synonymous. EPZs specifically focus on manufactured goods that are largely aimed for export markets. EPZ and assembly-based SEZ objectives are to create new jobs, boost growth in trade, exports, and foreign exchange earnings, facilitate economic diversification and industrialization, and provide access to foreign technology and management expertise. They provide a functional advantage to investors seeking to capitalize on the economies of scale that a geographic concentration of production and manufacturing may bring to a trade region. They compete primarily on the basis of fiscal and tax incentives, differential labor regulation mechanisms such as reducing or altogether banning trade union activity, relaxed environmental regulations, and/or proximity to major markets. For the latest generation of zones, EPZ is increasingly an anachronism, as most countries
So label manufacturing and assembly zones as SEZs, an obvious association with China’s zones.

The experience of SEZs and the benefits that they bring is a subject of much debate. While these zones can create jobs, promote investment, and catalyze regional development, they can also be associated with labor abuse, limited social and economic upgrading, low levels of investment, and excessive establishment costs (Nel and Rogerson 2013). Labor activists campaigned against restrictions on freedom of association, collective bargaining, and other basic rights in SEZs. Dispossessed farmers and peasants have mounted large-scale protests over state practices in acquiring land for the zones. The world’s most successful zones have been established in East Asia’s newly industrializing countries, and their achievements have not been uniformly replicated in the developing world’s less prosperous environs, particularly countries with small markets. SEZs tend to benefit FDI and larger domestic investors most in the short term; they are not a direct solution for the development of local small and medium enterprise development. While certain zones have demonstrated more positive long-run economic impacts, many neoclassical and neoliberal thinkers and institutions criticized zones for hindering economy-wide liberalization (Farole 2011; FIAS 2008). By the late 1990s it appeared that SEZs would be relegated to a footnote of history.

Despite criticisms, the number of zones has continued to expand over the past 40 years. From 1975 to 2006 the number of SEZs increased from 79 in 25 countries, to approximately 3500 zones in 135 countries, clustered mainly in Asia and the Pacific and the Americas (FIAS 2008). Globally, zones account for approximately $200 billion in gross exports per annum and directly employ some 66 million workers (FIAS 2008). EPZs and assembly-oriented SEZs remain central to many late industrializing countries’ development models (Figure 1).

**Historical evolution of zones**

Free zones have existed for centuries. They were originally established to encourage entrepôt trade, and mostly took the form of citywide zones located on international trade routes. Examples include Gibraltar (1704), Singapore (1819), Hong Kong (1848), Hamburg (1888), and Copenhagen (1891). By 1900, 11 free trade zones (FTZs) existed globally; of these, seven were in Europe and four in Asia (Farole 2011). Manufacturing entered the realm of free trade zone activities in the twentieth century. The Spanish FTZs established in the 1920s were among the first to accommodate industrial production, hosting one of the first Ford Motors plants in Europe. This and other examples of early manufacturing programs in FTZs were of limited scope and the focus remained very much on trade. The next major “innovation” in zone administration and policy was the introduction of export-orientation in developing countries. The 1948 Operation Bootstrap in the US Commonwealth of Puerto Rico was a key moment in changing SEZ policy and orientation. The program offered low cost labor to attract US firms to set up manufacturing operations to serve the mainland US market.

From the mid-1960s on, economic development strategies in industrializing countries took one of two forms (with combinations beyond the scope of this entry): import substitution and export-oriented industrialization. EPZs acted as globalization catalysts. The modern variation of the manufacturing-oriented zone is traced back to Shannon, Ireland, where an EPZ was set up in 1958. The Shannon approach was original because it combined the attributes of
the free trade zone with those of the industrial park into a single, integrated investment, industry, and trade development instrument (Farole 2011). It was followed by EPZs in Kaohsiung, Taiwan, and Kandla, India, established in 1965. These early EPZ policies were replicated in numerous developing countries, perhaps not coincidentally typically in authoritarian states, in the subsequent decades. South Korea opened its first zone, Masan, in 1971. Indonesia, Malaysia, the Philippines, Thailand, Singapore, and Sri Lanka all developed zones in this period as they shifted from import substitution to export-led development.

Mexico’s *maquiladora* program was another early and prominent assembly zone. Its overarching goal was to compensate for the termination of the US Bracero Program in 1964, a program initiated in 1942 which governed the flow of contract laborers from Mexico to the United States. Its termination left Mexico with a severe shortage of employment opportunities. The new program made surplus labor available to American-owned companies. The *maquiladora* scheme entailed legislation to allow and encourage American manufacturing firms to invest and operate along the border, marking a key moment in the liberalization of Mexico’s economy.

China’s remarkable economic growth over the last 30 years has been partially attributed to its SEZ model – in fact China is the first country to use the term. China’s approach to SEZs has been the most influential application of the policy, and it is not surprising that many developing countries are anxious to emulate at least part of China’s economic success, by adapting SEZs to their countries (Nel and Rogerson 2013). China’s initial SEZs were political experiments in response to stagnant economic growth; the first four zones were initiated in 1980, all near large urban areas pursuing similar objectives, namely to facilitate broad-based comprehensive

---

**Figure 1** EPZs and similar economic zones. Source: Boyenge (2007).
development (Yeung, Lee, and Kee 2009). This evolved into the “open door" policy leading to the establishment of SEZs in 14 coastal cities. Today, China has more than 200 zones of various types, sizes, and sectoral concentrations.

China’s SEZs afforded entry into the world markets, initially in labor intensive light manufacturing industries, and more recently in higher value-added manufacturing and services. For foreign investors, the size, location, flexible labor laws, and stable politics have been among the key factors driving investments. During the 1980s, SEZs drew significant investment from neighboring Hong Kong and Taiwan, but now that investment opportunities are made available throughout China, the current value of SEZs is questionable. Admission to the World Trade Organization (WTO) has further reduced the special attributes of many of the zone policies, as the WTO required that similar policies must apply to the whole country in terms of trade liberalization and foreign investment (Nel and Rogerson 2013). As a result, China has developed a range of new policies to stimulate economic growth. Thus, SEZs were not a “stand-alone” policy option fixed in time and space, rather in China SEZ policy was an element of a much broader policy package of economic reform, economic development, and global engagement relative to the needs of the Chinese economy at that time (Nel and Rogerson 2013). In addition, there were clear efforts to spread the economic benefits of SEZs outside of the privileged zones such that their operational evolution reflected global economic and trade policy shifts (Yeung et al. 2009).

In sum, the global economic context from which assembly-based EPZs emerged in Ireland and transitioned to China’s massive-scale SEZs has changed significantly. From the mid-1960s through the 1990s zones were central components of export-led development and were key to the impressive growth in East and Southeast Asia, and to a lesser extent Mexico. Many have argued that SEZs were losing relevance in the neoliberal era, as trade and investment barriers were disassembled through the WTO and other mechanisms. Meanwhile, global production networks have expanded and export-led development has become global orthodoxy. Global replication of zones has diminished their “special” characteristics. However, the number of SEZs has continued to increase dramatically. Many countries have implemented and replicated assembly-oriented SEZs in the hope of emulating China’s success, catalyzing a global “zone fever.” The following section reviews contemporary zones – their rationale and the challenges they present for labor rights, women, the environment, and land use.

Recent trends and debates

Late industrializing countries, those most likely to initiate the EPZ or assembly-oriented SEZ over the past decade, face an altogether different competitive environment from that faced by the earlier zones. The sheer number of states competing for investment is increasing, while almost all are offering similar incentives, limiting the capacity of all zones to attract FDI. For example, the average number of firms per zone is 35 in Africa compared to 300 in Asia and Latin America (Nel and Rogerson 2013). More specifically, the entrenchment of “factory Asia” leads to higher entry barriers to global production networks (GPN) in textiles and garments and electronics for other world regions; the expiry of the Multi Fibre Arrangement in 2005 has led to greater concentration of textile and garment sourcing, heavily favoring Asian-based producers; and recently slowing demand in traditional export markets has only heightened
global export competition – in which speed to market and production quality play fundamental roles in sourcing decisions, along with labor and other factor costs.

In certain countries and regions the speed with which SEZs have been approved is staggering. For example, the Indian government formally approved 462 SEZs between the enactment of the SEZ Act in 2005 and May 2008 (Banerjee-Guha 2009). The number of SEZs has mushroomed across Africa and zones now exist in over 20 countries (Nel and Rogerson 2013). In Continental Southeast Asia 49 SEZs were approved between 2005 and 2010, with 73 expected by 2015 (Arnold 2012). Recent World Bank research argues that contemporary SEZs have the potential to act as catalytic exclaves that both announce and prepare for liberalization under certain circumstances and provided certain prerequisites have been addressed (Farole 2011). If not, SEZs may, at best, provide limited economic benefits for a limited period and, at worst, may turn into welfare-reducing enclaves that restrict countrywide liberalization. In short, most zone programs continue to be designed as instruments for trade and investment; they continue to be built around low labor costs, trade preferences, and fiscal incentives.

Numerous SEZs have cost the host country more to build than they bring in trade revenues. This has contributed to the rise of privately developed zones and zone development as a form of real estate speculation. In the 1980s, the first privately developed SEZs were created in the Caribbean and Central America to compete with government trade zones that were deemed inefficient with cumbersome regulations. SEZ ownership has gone from 100% government owned and operated in 1975, to roughly 25% privately owned and operated zones in the 1980s, to 62% privately owned and operated zones in the mid-2000s (FIAS 2008).

The increasing privatization of zones does not necessarily entail a withdrawal of the state from zone promotion and regulation. In practice, the most “successful” zones are those intertwined with the national economy, the national investment environment, and the capacity of the government. This gives rise to government offering “one-stop service centers” on site, including customs and import-export officials and labor ministry representatives, for example. At the same time, many programs allow private zone developers to supply electricity and other utilities to the zone, and SEZ programs include provisions for commercial and professional activities. In sum, the increasingly complex intertwining of public and private concerns in zone development and administration may come at the expense of government control and oversight over economic development. Yet it offers a wide range of new opportunities for state involvement, including the finance and real estate speculation of land procured for zones, new forms of territorial control, and the increasing prevalence of politically connected domestic elites turned zone developers, thus combining neoliberal rationality with authoritarian political styles (Arnold 2012). In the past decade zones have been utilized as geopolitical tools, with private and public investors from China expanding its SEZ model globally by establishing “economic cooperation zones” in Africa, and SEZs in Southeast Asia. Zones continue to play a clear role in new forms and experiments with liberalization, land and labor regulation, and urban and regional planning, while social and environmental concerns persist.

Relaxed environmental standards are an incentive to increase profitability, often with severe environmental damage occurring as a consequence. This provides an incentive for relocating production to places where environmental regulation is less stringent. This response to
environmental regulation by enterprises may weaken the state’s determination to enforce environmental regulations. In Tijuana, Mexico, the Rio Grande is so polluted from maquiladora waste that it has caused an increased risk of Hepatitis A. In China, it is estimated that more than 80% of coastal water and about 70% of its rivers are polluted with industrial waste, raw sewage, and agricultural runoff.

Numerous EPZs have thrived as a space for globalized production – as a capital-led strategy for low-cost exports and as a state strategy to absorb surplus labor and attract FDI – yet they have typically failed to create decent jobs (McCallum 2011). Work in EPZs and assembly-based SEZs is synonymous with low pay, excessive overtime, and restrictions on trade union activity. Employment is gendered in the labor intensive sectors such as toy, textile and garment, and electronics manufacturing, the mainstay of EPZs over the past 50 years. The typical zone worker is a young female, rural-urban or international migrant, employed in factories for a relatively short period of time. Once these female workers have children, and/or lose the mental and physical faculties for which they were initially employed, they are dismissed and younger substitutes replace them. In other words, over time workers become a form of industrial waste, at which point they are discarded and replaced (Wright 2006). Yet the contradiction is these workers produce much prosperity through their own industrial destruction (Wright 2006). Despite these and other hardships, EPZ workers are not passive victims of structural forces. China’s light manufacturing workers at the heart of the “world’s factory” have led numerous and large-scale wildcat labor protest for better social and economic entitlements. This has contributed to substantial wage increases over the past 10 years.

Displaced farmers and peasants have also mounted numerous protests in different parts of the world, often in response to insufficient compensation for their land appropriated for an SEZ. This reflects development processes that rest on displacement of the poor to make way for SEZs, and the interrelationship that exists between spatiality of capital and the opening up of new economic spaces (Banerjee-Guha 2009). Displaced farmers not only lose their economic means of survival, but generally lack the skills required to be employed in construction of the zones and supporting infrastructure, and in eventual manufacturing, service, or other industries located in the zones. Yet dispossessed peasants and exploited workers employed in the zones are not mutually exclusive – the relation to one other, as well as state practices and global supply chain dynamics, are crystalized in zone development (Mezzadra and Neilson 2013).

Conclusion

EPZs have changed over time, from manufacturing enclaves effectively shuttered off from a country’s wider political economy, to incubators of economy-wide liberalization. The early EPZs were key components of East and Southeast Asia’s rapid industrialization and economic growth, and later SEZs in China proved to be an experiment with liberalization on the leading edge of an unprecedented social and political economic transformation. In recent years late industrializing countries are keen to replicate China’s SEZ “success,” initiating their own assembly-oriented SEZ programs. Yet the social and environmental costs often outweigh the economic gains. Rather than become a footnote to history, the number of zones has expanded, and along with it questions on the sustainability of dominant economic growth models that give
rise to economic spaces characterized by labor rights violations, environmental degradation, land confiscation, and gendered violence.

**Externalization**

W. Richard Goe  
*Kansas State University, USA*

Externalization refers to the use of market contracting by a firm to procure a good and/or a service (i.e., a product) from another independent firm as opposed to producing that product internally within the former’s organizational hierarchy. This phenomenon is also referenced by other concepts used in academic discourse in economic geography, regional science, economics, and economic sociology, including outsourcing, vertical disintegration, and flexible organizational forms. Research on externalization within these fields has predominantly focused on market contracting between: (i) manufacturing firms and their suppliers, and (ii) the headquarters of corporations and firms in the producer services sector.

**Externalization in manufacturing**

The decade of the 1980s witnessed the onset of a period of rapid and extensive “restructuring” in the economies of the developed nations that coincided with the rise of neoliberal, conservative political movements. One dimension of this process was the development and implementation of new models of business organization and strategy by multinational corporations (MNCs). An important prong in these strategies was the growing use of externalization to procure needed goods and services. Within the United States, for example, manufacturing firms increased their use of externalization while “downsizing” by closing facilities and/or eliminating jobs (also called vertical disintegration) in response to competitive pressures and/or the opportunity to elevate profits and stock valuations by reducing costs. This strategy had the additional benefit of transferring the investment risk associated with the production of needed goods and services to supplier firms. It was argued that the large, vertically integrated firm described by Alfred Chandler (1977) as the hallmark organizational form of twentieth-century capitalism was being superseded by new forms of organizing production that involved externalization and the formation of subcontracting networks between manufacturing firms and their suppliers. A second important dimension of change was the continuing rise in the competitiveness of Japanese and European firms across an expanding range of manufacturing industries, who utilized business strategies and modes of organizing production that were different from those used by manufacturing firms in the United States. Finally, the decade of the 1980s was not only a period of heightened corporate consolidation via mergers and acquisitions, but was also marked by the development and increasing use of important innovations in computers, robotics, and other forms of information technology, corporate finance (e.g., junk bonds), and employment practices (e.g., contracting for temporary workers), among others.

Economic geographers, regional scientists, economists, and economic sociologists developed stylized theoretical models that described the key features of the form of economic organization resulting from these changes. Building on concepts developed by the French school of regulation theory, it was posited that these new
forms of production organization were providing a key dimension to a new “mode of regulation” that would allow capitalist market economies to resume a long-term, stable period of accumulation. One such model that was subject to extensive theoretical debate and empirical research was flexible specialization, brought to the attention of the English-speaking world by Piore and Sabel (1984). A key feature of this model is the spatial clustering of small and medium-size firms to form a flexibly specialized, industrial district where they engage in stable, long-term subcontracting relationships. Firms within these industrial districts cooperate by sharing information and technical expertise, engaging in joint planning and contract bidding, and sharing technical, financial, and educational services from common providers. These subcontracting arrangements allow production costs to be spread across firms in the industrial network. Moreover, the sharing of information and technical expertise promotes interfirm learning and the more rapid development and introduction of new products. It was contended that the fragmentation of mass markets and shorter product cycles requires firms to respond with greater flexibility by more rapidly developing new products and producing a greater diversity of products with the help of computerized industrial machinery and robotics, in addition to other technologies. Empirical evidence to support the flexible specialization model was drawn primarily from central and northeast Italy (knitted goods, special machinery, ceramic tiles, textiles, agricultural implements, hydraulic devices, shoes, and electronic musical instruments), the Baden-Württemberg region of West Germany (textiles, apparel, textile machinery, machine tools, and automobile components), the “Second Denmark” region in Jutland (textiles, apparel, furniture, machine tools, and shipbuilding), and the motion picture industry in the Los Angeles region.

One point in the critique of the flexible specialization model was that the concept encompasses a diverse range of business practices, some of which may actually serve to reduce flexibility. For example, Sayer (1989) distinguished between functional flexibility (a firm changing its product configuration) and numerical flexibility (in output and employment). In turn, these are facilitated by flexible labor markets (internal and external), flexible working practices (e.g., job rotation), flexible machinery (e.g., robotics), flexibility in restructuring (e.g., corporations paring off and selling nonprofitable divisions), and flexible organizational forms (e.g., networks of specialist producers). Flexibility in restructuring, for example, could limit investment in flexible machinery due to increasing debt, which could in turn reduce flexibility. A second important criticism was that unless they grew into large firms (thereby presumably decreasing their flexibility), the firms that made up flexibly specialized industrial districts were not likely to become dominant competitors that exerted a strong influence over the field of practice within their respective industry(ies) in the global economy. Nonetheless, in the two decades that have followed this research program, the use of subcontracting networks in manufacturing, the ability to reconfigure production lines to produce a greater diversity of products, and the ability to more rapidly develop and introduce new products have become important features of manufacturing in the global economy.

A second model that was subject to extensive theoretical debate and empirical research was the Japanese system of manufacturing, which was described through such metaphors as flexible rigidities and innovation-mediated production (Dore 1986; Kenney and Florida 1993). The Japanese system was also characterized by a spatial clustering of firms that were engaged in subcontracting relationships. A key difference from
flexible specialization was that the subcontracting network (e.g., *keiretsu*) was anchored by a large manufacturing firm that produced the final assembled product. Similar to those in the flexible specialization model, however, the relationships between firms in the network of subcontractors were long term, relatively stable, and cooperative in nature. For example, Dore (1986) describes the relational contracting arrangements between manufacturers and suppliers in the Japanese textile industry as being “moralized trading relationships based upon mutual goodwill.” Trading partners forego the use of any advantages in bargaining superiority, fairly share the gains and losses during periods of growth and decline, and forego any short-term price advantages offered by alternative suppliers. In effect, while anchoring firms have greater economic power than supplier firms, opportunism is avoided in favor of the longer-term benefits that may potentially be realized from a trading partner in the future. Supplier firms deliver parts to the factory(ies) of the anchoring firm on a “just-in-time” (JIT) basis as they are needed on the production line. The long-term benefits of the subcontracting networks in the Japanese JIT system include decreased inventory, heightened utilization of equipment, minimal scrappage or rework of parts and supplies, higher quality, and increased technological efficiency. Increased technological efficiency is achieved through rapid, systematic transfer of information between firms in the JIT network which facilitates joint learning by doing, coordinated investment, joint product planning and design, and the diffusion of new techniques across firms in the network (Dore 1986; Kenney and Florida 1993; Sayer 1989).

As a result of the competitive advantages of the Japanese system, the dominance of the Japanese economy appeared imminent to some analysts in the 1980s. Changes in economic conditions in the 1990s, however, undermined these advantages as the Japanese economy entered a long-term period of economic stagnation and malaise. This ostensibly allowed surviving competitor firms in the United States and other developed nations to catch up and regain their level of competitiveness. While few would now contend that Japan will become the next hegemonic power in the global economy, elements of the Japanese system have been widely adopted as technologies in manufacturing, including the use of subcontracting networks for JIT delivery of parts and supplies, work teams, job rotation, and total quality management to continually improve product quality.

Externalization and producer services growth

Downsizing by firms in the manufacturing sector (i.e., deindustrialization) in the 1980s, combined with rapid employment growth in other economic sectors, produced an ongoing decline in the share of total employment accounted for by manufacturing in the economies of most developed nations. As the economic expansions of the 1980s and 1990s unfolded, the vast majority of new jobs created were in service sector industries, furthering the perception that the developed nations had undergone a shift to service-based economies. Closer examination of this growth revealed that the largest and most important source of job growth was in the “producer” services. In theory, producer services are services that are ultimately used by businesses and other productive enterprises. In practice, the producer services sector has been operationally defined as including all or a subset of: banking and financial services, insurance, real estate, business services, legal services, engineering services, accounting, and architecture. The business services, in particular, subsume a diverse range of
work activities including advertising and marketing, management consulting, computer and IT services, private security, and employment agencies, among others.

The growth of the producer services sector stimulated an extensive research program by economic geographers, regional scientists, economists, and economic sociologists to better understand the causes and implications of this growth. A key issue concerned the fact that from the demand side, producer services growth was being driven by the externalization of service functions by business firms, government, and other nongovernmental agencies. The growth of producer services employment was found to be concentrated in the metropolitan areas of the developed nations, which also served as the locations for the headquarters of MNCs and other large corporations. Decisions to externalize producer services are primarily made by managers at the headquarters of the outsourcing firm. Externalization therefore leads to the formation and growth in density of corporate complexes, which are interfirm networks, anchored by the headquarters of a firm, which engages in market contracting with one or more vendors of different types of producer services.

The potential of realizing agglomeration economies would suggest that the headquarters of a firm would choose to contract with nearby producer services firms that are located within the same metropolitan area. However, empirical studies of producer services firms indicated they extensively engage in interregional and international trade outside of the metropolitan area in which they are located (for example, see Beyers, Alvine, and Johnson 1985). This indicated that corporate complex networks frequently extend beyond the boundaries of the metropolitan area in which the headquarters of the contracting firm is located. Empirical research on the geography of network linkages within corporate complexes indicated that corporations tend to contract with producer services firms located in the same metropolitan area when the producer services being purchased require frequent contact between the contracting firm and vendor. The probability of contracting with a distant vendor increases when contact requirements are low (for example, see Goe et al. 2000).

A point of debate concerned the extent to which the growth of producer services was tied to the changes in the manufacturing sector described above. The industrial paradigm of economic development emphasized the role of manufacturing as the central lynchpin in economic growth. Service industries were viewed as parasitic to manufacturing and dependent upon the export of goods by manufacturing industries for the revenue needed to sustain their growth. One perspective of producer services growth argued that continued deindustrialization in the developed nations would result in the eventual decline of their producer services sector as well because of its strong direct dependency on the manufacturing sector. In contradiction to this perspective, a substantial number of empirical studies of producer services firms, conducted in a variety of metropolitan regions and nations, found that firms in other service sector industries were providing the primary source of demand for the producer services firms that were studied (Goe 1990; Illeris 1989; Ley and Hutton 1987). These findings suggested that producer services growth could be stimulated within a metropolitan region without a direct, primary dependency on manufacturing firms for revenue.

The externalization of producer services was also situated within the flexible specialization model. Coffey and Bailly (1991) contended that externalization by producer services firms to procure inputs provides them with flexibility in controlling their costs and externalizing the risks associated with the production of the inputs they
require. Similarly, the externalization of producer services by the headquarters of contracting firms allows them to realize these forms of flexibility in control over their production and administrative tasks. A related point of debate concerned whether the growth of producer services was being primarily driven by vertical disintegration (also termed unbundling) as firms externalized producer services functions and eliminated their internal capacity to provide these services. Empirical studies of firms who externalized producer services suggested this was not the case. Rather, employment in producer services occupations was found to be growing internally within these firms in conjunction with their use of externalization (for example, see O’Farrell, Moffett, and Hitchens 1993). These findings suggested there was likely to be some form of functional complementarity between the internal producer service activities and those that were externalized and/or contracting firms which used externalization to handle temporary work overloads in regard to specific internal activities.

Empirical research conducted on firms externalizing producer services has also found that externalization decisions are not based on pure cost considerations. Goe et al. (2000) found that contracting firms were willing to forego higher costs if the service being externalized was deemed to be of sufficient strategic importance to the firm. Coffey and Drolet (1996) found that the lack of sufficient in-house expertise to provide a high quality service and infrequent and/or irregular demand for a service were much more important in motivating externalization than cost considerations. These findings highlight the role of many producer services (e.g., management consulting, advertising, and marketing) in transferring strategic knowledge and expertise to contracting firms (see Harrington and Daniels 2006). Lindahl and Beyers (1999) found that the competitive advantage of producer service firms lies predominantly in their ability to differentiate themselves through their creativity, their ability to conduct research and development, and their ability to respond quickly and provide personal attention to their clients. Taken together, these studies underscore the role of knowledge creation and innovation as factors underlying the externalization of producer services and the growth of the producer services sector.

Conclusions

In sum, over the past three decades, the research programs on flexible specialization, the Japanese system of manufacturing, and producer services drew attention to the phenomenon of externalization. Each of these programs presented models of economic organization where firms favor the use of market contracting to externally procure parts and supplies, jointly manufacture a product, or purchase services used as business inputs. This body of research situated externalization as an element in the broader organizational strategies being employed by firms in response to the exigencies of international economic competition. During this time frame, manufacturing systems have become increasingly international in scale and scope as part of the so-called process of globalization. There has been a growing use of subcontracting for production work as China and other developing nations (e.g., Mexico) have become offshore manufacturing platforms for firms located in developed nations. A strong case could be made that an important characteristic of globalization is that production work has become a low value-added labor activity that is now externalized by MNCs and predominantly carried out in the low-wage environments of developing nations. Labor activities required for the management of MNCs as well as the invention, development, design, and marketing of
products represent higher value-added activities that are predominantly located in the developed nations. The acquisition of services to facilitate the management and operation of these complex organizations thus accounts for a component of producer services growth in the developed nations. The networks that bind corporate complexes have also become increasingly international in scale and scope. India has developed as an important offshore platform for firms in the developed nations to purchase software and other types of business services (e.g., call centers), thereby devaluing certain types of work in the producer services. An increasing number of firms in producer services such as management consulting, software development, and legal services, for example, have evolved into MNCs as the markets for their service products have expanded. At this juncture in time, externalization continues to increase as an element in global economic competition.

Factors of production

Dean M. Hanink
University of Connecticut, USA

At a basic level, any good or service is the result of the purposeful combination of its factors of production. The two elemental factors of production are capital and labor. At times land is also considered an elemental factor of production, but unless agriculture is being considered it is usually treated as a component of capital. By broad definition, capital is also taken to include natural resources such as mineral ores or water. Capital is typically considered in fixed form, such as the buildings and machinery used in production. It is rarely considered in financial form. Capital is often more finely defined with respect to its private or public ownership; publicly owned capital is often referred to as infrastructure. Labor is typically counted as number of workers or hours worked in production. It may be differentiated by skill level. Broadened definitions of capital and labor sometimes overlap in the factors of human capital and social capital. Human capital takes the form of education and health characteristics in the labor force that contribute to production. Social capital contributes to production through cooperation in social networks of producers. Technology is sometimes considered an independent factor of production and sometimes it is viewed as being embodied in capital or in labor or in both factors.

Production requires that both capital and labor be combined in their application as factors. Their combination and its effect are often described in production functions. The Cobb–Douglas production function (Douglas 1976) takes the form

\[ Q = (TL^\alpha K^\beta) \]

where \( Q \) is the maximum level of output, \( L \) is labor, \( K \) is capital, and \( T \) is total factor productivity, which accounts for the output not directly attributable to capital or labor singly. Elasticities of output to capital and labor are defined by the values of \( \alpha \) and \( \beta \), respectively. If their sum is less than one, then there are diminishing returns to scale, meaning that output is increasing on the margin at a slower rate than the combined factors are being used. If their sum is equal to 1, then there are constant returns to scale, and if their sum is greater than 1, then there are increasing returns to scale.

Goods and services can be classified by their factor intensities. Labor-intensive goods and services use relatively more labor inputs than capital in their production. Capital-intensive goods and services use relatively more capital than labor in their production. Variations in relative factor intensity among products and geographical variations in the distribution of the factors, or factor endowments, underlie a theory of location and trade developed by the economist Bertil Ohlin (1933). That theory suggests that trade that occurs among places is based on their relative production efficiencies, so labor-intensive products produced in places with rich labor endowments are traded for capital-intensive products produced in places with relatively large capital endowments. The factor content of a unit of production can be calculated by a method that uses an input–output table, as described by the economist Wassily Leontief (1986). That method is often used to analyze trade flows in the context of Ohlin’s factor endowment theory.
FACTORs OF PRODUCTION

Famine

Stephen Devereux
University of Sussex, UK

Famines used to be understood as natural disasters but are increasingly recognized as products of human action or inaction. Despite being seemingly straightforward events, only recently has an operational definition of famine that triggers a humanitarian response been internationally agreed. One reason is that famines are actually extremely complex phenomena, and have been analyzed from various disciplinary perspectives, including climatology, demography, economics, geography, and political science.

After reviewing alternative approaches to defining famine, this entry provides a brief historical overview, showing how famines have been geographically concentrated in a few regions – Europe, South and East Asia, and sub-Saharan Africa. The causes of twentieth-century famines are analyzed under four “c’s” – climate, conflict, colonialism, and communism – highlighting the role of politics in creating or exacerbating weather-related triggers. The recognition that politics is central to understanding recent famines is also seen in a review of the evolution of famine theories – from a focus on demographic and climatic factors towards the economics of famine, and “new famine” thinking about the failure of responsible actors to deliver humanitarian relief.

The four mass mortality twenty-first-century famines to date – in Ethiopia in 2000, Malawi in 2001/2, Niger in 2005, and Somalia in 2011 – are examined individually and patterns are identified that suggest why similar famines are likely to recur in the future. Four common factors are weather shocks, conflict or civil insecurity, weak or absent democratic institutions, and unaccountability of national and international actors with responsibility for famine prevention.

Defining famine

Famines are easy to recognize but challenging to define. Commonly understood as the death by starvation of large numbers of people, academic definitions have struggled with issues of scale (how many hunger-related deaths constitute a famine), duration (when a famine begins and ends), even causality (most famine victims die of diseases, not starvation) and outcomes (whether or not a famine process that stops short of mass mortality nonetheless constitutes a famine).

The Somalia famine of 2011 was unique in that it was the first to be officially declared a famine by the United Nations (UN), using an operational definition called the Integrated Phase Classification scale (IPC 2012), which identifies five escalating levels of acute food insecurity, where level 5 is a “Humanitarian Catastrophe/Famine.” The key indicators defining a level 5 situation for a defined population include a global acute malnutrition (GAM) rate above 30% and a crude death rate (CDR) above 2/10000/day. In July 2011, nutrition and mortality surveys conducted in 16 locations in southern Somalia found that the GAM and CDR rates exceeded the IPC level 5 thresholds in 11 and five locations, respectively. These findings provided the basis for the UN declaration of famine, which triggered a massive international humanitarian response, though too late to prevent a quarter of a million deaths (see the discussion of this famine below).
This episode highlights both the value and the limitations of a technocratic approach to defining famine. There is no doubt that having international consensus on an objective, measurement-based definition of famine is a major advance on the past, when disagreements between governments and aid agencies about whether famine conditions had yet been reached often led to fatal delays in relief efforts. On the other hand, two risks follow from defining famine in this narrowly technical way. The first is that no action will be taken until the thresholds for declaring a famine have been exceeded, meaning that large numbers of people are already starving, destitute, or dead before an emergency food aid appeal is launched. The second is that the focus on preventing mass deaths by starvation could divert policy attention away from less visible manifestations of hunger and food crisis, including the millions of malnutrition-related child deaths that occur every year in South Asia and sub-Saharan Africa.

People who have actually experienced famine identify different levels: minor famines cause hunger, severe famines cause destitution, and only catastrophic famines result in deaths. These insider definitions see famine as a continuum rather than a discrete event, but this subtlety is overlooked by binary definitions based on thresholds for food security indicators which trigger humanitarian responses that are invariably late. If the objective measurement approach was combined with the subjective perceptions of local people themselves – which could be validated by monitoring their coping strategies as food security deteriorates – and the IPC scale was relabeled with varying degrees of famine (instead of “stressed,” “crisis,” “emergency,” “famine”), this could ensure that responses are mobilized early enough to prevent not only mass deaths but also widespread destitution and unacceptable levels of hunger.

Geographical trajectories

Famine has a history as long as that of humankind itself. Famines were recorded in Egypt more than 6000 years ago, mostly triggered by erratic weather. The Bible reports conflict-related famines such as the siege of Jerusalem. Western Europe was famine prone at least from the time of the Roman Empire. China, India, and Russia – known historically as lands of famine – have each suffered famines for thousands of years. More recently, over 70 million people died in famines during the twentieth century (Devereux 2000). Although famine has been perceived as an exclusively African phenomenon since the Great Ethiopian Famine of 1984, the overwhelming majority of famine deaths since 1900 occurred not in Africa, but in Asia and Europe. China and the Soviet Union alone accounted for over 80% of twentieth-century famine mortality (Devereux 2000, 9).

In the past, when agrarian communities were isolated and where rural families depended on rain-fed agriculture as their principal source of food, a single harvest failure was often enough to trigger a food crisis. Geographers identified two climate-related “famine belts.” Northern Europe, the Soviet Union, and China were vulnerable to crop failures because of cold, excessive damp, and short growing seasons. Sahelian Africa, the Horn of Africa, and South Asia were vulnerable to crop failures because of drought or flood, often triggered by El Niño events (Cox 1981).

In the late nineteenth century a sequence of massive famines struck India, China, Ethiopia, and other countries in Asia and Africa. Although the Americas have been virtually famine-free, even Brazil was affected. These “Late Victorian Holocaus ts” killed between 30 and 60 million people (Davis 2001). They were the product of
a lethal combination of climate shocks, colonialism, and the introduction of capitalism and market-driven economic policies that included exporting food during famines.

In the early twentieth century, a series of small-scale famines struck countries across sub-Saharan Africa, mainly triggered by drought and colonial policies. In the 1920s and 1930s a sequence of famines struck China and the Soviet Union. In the 1940s, disrupted global food systems and the use of siege tactics as a weapon during World War II triggered numerous famines across Europe, Asia, Australasia, and Africa. The 1950s and 1960s were relatively quiet decades for famines, with the significant exception of the Great Leap Forward famine in China, the worst famine in history in mortality terms.

The late 1960s also saw a decisive shift in the prevalence of famine, away from South and East Asia and towards sub-Saharan Africa. Between 1968 and 1999, 13 of 17 major famines occurred in Africa, including three each in Ethiopia and Sudan and two in Somalia. Most of these were triggered by conflict and/or drought. The four remaining famines were all in Asia (Bangladesh, Cambodia, Iraq, and North Korea). There have been four twenty-first-century famines to date, all in Africa (Ethiopia, Malawi, Niger, and Somalia) – these are discussed individually below.

Causes of famine

Famines occur at the intersection of bad weather and bad politics. Most famines since the late nineteenth century can be attributed to four “c’s” – climate, conflict, colonialism, and communism – often operating in lethal combinations.

It is unfashionable to attribute famines to climate shocks (drought, flood) or environmental stress (Malthusian population pressure). However, climate shocks continue to be trigger factors, including for all four twenty-first-century famines to date. Climate shocks have the effect of undermining the subsistence basis of agrarian economies that depend on agriculture for their food supply. A common feature of famines that are triggered by natural disasters or weather shocks is that they affect mainly rural communities. It is a paradox that people who grow food – farmers, agricultural laborers, and livestock herders – are most susceptible to food crises. Droughts, floods, and cold spells – most prevalent in sub-Saharan Africa, South Asia, and Northern Europe, respectively – trigger harvest failures that can leave entire communities with no food crops to eat and no cash crops to sell for income to buy food.

Secondary effects include loss of livestock (or depleted value of livestock if they lose weight due to lack of grazing and water) and loss of local employment opportunities (because farmers have no need to hire labor for weeding or harvesting, while demand for services collapses because of the income shock). In isolated rural areas with fragmented markets, food prices typically rise as market supplies are depleted and demand for food surges, when normally self-provisioning producers unexpectedly become market-dependent consumers. The collapsing terms of trade as food prices rise and asset (e.g., livestock) prices fall leave the poorest unable to buy the food they need. Unless they find alternative sources of food and income (including by migrating out of the famine zone) or humanitarian relief arrives, mass starvation will follow.

Key characteristics of famine-prone communities that are vulnerable to climate shocks include: local livelihoods are undiversified, so a harvest failure cannot be compensated with income earned from other sources; local economies are weak, so traders do not react promptly to move
food from surplus to deficit areas; insurance markets are effectively nonexistent, so farmers have no possibility of insuring against crop losses; and local communities are geographically isolated and politically marginalized, so food aid is either not mobilized or arrives too late. The point is that climate shocks do not cause famines, but vulnerability to climate shocks does. In countries like Ethiopia, Niger, and Sudan, economic and political vulnerabilities persist into the twenty-first century, which is why the deep rural areas of these countries remain vulnerable to famine.

In this sense, the eradication of famine from large parts of the world, especially in Europe and most parts of Asia, can be seen as a by-product of normal economic development processes. In countries like China, India, and Russia in the late nineteenth and early twentieth centuries, rapidly improving transport and communications infrastructure had the effect of integrating previously isolated communities into larger – national and even global – economies. Livelihood options expanded, trade flows into and out of rural communities increased, and governments and traders were aware earlier and had more capacity to respond promptly to signals of distress from districts where slow-onset food crises were developing. In northern China, for instance, a protracted drought in the 1870s resulted in an estimated 9–13 million famine deaths, but in the next 40 years 6000 miles of railway were constructed and, when a comparable drought struck the same region in the 1920s, relief supplies were delivered by rail from other parts of China and mortality was contained to approximately half a million.

A second major trigger factor for famine is conflict, including the use of food as a weapon of war, which has been recorded since Biblical times, when cities such as Jerusalem were besieged and their inhabitants were deliberately starved. During World War II this tactic was responsible for mass death by starvation in several European cities – in Greece (Athens), Poland (Warsaw), the Soviet Union (Leningrad, Kharkov, Kiev), and the Netherlands (Amsterdam, The Hague, and Leiden). These famines were atypical in that they affected urban centers more than rural areas, and wealthy people were as vulnerable as the poor. Vulnerability in blockade famines is related to the separation of urban populations from food supplies. Mass starvation is caused by blocking flows of food into the city and preventing movements of people out of the city.

The scale of famine-related mortality during World War II has only recently become evident. Collingham (2011) claims that at least as many people died during World War II from starvation, malnutrition, and associated diseases (20 million) as from military action (19.5 million). Apart from deliberate blockades, the causes of famine deaths in World War II ranged from disruptions of food production and supplies, to systematic starvation of prisoners of war, to failure to respond to natural disasters because all efforts were focused on the war.

Conflicts have the potential to disrupt all components of the food system: production, trade, and relief. In rural areas, conflict causes farmers to be displaced from their land, conscripted into armies, disabled or mutilated by landmines and militia, or killed. Often standing crops are burnt, granaries are raided or destroyed, water sources are poisoned, and livestock are stolen or slaughtered. All of these side effects of conflict undermine agricultural production. Conflict also disrupts trade in food and other commodities. Roads become unsafe or blocked by military checkpoints, so traders either cannot purchase food or cannot transport food to conflict zones. Markets are targeted by militia or military aircraft: during the Ethiopian famine of 1984, many rural markets operated only at night, to avoid being
bombed. Humanitarian relief operations are also compromised. Governments or rebel forces sometimes ban humanitarian agencies from operating in conflict zones, or agencies withdraw their staff, either fearing for their safety or to prevent relief supplies and vehicles being conscripted by the warring parties. In Somalia in 2011, for instance, famine-affected communities were “no go” areas for most humanitarian agencies. As a consequence, people living in conflict zones become cut off from external food supplies, and when their own stocks are depleted, raided, or destroyed, they face the threat of famine.

Many of the worst twentieth-century famines occurred in totalitarian regimes: the Soviet Union, China, Cambodia, North Korea, and Ethiopia. Policies such as collectivization of agriculture reduced farmers’ incentives to produce food, excessive extraction of food through quotas reduced farmers’ access to food, pressure on local officials to demonstrate success reduced their incentive to report food shortages to the central level, and an authoritarian regime that was unaccountable to its citizens had little incentive to admit to policy errors or to respond to prevent famines.

Conversely, a powerful antidote to famine is democracy. Amartya Sen (1999) argued that the defining features of democratic systems, notably free and fair elections and a free press, help to prevent famines. Regular elections give citizens an opportunity to throw out a government that fails in its duty to prevent famine. A campaigning press exposes problems such as evolving food crises to public scrutiny and allows the electorate to hold their leaders to account, unlike in totalitarian states where the media are strictly controlled, civil society is suppressed, and leaders are unaccountable. More recently, political scientists have nuanced this argument, pointing to the limitations of democracy as a famine prevention mechanism (Rubin 2011), especially where it is weakly embedded institutionally, or if demographic structures generate ethnic majorities that allow elected political leaders to neglect marginalized minority groups with impunity. This is a feature of recent African famines, which have often occurred in countries like Ethiopia and Malawi that are nascent democracies.

Famine theories

Crudely speaking, the evolution of famine theorizing has reflected shifts in disciplinary emphasis, starting from geography (climate and environment), demography (Malthusianism), and then economics (Sen’s entitlement approach), and most recently political science (social contracts). However, a comprehensive but cogent political theory of famine has yet to be elaborated.

The simplistic view that famines are natural disasters, caused by environmental catastrophes or population pressure on overstressed ecosystems, dominated famine thinking and analysis until the 1980s, when Sen’s “entitlement approach” shifted the focus of analysis from geography and demography to economics, and the 1990s, when political scientists drew attention to the politics of famine processes.

Famines were initially conceptualized as failures of food supply or availability: a harvest failure that leaves too little food (climate theories), or population growth in a resource-constrained environment until there are too many people to feed. Malthusian demographics even characterized famine as a stabilizing mechanism, balancing the carrying capacity of the natural resource base with the consumption needs of human and animal populations (Ghatak and Ingersent 1984). More recently, political scientists and geographers increasingly saw this environmental determinism as inadequate.
FAMINE

After Amartya Sen demonstrated that there was adequate food at national level in at least three of four twentieth-century famines that he reanalyzed, the focus shifted from “food availability decline” to failures of effective demand or access to food. Sen’s entitlement approach refers to people’s ability to acquire food based on their resources (own production, labor, purchase, or transfers), rather than to moral or legal claims on the state to secure their right to food. Sen (1981) pointed out that famines never affect entire countries, and that rich people rarely die during famines, except in wartime. It is poor, vulnerable, and marginalized population groups who are most likely to lose access to available food and to face starvation.

Building on this, Watts and Bohle (1993) defined vulnerability to hunger and famine in terms of social spaces, not just physical spaces. They argued that analysis of hunger and famine should examine not only “the particular distribution of entitlements and how they are reproduced in specific circumstances,” but also “the larger canvas of rights by which entitlements are defined, fought over, contested, and won and lost (i.e., empowerment or enfranchisement); and the structural properties (what we shall call crisis proneness) of the political economy which precipitates entitlement crises” (Watts and Bohle 1993, 44).

These insights shifted the focus of famine analysis from aggregate supply failure to group-specific demand failure, and initiated a paradigm shift in the famine discourse. Before Sen, most proposed solutions to famine focused on increasing foodcrop yields to increase national food availability, whereas the implications of the entitlement approach are that access to food must be protected for specific groups of people who are vulnerable to a collapse in their livelihoods following a shock to the (local, national, regional, or global) food system.

“New famine” thinking (Devereux 2007) argues that a second paradigm shift is needed, to reflect the reality that most contemporary famines could and should have been prevented. If local food supplies are inadequate, and if impoverished people lack resources to buy the food they need for subsistence, national and international duty-bearers have a moral responsibility to protect the basic human right to adequate food for all. Alex de Waal (1997) has argued that the most effective famine prevention system is an “anti-famine political contract” between states and citizens, which makes famine politically unacceptable. De Waal points out that there has been no major famine in India since the Bengal famine of 1943. Successive post-independence governments have implemented interventions such as the Scarcity Manuals, the Employment Guarantee Scheme, and the National Food Security (“Right to Food”) Act, knowing that allowing another famine to occur will not be tolerated by India’s robust media and activist civil society.

The capacity to intervene has increased exponentially since World War II, with rapid advances in crop yields, global transport and trade networks, famine early warning systems, and the international humanitarian system. Famines happen because they were not prevented. This is a political failure (or political intent) for which national governments, rebel militia, or humanitarian relief agencies should be held accountable.

Twenty-first-century famines

The four famines that have occurred since the year 2000 give insights into why famine has not yet been eradicated, despite unprecedented improvements in global technical and institutional capacity to do so in recent decades. These famines also give insights into the likely risk factors for famine recurring in the future, and
therefore into how they might be prevented. It is no coincidence that the four African countries that experienced famine between 2000 and 2012 are among the poorest in the world and have weak political institutions, with citizens whose livelihoods are dependent on rain-fed agriculture which is highly susceptible to weather shocks. However, contemporary famines are analyzed as failures not only of food production (the focus of earlier natural disaster and (neo-) Malthusian theories), but also of access to food (due to market failure, entitlement failure, or poverty) and of humanitarian response (food aid).

The famine that afflicted Somali region, Ethiopia, in 2000 caused 70,000–122,000 deaths. This was a slow-onset crisis, triggered by a protracted drought that started in 1997 which decimated livestock herds, the main source of both food and income for pastoralists. The drought was compounded by a ban on livestock exports to Saudi Arabia due to a Rift Valley fever outbreak in East Africa in 1998, which halved exports to this lucrative market from 3 million to 1.5 million head and cost pastoralists and traders an estimated US$100 million in lost income. So this was simultaneously a production and an income failure. Unable to sell their animals, many pastoralists watched them die and were left with no income or assets to exchange for food.

Ethiopia has had a famine early warning system since the 1970s, but it monitors the crop farming highlands rather than the pastoral lowlands, which were the epicenter of the famine in 2000. Nonetheless, anecdotal evidence about deteriorating food security conditions in Somali region was ignored by the federal government, which was preoccupied with a border war with Eritrea at the time, and by the donor community, which was concerned that food aid intended for the famine-affected south might be diverted to feed soldiers fighting in the north. By the time the international media drew attention to the famine and food aid was delivered, three-quarters of famine deaths had already occurred. The food crisis in Somali region might have been triggered by drought and livestock disease, but the ultimate cause of the famine was the politicization of the humanitarian response.

An agricultural drought in Malawi in 2001—a break in the rains during the growing season—reduced the national maize harvest by 32% and was blamed for the estimated 47,000–85,000 excess deaths that followed. However, this harvest followed two bumper years and was 6% higher than the 10-year average, so food availability decline is an inadequate explanation for this famine. The famine was concentrated in the densely populated southern and central districts, where landholdings are too small to produce a full year’s food supply so smallholder families are market-dependent for several months. The reduction in maize supplies in local markets triggered an increase in retail prices of up to 500%, making the acquisition of adequate food during the hungry season impossible for poor smallholder families, even as they sold off their livestock and other assets at distress prices to finance food purchases. There was too little work and the oversupply of labor caused agricultural wages to collapse. Some analysts argued that the food price spike rather than the harvest failure was the main factor explaining how a moderate production shock became a major food crisis.

Malawi’s famine early warning system failed to predict the food shortage in 2001, instead forecasting that any maize deficit would be more than covered by drought-tolerant cassava. These inaccurate projections prompted the World Bank and International Monetary Fund (IMF) to advise the government to sell off its strategic grain reserve (SGR) and replenish it after the harvest. This left Malawi with no buffer stocks to distribute, and when suspicions arose that government officials had profiteered corruptly.
Famine

from sales of SGR maize, the donors demanded an explanation, which fatally delayed their humanitarian response.

The food crisis in Niger in 2005 seems like a classic food production failure. Drought and locusts destroyed food production across the West African Sahel. Niger’s grain harvest was only 11% below the five-year average, but this decline was not evenly distributed across the population, and 13,000–47,000 people died in the worst affected rural communities. On the other hand, similar crop failures were recorded in neighboring countries, but only Niger experienced a famine, so once again food availability decline explains only the trigger, not the entire famine process. Rapidly rising food prices – staple cereals increased by 200–300% between the harvest and the peak famine months – were mirrored by rising malnutrition rates. Smallholder farmers, pastoralists, and farm workers all adopted coping strategies which included selling their assets for food. The livestock/grain terms of trade collapsed to one-quarter of pre-drought levels.

The Niger government was aware of the evolving food crisis, but its appeals for aid were initially ignored. Unlike in neighboring Mali, where a famine was averted through distributions of free food to drought-affected families, the government of Niger chose a market-led response, by selling grain at subsidized prices. The intention was to minimize “dependency syndrome” and market destabilization, but prices were too high for people who were already destitute, and the subsidy was largely captured by nontarget population groups. Niger’s development partners endorsed this market-led approach. The International Monetary Fund enforced tax hikes on food staples as a condition for budget support, in the famine year.

The famine in Somalia in 2011 was also triggered by a severe drought – the lowest rainfall in 50 years in the 2010 deyr season – that caused harvest failures and livestock deaths and reduced employment opportunities in the crop farming and agropastoral southern regions. The cereal harvest in 2011 was just one-third of the 2006–2010 average. The drought was accompanied by a dramatic rise in food prices, partly because of reduced food supplies in local markets and partly because of global food price rises at the time. These factors reduced both availability of food and access to food for farmers, agropastoralists, agricultural laborers, and internally displaced persons (IDPs).

The main reason why the food crisis in southern Somalia became a famine was protracted conflict and civil insecurity, which had displaced more than a million people by 2009. The area was controlled by the militant group Al-Shabaab, which was declared a terrorist organization by the United States government in 2008, prompting USAID to cut off food aid and the World Food Programme to withdraw from southern Somalia. Al-Shabaab also forced CARE to pull out in 2008, leaving the local population with no access to humanitarian relief when harvests failed in 2010. The politicization of aid by both the donor community and Al-Shabaab was responsible for a response failure that persisted until the famine was officially declared in July 2011. Even though donor pledges escalated immediately, the relief operation was too late to prevent an estimated 258,000 deaths, and was further compromised when aid workers were killed and Al-Shabaab closed down several programs run by nongovernmental organizations.

Future famines

Conflict is likely to continue being a driver of most famines that occur in the future. The 2011 famine in Somalia is the most recent example of a “complex emergency” famine, where food production was first disrupted by drought, then
trade and aid responses were undermined by violence and insecurity. The combination of a weak national state, the obstructive practices of Al-Shabaab, and international donors that withdrew under Al-Shabaab pressure and United States counterterrorism laws that effectively criminalized aid flows into southern Somalia, all contributed to a failure of humanitarian response, despite adequate early warning information. Future famines that are triggered or compounded by political instability and civil insecurity will be exacerbated by similar “no go” geographical spaces that prevent food aid from reaching starving people. In such situations, airborne food drops might by necessity become a more common way of delivering humanitarian relief than truck convoys.

Weather shocks will continue to trigger harvest failures for as long as farmers practice rain-fed agriculture, and this trend could be exacerbated by climate change in fragile agroecologies. In poor agrarian communities where markets are weak, food prices will spike and asset prices and wage rates will collapse as families sell off their possessions to buy food. So food availability will fall for vulnerable groups, and their access to food will be compromised. However, whether these episodes progress towards full-blown famine will depend crucially on the response of governments and the international community – whether aid is mobilized and delivered promptly – which in turn will depend on the nature of relations between governments and citizens and between national governments and their development partners.

Contemporary famines are preventable, and most recent famines could have been prevented. In all four twenty-first-century famines to date, it is the failure of the humanitarian response to production and market failures, by governments and agencies, that has tipped affected communities over the edge from food crisis to famine. Unless and until accountability for allowing famines to occur is enforced, it seems likely that these avoidable tragedies will recur in future, not because of natural disasters but because of politics.

**Feminist geography**

Robina Mohammad  
*National University of Singapore*

Feminist geography is plural, heterogeneous, and fragmented, intersecting with many fields within and across geography, the social sciences, and humanities. Feminist geographers are thus located within multiple intersecting webs of knowledges that connect geographers not only to feminist scholarship within the academy but also beyond it, such as to those active within the new social movements and nongovernmental agencies. There are, therefore, many feminist geographies and many ways to document such a historiography.

Feminist geographies bring feminist concerns together with a geographical focus. They can be defined as those “Perspectives that draw on feminist politics and theories to explore how gender relations and geographies are mutually structured and transformed” (Pratt 2000, 259). Feminist geography only started to emerge as a field of geographical inquiry from the early 1980s. In the decades since then, it has grown to become much more than a subfield of the discipline, but rather permeates every aspect of human geography and, significantly, mounts a critique of the geographical tradition. Feminism’s impact on the discipline of geography, as with other academic disciplines, was supported by post-World War II social movements. The women’s movement and the Civil Rights Movement, in particular, brought a focus to different structures of inequality and how they intersect to shape experiences of power and social exclusions, setting the sociopolitical context in which feminism was put back on the political agenda in North America and Europe, informing activism on the ground, as well as extending its influence to the academy, particularly to sociology and anthropology and more recently to geographical scholarship. Dialogues between feminism and geography, and feminist geographies and post-modernism/poststructuralism, have undergone three major shifts: first, from geographies of women to feminist geographies (it may also be viewed as a move from description to grand theory); second, from a focus on equality (between men and women) to a concern with differences and diversity between women, examining the ways that gender intersects with other forms of social oppressions; and, third, an epistemological shift that is sensitive to plays of power.

**Conditions of possibility**

Feminism is a set of philosophical perspectives as well as a social movement that gathered pace in different places and at different times, shaped by national, socioeconomic, and political contexts and serving particular political agendas. The early twentieth century had witnessed women’s militancy against political disenfranchisement, leaving the issue of wider gender inequalities unchallenged.

In some places, feminism was a top-down phenomenon, connecting to struggles for independence (colonial India, colonial Egypt, and post-1923 Turkey) and/or struggles for democracy (Franquista Spain, 1939–1975). The “woman question,” the role of women, and their rights and obligations were linked to issues
of governance and development. The feminist movement that resurgence in the Anglo-American world in the post–World War II period, referred to somewhat problematically at times as the “second wave” of feminism (Nicholson 2013), was a grassroots, albeit middle-class, phenomenon that has challenged the core basis of gender differences that translate into inequalities.

In postwar North America liberal feminists (of whom one of the most visible was Betty Friedan) pointed to the home and the private sphere as the basis of women’s social marginality. Women’s wartime, large-scale, cross-class entry into the public sphere, as part of their role as a reserve army of labor, and the opportunities it brought to enter occupations that were historically viewed as men’s work, served to some extent to destabilize the gender division of labor and the ideology of separate spheres. It was not until after World War II that feminists began to formulate critiques of the naturalization of the spatialized gender divisions of labor. Part of the feminist critique was the insistence that the “personal is the political,” which challenged the idea of politics as formal governance in the public sphere and, by the same corollary, of the private sphere as a domain outside of politics. Feminists asserted that intimate relations in the private sphere connecting with fertility, reproductive rights, and heterosexual coupling were also underpinned by power, defined as the “arrangements whereby one group of persons is controlled by another” (Millet 1970, 23).

The sex/gender distinction is key to contesting the ideology of biological determinism, which holds that biology determines women’s place in the home. This binary distinguishes natural and given attributes of sex, that is, biological attributes and the social meanings ascribed to them (Rubin 1975). As French feminist Simone de Beauvoir (1989/1949, 267) pointed out, “One is not born but rather becomes a woman.” For de Beauvoir, the meaning of “woman” is not innate. It does not have an inherent nature; rather, it is socially constituted in relation to the meaning of man. By separating the natural and the social, feminists could challenge the givenness of the meaning of the feminine. If women’s position in society is not natural but rather socially produced, then it can be changed. Yet as Donna Haraway (1991) points out, while feminists mounted fervent critiques of binary oppositions such as culture/nature they were reluctant to undo the sex/gender binary because of its centrality in confronting the pervasive biological determinism that formed the basis of women’s inequality and disadvantage. Thus feminist scholarship of the 1960s and 1970s made no attempts to bring the category of nature, whether external or in terms of biology/sex, into culture by historicizing it, which meant that the categories of woman and man continued to be treated as essential. In this way the category of nature continued to threaten the notion of gender through slippage as sexual difference. As Haraway (1991, 28) explains:

In the political and epistemological effort to remove women from the category of nature and to place them in culture as constructed and self-constructing social subjects in history, the concept of gender has tended to be quarantined from the infections of biological sex.

Biology continued to be treated by feminist scholars as a study of the natural world rather than a social discourse through which the category of nature becomes constituted. It was not until the 1990s that deconstruction was applied to the sex/gender dualism by the post-structuralist critiques of scholars in the field of queer and transgender studies. This was a necessary starting point for developing theories of heteronormativity, but it served to trouble the category of woman in the process (Butler 1999).
Butler (1999, xv) and others argued that the heterosexual matrix is a prerequisite for gender. In this view gender becomes a fiction that is produced through performativity, so

that what we take to be an internal essence of gender is manufactured through a sustained set of acts, posited through gendered stylization of the body … [so that] what we take to be an “internal” feature of ourselves is one that we anticipate and produce through certain bodily acts.

Challenges to the category of “woman” were a source of concern for feminists whose project depended on her emancipation. The impact of postmodernism and poststructuralism on theories of subjectivity, identity, conceptions of power, and, as part of this, the deconstruction of dualisms would bring about epistemological shifts in feminist scholarship but not without great anxiety.

Spatiality was implicit in Anglo-American feminist critiques and countercritiques of the gender order and hierarchy, but it was not subject to explicit analysis. It would be almost a decade before geographers began to turn their attention systematically to the study of gender. The “radical,” or perhaps more appropriately “critical,” turn in the discipline saw geographers such as David Harvey turn to Marx for the analytical tools to examine the role of power in sociospatial relations and in structural inequalities. By the late 1970s the Palestinian American scholar Edward Said’s influential work on “Orientalism,” combined with the burgeoning field of queer studies, opened new directions for geographical inquiry to focus on forms of marginality that were not directly related to class, setting new agendas for feminist geography.

In the historiography of geography, feminist geography as a distinct perspective is narrated as emerging much later than in the other key social science disciplines, including sociology. In the United States during the late 1960s, the gains made by social movements began to affect academic disciplines with the implementation of antidiscrimination legislation targeting gender as well as racial discrimination (Rose 1993). Policies of affirmative action saw the establishment of quotas for hiring underrepresented, minority populations underlining their lack of presence and invisibility within the academy. Their absence was particularly notable in geography, historically a masculinist discipline linked to imperial practices (Rose 1993). The androcentrism of geography had been left unchallenged by the critical turn in geography, in which the gender blindness of spatial science, which privileged a disembodied, rational, economic man, was emulated by gender-blind Marxist and humanistic geographies. An obvious example was the taken-for-grantedness of the use of “man” to refer to all of humanity. Courses with titles such as “man and the environment,” “man and nature,” or even “man and culture” could still be found on the geography curricula (WGSG 1984). Rose (1993, 2) points out that masculinism in geography is not restricted to teaching and research but can be found in the everyday forums of disciplinary spaces, and that it delineates its borders:

[It] can be seen at work not only in the choice of topic made by geographers, not only in their conceptual apparatus, not only in their epistemological claim to exhaustive knowledge but also in seminars, in conferences, in common rooms, in job interviews.

Masculinism was accentuated, and some would argue supported, by the paucity of women faculty and graduate students. Some departments, such as the one at Clark University, accepted higher numbers of women for postgraduate studies but those graduating struggled to find jobs in the discipline. The pioneering feminist geographer and former president of the
American Association of Geographers (AAG) Susan Hanson has narrated in a session at the AAG annual meeting in Boston (2010), and documented in a special issue of Gender Place & Culture, as well as in other disciplinary sites, how both she and her husband, Perry, graduated from Northwestern at the same time (1973), yet, while he gained employment immediately, Susan was not even able to get an interview despite sending out many applications for positions in geography. That the geographer was normatively male and heterosexual was underlined to her again when attending the AAG’s annual meeting in the early 1970s where women geographers would routinely get mistaken for “wives” of the geography delegates and were expected to attend activities laid on especially for ladies. Women’s lack of disciplinary presence is confirmed in quantitative terms by examining the gender of the authors of geographical scholarship, the membership of scholarly societies (some of whom had, historically, formally excluded women), and faculty of institutions of higher education. Gillian Rose (1993) shows how, until the 1970s, the number of papers published by women scholars in the American flagship disciplinary journal Annals of the Association of American Geographers was just over 2%; similarly, women made up only a little above 10% of the membership of the AAG, something that was also reflected in their relative absence from American higher education institutions as teachers of geography.

Yet a focus on the numbers of women within the discipline neglects those women located outside of it by particular constructions of the geographical tradition, thereby legitimating certain kinds of knowledge and knowing subjects who were not feminine. At the same time Rose (1993, 4) suggests that the subject position of those women working within the discipline, such as Monica Cole and Alice Coleman, was inherently masculine, for to do geography, to think within the parameters of the discipline in order to create knowledges acceptable to the discipline, was to occupy a masculine subject position. Women’s presence within the discipline certainly says little about the presence or absence of a feminist perspective since being a woman geographer does not necessarily equate with being a feminist. Early women geographers mostly worked within the androcentric parameters of the discipline and made few attempts to contest, resist, or rework these as feminist geographers aimed to do.

Feminist voices began to emerge during the 1970s and would gather ferment by the end of the decade. Prominent were those of Susan Hanson and Sophie Bowlby, both of whom graduated from Northwestern University and gained employment in geography departments during the early 1970s. They were practitioners of a feminist geography that maintained a dual focus: to attend to the geographies of gender and to the gender of geography. The aim was to rectify the neglect of women as subjects capable of knowing and producing geographical knowledge by promoting equal opportunities for women as practitioners. The absence of women was regarded as one of the main reasons why feminism was so late in having an impact on geography. The presence of women was viewed as key to bringing feminism and geography into a productive dialogue for the transformation of geographical scholarship and teaching. Another aim was to rectify the neglect of women as the objects of geographical research by advocating a woman-centric focus, documenting and explaining women’s experiences of inequality from their own perspectives.

Feminist research remained situated within the disciplinary paradigmatic context as well as influenced by the wider social and political milieu within and beyond the academy. In keeping with this, feminist geography at the time was largely descriptive and positivist in
Feminist geography. The implicit assumption that feminist geographies were geographies of women seemed to be validated by the work that was being done. “Geographies of women” drew on the prevailing approaches of humanist, Marxist, or socialist and welfare geographies, extending and developing these toward a focus on gender. In this way they brought attention to areas that had hitherto not been considered worthy of attention by mainstream or “malestream” geography to animate the silences around women’s life experiences, social marginality, and disadvantage vis-à-vis men. Marxist approaches to feminist geographies were also informed by the theories of socialist feminists who interrogated the gender blindness of Marxism to examine the ways in which patriarchy intersected with capitalism to impact on women’s social position. Feminist geographies examined women’s socioeconomic position within capitalist societies through a focus on the spaces of women’s paid and unpaid labor and its social and economic contribution. Other work examined the historical separation of production and reproduction, and the emergence of a spatialized gender division of labor and its inscription into the urban form (Bowlby et al. 1989).

Welfare and neo-Weberian approaches, by contrast, focused on the spatial, material, and ideological constraints experienced by women in their gender roles as mothers and wives. Jackie Tivers drew on Hägerstrand’s time–space model to examine the impact of women’s mothering and domestic roles on their spatiotemporal mobility and how their activities might affect their access to paid work (Bowlby et al. 1989). A humanist approach explored women’s perceptions of space, place, and environment through a focus on their experiences of social and physical landscapes, to demonstrate how women’s experiences differed from those of men. This work tended to valorize women’s difference, constructed in terms of their sensitivity and perceptiveness (Bowlby et al. 1989). This risked not only essentializing women’s difference but also reaffirming the male norm, from which women were seen to deviate. Similarly, by documenting and describing the lives of women as they were being lived – as they performed activities such as domestic labor, provision of care, and nurturing children in spaces culturally associated with femininities – feminist geographers risked reinforcing the naturalness of women’s place and role. In addition, there was a notable lack of attention paid by feminist geographers to the variations of women’s lives across places, either intra- or internationally, which is surprising given that areal differentiation was a significant paradigm within the discipline (Bowlby et al. 1989).

The move from documentation and description toward analysis and explanation led to a growing recognition that the notion of gender roles was a conceptual cul-de-sac. Gender roles could not offer an account of how change might occur; how, for example, they might be negotiated or resisted; and how their meaning might change through such practices. In this way they seemed once again to lock women into particular positions, just as the focus on sexual difference had done earlier. By contrast, the notion of gender relations contained explanatory potential, drawing attention to the social structures through which gendered patterns of behavior, inequality, and disadvantage were constituted.

While feminist geographers were grappling with questions of how to approach the geographies of women/gender and to address the masculinism within the discipline, the importance of feminist approaches to geography was affirmed with the establishment in 1980 of the Women and Geography Study Group (WGSG) within the Institute of British Geographers (IBG). The IBG was a professional body for critical geographers maintaining, at the time, a
Feminist Geography

distinction from the Royal Geographical Society, which was associated by many with geography’s complicity with imperialism. The WGSG’s objectives were:

- to encourage the study of the geographical implications of gender differentiation in society and geographical research from a feminist perspective;
- to encourage and facilitate the exchange of information and ideas with reference to research and teaching in these areas, and to disseminate information through its publications.

These aims reflect a shift away from the “geographies of women” approach toward feminist geographies. As the WGSG (1984, 20) explains, a feminist perspective requires more than just to “increase … the number of studies of women per se in geography but an entirely different approach to geography as a whole.” Hanson (1992, 570) elaborates this point in her 1992 presidential address to the AAG: “feminism looks at the world through the lens of gender (note: not women or femaleness) while seeking to build a world in which gender is no longer a key dimension along which life’s possibilities are defined and resources are allocated.” This shift in focus and feminist geography’s stronger institutional presence were confirmed in 1994 with the establishment of a new interdisciplinary feminist journal *Gender, Place & Culture* (which recently celebrated 20 years), creating a dedicated (inter)disciplinary space for feminist scholarship.

Spatiality and gender relations

This shift did not mean that “geographies of women” disappeared entirely, but rather it began to mutate into a feminist geography that could take forward the achievements of the earlier focus on women to bring about a broader focus on gender. By the late 1980s, as the United Kingdom and other Western economies experienced huge economic restructuring, the issue of gender could not be ignored by Marxist and neo-Marxist economic geographers studying industrial change and uneven spatial development that normatively centered analyses on class relations. Their attention to gender was forced by the changing gender composition of the labor market in regional, local, and urban economies, with the simultaneous growth of women’s presence in paid work and men’s unemployment. Yet it was feminist geographers who examined more fully the relationship between the economy and patterns of gender relations to demonstrate how different regional economies produced distinct gender relations and divisions of labor. Moreover they suggested that historical patterns of gender relations and divisions of labor shaped the changing composition of regional economies. These kinds of studies foregrounding the scale of the locality allowed for a broader focus on gender relations than a narrower labor market focus.

Much of the feminist scholarship of the 1970s sought to explain women’s oppression by theorizing sex/gender systems through reference to Marxism in combination with psychoanalytic theories. The gender division of labor and the psychology of desire were posited as translating into a compulsory (Rich 1980) or obligatory heterosexuality (Rubin 1980; Wittig 2013) that held the key to women’s subordination by men. Yet Bowlby et al. (1989) note how feminist geographers were not examining the source of women’s subordination, which was implicitly or explicitly understood as emerging from a capitalist social system that was inherently patriarchal such that it could be referred to as a capitalist patriarchy. In an early exception to this assumption, Foord and Gregson drew on a realist approach to
Feminist geography examine the conditions for the development of patriarchy. They supported the idea of a dual system of capitalism and patriarchy each with its own distinction. This position was rejected by McDowell, who argued that patriarchy is inherent to capitalism and serves to resolve its internal contradictions (Bowlby et al. 1989).

By the early 1990s the critiques of white, Western feminism taking place in other disciplines and outside the academy began to filter into geography, articulating with postcolonial critiques from literary theorists, such as Edward Said, to draw attention to an issue that hitherto had been conspicuous as an absent presence: “race” and difference. Registering difference and diversity in turn opened up epistemological questions as well as ethical concerns, bringing under critical scrutiny the power relations and exclusions marking research and representations.

From the 1970s onward, the women’s movement had become increasingly divided by feminisms of different persuasions, with multiracial feminism also beginning to gather force alongside its radical, socialist, difference, liberal strands (McCann and Kim 2013). Despite the diversity of these ideas, primacy was still given to the division between men and women. Feminist geographers also neglected attention to other dimensions of social exclusion such as race/ethnicity, postcoloniality, and nonheteronormativity. Lesbian feminists’ 1970s critiques of feminist privileging of heteronormativity were followed in the 1980s by African American and black British feminists’ voices in powerful critiques of white, Anglo-American feminism with charges of a totalizing universalism, the same charge that white feminists had earlier made to androcentric knowledges. Women of color from both sides of the Atlantic joined voices to call into question universalizing concepts such as patriarchy and global sisterhood, pointing out that a feminist theory that does not take account of race cannot fully explain their experiences of oppression. To substantiate their point, they drew attention to the idea that it is not only black women who are oppressed but, in a world of white, capitalist supremacy, black men are also subordinated. In this way they problematized feminism’s goal of equality with men. Hooks (2000, 19) posits the question, since all men are not equal, “which men do women want to be equal to?” She uses the term “white supremacist capitalist patriarchy” to define the experience of multiple interlocking forms of oppression. The experiences of oppression of women of color highlighted the ethnocentrism of the sex/gender division which constructed the body as located in nature rather than culture, a body that is not only gendered but also raced, classed, and sexed. Hooks (2000) notes how a text that is considered as a founding text of the women’s movement, Betty Friedan’s Feminist Mystique, remains silent on the experiences of women who are the most oppressed. These are the women who have toiled in low-paid jobs outside of the home and are not fortunate enough to have the luxury of a gender division of labor that locates them in the home: the sphere of social reproduction. Women of color argued that the home has different meanings for them: in alliances with men of color, the home space can be a site of resistance and solidarity as well as a refuge from racial violence in the world outside. These voices both supported and were supported by the epistemological shift from modernism to postmodernism and its emphasis on difference, plurality, and multiplicity. As Linda McDowell (1993, 307) notes in her reflections on the trajectory of Anglo-American feminist geography, there has been a shift in focus from “equality towards that of difference.”

The 1990 meeting of the WGSG at University College London is insightful about feminist geographers’ concerns about, and responses to, postmodernism and difference. One of the three
issues for discussion at this meeting was postmodernism’s relationship to feminisms and the implications of difference for feminist politics. Informal presentations by Linda McDowell, Eleanore Kofman, and Gillian Rose explored whether postmodernism posed a challenge to feminist geographies or if it was complementary, particularly around the issue of difference and diversity. These presentations were subsequently summarized in *Antipode* (1992). Jan Penrose (*Antipode* 1992, 220) reflects on how “support for postmodernism – the theoretical framework that purports to celebrate difference … has become one of the most contentious and divisive issues within the WGSG.” Yet Monk, McDowell, and Kofman insist that there is nothing new for feminists about the concepts identified with postmodernism. While feminists were slow to recognize diversity among women as a group, they had been at the forefront in highlighting the processes of subjectification, the recognition of difference, polyvocality, plurality, and deconstruction of dualisms. Moreover, they were also the first to critique “classic modernist notions of rationality, equity, fairness, citizenship” (*Antipode* 1992, 221). Thus Penrose (*Antipode* 1992, 220) suggests that feminists’ contentious attitude toward postmodernism arises from the “new paradigm’s usurpation of long standing feminist tenets without any acknowledgement of its debt to feminist thought and practice.”

McDowell echoes wider concerns of feminists when she points to a number of problems with the postmodernist paradigm. First, although postmodernism recognizes and even celebrates the plurality of difference, such differences continue to be located in a hierarchy, constructed in relation to a norm that is reaffirmed by the presence of difference. Second, the emphasis on diversity serves to relativize gender, making it just one among many significant differences. This claim is refuted by feminist assertions that gender “is not one relevant strand but our uniting perspective” (McDowell in *Antipode* 1992, 226). Third, in addition to the category of “woman” being fractured, it is under threat of annihilation by the dissolution of the subject (for a detailed discussion see Butler 1999) – a source of great feminist anxiety because, as Pratt (1993, 56) in a paper published in the same journal two years later pointed out, “the dangers to feminism are clear enough: feminism threatens to self-destruct as feminists deconstruct its central analytical category.” Finally, postmodernism’s abandonment of the notion of a singular truth for multiple truths was said to risk the relativization of truth. Kofman (*Antipode* 1992, 229), who refers to postmodernism as a “male-created theorization,” reiterates wider feminist critiques when she suggests that, just when the truth installed by white Western men was being called into question by women and other “others,” postmodernism asserts that there is no truth to be discovered.

**Doing feminist geography: difference, polyvocality, and situating knowledges**

Assertions of the importance of difference and diversity among women, from feminists across a range of academic fields, gained further ground through articulation with the postmodern/cultural turn’s refusal of grand narratives and universality that also foregrounded difference, plurality, and multiplicity. Moreover, poststructuralism’s relativization of truth worked together with the decentering and dissolution of the subject, the destabilization of social categories and meaning, and modernist certainties to create epistemological concerns, anxieties, and ambivalence for feminist geographers. These concerns and anxieties prompted a rich debate on the nature of feminist epistemologies and
ontologies and the politics of fieldwork praxis, representation, and authorial claims (Nast 1994).

It is worth reminding ourselves that the focus on difference, diversity, and polyvocality pertains in large part to the demands of previously excluded groups to be heard and to have their claims accepted as authentic and legitimate. Feminists’ voices, alongside the voices of nonwhite, non-Western, postcolonial subjects, pointed to the nexus of power–knowledge in their critiques of androcentric, ethnocentric, rational, Western knowledges and their claims to universality.

Neopositivism, a system that served as a guarantor of the validity of hegemonic knowledges, was vociferously critiqued. Neopositivist ontologies expressed in the aims for discovering universal laws pertaining to the social world were abandoned and epistemological claims of objectivity, value freedom, neutrality, and replicability were posited as myths that merely served to cloak the biased, partial, and contingent nature of all knowledges. These critiques were instrumental in shaping the contours, content, and goals of feminist methodologies with the aim of producing knowledges supporting the emancipation of women and the researched through an emphasis “on the mutuality of the research process; intersubjectivity not objectivity and dialogues in place of monologues” (Gilbert 1994, 90).

A central plank of feminist epistemologies was an acknowledgment of the limits of seeing as the basis of the capacity to know. Feminist geographers asserted that – by contrast to the false universalities propped up by neopositivism’s attempts at a god trick, a view from nowhere, a disembodied, omnipresent vision – true objectivity lies in the recognition that all knowledges are embodied, situated, contextual, and therefore partial. In more recent years critical feminist modes of reading the visual, as well as feminist visualizations as method, have been advocated.

This has included an exploration of the possibility of recuperating geographic information systems (a military technology) for visualizing qualitative data.

Situating knowledges as a practice translated into a self–reflexive approach that would make transparent researcher biases and the processes by which knowledges become enframed and staged, making visible the relationship between the researcher and researched (Gilbert 1994) as part of making the researcher accountable by acknowledging power relations involved and the exclusions that their account rested on. In keeping with wider debates among feminists in other disciplines, feminist geographers also pointed to the distinctiveness of women’s sociospatial experiences from those of men and their capacity to know. The focus on difference and the politics of representation opened up two key questions: Who can speak for whom? With what authority? For example, on the question of speaking for others, England (1994, 81) asks whether, “if in a rush to be more inclusive and conceptualize difference and diversity might we be guilty of appropriating the voice of others.”

In resolving these questions, greater emphasis was placed on the researcher’s social location, positionality, and personal biography (see Mohammad 2001). These became regarded as key, in the academic community as well as in the field, to establishing the researcher’s capacity to know, the validity of his/her accounts, as well as his/her right to study particular groups. Identity on the basis of structurally similar social positioning or sameness of color/culture/gender and/or sexuality was seen as conferring an “insider” status, translating into a greater capacity to know and to understand the researched than that of those who attempt to study a group from the position of an “outsider” (England 1994). There was also an implicit acceptance that the position of an “insider” ensured greater equality between
Feminist geography

researcher and those researched (see England 1994).

In contrast to the privilege enjoyed by white, middle-class, European masculinities as knowing subjects, marginality was seen as conferring a moral authority and a privileged way of knowing. This recognition led to the emergence of a form of identity politics in which differences were placed in a hierarchy of oppressions ... [and] multiple oppressions came to be regarded not in terms of their patterns of articulations/interconnections— but rather as separate elements that could be added in a linear fashion, so that the more oppressions a woman could list the greater her claims to occupy a higher moral ground. (Brah 1992, 135–136)

The additive approach to identity critiqued by Brah was also problematized for suggesting that those who were marginally located along two or three axes of identity suffered double or triple oppression, neglecting the ways in which multiple marginality qualitatively changes the experience of oppression.

Feminist geographers have drawn on the concept of betweenness to deconstruct the insider/outsider dualism. In practical terms it offers a means of negotiating difference in the field. Nast (1994, 57) elaborates on how betweenness highlights the fact that we can never not work with “others” who are separate and different from ourselves; difference is an essential aspect of all social interactions that requires that we are always everywhere in between or negotiating the worlds of me and not-me.

This point also underlines the recognition that identity is fluid, relational, and constituted through a range of social narratives so that one can also be simultaneously an insider and outsider (Nast 1994; Miraftab 2004).

It is notable that, in contrast to neopositivist knowledges, many feminist geographers’ situated and reflexive accounts of the politics of fieldwork point to myriad complexities entailed in their embodied presence, bringing them into confrontation with different kinds of differences. These accounts are frequently saturated with emotions, concern, fear, guilt, and anxiety at possible or potential unequal power relations and exploitation of the researched. These feelings risk reading the relationship with the researched in binary terms: the all-powerful, active researcher presiding over an absolutely powerless and passive researched, negating the agency of the latter. Yet Miraftab (2004) draws on her experiences in the field to foreground the dialogic nature of interactions through which both the researcher and the researched encounter, read, and position each other. She points out how, despite the researcher’s often heightened sense of his/her own privilege, he/she is open to being positioned in very different ways from that imagined by the researcher, including being positioned as impoverished and even oppressed on different axes of identity.

Despite the best intentions of feminists, critiques of feminist methodologies point to the ways in which the emphasis on closeness, trust, and sharing in feminist methods can often carry greater potential for exploitation and even betrayal of the researched, who may come to see the researcher as a friend.

Some ways in which such feminist agendas of the politics of research and representation have been taken forward since the 1990s include participatory action research, in which the research is driven by those who have a stake in the project rather than by an outside researcher. It is democratic, collaborative, and designed to achieve some form of action that benefits the participants. The ethical turn during the 2000s has also configured the politics of research through the institutionalization of ethical frameworks within...
universities and funding bodies across Europe, North America, and increasingly beyond. All postgraduate, and in some institutions even undergraduate, research must have ethical approval prior to commencement; thus ethics committees have become gatekeepers, enabling, blocking, and modifying research projects. Yet feminist scholars continue to reaffirm the importance of self-reflexivity, positionality, and critical attention to the circulation of power in the field in achieving ethics objectives. At the same time, postcolonial feminist geographers have argued that sensitivity to the politics of representation has encouraged an “impasse” in feminist geography now, where fears of (mis)representation and (in)authenticity have led to a general withdrawal from fieldwork in the Global South, which means that fewer scholars are engaged in research that can be politically and materially useful for the poor in the Global South. (Sultana 2007, 375)

They also suggest that ethical guidelines of universities in the Global North may not be adequate for research settings in the Global South. There is a need to pay attention to the greater complexities involved in the research process introduced by “The complex movements of footloose researchers’ in this era of globalization” (Miraftab 2004, 597) and the impact on fieldwork dynamics.

Feminist geographies of the new millennium reflect the theoretical and substantive impacts of the cultural turn, articulating with the wider social context of deindustrialization, intensification of globalization and mobility, and important geopolitical shifts. Three emergent areas of study that have become established during this time are the focus on the body as part of the corporeal turn; geographies of masculinities; and Muslim geographies of gender as part of the new subfield of geographies of religion. This broader focus of feminist geography is reflected in the changing of the name of the Women and Geography Study Group in 2012 to Gender and Feminist Geographies Research Group.

In its 40 years of existence feminist geography has negotiated a range of institutional as well as epistemological challenges to become a significant institutional presence, transforming the discipline from within in terms of ontology, epistemology, and methodologies, constantly broadening and extending its focus in new directions.

**FEMINIST GEOGRAPHY**

Feminist methodologies

Linda J. Peake
York University, Canada

There is genuine confusion and misunderstanding about the term “methodologies” among and beyond feminists. A search of the term yields definitions that range through vague (“general research strategy,” “the design process for carrying out research”) to inadequate (“the study of methods”), the latter equating methodology with techniques for data collection. While the term is mercurial, it still requires definition and is taken here to refer to the theoretical underpinning of the practices, procedures, and rules used by feminists to conduct research. As such it accounts for many aspects of how research is conducted, but it also explains “the literature the researcher is using, the language and terminology, the other theories and explanations being used, the methods and the type of analysis that will be used to interpret the data and information collected” (Rangahau n.d.), as well as the formulation of research questions. And yet, despite its central importance to conducting research, to producing new practices of knowledge production, and to linking the intellectual and political, feminist geographers, surprisingly, have had much less to say on the geographical tradition of fieldwork than feminist anthropologists (see Wolf 1996), the last major intervention being in *The Professional Geographer* in 1994 and the most recent a 2016 theme issue published by *ACME*. Feminist geographers, however, have made significant interventions into methodological debates in other parts of geography, in particular, the development of visual methodologies (Rose 2016), critical geographic information science (GIScience), and indigenous methodologies.

Understandings of what is feminist about methodology are contested and have changed over time, paralleling the struggles of second and third wave feminisms. In the early 1970s, the political goals of the women’s movement in countries of the Global North were central to feminist research and this was when feminist scholars first started to challenge processes of knowledge production. In particular, the dominant and androcentric positivist scientific method was critiqued for its inability to address the experiences of women (Harding 1987). Work by feminists of color (Baca Zinn 1979; Hill Collins 1990) served as a corrective to the ethnocentricity of these critiques and brought the experiences of women of color into knowledge production. Poststructural feminists’ questioning of the unified subject of women 2002), whereas in sociology, for example, feminists have been publishing extensively on issues of methodologies and pioneering interventions into feminist methods since the early 1980s (see, e.g., Annie Oakley’s (1981) seminal piece on feminist interviewing; Dorothy Smith’s (1987) work on institutional ethnographies).
and postcolonial feminists’ broadening of the remit of feminist knowledge production, to encompass not only women but all marginalized groups, further expanded the grounds of feminist methodologies. By the 1990s, an analytical approach of Intersectionality (Crenshaw 1993), which highlights the relational connectedness of race, class, gender, and sexuality in examining women’s lives, was widely adopted, but in becoming increasingly divorced from its roots in explaining the oppression of African American women, intersectionality is coming under criticism. And the important ethical and political questions raised by antiracist and indigenous perspectives on decolonizing methodologies (Smith 2012) have served to highlight questions around the fixity of power and the limits of feminist critiques of knowledge production from the predominantly white Western academy. Interrogating the feminist grounds of knowledge production thus depends on the analytical and political positioning of feminists, which currently range through liberal groups, mostly in the Global North, with interests in women’s positioning in relation to men, to radical groups, both in the Global South and North, whose interests in women form part of a broader concern with community and communities, to those whose focus on gender cannot be separated from interests in colonialism, race, and/or sexuality.

The particular contributions made by feminist geographers to debates on feminist methodologies relate to the intersections of space, power, and knowledge. They can be seen as fourfold: spatializing existing feminist approaches to knowledge production; new spatialized contributions to feminist methodologies; engagements with methodological practices that speak to the valorizing of epistemology over praxis; and debates on methods, particularly in relation to quantitative versus qualitative approaches.

Spatializing existing feminist approaches to knowledge production

Inserting notions of spatialities into work on the production of knowledge and of subjectivities, feminist geographers have drawn especially on the work of two feminist scholars, Sandra Harding and Donna Haraway. A feminist philosopher, Sandra Harding’s interest in how relations of power shape the production of knowledge in different contexts led her to argue for a self-reflexive and collective approach to theorizing in which the viewpoints of all those involved in knowledge production processes must be acknowledged (Harding 1987). In this call, she went to the heart of a critique of hegemonic Western Enlightenment knowledge, built on the supposed bedrock of complete “objectivity,” that is, that the application of objective rules of science leads to the “truth.” She came to call her approach “strong objectivity,” in contrast to the unreflective positivist approach based on the distanced and top-down viewpoints of only a few so-called experts. Moreover, Harding emphasizes a relationship that proponents of the scientific method either see as irrelevant or seek to neutralize, that is, the centrality to strong objectivity of the relationship between the subject and object of inquiry, which highlights the importance of subjectivity. Harding (2004) also supported the epistemological stance of standpoint theory, in which Marxist feminist standpoint theorists, such as Nancy Hartsock, argue that women can produce more complete and less distorted knowledge than men because of their sex–class position. The universalism presumed by feminist standpoint theory was rejected by the poststructural feminist scholar Donna Haraway, however, who argues that neither women nor men can ever have total knowledge. She claims that the understanding of complete objectivity should be redefined and replaced by
that of “situated knowledge,” which acknowledges not only the partial and situated nature of all knowledge production but also its embodied nature, grounded in real bodies (Haraway 1988).

Understandings of all knowledge as situated, embodied, and geographically placed have come to characterize feminist geographic knowledge production. Gillian Rose in her landmark book *Feminism and Geography: The Limits of Geographical Knowledge* (1993) was arguably the first to develop a specific feminist critique of the “transparent space” of masculinist geographic knowledge production in which claims to know, divorced from experiential and emotional knowledges, transcend the specificities of the body and are equated with (violent) claims to space and territory. In contesting both what counts as legitimate geographic knowledge production and the masculinism of geographic discourses, Rose argues that “various forms of white, bourgeois, heterosexual masculinity have structured the way in which geography as a discipline claims to know space, place and landscape” (Rose 1993, 137). Drawing on the work of other feminists, her aim is to challenge the epistemic violence of the masculinist geographical desire to know by exploring feminist constructed spatialities that acknowledge and allow for difference. Utilizing the work of Teresa de Lauretis, who draws on the spatial imagery of “elsewhere” to describe “resistance to hegemonic identities of the subject of feminism” (Rose 1993, 139), and Adrienne Rich’s spatialized notion of a “politics of location” in which Rich explores her body as female, white, Jewish, and as a body within a nation, allows Rose to connect thinking through the body to scales both bodily and geopolitical, and to refuse the divide between metaphorical and real spaces.

These spatialities form the basis of Rose’s notion of the subject of feminism occupying a space that is “multidimensional, contingent and shifting” and that is also “paradoxical,” in the sense that “spaces that would be mutually exclusive if charted on a two-dimensional map – center and margin, inside and outside – are occupied simultaneously” (1993, 140). Constituted through, but also working to destabilize, the same–other masculinist discourses of the master subject that limit what women are and can be, the subject of feminism is simultaneously in two places. Rose suggests a different territorial logic to the transparent space of dominant subjectivities, one in which geographic imaginaries are built on a refusal of territoriality (namely, the claiming of territory), thus allowing for difference. Indeed, feminist geographic imaginaries are infused with multiplicities of situated differences that speak to class, race, sexuality, ablebodiedness, religion, and multiple other relations of power and relational understandings of subject formation.

Within the discipline of geography it is situated racialized differences that have most exercised issues of knowledge production within feminist geography (see Women in geography). The hegemonic discourse of whiteness speaks to epistemic exclusions that limit feminist geography’s ability both to speak across differences and to occupy an emancipatory paradoxical space. Drawing on the work of the African American feminist scholar Patricia Hill Collins (1990), women of color in Anglo-American geography have taken their simultaneous occupation of center and margin as an “outsider within” position (Mullings 1999) to describe their paradoxical position within feminist geography, of being inside the same and outside as other same/other. Such paradoxical positions are characterized by their troubled relation to the hegemony of whiteness and the hard-won political spaces from which challenges to it are launched.
New contributions to feminist methodologies

Attempts have been made not only to apply but also to add original contributions to feminist knowledge production, perhaps most clearly in Cindy Katz’s theoretical construct of “counter topography” (2001a; 2001b). Katz argues that Haraway’s concept of situated knowledge is often taken to refer to knowledge from a single site and a knowing subject, and, while situatedness may imply locale, it is most commonly constituted as a subject position – as Katz (2001a, 1230) puts it, “a space of zero dimensions,” located nowhere specifically. Situatedness, Katz suggests, implies location in abstract location to others, but not any specific geography leading to a “politics of ‘sites’ and ‘spaces’ from which materiality is largely vacuated” (2001a, 1230), erasing the effect of specific historical geographies and the difference that space makes. She also argues that situated knowledges are “simultaneously universal … and specific. … The politics of extension and translation, from the site (point) to the global is too easily assumed in the insistence on situatedness, when, of course, that is what has to be explained” (Katz 2001a, 1231).

Katz’s response to the inherent universality of situated knowledge has been to redefine it as the “local particularities of the relations of production and social reproduction” (2001a, 1230) and to employ the method of topography to show how social relations are far from abstract, but rather are “sedimented into space” (1229). Turning from the abstract topological representations of space inherent to Haraway’s formulations she gives ontological priority to topographical (territorial) space. Katz’s intention is to reinsert materiality into feminist theorizing through an insistence on studying the processes of global capitalism in particular places, each with its own specificity but also with its connections to other places. Drawing on the metaphorical idea of contour lines, which are lines of the same elevation that connect places at the same altitude, to describe how places are connected to each other, she imagines each contour line as representing a process, such as deskilling. Tracing these contour lines across places shows how they are materially connected to each other by the same processes. Countertopography, then, is a means of recognizing the historical and geographical specificities of particular places while also inferring their analytic connections in relation to specific material social practices. It is these material connections based on common interests, as opposed to shared identities, that serve as the basis for a feminist politics of connection. The intent underlying Katz’s notion of countertopographies is to suggest the importance of situated knowledge for a gendered oppositional politics that “works the ground” of and between multiple social actors in a range of geographical locations – crossing space, boundaries, and scales – in order to disrupt hegemonic understandings of capitalist processes. Katz eschews any suggestion of being able to predetermine how such politics may play out. She argues that, for politics to be effective in combatting globalizing capitalism, it is not simply a matter of building coalitions between places (vital as they are), but of building a politics sensitive to global processes while being grounded in the local.

The work of imagining knowledge production, of bringing together the intellectual and the political through the mobilization of situated solidarities, has been practiced by a number of feminist geographers and is most comprehensively documented in the work in Uttar Pradesh, India, of the Sangtin Writers Collective and Richa Nagar (2006). They argue that praxis – the simultaneous and continual interplay between thought and action – through the interweaving
of theories and self-reflexive practices of knowledge production via collaborative dialogues, provides a way to radically rethink existing approaches to knowledge production and issues of subalternity, voice, authorship, authority, and representation. Nagar and Lock-Swarr’s (2010, 2) work on critical transnational feminist praxis also speaks to the importance of recognizing the collaborative nature of knowledge production in developing feminist alliances across difference. Collaboration can be thought of then as a methodological tool that bridges the gap between (academic) feminists engaged in theorizing the complexities of knowledge production across borders and those (activists) concerned with imagining concrete ways to enact solidarities across nations, institutions, sociopolitical identifications, and economic categories and materialities.

**Valorizing epistemology over praxis**

Although praxis involving alliances across difference lies at the heart of feminist geographic knowledge production for many feminist geographers, such alliances have been marginalized, some would argue increasingly so, in the neoliberal academy, which values the fast creation of outputs best secured from short-term research engagements that limit the longer-term engagements that praxis usually requires (Peake and de Souza 2010). Throughout the 1990s and 2000s, it could be argued that feminist geographers’ interests in how the practices of research influence knowledge production were dominated by analyses of how the researchers’ identity and experience shape the research process. Praxis, for example, is a term that rarely appears on the pages of the feminist geography journal *Gender, Place & Culture (GPC)*. Instead, it has been a much narrower range of epistemological issues, namely, questions of Positionality, self-reflexivity, representation, and accountability, that have come to occupy feminist geographers, threatening to obscure feminist knowledge production as a political act and divorcing it from questions of praxis.

Positionality highlights how people, including researchers, see the world from different social, cultural, and geographical locations, with those dimensions of a researcher’s lived experience most commonly assumed to influence the research process being her gender, race, class, and sexuality. Building on the work of Gillian Rose, feminist geographers have highlighted how the positionality of the researcher is itself both contextual and mercurial. Awareness of one’s positionality has been most commonly explored via the methodological tool of self-reflexivity that Kim England (1994, 82) defines as “self-critical sympathetic introspection and the self-conscious analytical scrutiny of the self as researcher” (emphasis original) or being aware of the partiality of one’s own social location and knowledge. Indeed, reflexivity is critical to the conduct of research; it induces self-discovery and can lead to insights and new hypotheses about research questions. Self-reflexivity has also been critiqued, however, for its uncritical adoption, for being seen as an end in itself, as a reflexive accounting of individually held beliefs that all too often turns to introspection divorced from the situated power relations within which the researcher operates, with the effect of recentering the concerns of the researcher. Moreover, as Nagar and Lock-Swarr (2010, 7) have pointed out, understandings of positionality “often assume transparent reflexivity in ways that the very desire to ‘reveal’ the multiple, complex, and shifting positionality of the researcher freezes identities and social positions in space and time,” preventing analysis of the ways in which the embodied subjectivities of the researcher and the
researched are mutually constituted, interactive texts through which research-based knowledge production is produced and negotiated.

Feminist researchers’ engagement with what can count as evidence of explanation and how we can know if it is “correct,” or the extent to which it holds in the social world, has focused on challenging the authority of the researcher’s voice, which positivist epistemology, in its dichotomous representation of object and subject as a prerequisite for objectivity, has presented as that of an omnipotent expert. Feminist geographers have sought to dismantle their authoritative positions, giving voice to participants by respectfully engaging them in the decision-making processes of the research, conducting research with as opposed to on participants, experimenting with writing styles, diversifying practices of dissemination, producing materials that speak to nonacademic as well as academic and policy audiences, and sharing research products, such as interview transcripts and publications, with participants. In doing so, feminist geographers are also engaging in the practice of accountability, in pushing boundaries of knowledge production, yet it remains unclear just how systematic or influential such practices are; given the constraints of time and resources, they may not often be rigorously employed. And as Nagar and Lock-Swarr (2010) state, the limitation of these epistemological concerns is that, despite their progressive intentions, they do little, if anything, to dislodge the hierarchy of knowledge producers or to trouble the notion of the capacity of a researcher to “empower” research participants or the orientation of processes of praxis toward progressive humanization. Similarly, Smith (2012) urges researchers to take deliberate care to examine the effects of knowledge as a legitimating process, and to consider whose agendas and beliefs are legitimized in any research project.

Debates on methods

Initially, methods in feminist geography were influenced by the second wave women’s movement and quantitative research (most of its practitioners in the 1970s had come up through geography, at least at the tail end of the quantitative revolution). Feminist geographers documented the low numbers of women in the discipline, mapping their locations and documenting spatialized dimensions of their experiences. It was this early work that not only showed women as subjects of geographic research but also served to make women geographers into legitimate producers of knowledge (Thien 2009). By the mid-1980s, feminist geographers had moved on from such empirically oriented work to engaging further with theoretical perspectives and the masculinist underpinnings of the subfields of human geography. In moving away from quantitative methods, feminist geographers were part of the general shift in research practices in human geography to qualitative analyses. The arguments feminist geographers developed against the use of quantitative techniques are well rehearsed. Implicitly masculinized, quantitative techniques were seen as incapable of reflecting the complexity and richness of women’s lives, with many aspects of experience being difficult if not impossible to quantify, and as producing disembodied and abstracted knowledge that can only speak to predetermined categories that may neither “fit” women’s experiences nor capture interrelationships. The most common objection has been cast at an epistemological level, namely the association of quantitative research with positivism. Positivist knowledge production is critiqued for its assumption of universality, what Donna Haraway (1988) refers to as the “god-trick,” the “view from nowhere.” It is another sleight of hand altogether, though,
that has relegated quantitative techniques to an association *solely* with positivism.

Tainted by their association with positivism, quantitative methods today, such as statistical analyses of survey or secondary data and geocomputation and geovisualization based on geographical information systems (GIS), are not absent (Mattingly and Falconer Al–Hindi 1995) but they are much less likely to be employed by feminist geographers. The epistemological shifts in understanding gender – from its being a role to a power relation, to its identification with identities with different meanings and spatialities, to being something processual, something that subjects do that is considered as embodied, performative, and spatialized – have methodological implications and have served to promote the use of qualitative methods. Such methods are considered more open to relationships, to encouraging engaged dialogue between researchers and communities, to what can count as data – perceptions, experiences, representations – and to what counts as ethically sound research practice.

Indeed, a rich variety of qualitative methods are employed by feminist geographers, including interviews, focus groups, participatory action research (not to be confused with praxis), ethnographies, discourse analysis, archival analysis, visual techniques such as photography and video, plays, oral and life histories, and personal narratives. Notwithstanding the use of multiple qualitative methods, and triangulation between them, however, the overwhelming method of choice is the interview. A review of all the articles based on primary research (from 1993 onward) in *GPC* shows that by far the most frequent, and often only, method employed is that of the “in–depth” interview (a term that has become virtually meaningless as the meanings attached to it are rarely defined, and they may vary tremendously in length from 30 minutes to two– to three–day events) usually employed with small samples of under 50 participants. Within the pages of *GPC*, moreover, the overwhelming focus on qualitative methods and the virtual absence of quantitative research (less than 5% of all research articles) have allowed a vacuum to occur, legitimizing the absence of any reference to broader questions of the politics of knowledge production. Thus the extent to which debates by feminists in other disciplines about quantitative versus qualitative methods have been recognized as a red herring is still unclear, with many of the critiques of quantitative methods no longer being applicable when they can be deployed within a feminist research design. It is as if the recognition that the association of quantitative techniques with positivist science has been socially and historically constituted, and is moreover an ideological position that is neither necessary nor inevitable (Lawson 1995), has bypassed submissions to the journal.

Since the early 2000s, a small but increasing number of contemporary feminist geographers have been using postpositivist geospatial technologies (GIS, Global Positioning System (GPS), remote sensing), and it is in these feminist applications that some of the most innovative possibilities of feminist methodologies are being explored. The work of the feminist geographer Mei-Po Kwan serves as an example of hybrid geographies combining methods and perspectives commonly thought to be incompatible, integrating spatial analytical methods with feminist theory. For example, in her study of the impact of anti-Muslim hate violence in the United States after 9/11, Kwan attempts to produce a counternarrative to recover the lived affective experiences of American Muslim women in Columbus, Ohio, in order to understand the short–term and long–term impact of their fear of being attacked while going about their daily activities and using public space, and
the strategies they have adopted to cope with it. In her mixed-methods study she utilized interviews, mental mappings, digitally recorded oral histories, and GIS-based visual narratives using ArcScene (the 3-D geovisualization environment of ArcGIS). The video she produced is based on the oral history of a Muslim woman in Columbus, Ohio, which

not only shows the routes and the spaces her body moved through, but also tells her story through the images and her oral narrative as she recalls what happened to her life and how she negotiated the hostile urban spaces after 9/11. The video shows what she saw and experienced from her personal point of view (i.e., from the position of a driver who was traveling along various roads in the study area). It is a powerful form of individualized storytelling based on her personal movements, memories, feelings, and emotions. (Kwan 2007, 27)

The woman herself is absent from the video, unable to be watched by spectators; taking the viewpoint instead of the protagonist, the videographer serves to contest the objectifying gaze of dominant practices of geovisualization. Kwan argues that such alternative uses of geospatial technology not only have relevance for a world characterized by natural disasters, global-level conflicts, and wars through, for example, community-based mapping and progressive uses of Big data, but also to contest the dominant uses of geospatial technologies to combat their usage for violent and oppressive ends. She argues that a moral use of these methods requires that geospatial practices are embodied and attentive to emotions, claiming that feminist geospatial technologies (GT) practitioners “can appropriate the power of GT, contest the dominant uses of these technologies, and reconfigure the dominant visual practices to counter their objectifying vision … and explore the possibilities of performing (practicing) GT as resistance” (Kwan 2007, 23–24). Kwan’s work shows how quantitative data and methods can be powerful ways of initiating progressive social and political change, revealing not only broad but also micro-contours of difference and similarity and speaking to policy. The reality, however, is that many feminist geographers cannot take up these challenges because they lack training in quantitative analysis, which reduces the scope of the research questions that many feminist geographers can ask.

**Whither feminist methodology?**

While feminist methodology served initially to critique the epistemological claims of masculinist knowledge production and bring into view the female subject and embodied knowledges, currently it is the substitution of the use of qualitative methods for discussions about feminist methodologies, a restricted engagement with praxis and its replacement by questions of epistemology, and the reduction of these questions predominantly to those of reflexivity and positionality that have come to define the parameters of debates about the current production of feminist knowledge in geography. These are narrow parameters and we need to be wary of the limitations they place on feminist geographical knowledge production and on geographical imaginaries. For feminist geographers concerned with the intellectual and political practices of knowledge production – what constitutes knowledge, what knowledge is considered legitimate, and how it is produced – there is a need to move on from the dead-end debate about quantitative versus qualitative methods, which serves only to replicate dualist thinking; to ask broader methodological questions that include a place for praxis and a recognition of the need for much greater flexibility over suitable methods, including tolerance
and respect for a variety of methods; and to understand that no method is inherently feminist and that all data are representations. Furthermore, with big data rapidly gaining traction and with some of the most exciting methodological innovations in geography coming from geospatial techniques, a monistic take on qualitative methods by far too many feminist geographers runs the risk of reducing the epistemic authority of feminist work and the dynamism of the field. Clearly, it remains critical for feminist researchers to acknowledge and continually to problematize power relations in research.

Feminist political ecology

Juanita Sundberg
University of British Columbia, Canada

Feminist political ecology (FPE) is a subfield that brings feminist theory and objectives to political ecology, which is an analytical framework built on the argument that ecological issues must be understood and analyzed in relation to political economy (and vice versa). Feminist political ecologists hold that gender—in relation to class, race, and other relevant axes of power—shapes access to and control over natural resources. FPE also demonstrates how social identities are constituted in and through relations with nature and everyday material practices. FPE builds bridges between sectors that are conventionally kept apart—academia, policymaking institutions, activist organizations—thereby connecting theory with praxis. In addition, FPE weaves threads between sites and scales to produce nuanced understandings of the socioecological dimensions of political economic processes. Rooted in feminist critiques of epistemology (the study of how knowledge is produced and legitimized), FPE asks compelling questions about who counts as an environmental actor in political ecologies and how ecological knowledges are constituted. As such, FPE has made substantive, epistemological, and methodological interventions in political ecology, environmental studies, and gender studies.

Sites of inspiration and formation

Feminist political ecology was forged out of feminist and women-centered scholarship and activism in environmental and livelihood/quality of life issues. Inspired by feminist movements of the 1970s, many scholars and activists began to approach nature–society issues with a feminist sensibility, characterized by a persistent linking of the personal and the political. Such feminist environmental engagements brought the feminist movement’s diverse political objectives to bear on the most intimate sites of daily life including relations between humans and nonhumans, food consumption, and corporeal wellbeing. Feminist scholarship in this vein both elaborated critiques of research that excludes women, and advanced alternative theoretical framings to account for women (Haraway 1991; Seager 1993). This now extensive and theoretically varied body of work asks fundamental questions about the relationship between forms of oppression and the domination of nature as manifest in environmental degradation, species extinction, industrial slaughter, toxic contamination, and so on. Feminists also advanced alternative ethical framings built on concepts such as relationality, care, responsibility, and friendship (Cuomo 1998).

Feminist political ecology emerged from this arena of lively debate and theorizing. Three bodies of work are particularly relevant to the consolidation of FPE as a subdiscipline: ecofeminism, feminist science studies, and feminist...
FEMINIST POLITICAL ECOSYSTEM

critiques of development. Ecofeminists point to links between the oppression of women and the exploitation of nature, although how such links should be analyzed and acted on is highly debated (for an overview, see Diamond and Orenstein 1990). Although some suggest that women are closer to nature because of their biologically constituted corporeal experiences, the majority of ecofeminist scholars turn to historical shifts in Europe, including the scientific revolution, capitalism, and colonialism, to demonstrate how and why women in Western societies (and their colonies) are so frequently associated with nature, as well as how nature is feminized (see Merchant 1980). For example, environmental philosopher Val Plumwood (1993) traces associations between women and nature in Western societies to oppressive material relations – for example, sexism, colonialism, anthropocentrism (a belief that humans are the most important entities) – that have left their mark on epistemology (or ways of knowing) in the form of a network of dualisms. Accordingly, the human has been framed in opposition to nature in Western thought, with the human capacity for reason and abstract thought as the grounds for transcendence and domination of nature. In turn, reason is framed as masculine through its opposition to and domination of all that is associated with nature, the body, reproduction, emotion, and ultimately the feminine. Plumwood’s work demonstrates how such dualisms underpin oppression.

Postcolonial feminist scholars have criticized Western ecofeminism for its narrow focus on the philosophical or conceptual dimensions of oppressive relations as well as its neglect of the political economic arrangements – at multiple and intersecting scales – that constitute actual ecological relations in particular places (see Shiva and Mies 1993). Debates in ecofeminism continue to inform feminist political ecologists’ interest in how women and men’s relations with the natural world, in particular, played an important part in defining gender norms, such as notions of appropriate femininity and masculinity.

An equally important arena of inspiration for the emergence of FPE is feminist critiques of science and epistemology. Sandra Harding (1986), Donna Haraway (1991), and others argue that patriarchal gender norms inform basic conceptions of who counts as a knowledge producer, what counts as knowledge, and how knowledge is produced. Scholars in this vein demonstrate how women and other marginalized groups are systematically disadvantaged by conventional scientific practices that exclude them as knowers, while producing knowledge that renders their experiences invisible or represents them as inferior. As such, feminist studies of science problematize the concept of objectivity. Conventionally framed as a value-free view from nowhere, objectivity is predicated on the assumption that the researcher’s mind is separate from his or her body, social position, and geopolitical location. Feminists argue that, historically, claims to objectivity masked and protected what were actually the partial perspectives of dominant social groups, specifically European or white, heterosexist, bourgeois men. Hence, the aura of objectivity is an achievement, derived from denying or concealing the researcher’s embodied subject position. In addition to these critiques, feminists introduced various alternatives to masculinist forms of objectivity. For instance, Haraway’s (1991) concept of situated knowledge suggests that knowledges emerge in relation to embodied social locations. Harding’s (1986) proposal for partial objectivities takes subjective or local knowledges seriously by developing methods to verify and validate them within specific contexts of shared experience. Theirs are not calls for relativism but for responsibility and accountability in practices of knowledge production.
production. Feminist political ecologists build on these conversations to address how research practices are implicated in (re)producing and contesting power relations.

A third body of scholarship important to FPE is feminist critiques of development, which demonstrate how women have been excluded from or exploited by (sustainable) development and conservation projects (Shiva and Mies 1993). Feminist postcolonial scholars such as Chandra Mohanty (1991) complement this work, exposing how Western feminists leading development projects tend to depict what she calls “Third World women” as victims in need of Western help; such homogenizing portrayals deny the diversity of women’s locations, experiences, and knowledges. Scholars working in this field address the ways poverty is deepened and feminized when women are neglected as agents of environmental transformation (e.g., as managers of natural resources) and environmental knowledge bearers/producers. For instance, Judith Carney (1992) revealed how gender differences in land use, labor obligations, and crop rights articulate with development in The Gambia, Africa. International donor projects that introduced irrigation systems and improved rice production packages to male household heads resulted in women’s loss of access to land and, in some cases, income. Richard Schroeder’s (1999) research, also in The Gambia, centers on conflicts between men and women sparked by international donor projects in the 1970s, which were designed to include women in development by supporting women’s expansion of market gardening. When donor interests shifted to environmental concerns in the 1980s, however, men were encouraged to engage in agroforestry on the same plots of land as the gardens. Consequently, men’s and women’s crop production systems came into conflict. Ultimately, as scholars have documented, if development agency personnel and researchers consult only men, then the relevance of particular resources, women’s specific knowledge of them, and women’s livelihood strategies are made invisible. This, in turn, generates resistance among women toward development and conservation interventions. The importance of this body of work is evident in FPE’s ongoing emphasis on the potentially devastating consequences for women and their dependents when gender differences in resource management and land-use practices are neglected.

Building on these three bodies of work and debates, Dianne Rocheleau, Barbara Thomas-Slayter, and Esther Wangari (1996) put forward feminist political ecology as an integrative conceptual framework in the edited volume Feminist Political Ecology. The book situates gender as a crucial variable – in relation to class, race, and other relevant dimensions of political life – in shaping environmental relations. Rocheleau, Thomas-Slayter, and Wangari (1996) suggest that gender norms result from social interpretations of biology and socially constructed gender roles, which are geographically varied and may change over time at individual and collective scales. As such, the editors shift away from essentialist (i.e., one-dimensional and universalizing) constructions of women found in some ecofeminist work to treat gender differences and gender relations as constituted in and through material political ecological relations. The book’s conceptual agenda advances three primary areas of research: (i) gendered environmental knowledge and practices; (ii) gendered rights to natural resources and unequal vulnerability to environmental change; and (iii) gendered environmental activism and organizations. And, the editors outline an exciting call for research that connects the local and global, urban and rural, North, South, East, and West, through close analysis of everyday experiences and practices of gendered
environmental risks, rights, and responsibilities. Chapters feature case studies from across the globe rooted in collaborative and activist methodologies. Authors address issues such as the struggles of women on the front lines of the rubber tappers’ movement in Brazil, women in environmental justice organizing in West Harlem, New York, as well as women dealing with industrial waste in Spain. Feminist Political Ecology marks a noteworthy moment in environmental studies by demonstrating the analytical purchase of feminist political ecology to identify how inequality is (re)produced when women’s environmental engagements, knowledge, and activism are neglected. Recent work in feminist political ecology continues to engage with the agenda and debates outlined in the book.

Sites of intervention and contribution

Feminist political ecologists have produced a vibrant body of work that significantly enriches understandings of the political–ecological nexus. Moreover, researchers’ substantive contributions have prompted epistemological shifts and methodological innovation. Simply by engaging women as political actors, agents of environmental change, and bearers/producers of environmental knowledge, feminist political ecology revolutionized research in political ecology. While seemingly straightforward, considering women has far reaching consequences, for it is not possible to simply add women to existing frameworks and proceed as before. Indeed, to disrupt conventional assumptions about men as the primary environmental actors is to ask fundamental epistemological questions about how knowledge is produced and legitimized. For instance, feminist political ecology challenges claims to objectivity by pointing out that if researchers only engage men in any given site (as if they represent the only or primary actor), then their results are partial rather than neutral or unbiased.

Dianne Rocheleau and David Edmunds (1997) make this point by showing that women in many rural areas manage spaces – along with specific natural resources – that are nested in or between spaces controlled by men. Their analysis of the gendered dimensions of tree tenure around the world sheds light on the complexity of customary laws that grant men and women differing rights and responsibilities to multidimensional fields with distinct and overlapping species. For example, women often have customary rights to species above, below, or between men’s crops or trees; as such, they are subject to men’s decisions about changing the species they plant or tend (see Schroeder 1999). As this research highlights, attending to women as resource managers reveals the limitations of existing two-dimensional concepts of land and landownership, which are based on fieldwork with men only. These concepts do not account for the multidimensionality of species management by men and women.

Likewise, the personal experiences of white middle-class Western feminists/scholars may restrict their interest in or attention to particular spaces or activities, which, in turn, has the effect of shaping knowledge production. Maria Elisa Christie (2008) makes this point in relation to the kitchen, which is often framed as a principal site of women’s oppression in Western feminism. Christie’s close engagement with women’s “kitchenspaces” in central Mexico demonstrates the importance of food preparation in the enactment of rituals and fiestas that sustain extended family and kinship networks as well as unique skills and knowledge. In short, FPE demonstrates that political ecological stories are implicated in power relations, and researchers risk reproducing gender inequalities if and when women are left out as agents of environmental change.
Accounting for women as actors brings about additional epistemological shifts. Since many women around the world labor in social spheres that, historically, have been excluded from analysis, addressing the particularities of their knowledges and practices requires asking questions about what scales of political ecological life count as relevant. Building on feminist economics and feminist geography, research in FPE draws attention to everyday intimate and embodied practices along with household micropolitics. The scale of the everyday is where social reproduction takes place, where subject identities and social orders are brought into being and contested. Attending to daily life allows FPE to shed light on otherwise neglected dimensions of environmental engagements. For instance, Shubhra Gururani’s (2002) research with women collectors of fuel and fodder in the Kumaon Himalayas suggests that forests are sites of emotion, memory, and meaning. Women engage the forest as much more than simply a backdrop or site of resources where they meet livelihood needs, Gururani argues; indeed, women’s everyday material engagements constitute but also challenge culturally specific gender norms. As such, Gururani’s findings contest predominant utilitarian and mechanistic assumptions of human–nature relations in political ecology.

Likewise, Farhana Sultana (2011) examines how natural resource access is mediated through emotions, which are defined as intersubjective (e.g., produced in relationships between people or people and nature) rather than as individual mental states. In rural Bangladesh, where drinking-water wells are contaminated by naturally occurring arsenic, women’s relations with water are saturated and constituted by emotions, particularly suffering. Thus, Sultana suggests, women’s daily lives are configured not solely by struggles to obtain safe drinking water for their families but also by emotional distress; these emotions, in turn, shape women’s decisions about how to negotiate the power relations that constitute water access and control. As Leila Harris (2015) notes, attention to emotions allows feminist political ecologists to demonstrate not only that resource access is important for livelihood and health but also people’s sense of dignity and belonging.

Even as FPE legitimizes the everyday as a significant scale of analysis, researchers also excel at demonstrating how the intimate connects with other scales such as the nation or global political economy. For instance, Yaffa Truelove’s (2011) research on women’s water-collecting practices in Delhi, India links the body to city and state. While city planners look to market mechanisms to fulfill their vision of a modern city with efficient services, Truelove shows how the establishment of metered water sources creates a whole range of “illegal” water practices. Such legal mechanisms particularly affect women in slums without legal water connections, as they must engage in time-consuming, dangerous, and illegalized activities just to procure water for daily needs. As a consequence, young girls in marginalized communities are often kept out of school because of the amount of time required to meet family water needs; this, in turn, limits their life opportunities but also their sense of belonging in a city with global aspirations. For Harris (2015), the importance of research such as Truelove’s is to challenge existing claims made by state and nonstate actors (such as the World Bank) that the commodification of water leads to increased efficiency. As Harris contends, addressing embodiment and the scale of the everyday serves to demonstrate how capitalist logics privileging efficiency ignore nonproductive needs and uses associated with health, poverty reduction, or cultural and spiritual values (e.g., preservation of heritage seeds/crops).
Another important epistemological intervention stemming from the seemingly straightforward act of accounting for women relates to how the subject or person is conceptualized in political ecology. Historically, political ecologists have tended to assume that subject identities are narrowly defined based on taken-for-granted or congruent notions of class position, sex, or race. Juanita Sundberg (2004), Leila Harris (2006), and Andrea Nightingale (2006) draw from feminist poststructural theory to outline anti-essentialist framings of the political ecological subject. Judith Butler’s (1999) work is particularly significant here. Butler argues that gendering practices are not simply built on sex difference; instead, bodies are gendered in and through the regulatory practices of disciplining institutions such as the family, along with medical, educational, and religious institutions. In other words, gendered bodies have no natural foundation (in sex) but are constituted in and through gendering practices that are reiterated or performed in daily life. For Butler, everyday performances produce gendered subject positions rather than simply reflect them.

Sundberg, Harris, and Nightingale build on Butler’s work to insist there is no necessary or pregiven relation between men or women and the environment; rather, such relations are forged through geographically contingent, power-laden practices. Sundberg (2004) analyzes how conservation discourses, practices, and performances in Guatemala are instrumental in mapping gendered and racialized ways of life. In the process, Sundberg also reflects on her research collaboration with an indigenous women’s group to highlight how research practices are constitutive of gendered and racialized performances that (re)produce asymmetrical geopolitical relations. Likewise, Nightingale (2006) treats gender as a process to show how performances of masculinity, femininity, and caste are constituted in community forest management in Nepalese villages. Harris (2006) demonstrates how differences between men and women are (re)cited and naturalized in relation to new irrigation economies and ecologies in Turkey; gender comes to matter to irrigation practices, she argues, through the regulatory insistence on difference.

Feminist critiques of knowledge production also prompt methodological innovations in FPE so as to include previously excluded actors and to account for their knowledges as well as how they come to know their environments. Women and other marginalized groups may consider themselves or their work to be unimportant and their life experiences may lie beyond those of researchers. Moreover, as noted, women’s spaces of work are often nested in those controlled by men. Examining what was made invisible or neglected requires methodological creativity. Many feminist political ecologists work with feminist participatory or collaborative methodologies to enable research that supports feminist political objectives. In this context, feminist scholars tend to conduct qualitative research from the bottom up by privileging the experiences, spaces, and categories of marginalized people. Along these lines, Louise Fortmann (1996) specifically addresses strategies for ensuring that women’s distinct experiences with trees, plants, and animals are included in natural resource mapping. For example, forming separate groups of men and women while undertaking natural resource mapping helps to ensure that women have the space to express themselves freely (see also Sundberg 2004).

Some feminist political ecologists suggest that qualitative methodologies need not be the only ones appropriate to feminist research. Rocheleau (1995) pioneered the development of methodologies to triangulate data derived from
In her discussion of research evaluating the results of a forestry and agricultural initiative in the Dominican Republic, Rocheleau notes that gender-informed quantitative analysis contradicted predominant assumptions of women as auxiliaries to men; in addition, counter-mapping – map-making that starts with rural people and their homes – produced images that resulted from the mixing of local people and researchers’ specific skills and knowledge. Relatedly, Nightingale’s (2003) study of a community forestry program in Nepal combined aerial photo interpretation with ecological oral histories to analyze the effectiveness and sustainability of community forest management. Each of these two methods is rooted in a distinct epistemological tradition and, therefore, produces distinct kinds of knowledge. Working with Haraway’s concept of situated knowledge, Nightingale (2003) treated both aerial photo interpretation and oral history collection as partial yet internally valid methods of generating distinct stories about forest change. Rather than triangulating data, Nightingale attended to the inconsistencies between the data, thereby producing new insights about the pace and location of forest regeneration as well as how and why local people claimed the community forestry program as a success. In so doing, she also framed local people as legitimate producers of environmental knowledge.

In short, research that accounts for women necessitated epistemological innovation, and feminist political ecologists have been at the forefront of developing new theoretical and methodological tools. Nonetheless, the contributions of FPE tend to be assimilated into mainstream political ecology with little explicit acknowledgment. Indeed, in the recent trend to canonize political ecology through the publication of textbooks and edited collections, feminist political ecology is only marginally addressed. And yet, Rebecca Elmhirst (2011a) suggests, political ecology owes an epistemological debt to feminist theory for the range of fresh perspectives it offers. Nonetheless, many scholars whose work articulates with the political and theoretical objectives of FPE do not identify as such. Thus, a review of recently published research demonstrates that the field of gender and environment is flourishing although few identify as feminist political ecologists, leading Elmhirst (2011a) to ask if FPE is a disappearing subject. The response to her question is evident in renewed attention to FPE along with debates about its analytical purchase.

Sites of challenge and debate

In part, the apparent disappearance of FPE is due to the emergence of anti-essentialist framings of gender, which have destabilized assumptions about who counts as the (natural) subject of feminist-oriented research. In addition to Butler’s argument, noted earlier, postcolonial scholars have challenged homogenizing views of women as a pregiven, coherent category that is studied using similar theoretical frameworks the world over (see Mohanty 1991). Such critiques lead to a crucial question: if women are no longer the organizing purpose of feminism and gender is no longer its central analytical category, then what is the point of FPE?

A new generation of feminist political ecologists responds to the destabilization of gender by emphasizing intersectionality as the primary method of addressing how social subjects are constituted in and through diverse and interlocking processes of differentiation such as gender, sexuality, race, ethnicity, class, and livelihood. In other words, new FPE seeks to account more fully for the ways systems of power articulate
in time and place. Farhana Sultana and Andrea Nightingale advance the concept of intersectionality by explicitly considering how subject identity is constituted in and through material ecological relations. While FPE has long treated the natural environment as a constitutive element of political subjectivity, this dimension is often neglected in feminist theory more generally and is in need of further theorization. Sultana’s (2011) analysis of gender–water relations in Bangladesh highlights how the geologic distribution of arsenic in the local aquifer plays a crucial role in configuring gendered subjects. By and large, the contamination of water sources and the resulting need to travel longer distances to fetch safe water has worked to entrench the notion that masculinity is not compatible with water collection. Nightingale (2011) examines how imaginaries of gender and caste boundaries are materially enacted in postconflict Nepal. Normative femininity, she notes, requires Hindu women of a particular caste to be spatially segregated during menstruation because their bodies are considered polluting and therefore damaging to the environment. As such, appropriate performances of femininity are enacted in and through such spatial moves. Nightingale found that the Maoist insurgency disrupted gender and caste performances by enacting shifts in embodied spatial practices like sitting and eating in mixed caste and gender groups.

Sharlene Mollett and Caroline Faria (2013) present a strident critique of new FPE, suggesting that researchers too often continue privileging gender without also giving full consideration to the ways it intersects with race. Race is a crucial variable in subject formation, the authors suggest, while racial thinking constitutes the very categories used to name and order the modern world (e.g., racial labels such as “European” or “African” along with binaries like civilized/primitive, modern/traditional, formal/customary). In other words, the environment and environmental politics are not raceless. Mollett and Faria (2013) point to whiteness as an institutional factor that shapes the production of knowledge in FPE; the predominance of whiteness in the Western academy works to normalize the absence of critical race perspectives. Mollett and Faria (2013) call for a postcolonial intersectional approach that situates patriarchy and racialization as entangled in postcolonial genealogies of nation building and development.

Even with these critiques and reflections, some feminist political ecologists stress the continuing relevance of gender as a key variable due to the persistence of masculinist forms of objectivity and ongoing neglect of women as environmental agents. For instance, Aya Hirata Kimura and Yohei Katano (2014) suggest that performances of gender are at stake in times of crisis or disaster, such as Japan’s Fukushima nuclear reactor accident. Their study highlights how gender norms informed perceptions of risk in the aftermath of the nuclear disaster. Political elites called on binary constructs of appropriate masculinity and femininity to manage the disaster; in emphasizing the need for patriotism, normalcy, and safety, citizens concerned about radiation were feminized as irrational or hysterical. For her part, Elmhirst’s (2011b) study of forests in Indonesia introduces queer theory, which examines how normative gender categories are produced and contested. Elmhirst demonstrates how the Indonesian state manages and controls access to natural resources by privileging heterosexual conjugal couples. In other words, heteronormative marriage becomes an important conduit for resource access and therefore affects women as well as men. Elmhirst calls on political ecologists to question the naturalness of categories such as conjugal relationships and heterosexuality as they are deployed in the practices of knowledge production.
Future directions in feminist political ecology

Even as feminist political ecologists clearly demonstrate the ongoing importance of gender relations in natural resource struggles, feminists work on a range of topics wherein gender is not the primary analytical variable. In other words, feminist scholarship is not restricted to analyses of gender. This is evident in recent FPE scholarship centering on the body as the primary analytical category and site of analysis (Sultana 2011; Truelove 2011). In this vein, Jessica Hayes-Conroy and Allison Hayes-Conroy (2011) elaborate a political ecology of the body framework to account for the intersection of material and affective/emotive practices. Intended to facilitate analysis of food–body relations, especially how schools seek to promote healthy eating habits, the framework insists on considering the articulation of variables at multiple scales: structural factors that (re)produce inequality and therefore access to particular foods; discursive practices that constitute imaginaries of health and good food; and the material interactions that shape the emotive and bodily experience of eating. Hayes-Conroy and Hayes-Conroy’s framework is attuned to the unpredictability of bodily dispositions and potentialities and, as such, makes space for explanations that are complex, partial, and unfinished (as called for by feminist theories of knowledge production). In many ways, their approach is in line with Harris’s (2015) appeal for an FPE centered on the everyday, embodied, and emotional aspects of society–nature engagements.

Another exciting new direction in FPE is evident in recent efforts to more actively consider relations between humans and other-than-human beings such as animals. Here, two concerns found in ecofeminism are given new life: the connections between different forms of oppression; and, proposals for a feminist ethics of care. Building on work that registers the active presence of other-than-humans in coproducing our world, as well as ongoing feminist concerns about who counts as a political actor and what counts as politics, Kirsty Hobson (2007) argues for the inclusion of animals as political actors in political ecology. As Hobson notes, political ecologists risk reproducing oppressive relations between humans and nature by treating animals as mere objects over which people struggle rather than as living beings whose ecology, behavior, and wellbeing are caught up in (shaping) political ecological outcomes. These concerns are taken up in Sundberg’s (2011) elaboration of a more-than-human methodology to consider other-than-human beings as actors in geopolitical processes. As Sundberg demonstrates, desert soils, thornscrub landscapes, and ocelots (a small feline) constitute, inflict, and disrupt the United States’ enforcement of its southern boundary, forcing state actors to call for more funding, infrastructure, and boots on the ground. Sundberg tells alternative stories about the escalation of US boundary enforcement strategies, stories that refuse the US government’s narratives of mastery over borderland environments. With its unique focus on oppressive formations, corporeality, and the politics of knowledge production, FPE is ideally positioned to make innovative contributions to the shift away from treating nature as backdrop and toward an understanding of agency on the part of other-than-human actors.

Finally, recent work suggests that FPE is moving in the direction suggested by Rocheleau (1995) over two decades ago: to undertake research touching on gender, class, and other systems of difference from a position of affinity as opposed to identity. If identity politics implies assuming that women share concerns as women, affinity politics entails situating ourselves and research participants in webs of power and identifying research questions on the basis of issues
FEMINIST POLITICAL ECOLOGY

of shared concern, such as neoliberalization, environmental degradation, and imaginative geographies of distance and difference. A useful template for the establishment of research collaborations across sites and scales is Cindi Katz’s (2001) concept of counter-topographies, which entails tracing lines between places to show how they are constituted in and through the same processes of development or environmental change. In this vein, Roberta Hawkins (2012) forges new ground in her critique of ethical consumption campaigns that position Northern (female) consumers as saviors of (feminized) people and environments in the Global South. Approaching consumption as a gendered and environmental act that connects the intimate and global across geopolitical space allows Hawkins to chisel away at entrenched binaries such as North/South and researcher/researched that continue to structure political ecology.

Likewise, Harris (2014) considers the implications of Western models of environmentalism in Turkey through a framework she terms imaginative geographies of green, which builds on postcolonial and intersectional analytics. Harris examines how everyday narratives of environmental politics in Turkey articulate differences between East and West and, in so doing, evoke painful legacies of colonialism. Harris calls on scholars to problematize what counts as appropriate environmental politics so as to refuse the West as the primary or only legitimate point of reference and thereby initiate the process of decolonizing conceptualizations of green politics, citizenship, and subjectivities. Research that begins from a position of affinity rather than identity promises to shift political ecology away from studies that examine the concerns of distant and different others and toward research that is accountable to the many ways in which scholars are entangled in and complicit with the very webs of power, privilege, and oppression they seek to analyze.

As a style of research, FPE works with feminist concerns about how oppressive relations are (re)produced at various scales of everyday life and makes significant epistemological and methodological interventions in feminism and political ecology alike. Working at the nexus of nature, power, and knowledge production, FPE promises to continue supporting broader feminist political objectives for more equitable and ecologically viable futures.

FEMINIST POLITICAL ECOLOGY

Fertility

Yvonne Underhill-Sem
University of Auckland, New Zealand

Fertility is understood most widely in geography as one of the three determinants of population change alongside migration and mortality. Everyone is born, everyone moves geographically in some manner, and everyone eventually dies: however, such self-evident understandings belie the importance of the conceptual framing of these processes, and none more so than fertility. A fertile concept, idea, or process is one that promotes further inquiry, knowledge, and understanding. Yet, within geography, connecting these understandings of fertility through research and analysis is neglected. Instead fertility is incorporated in a routine, uncritical way, with the result that geographic understandings of fertility remain largely taken-for-granted and under-researched. A partial reason is that within geography there has been a preoccupation with migration as the main demographic process that distributes people spatially. Yet this preoccupation overlooks the vital fact that one needs to be born to be able to move, and birth is something that occurs in diverse ways and with potentially problematic consequences for all involved. A more complete understanding of fertility involves inquiry into the spatiality of vital population acts (such as giving birth), performances (such as becoming pregnant), and institutions (such as bride wealth exchanges). Such inquiry would provide insight into areas such as reproductive practices, sexualities and embodiment, and notions of family and motherhood.

Developing critical analysis from the foundation of classic fertility narratives, statistical examination of survey and census data, and multilevel interdisciplinary methodologies can provide more nuanced insight into the dynamics of population change. Such insight promises to contribute to debates both within and beyond geography. For instance, the global mobility of domestic workers into Singapore can be understood as groups of women moving to care and nurture the aged and young in distant places. This practice can also be understood as sexualized subjects carrying with them particular fertility potentials that change their childbearing possibilities. Such a view allows a recognition of new fertility patterns and their implications. For instance, in what ways is their fertility controlled in new workplaces? In what ways might it appeal to have children born in places where they might have new possibilities for citizenship? And in what ways might new, informal sexual relations in different places affect formal sexual relations in home countries? Similarly, with new reproductive technologies available in low-fertility countries such as those in Europe, the social relations between the different biological contributors to a particular pregnancy are increasingly complex and variable. In what ways are new configurations of parents affecting understanding of households and families? In what ways does the particular scale of new reproductive technologies affect analysis of small-scale population dynamics, and in what ways does this development produce new options for citizenship and inheritance? Furthermore, how have historical patterns of
FERTILITY

reproduction, such as China’s one-child policy, or localized environmental events like nuclear contamination in the Ukraine, or large-scale political catastrophes like genocide in Cambodia, affected the fertility of people and their procreative practices?

Mainstream understandings of fertility and reproduction

Fertility routinely refers to the ways in which groups of people produce offspring. Some demographers argue that the term “fertility” refers to a more refined analysis of “natality,” which refers more broadly to the role of births in population change and human reproduction, and invites a more comprehensive analysis. This framing has not, however, flowed into other disciplines, such as geography or anthropology, which also appropriate demographic analysis. Instead universal assumptions about biology mean that similar measures of fertility are used in nonhuman populations such as plants and animals. Population geography, however, offers distinctive possibilities of shifting analysis across scales between bodies and populations and back again. In human populations there are many measures of fertility and each one attempts, at increasing levels of “accuracy,” to represent the rate at which a population is growing by relating the number of live births to a specific population and time period. Unfortunately, even identifying a live birth, let alone ascertaining how many there are, is difficult.

The simplest measurement is the crude birth rate, which represents the number of live births in a given year by the number of people in that population in the middle of the year. Slightly more refined and commonly used measures include general fertility rates (the number of births by the number of women of childbearing age), age-specific birth rates (the number of births by the number of women in a given age group), and total fertility rates (the sum of age-specific birth rates over all ages of childbearing women). More sophisticated measures include completed fertility rates, which show the fertility progress of a cohort through the childbearing years, and age-specific birth probabilities. The former provides some insights into historical shifts in the timing of child-bearing and the latter provides for the calculation of population projections.

The variability of fertility among subgroups of a population means that it is important to refine measures of fertility specific to known age, nuptial status, and other social and temporal features. Further, because of the total absence or unreliability of records about birth dates or total populations in many parts of the world – especially in the demographically largest and fastest-growing parts of the economic south such as sub-Saharan Africa and China – continual efforts are made to develop the best techniques to estimate fertility rates. Despite ongoing and often justified skepticism as to the accuracy of fertility rates, they are still ubiquitously used and are relevant for comparative accounts of progress toward social equity. All fertility rates have temporal and spatial dimensions. Used carefully, with due regard to the assumptions and methods of data manipulation, the comparative analysis of fertility rates provides a convenient representation of change. For this reason it is useful to calculate fertility rates, refining them as best one can, but keeping in mind that they are often a crude tool for analyzing more complex processes.

Closely related to the notion of fertility is the term “reproduction,” or the extent to which a group of people are replacing themselves by natural processes. The term “reproduction” has
FERTILITY

A wider scope than the term “fertility,” and is defined demographically as the act or process of producing offspring, giving birth, bringing forth offspring, producing, yielding, making, manufacturing, working, and/or creating unity. Used in demography and population studies, including population geography, this term is often limited to the biological event of producing babies. It clearly has a wider meaning linked to the production of human beings and is the focus of a range of social sciences, especially those interested in class differentiation. The main problem with this concept is that, like “fertility,” biology tends to be treated as an uncontested universal concept that takes agency away from people, and especially women.

Central to the shortcomings of these mainstream conceptualizations of fertility and reproduction is the unproblematic treatment of the body as exclusively a biological given. Bodies are now accepted as being both biologically configured but also socially, culturally, and politically constituted by places and people. This recognition provides for nuanced analysis of the complex layering of meaning regarding how groups and individuals produce offspring.

Reconceptualizing fertility:
of epistemologies, bodies, and desires

Interest in fertility within demography is matched by a similar longstanding interest within anthropology in documenting ethnographic accounts of childbirth in different places. In the process of documenting the many different cultural interpretations of the “universal” process of birth, however, it becomes clear that childbirths are as different as the overlapping and frequently contradictory discourses that are used to describe them. For example, in the English-speaking world, it is not unusual to hear fathers-to-be saying “we are pregnant.” Clearly, there are solid grounds for reconceptualizing another epistemological position from which to interrogate notions of fertility.

Population geographers increasingly examine the implications of an epistemology in which demographic events and process are socially constructed and therefore partial. Following the work of feminist anthropologists and demographers, population geographers also consider how “places” construct bodies so that they are not simply understood as a biological given. To do so requires a research process that combines critical ethnographies and geographies with statistical analysis.

This process begins with recognizing that all categories are “marked” in one way or another. Feminist scholars have long drawn attention to such marking by showing how the default body in social theory is often a white male body. More robust scholarship would specify more precisely what bodies are being discussed. Thus even fertility analysis would require consideration of what precise body is being represented in mainstream analysis. An embodied analysis would give corporeal form to otherwise abstract definitions, and doing so would subvert taken-for-granted understandings whose privileging has suppressed other ways of knowing. Such analysis is likely to include other discursively constructed realities such as the existence of “specialists,” “sorcerers,” “deceased ancestors,” and even God. Placing the analysis of fertility within specific historical contexts and places gives explanatory preference to the complex interplay of structural features like the dynamics of social, cultural, and political issues. Thus a study of fertility would not simply focus on the event of the birth of a child but would also examine how the mother and the others involved talk about the child, the pregnancy, and the birth. In this way fertility can be understood as relating to bodies as biological
FERTILITY

constants, but also bodies situated in historical processes in particular places.

Such understanding requires looking beyond mainstream measures such as total fertility rates to also examining the discursive processes that constitute the body and particular subjects. This approach opens up the possibilities of considering subjects such as, for instance, the bodies of trafficked women, of sexually active people who live with physical impairments, disabilities, or chronic illness, or women living in isolated villages in the economic south.

The intersection and interrelationships of material and discursive fields in relation to bodies and places is a critical place from which the analysis of fertility can expand. When one begins to capture the workings of communities and family groups, enmeshed in the overall agreements as to the aim of particular fertility outcomes, different gendered versions of these agreements will emerge. For instance, the reasons for women wanting children, and especially sons in some places, may not be only to maintain lines of male descent but also to provide comfort, loyalty, and security in one's daily life. These fertility desires and sentiments last as long as mothers and caregivers do, but they play an important part in understanding otherwise contradictory fertility practices.

Depoliticizing fertility: abortion, the International Conference on Population and Development, and HIV/AIDS

Fertility studies in geography are an important route into working with contemporary social justice issues around women’s sexual and reproductive health and rights. Abortion remains a controversial and complex issue that incorporates moral positioning and political responsibility in ways that can threaten the overall development of a country as well as inflame debates around when a fetus acquires the right to life. The situations leading to pregnancy, the availability of safe abortion services, and the legal definitions of the fetus are entangled in ongoing political debates globally. In some places, such as the United States and the Caribbean, this entanglement is combined with the increasing use of the morning after pill, “virgin clubs” (i.e., young people committed to saving sex for marriage), and the return of traditional marriages to recast societal norms around families and households. In other places, such as the Sudan and Central African Republic, death and chronic illness as a result of repeated unwanted pregnancies – often in places of civil war and disasters, with the subsequent displacement of domestic life – also have the effect of shifting social norms around families and households. So too has the high incidence of HIV/AIDS, with a growing number of deaths of young adults, especially women, threatening to radically alter notions of family and household because different members of the household become the ones whose fertility is most sought after – especially young uninfected girls. Combined with practices such as female genital mutilation, sex work, and the cross-country adoption of the girl child, the examination of fertility from a geographic perspective is sorely wanting.

In the global policy arena, the twentieth anniversary of the International Conference on Population and Development and its outcome, the Cairo Program for Action, is poised to promote a comprehensive sexual and reproductive health and rights agenda. This has happened even with strong arguments to return to the demographic target-setting of population processes pre-1994. The decennial international population conferences before 1994 (Bucharest in 1974, Mexico in 1984) reflected many struggles
because the fertility of women—especially from the economic south—was the primary concern. Over time the debates have moved from Malthusian-inspired theories that targeted family planning to neo-Marxist influenced theories of economic development. In 1994, however, the relationship between demographic theory and population policy, especially as it concerned women’s fertility, witnessed a remarkable ideological and political shift. The more explicit human rights focus of the Cairo Program of Action emphasized that empowerment of women is the way to reduce gender and other social inequalities. This has been a well-recognized milestone moment in both the history of population and development and in the history of women’s rights.

Few fertility studies within geography work explicitly with this framework. Instead there is an apparent comfort in adhering to conservative gender agendas and continuing to work on descriptions of population dynamics that are immune to the politics of fertility research. For instance, there are defendable empirical and political reasons for such research in South Asia where specific countries make key contributions both to global population dynamics and to geopolitical dynamics. However, when the analysis of marital unions in Europe is undertaken with little consideration given to sexuality, it is less clear why conservative advice prevails. This disinclination is constraining the potential for geographic thinking on the fertility process to contribute to critical research-based policy debates at national and international levels.

While few geographers have actively engaged with the national, regional, and/or global policy processes around the International Conferences on Population and Development, many more have taken on issues concerning HIV/AIDS and new reproductive technologies. Closely linked to patterns of mortality, the analysis of HIV/AIDS provides fresh insights into the ways in which fertility intersects with the mortality of sexually active populations. For instance, reduced fertility can be due to shifts in traditional partnering patterns, biochemical reactions to medication, or changing sociocultural values over sexual reproduction such as polygamy, slavery, bride-stealing, or sexual trafficking. These are issues that are experienced and embodied in very diverse places and provide huge possibilities for new approaches to fertility analysis.

**Conclusion**

The traditional assumption that groups of people are best understood when they are studied as collective outcomes of individual population actions is challenged by contemporary fertility research in geography. New approaches to analyzing fertility might begin by mapping or recording patterns of fertility using standard demographic techniques; however, other texts, such as maternity histories, life course analysis, analysis of religious records, and analysis of naming practices or burial practices and sites also need to be incorporated. This is not just because it is highly likely that standard techniques cannot capture complex human processes, but also because there is greater access to such texts. Drawing on interdisciplinary insights from, for instance, anthropology, history, and literature will ensure geographers are more informed of the limitations of particular texts or measurements.

Patterns of fertility are not only the result of biological processes. They also represent complex and interesting social, cultural, and political processes that create new subjects such as adopted children, orphans of war and HIV/AIDS, rural bachelors, “tiger parents” (a phrase associated with parenting within Asian–American families), and children conceived by in vitro fertilization.
or surrogacy. These new subjects are constituted differently across time and place, and many more will emerge on the global population landscape. Critical geographies of fertility have much to consider and, as with population geography in general, the analysis of fertility needs to move beyond method and concern over technique and toward asking critical questions about contemporary issues: for instance, what is the relationship between pro-natal policies in Iran and antenatal tendencies in the Ukraine? In what ways do impoverished families negotiate fertility futures for themselves and their children? What are the multiple connections between environmental degradation, menstruation, and young women’s reproductive health in boarding schools? The opportunities are wide-ranging for critical population geographers informed by new social theory, to interrogate fertility comprehensively and justly.

Fiat and de facto objects

Thomas Bittner
The State University of New York at Buffalo, USA

Spatial entities are located at three-dimensional regions of space (Casati and Varzi 1999). Ontologically this category of entities is characterized by mereological (Simons 1987; Varzi 1996), mereotopological (Casati and Varzi 1994), and mereogeometrical (Borgo and Masolo 2010) properties and relations. Here the focus is on ontological makeup of fiat and bona fide spatial entities. As illustrations, three bona fide and fiat boundaries and objects in three kinds of geographic environments are discussed: built environments, large-scale geographic environments with individual objects such as mountains and valleys, and systems of regional partitions that structure the surface of the Earth. Ontologically relevant aspects of each kind of environment are discussed in the context of a prototypical running example: (i) a parking lot as an example of a human-made built environment of intermediate scale (Figure 1a); (ii) Europe as a large-scale geographic entity with natural phenomena, cultural and human resources, and a political subdivision into nation-states (Figure 1b) (Burrough and Masser 1998); and (iii) categorical classification and delineation systems (Figure 2).

Mereology, mereotopology, and mereogeometry

Mereological properties and relations characterize the ways in which wholes are made up of parts (Simons 1987). For example, parking spot 6 (P6) as well as the service booth (SB) are parts of the parking lot in Figure 1a; P6 and SB are disjoint, that is, they do not have a part in common. Part-of and disjoint are examples of mereological relations (see Simons 1987 for more examples). At the topological level there are two classes of fundamental distinctions (Casati and Varzi 1994). First, there is the distinction between entities that are singly connected (e.g., parking spots) and entities that have disconnected parts. For example, (i) there is the union of all parking spots in Figure 1a that are labeled by an odd single-digit number; or (ii) there is the United Kingdom with its multiple disconnected parts (Figure 1b). Second, there is the mereotopological distinction between parts of spatial entities that form their interior (P6 is an interior part of the parking lot) and parts that form their boundary. Boundaries demarcate spatial entities from their surrounding environments (Casati and Varzi 1994; Smith 1995); for example, a boundary separates P6 from P7, P14, P15, SR, and MR. Singly connected entities have a continuous singly connected boundary. By contrast, entities with disconnected parts are such that every mereologically maximal disconnected part has its own continuous singly connected boundary. Boundaries have parts; for example, the boundary separating P6 and P15 is a part of the boundary of P6 as well as a part of the boundary of P15. Boundaries are dependent entities (Smith 1995): there cannot be a boundary without some spatial entity to bound.

Mereogeometric properties establish the distinction of entities and their boundaries according to their shape and size (Borgo and Masolo 2010): boundaries can be straight versus curved,
and entities can be convex versus concave, spherical versus nonspherical, and so on. Scale is an inherently mereogeometric phenomenon.

Bona fide and fiat boundaries

Boundaries fall into the major categories of bona fide boundaries and fiat boundaries (Smith 1995). Bona fide boundaries are boundaries in the things themselves and exist independently of all human cognitive acts. They are a matter of qualitative differentiations or discontinuities of the underlying material reality. Examples are surfaces of extended objects such as cars, walls, and the floor of the parking lot in Figure 1a. Projections of bona fide boundaries onto the floor are marked by bold solid lines in the figure. Examples of bona fide boundaries of entities of larger scale include the boundaries that separate the mainland of the British Isles from the surrounding North Sea (Figure 1b).

There are also boundaries that do not correspond to qualitative differentiations or discontinuities of the underlying material reality and that may lie skew to boundaries of the bona fide sort. Examples include the boundaries of parking spot 6, P6, in Figure 1a, large parts of the boundary between Germany and The Netherlands, and large parts of the boundary of the Alps along the foothills (Figure 1b). Such immaterial boundaries either (i) exist by virtue of certain geometric features of their environments or (ii) are brought into existence by human fiat.

As an example of an immaterial boundary of type (i), consider the parking lot in Figure 1a. By virtue of its rectangular shape it has parts that are separated by geometric boundaries. Due to the orientation of its representation in the figure, those purely geometric parts of the parking lot can be referred to as left/right half, top/bottom.
half, lower-left quarter, top-right quarter, and so on. Similarly, the equator is a purely geometric boundary that divides the surface of the Earth into two parts: the Northern Hemisphere and the Southern Hemisphere.

Fiat boundaries, on the other hand, exist by virtue of demarcation and are affected by human cognitive acts (Smith 1995). Prototypical examples are the boundaries of the parking spots in Figure 1a. They were brought into existence by the cognitive act of a planner when dividing up the space of the parking lot into parking spots.

The classification of spatial boundaries generalizes to a classification of spatial entities (Smith 1995): bona fide objects are spatial entities that have a single topologically closed bona fide boundary. Examples include the service booth, SB, in Figure 1a, or the mainland of the United Kingdom. By contrast, fiat objects have fiat boundary parts. Examples include the parking spots in Figure 1a and the political units in Europe in Figure 1b.

Properties of fiat boundaries

Bona fide and fiat boundaries have very different properties. These include properties such as observability, co-locatability, being a barrier, and many more. While bona fide boundaries have their properties by virtue of the material structure of physical reality, the properties of fiat boundaries are often established by conventions.
FIAT AND DE FACTO OBJECTS

Observability

Fiat boundaries are not directly observable because they do not correspond to discontinuities in the underlying material reality. Therefore the location of fiat boundaries must be either inferred from the location of other observable features or determined by measurement (e.g., surveying).

Consider parking spot 15, P15. It is located in the middle of the parking lot where there are no bona fide boundaries nearby (except the floor). The parking spot, in conjunction with its boundaries, was brought into existence by a cognitive act of a planner when dividing up the space of the parking lot into parking spots. In order to make the demarcated parking spots perceivable, the back, left, and right boundaries had to be first identified by surveying procedures and were then marked in paint so that they would be directly observable. Examples of explicitly marked boundaries are the thin solid lines in Figure 1a.

In certain situations cognitive agents are able to infer the location of immaterial boundaries from the structure of the material features of a given environment. For example, the front boundaries of the parking spots in Figure 1a are not marked, but nevertheless human agents are able to infer their location as coinciding with the shortest line connecting the ends of the left and right boundaries. Similarly, the location of the upper and lower boundaries of the side road, SR, toward the main road, MR, are to be inferred. Nonmarked, and hence invisible, fiat boundaries for which location is to be inferred are marked by dashed lines in Figure 1a.

Inferring the location of the boundaries of large-scale objects is usually more difficult than for small-scale objects because (i) there are fewer cues in the environment (ignoring cases such as the Berlin Wall or parts of the border between the United States and Mexico, etc.); and (ii) boundaries of fiat objects such as “The Ruhr,” “The Paris–Brussels Axis,” “The Sunshine Coast,” and “The Alps” in Figure 1b are subject to vagueness (see “Vagueness of boundary location”).

Co-location and overlap

Two spatial entities are co-located if and only if they are located at exactly the same three- or two-dimensional region of three- or two-dimensional space at the same moment in time (Casati and Varzi 1999). It is a defining property of bona fide objects that they exclusively occupy a given location. This means that no distinct bona fide spatial objects can be co-located or overlap.

Moreover, there seem to be good reasons to assume that distinct fiat objects of the same ontological kind cannot overlap and therefore cannot share their location (not even partially) (Smith 1995). Examples that illustrate this point include my land property and your land property, your parking spot and mine, the objects forming a political subdivision such as countries, and so on.

The situation is different for fiat objects of a different kind and for fiat boundaries in general. Fiat objects of an ontologically different kind can be co-located (Casati and Varzi 1999, 1994). For example, the “City of Vienna” is co-located with the “Federal State of Vienna” of the Republic of Austria. Similarly, fiat boundaries of neighboring fiat objects of the same and of a different kind can be co-located (Casati and Varzi 1999, 1994); for example, P6 and P15 share parts of their boundary and so do P6 and MR.

Moreover, some boundary parts of bona fide and fiat objects can be co-located; for example, the back-boundary of P1 is co-located with a part of the bona fide boundary of the outer wall of
the parking lot, which faces the interior of the parking lot.

According to what was stated above, fiat objects can have bona fide boundary parts. It may be more precise to say that fiat objects have fiat boundaries, parts of which may be co-located with parts of boundaries of bona fide objects.

Temporal properties

Although physical reality changes over time, such changes happen relatively slowly. By contrast, the location and properties of fiat boundaries can change instantaneously. As an example consider the intersection of 5th Avenue and 110th Street, which are located on the Manhattan island of New York City. They are fiat objects because they have fiat boundary parts, for example, at their intersections. Moreover, both streets are spatial entities of the same kind (streets).

Fiat objects of the same kind cannot overlap. For this reason there are traffic lights at the intersection of 5th Avenue and 110th Street which determine when the intersection of the two streets is a part of 5th Avenue and when it is a part of 110th Street. Therefore, the streets do not overlap because there are no parts of them located at the same region of space at the same moment in time (see Simons (1987) for an extended discussion of the temporal properties of the parthood relation).

The temporal changes that occur when the traffic lights change are instantaneous: the mereotopological makeup of both streets changes instantaneously when one street gains a part while the other loses that part; the topological structure of one street changes instantaneously from a singly connected whole to a whole with multiple disconnected parts, while the other street undergoes a corresponding change in the opposite “direction.”

Boundaries, environments, and conventions

Fiat boundaries that are co-located with bona fide boundaries “inherit” some of the properties of the bona fide boundary they are co-located with (Smith 1995). In an obvious way, this includes the property of being a barrier to the movement of other material entities.

Immaterial boundaries by themselves cannot affect the physical degrees of freedom (such as the movement) of material entities. Nevertheless, some fiat boundaries – in conjunction with systems of conventions – seem to create affordances in a Gibsonian sense that do affect the degrees of freedom of cognitive agents. Consider your favorite parking lot. Marked fiat boundaries seem to afford agents (in cars) not to cross despite the fact that there is no physical barrier. By contrast, nonmarked boundaries seem to afford crossing in the sense that the nonmarked boundary of an empty parking spot “invites” you to cross this boundary and park your car at this spot. Presently there are no fully developed theories of how the structure of an environment affects the properties of fiat boundaries.

In many cases there are no obvious affordances in the environment that enable human agents to perceive or to infer specific properties of fiat boundaries. For this reason, humans have designed complex systems of signs and corresponding conventions that regulate the properties of fiat boundaries and thereby affect the degrees of freedom of the movement and other activities of cognitive agents. Consider the boundary of the side road (SR) in Figure 1a. Traffic rules in conjunction with stop signs require one to give way to cars on the main road, MR, when leaving the side road, that is, when crossing the boundary between side and main road. Other examples include conventions for one-way
FIAT AND DE FACTO OBJECTS

streets, posts or signs demarcating property lines, nonsmoking zones, and so on.

Vagueness of boundary location

Large-scale natural geographic objects such as mountains, hills, valleys, ridges, and capes are fiat objects because they have fiat boundary parts that demarcate them from their surroundings (Smith and Mark 2003): many mountains are separated from their surroundings by mostly fiat boundaries along their foothills, many valleys are separated by mostly fiat boundaries from adjacent hills, and many capes are separated by mostly fiat boundaries from the mainland. Such large-scale fiat objects are well defined in the sense that there are determinate facts of where the top of a mountain or the end of a cape are located. That is, there are determinate facts that identify a given mountain or a given cape. By contrast, there do not seem to be determinate facts about the exact location of the boundaries that demarcate those geographic objects from their surrounding environments. That is, the location of the boundaries of certain kinds of spatial objects of geographic scale is subject to vagueness.

The notion of vagueness is complex and there are a number of different views of what vagueness actually is (Keefe and Smith 1996). On the semantic view of spatial vagueness, certain concepts and associated language expressions provide determinate means to identify the objects that fall under the given concept, but they do not provide means to deterministically pick out the location of the boundaries of those objects. For example, it is determinate that Mount Everest (ME) falls under the concept of a mountain. Moreover there is a determinate fact about the location of the highest mountain peak on the surface of the Earth which identifies ME. By contrast, there is no determinate fact about the location of the boundaries of ME along its foothills. Similarly, there are determinate facts that identify the objects marked by the bold ellipses in Figure 1b but there are no determinate facts about the location of their boundaries.

Regional partitions

Regional partitions are collections of pairwise disjoint regions that jointly cover a given part of the surface of the Earth. Such regional partitions are created, for example, by categorical classification and delineation systems, administrative subdivisions, or purely geometric subdivisions of the surface of the Earth into raster cells.

Categorical classification and delineation systems

In categorical classification and delineation systems, regional partitions of the surface of (parts of) the Earth are created by delineating spatially (i.e., mereologically) maximal regions that are homogeneous with respect to the categories of some classification system. The boundaries that delineate homogeneous regions are located where there is inhomogeneity in the spatial distribution of the qualities categorized in the underlying classification system. Such boundaries may or may not correspond to discontinuities in the underlying material reality. This is because the underlying classification that identifies the relevant qualities may be of the fiat sort and the delineation itself may be subject to vagueness.

Consider a classification system according to which the quality of temperature is subdivided into three (bona fide) intervals: the interval below the freezing temperature of water, the interval above the boiling temperature of water,
and the interval between the freezing and boiling temperatures. Suppose further that, to provide a more detailed classification system, the last interval is further subdivided by fiat into 10 equally sized intervals. The boundaries of the corresponding partition of the surface of the Earth according to some temperature distribution during the summer months will be of the fiat sort (Figure 2b).

By contrast, the boundaries of regional partitions based on the subdivision of the surface of the Earth according to kinds of land uses (urban or built-up land, agricultural land, forest land, etc.) will be often of the bona fide sort. This is because land use affects the material makeup of the surface of the Earth and thus boundaries delineating regions of different land uses are likely to correspond to discontinuities in the underlying material reality.

The nature of the boundaries of the regional partitions created by ecosystem classification and delineation systems (e.g., Figure 2a) is to a certain degree scale-dependent. The boundaries of systems that focus on the delineation according to locally observable land-surface forms, vegetation, and so on are (ideally) of the bona fide sort (e.g., Omernik 2004). By contrast, ecosystem classification and delineation systems, which are based on subdivisions with respect to highly nonlocal climate qualities, are to a larger degree of the fiat sort (e.g., Bailey 1996).

**Administrative subdivisions**

Administrative subdivisions such as subdivisions of the surface of the Earth into postal districts, counties, federal states, states, and so on are prototypical examples of subdivisions for which boundaries have been created by fiat for political and administrative purposes. As such they are not the result of classificatory activities that result in categorical classification and delineation systems. Historically, older administrative and political boundaries tend to be aligned with discontinuities of the underlying material reality such as rivers, mountain ranges, and so on. Examples include political subdivisions into national states in Europe (Figure 1b). By contrast, more recent administrative and political boundaries tend to be purely geometric in nature and lie skew to the discontinuities of the underlying material reality (e.g., Smith 1995). Examples include many of the political boundaries in the United States (Figure 2b) and in North Africa.

**Geometric partitions**

The boundaries of many regional partitions are purely geometric in nature and are often created by measurement processes. For example, clocks partition the timeline into intervals separated by clock ticks. The spatial equivalent of the partitioning of the timeline into intervals is the subdivision of space into raster cells (Figure 2c). More specifically, the georeferencing of remotely sensed images creates (roughly raster-shaped) partitions of the surface of Earth.

**Conclusions**

The aim of this entry was to give examples that illustrate the interesting and complex relationships between the fiat boundaries that structure geographic reality and the acts of cognitive agents that bring such boundaries into existence, discover and measure their location, and possibly change their properties over time. Bona fide boundaries are directly observable and restrict the degrees of freedom of other material entities by virtue of their physical properties. By contrast, fiat boundaries are not directly observable but, nevertheless, are capable of restricting
FIAT AND DE FACTO OBJECTS

the degrees of freedom of cognitive agents in conjunction with complex systems of signs and conventions. The signs and conventions presuppose that cognitive agents are able to perceive or infer the location of fiat boundaries despite the fact that they are not directly observable.

Presently there does not exist a comprehensive theoretical framework of the complex relationships between the material components of a geographic environment, systems of signs and conventions of cognitive agents, and the location and properties of fiat boundaries that structure geographic environments. To illustrate the challenges that are faced by those who aim to develop such a framework, three classes of geographic environments of different nature and scale were discussed: (i) built environments, (ii) large-scale geographic environments with individual objects such as mountains and valleys, and (iii) systems of regional partitions that structure the surface of the Earth. The cognitive acts that bring the fiat boundaries in those environments into existence range from conceptualization to design to classification and demarcation. Vagueness is a defining and not yet well understood phenomenon that illustrates the complexity of the interrelations between cognitive activities in the form of conceptualization and classification and the corresponding fiat boundaries in the respective geographic environments.

Fieldwork in human geography

Cynthia Pope
William Price
Central Connecticut State University, USA

History of fieldwork and methods through the 1960s

Until the early twentieth century, human geography fieldwork was based on exploration and describing in detail a certain area or region. It must be noted that geographic knowledge and geographic philosophies in Western geography have been heavily influenced by European individuals and thinking. Geography as a discipline may be traced back to Greek philosophers and mapmakers, such as Plato and Miletus. Learning about different global regions occurred concurrently with the Age of Exploration and the expansion of European colonial empires throughout the world. Ideas emerging from the Enlightenment and Scientific Revolution became the foundation of fieldwork during the nineteenth and early twentieth centuries and are highlighted by the influential books written by the Prussians Alexander von Humboldt and Karl Ritter in the 1800s that described international explorations.

Humboldt, in particular, is often identified as the quintessential example of an individual who personally explored the world. He collected data points on physical geography and cultures he encountered during his numerous expeditions. In doing so, he produced a voluminous body of knowledge about places that were heretofore unknown or unexplored by Europeans. Humboldt’s five-volume work Kosmos was encyclopedic for its time and sought to establish universal laws for nature, particularly in Latin America and Asia.

Observation, description, and categorization were considered objective ways of viewing the world during this period, and were integral in the development of geographic field methods, including Darwin’s work documenting the role of evolution and nature in the Galapagos Islands. This work, in the latter half of the nineteenth century influenced Carl Sauer, founder of the Berkeley School. For Sauer, observation was critical to understanding the landscape and the human–environment linkages in it. He looked specifically into the ideas of Earth and its life forms, the study of life forms in the environment, and the study of differing habitats of the Earth. Sauer argued that each place has physical qualities, known as “landscapes,” which are connected by certain types of phenomena, such as population and land use. From his observations came the term “cultural landscape,” which has been a backdrop to human geography fieldwork ever since. How did the physical environment shape cultural practices? How did a population create practices to fit in, or alter, their environment? In essence, what is the morphology of these landscapes? This idea of human–environment relations led to work in environmental determinism and possibilism, some of which, while international in nature, often veered toward racial and ethnic stereotypes – such as the work of Ellen Churchill Semple. One of Sauer's most influential works, Morphology of Landscape (1925),
shaped the international fieldwork approach utilized by many subsequent human geographers, particularly those conducting fieldwork in Latin America.

Applied geography took center stage in the discipline during the two world wars as geographers’ skills with mapmaking and their knowledge about other parts of the world were used in war efforts by different countries. With the dawn of the quantitative revolution in geography in the 1950s and 1960s, geographers integrated statistical analysis into their fieldwork to gauge international trends, such as migration. This work was generally conducted with large data sets and involved little, if any, interaction between researchers and participants. During this time period, fieldwork in human geography was at its nadir.

The cultural turn in geography starting in the 1970s

The “field” in human geography can be the international arena where one emerges oneself for months (and perhaps years) at a time, living among those being studied. It is not unusual for the researcher to become directly involved in participants’ lives and/or communities. In the last few decades, however, there has been a theoretical shift concerning how and why a place is defined as worthy of being studied. Throughout the evolution of human geography as a discipline it is important to note how the idea of “the field” has changed from a “taken-for-granted” (Gregory et al. 2009, 253) place to a subject that is complex and an object of study in its own right. Traditionally, as in all social sciences, the idea of objectivity was the goal of geographic fieldwork, stemming from a physical sciences tradition of observation and repetition of studies. In the last several decades, however, a critical geography has emerged that integrates ideas from other social sciences, humanism, and the general zeitgeist in the humanities and social sciences of the post–1960s era of community experiences, multicultural perspectives, and multiple vantage points in both shaping research topics and carrying out the projects.

This critical turn in geography introduced newer methodologies and questioned assumptions of the past about objectivity and the belief in an absolute truth. Ideas concerning fieldwork have changed from the notion of a universal truth and order to the world that could be understood through a researcher’s observation and categorization to an understanding that all knowledge is situated. Though, given the breadth of geography as a discipline, often these two ideas (one based on Enlightenment notions of rationality, reproducibility, and a natural order or truth and the competing philosophy based on situated knowledges, process, places, and the partial nature of information) are often at epistemological odds with each other.

The guiding questions of the critical turn in geography, and the accompanying field methods and internationalization of the discipline, are: Whose Science? Whose traditions? Whose knowledge? (Harding 1998; Haraway 1988). As such, a cornerstone of the post-quantitative period of research is the problematizing of the idea that an unbiased perspective is even possible, given unlimited material interactions and information. Power dynamics and subjectivity became the foundation of much of human geography inquiry and subsequent methodologies during this period.

Advances in social theories – mapping how social forces work as a whole – have led to a critique of what has come to be called the modernist view of the world. This view, rooted in the European Enlightenment and Scientific Revolution, values human rationality over emotion
and the individual over the collective. This view has also separated human society from nature in an explicit division, putting humans “outside” of nature. While this view did, and has, helped advance humanity and our understanding of the physical world in innumerable ways, it has also come under heavy scrutiny for: (i) homogenizing human experience when vast differences occur among peoples’ experiences, shaped by gender roles, racial histories, colonial histories, sexual identities, among other important factors; and (ii) denying the interconnectedness of humans and the planet (Urbanik 2012).

The integration of open-ended interviews, oral histories, documentary work, participatory action research have all taken positions of prominence in human geography fieldwork with the advent of the paradigm shift from quantitative geography in the 1950s and 1960s to more critical geographic inquiry in the 1960s and 1970s to present day. Del Casino (2009, cited in Gomez and Jones 2010) outlines the trends in human geography fieldwork in the past decades.

Humanism updates the cultural landscape tradition by critically examining “places of meaning” or “sense of place.” Instead of viewing space as a two-dimensional entity that can easily be bounded, this viewpoint expands space to reveal that particular objects are placed within a landscape in order to represent feelings and emotions, thus contributing to a “sense of place.” This “sense of place” is highly individualistic and differs across cultures and time periods. This approach leads to field researchers developing empathy with their study participants and contemplating what the research means to the individual conducting the research. Instead of being an objective, nonpartisan observer, the researcher is enmeshed in their methodology. In the humanistic tradition, oral histories of individual life stories, archival research, in-depth interviews, and cultural immersion all have a role in conducting fieldwork. As an example of the increased influence of humanistic interpretations in fieldwork, tourism studies have grown within human geography. In this subdiscipline, there is an increasing recognition of the power of the “tourist gaze,” a term popularized by John Urry (1990). Tourism geographers have utilized participatory methodologies and applied semiotics to understand the difference between how tourists and residents perceive and encounter places and the role of mediums such as the photograph and promotional material.

Structuralism, or critical realism, is another contemporary tradition that has influenced human geography fieldwork. The structuralist assumption is that structures (such as education, health insurance, political systems, and economic systems) vary across societies and locales to the extent that research is necessarily context-specific, and therefore case studies are necessary. Structuralist methodologies are varied, but there is an emphasis on ethnographic data, structured interviews, and participant observation. This work reveals the ways individuals interact with social structures and the case studies allow for concrete insight into different cultures. Structuralism is based on the assumption that individuals, both participants and researchers, have situated knowledges that shape the way they understand the world. The researchers’ “positionality,” how their own worldviews influence interpretation of data and outcomes, becomes an important consideration.

Poststructuralism is “interrogating the production and import of social discourses.” While researchers in this trajectory also examine their role in creating knowledge, they arguably go one step further in self-understanding than structuralism. The researcher her/himself becomes an object of analysis, a process termed “reflexivity.” In this perspective, the research cannot be viewed as detached from the researcher. In
FIELDWORK IN HUMAN GEOGRAPHY

this method, textual analysis, participant observation, ethnographies, and cultural immersion are essential. It is the way in which people speak and write about objects that give those objects meaning. Discourses are the socially constructed ways we use to define the world, and this way of thinking has opened the possibilities for understanding how the researcher and researched are intertwined in the research process when creating a set of meanings about the world. It also opens the research process to understanding how human and nonhuman are embedded in wider worlds of meanings and relations.

In contemporary human geography, there is an increasing recognition that working with people is an opportunity for empowering the subject. Researchers recognize the increasing interconnectedness of the world and the analyzed topics reflect this. International work and global trends have always been important for geographers. Immigration, for example, has been studied in its multiple dimensions across various cultures and working in the “in-betweenness” of sending and receiving areas, an idea that considers how migrants may not feel at home anywhere, whether that be Africans migrating to Europe, Latin Americans to North America, or Pacific Islanders to Australia and New Zealand. Trends in global health, particularly with HIV/AIDS, expanded geographers’ fields to areas of high prevalence of HIV, such as sub-Saharan Africa, the Caribbean, and Brazil, a country with a breadth of knowledge and research on the virus that has informed many North American geographers. HIV research in particular has shown how the discipline moved from mapping disease (an outcrop of the quantitative revolution) to theoretical and international investigations into the gendered and national power relations that lead to transmission.

Human geographers investigate how different cultures define and interpret such “objective” things as disease, natural resources using a variety of methods and vantage points. However, human geographers have shed light on how Eurocentric definitions of traditional research topics have been biased and need to be re-examined in a more contemporary and multicultural light. Increasingly vital in recent fieldwork is calling attention to whose geographies are traditionally not told. Thus, we see more fieldwork on the level of the body and corporeality, queer studies, and geographies of emotion. Indeed, much of the foundation of current human geography fieldwork asks the perennial question about whether the subaltern can speak, put forward by Spivak (1988). By analyzing power relationships (whether they develop through gender, age, economic, ethnicity, physical ability, health, or other factors) human geographers are ensconced in revealing the thoughts, motives, and spaces that influence those individuals or groups who were traditionally excluded from research and political and economic power. In this way, human geographers have often become involved in social justice movements whereremedying these power inequities are important.

Participatory action research has been important for researchers across the globe, nationally and locally when geographers have taken up notions of spatial injustices. This may be manifest in the unequal distribution of wealth across city neighborhoods or in the unequal access to resources at the global scale. It is this social justice motif and the quest to expose and remedy these situations that intersects many subdisciplines of human geography – such as feminist geography, queer geography, medical/health geography, sustainability studies, urban geography, and environmental geography. David Harvey’s social activist work in Baltimore and human geographers founding and participating in nongovernmental organizations (NGOs) around the world highlight the intersection and
the blurring of boundaries between researchers and participants. It is often an impulse to improve the living conditions of the researched community that leads geographers to take an active role in the participants’ lives and communities.

More and more, human geography fieldwork methodologies and research topics are cutting across subdisciplines and scales, such as urban geography, development studies, geopolitics, health geography, economic geography, GIS, and historical geography. Human geographers address global issues, such as gendered mobility, women’s travel writing, racism in the academy, tourism in the Global South, responses to environmental change, and refugees and asylum-seekers, among many others – constraining and enabling spaces, queering inquiry, and coloring research methods (Moss and Falconer Al-Hindi 2014).

Feminist perspectives question the assumption about the researcher’s ability to see a particular truth that participants cannot see, to judge the authenticity of participants, and to ascribe a kind of subjectivity to research participants. The role of gender became increasingly visible during the critical turn and continues to be one of the axes on which geographers understand power relations throughout the world. In this approach, importance lies not only in the topics and places that are studied, but also with who is doing the research. In Anglo and North American geography, editors are increasingly seeking contributions from scholars and activists with different life experiences and worldviews. A growing female student body at all levels of higher education and from diverse backgrounds has resulted in a changing dynamic in human geography fieldwork that can be seen around the world. As more women are entering the field, more research has taken on the roles of gender and sexuality and revealing situated knowledges. Increasingly, topics concerning women’s lives around the world are more common in geographic publications including, for example, research into reproductive health, gendered migration patterns, political violence, and the role of the body in society.

Human–environment relations has also been one of the main themes in fieldwork, but the perspective has changed quite a bit from the Carl Sauer and Ellen Churchill Semple period of the early twentieth century. Much contemporary fieldwork is interested in exposing struggles based on power and powerlessness at global, national, and local scales and understanding interactions between individuals and their spaces, whether that is at the geopolitical or personal level. Within the human—environmental theme, political ecology has been a framework that has cut across human geographers’ research in many international contexts.

We can see this political ecology framework at work where traditional foods are still eaten, despite the fact that their numbers have dwindled, such as turtle soup in Central America and the Amazon. Political ecology is an approach that has been particularly useful when looking at issues of nature—society relationships. From bear bile in traditional Chinese medicine to Amazonian dark earths to whale killing in the Northern Atlantic to whale hunting as a mode of cultural survival in Canadian First Nations’ lands, the link between nature and culture has long been a focus of human geography fieldwork. Geographers have used ethnography in the US–Canadian border, as well as in Scandinavia, to weave narratives about traditional whaling whereby a community wanted to revive the whale hunt as part of their cultural survival, but with contemporary weapons such as guns. This contrasted with the environmental groups who were more interested in the harm of an animal than in the cultural survival of a nation. This shows the divide, or the intricacies, that exist in fieldwork when we see...
the tensions between sustainable resource use, cultural survival, technology, and even animal geographies.

Participatory action research allows participants to record their own experiences of the world and their everyday lives through uses of mental maps, diaries, paintings, and more recently photography with disposable cameras, which has proven especially useful when dealing with the growing field of child and youth geographies. Using cameras literally changes the viewpoint of the subject into fieldwork. This has been particularly useful on work with children on the US–Mexico border. Autoethnographies are another way to understand the researchers’ stance and inherent biases that come into a project, but also allow participants themselves to describe and reflect on their lives. Indeed, the way individuals make their way through places has been important for geographers who examine disabilities and who focus on the everyday life paths of individuals. In this way, human geographers expose here a critical eye toward how humans define and use their space, particularly those who are in wheelchairs and others who navigate spaces with physical limitations in mind.

Recent and future trends in fieldwork places and methods

Fieldwork takes place in different types of environments and the definition of both words are being expanded and re-examined on a continual basis by geographers. In this section, the entry reflects on several of the current research trends in human geography fieldwork. Being physically in the field, whether that means the university campus, the local neighborhood, national parks, or in international arenas, has always been a cornerstone of human geography fieldwork and exploration. In the last couple of decades we have also seen a growing confidence in using secondary data sets in creative ways to describe how humans interact with their environment. Although these data sets traditionally have been used in quantitative analysis and associated more with perhaps physical geography or even with demography, by using these data sets in a visual sense (vis-à-vis geographic information systems) geographers have the capacity to be in the space of the home or office and use the data in a creative way to enhance the themes of human geography fieldwork. Indeed, “while often associated with standard analytical techniques, secondary databases might useful be thought of as vast territories to be explored, visualized, and understood using new critical and creative approaches” (St Martin and Pavlovskaya 2010, 191).

Human geography research has taken a qualitative turn, but there is now a movement to integrate newer technologies, such as GIS, to combine with traditional qualitative methods to create a more nuanced interpretation of various situations. GIS has evolved from a set of technical tools into an integral part of mixed methods in fieldwork and is utilized to examine topics that are much more cultural and qualitative than ever before. We are at a point in human geography fieldwork where varying topics at various scales can be examined by integrating the cultural trends that qualitative methods can reveal through the heavily data-driven methods of GIS and statistical analysis. Geographers, including Kwan (2002), are examining how traditional quantitative methods can be used to highlight trends that can actually reveal power relations, which are typically the domain of quantitative field methods. These traditional quantitative methods include examining secondary databases (such as national census data) that can be used to create data layers in
GIS to highlight spatial correlations between phenomena. The participatory GIS method underscores the increasingly blurred boundaries between applied research and participatory action research. Examples include helping tribes to map traditional boundaries and settle longstanding disputes (Ghana, for example) to understanding the role of racial profiling in police stops in Canada.

For example, feminist geographers have been at the forefront of examining women’s everyday lives as an aspect of the field. The field can be the individual’s experience with space and place and the emotions that one develops in reaction to the world around him or her. Thus, this inner space of emotions becomes the field, in essence, and the fieldwork techniques are centered around trying to expose those private emotions in a more public platform. New spaces, such as those exposed in medical ultrasounds, reveal the body and society interaction at the most personal scale. Geographies of emotion highlight an openness in the field to expanding boundaries of what are considered “acceptable” topics for field research. In particular, the spaces of the body, whether how the individual body moves through or reacts to space or how large-scale political processes affect individual bodies (through migration policies, ethnic segregation, war) is apparent. However, the individual scale has been taken to an extreme and looks at the interior of the human body – at one point, looking at the emotions of a person and in another direction even looking at the space of the body that viruses inhabit.

Defining the field, and the reasons for the parameters, is an important element for geographers to consider. The field can be a piece of land or a specific place with defined boundaries, but it can also be something as amorphous as cyberspace. This new space has been used as both a focus of study for geographers and also as a means by which to elicit responses from participants to conduct research from a wide array of international sources and to show disparity in resources through a disparity in access to the Internet or to cyberspace. It is important to see how the definition of the field is evolving. It does not need to be a place with defined borders and in places that are outside the lived experiences of the researchers.

The emerging fieldwork “space” of cyberspace is increasingly important because of the notion of positionality. The researcher and the participants, when using online methods, become placeless. This can have both advantages and disadvantages. While online questionnaires can reach many people, the disembodied nature of them provides an anonymity that many research projects cannot (or do not even desire). Another way of thinking about this, however, is that this space is both an opportunity to create bonds (however superficial) with others in the same situations. The Internet is growing in popularity as a research site and is often framed as the next frontier in human subjects research. Online research presents a way to cross international boundaries and perhaps may allow access to gaining global information even for those researchers with not enough resources to travel. It also allows participants in these projects to create global linkages while being in their home communities. The Internet provides the opportunity for researchers to engage in participants’ lives from a literal distance.

This new research environment raises questions for researchers concerning: (i) interpreting politics and visibility in online spaces; (ii) researcher positionality across virtual and material study sites; and (iii) subjectivity and power in online research ethics (Oona, Hawkins, and Kern 2014). Online research opens up new ways of conceptualizing central ideas within human geography, including politicization and power.
FIELDWORK IN HUMAN GEOGRAPHY

Cyberspace is providing the opportunity for geographers to reflect on and challenge their traditional place-based stance that tends to assume face-to-face contact and “field” settings.

Another example of contemporary fieldwork issues includes climate change and sustainability. Both of these very broad topics are being examined at the local scale by human geographers in diverse places such as Micronesia, the Sahel region in Western Africa, Greenland, and even university campuses. Around the world, geographers are increasingly working with Indigenous communities to integrate traditional ecological knowledge into climate change and resource use models. Utilizing participatory methodologies and emphasizing capacity building approaches, geographers are building mutually beneficial relationships with communities. In this way, geographers seek to not only further their understanding of the mechanisms and extent of environmental change, but also to gain insight into potential human responses and adaptations, ranging from the application of sustainability principles to migration.

Human geography is growing to encompass the world beyond humans. Indeed, the field of animal geographies presents newer frontiers for defining the field, the ethics of research, and what issues merit study. This geographic perspective forces the researcher to dig even more deeply into understanding the interconnectivity of perspectives in fieldwork and question power dynamics. Many of the power relations (patriarchal, heterosexist, racist, neoliberal) that structure our daily lives in spaces have not improved dramatically for the better since the mid-1990s. As social theories have moved into a “postmodern” period that differentiates humans’ subjective experiences, so too are they moving into a “posthuman” period with challenges to notions of what has historically been seen to separate humans from animals coming almost daily from academic disciplines like biology. From the social sciences, posthumanism has emerged as a challenge to what constitutes a subject and how we might live in a world that includes not only humans and the appropriate methodologies to investigate it. Animals are now being no longer only objects to be studied and categorized by the academy, but their experiential lives and humans’ experiences with them are becoming more popular subjects of research and fieldwork (Urbanik 2012).

In the last three decades there have been five major edited collections giving form to the breadth and trajectory of film geography research. Uniting each of these works is the lurking reified construct of the real/reel, a binary understanding of film and media as a re-presentation of reality. With the release of Burgess and Gold’s Geography, the Media and Popular Culture in 1985 a sustained inquiry into film by geographers had begun. This was a landmark book in geography because it broke from the normative belief that media and popular culture are mere entertainment. Although this and Zonn’s book, Place Images in Media (1990), had some chapters on film, it was not until Aitken and Zonn’s Place, Power, Situation and Spectacle (1994) that a full volume was dedicated to film geography. Whereas Burgess and Gold (1985) and Zonn (1990) had unwittingly operated through a real/reel perspective, it was not until Aitken and Zonn (1994) that the binary was identified and challenged. In Engaging Film (2002), Cresswell and Dixon argued that the textual metaphor, or a hermeneutic approach, had become hegemonic in film geography. This assertion was significant because it pointed to the way that the text/context couplet that the textual metaphor relies upon reinforces the binary logic of re-presentation. In The Geography Cinema: A Cinematic World (2008), Lukinbeal and Zimmermann argue that while film geography includes research on text, it also includes a focus on film form and the affects generated by film, which provide new avenues of research beyond representation. The history of the real/reel binary sketched here provides an entry point to key debates within this subfield including hermeneutics and other supporting binaries such as material/nonmaterial, direct/indirect experience, and subject/object.

Beginning in the late 1980s and early 1990s geographers began discussing issues associated with the cultural turn and crisis of representation. Of importance to film geography is the questioning of the reification of a series of binaries ingrained in geographic thinking that control and delimit the terrain of representational studies and how film and media are positioned within them. First were the debates over the cultural turn in geography, best illustrated by the Price and Lewis dialog in 1993 in the Annals of the Association of American Geographers (hereafter Annals). Whereas those cultural geographers following the Berkeley School tradition privileged material artifacts as indicators of the transformation of natural landscape to cultural landscape, the new cultural geographers questioned the discursive construction of categories such as “natural” or “cultural,” thus shifting the conversation to landscape (and other primitives) as nonmaterial representations. It is difficult to imagine the subfield of film geography appearing if not for the passionate offense of the new cultural geographers in their then-unorthodox assertion of the legitimacy of the nonmaterial as an object of geographical inquiry. This debate between traditional and new cultural geographers was not felt only in cultural geography, however, but paralleled the normative belief throughout
geography during the 1980s that film and media
do not have the power to effect true change in
the material conditions of everyday life and are
mere entertainment, not a part of high culture.

Despite these important dialogs, the legacy
of the turn was the production of a politi-
cized binary empowered to police and regulate
knowledge production. The result of the cul-
tural turn for film geography was the reification
of the material/nonmaterial binary. Taken in
conjunction with the crisis of representation, the
cultural turn helped generate a second binary,
that between direct and indirect experiences.

The crisis of representation blurred any clear
distinction between a direct and indirect expe-
rience of the world by challenging our ability
to access a reality not mediated through cultural
ways of knowing. The roots of this binary can be
traced even further, however, to environmental
perception and humanist geography’s rebellion
against the mimetic beliefs of the quantitative
revolution. The solidification of this binary at
that time was significantly aided by Lowenthal’s
essay in the Annals in 1961, which emphasized
sensory perception as the dominant mode of
understanding. Both the material/nonmaterial
and direct/indirect binaries position film as
holding less value in terms of knowledge pro-
duction because research on film is perceived as
not dealing with things that are real or directly
experienced. Equally problematic is that they
fuel film geography’s recurring ontological
distinction between the real and the reel.

The real/reel binary is the idea that film is a
representation of reality, a mode of theorizing
that has two important outcomes. First, there
is a continual deferral of meaning produc-
tion away from film and onto seemingly more
important thematic areas like gender, sexuality,
race, colonialism, or class. Second, the emphasis
placed on epistemology by poststructuralism
reinforces hermeneutics as the dominant mode
of film analysis, thus keeping the focus of film
geography on reading narratives and exposing
underlying or hidden meaning. Hermeneutics,
or textual analysis, can be understood as the
author-text-reader (ATR) model. Research
using this approach frequently focuses on under-
standing the films’ constructed meanings and the
power relations that produce them by focusing
on one of the three given modalities.

An author-centered approach focuses on how
the text is influenced by the conditions of
production, including the filmmakers, cast and
crew, location of production, and sociohistorical
milieu. Dixon and Grimes (2004), for example,
use good and bad dialectics as a trope to explore
the production site of Tarzan’s Secret Treasure.
They argue that while a bad dialectic actively
deploys the real/reel binary, leading to essen-
tialized identities, a good dialectic sees the real
and reel as relational, leaving these categories
open. Using transactionalism and psychoanalysis,
Aitken and Zonn (1993) interrogate gender
and landscape in the films of Peter Weir. Through an
auteurist reading they find that these films res-
sonate with themes of ecofeminism and how class
and gender construct cultural identity. Lukinbeal
(2012) explores the production of the cinematic
landscape of San Diego using spatial analysis and
performance theory. Rather than an examination
of a single text, Lukinbeal shows how a land-
scape is a palimpsest, continually produced by
individuals working in the regional film industry.

A text-centered approach critiques the produc-
tion of reality and seeks to uncover naturalized
ideological claims. Natter and Jones (1993),
for instance, investigate how class and power
lead to the imaging of public/private spaces in
Michael Moore’s Roger and Me. Using a dialec-
tic understanding of the real/reel binary they
contest the notion of objectivity and narrative
neutrality in documentary films. Lukinbeal
and Aitken (1998) explore the power relations
embedded in masculinity through films by Gus van Sant. Through a framework of psycho-analysis and scale they show how masculinity is a battleground where hysteria is ensconced. Dando (2005) examines the film *Boys Don’t Cry*, looking at how gendered landscapes are constructed, policed, and transgressed. She shows that the plains are more than a mere frontier zone dividing civilization from the wilderness. The plains are also a place where meaning and identity oscillate and are constantly reworked.

The reader-centered approach focuses on the diversity of reception. In their book, *The Place of the Audience*, Jancovich, Faire, and Stubbings point out four areas of film reception studies: one, the audience as market; two, the situatedness of reception; three, ethnographies of reception; and four, exhibition. The audience as market examines preference, demographics, and how the film industry conceives the audience. The situatedness of reception is archival in nature, as it explores movie reviews, marketing material, and other media to contextualize the reception of a film to a social group within a given era. Ethnographies of reception engage the everyday practices and motivations of viewing and the social activity of cinema going. Finally, exhibition studies examine the historically and geographically contingent sites of reception, emphasizing the architecture within which films are viewed. Bypassing these four approaches, Kennedy (2008) takes an autobiographical look at how film has impacted her own life, suggesting that our lives are so mediated it is difficult to distinguish between real and reel.

Inherent to reader-centered analyses are the issues of relativism and essentialism. Where essentialism appears when found meaning is granted the authority to speak for everyone’s viewpoint, relativism exposes that essentialism has been naturalized. Essentialism further underlies the assumption that there is an archetypical (male, white, young, middle class) text-centered subject that consumes a film’s meaning, when in fact there is an infinite array of possible outcomes. While the poststructuralist belief in the “death of the author” has been much discussed in theory, there is a lack of research by geographers on understanding the relativism of meaning reception.

The power of the ATR model lies in its ability to help methodologically organize an investigation of a film; however, when the ATR model is constructed through linguistics and optical theories, an epistemological trap is created that prevents one from getting outside of the text, thus reinforcing the real/reel binary. The problem with this conceptualization is that images are not text and film is more than an image. In the book *Picture Theory* (1995) W.J.T. Mitchell points out that images and texts are two different types of representations; we have very few theories to explain images. Furthermore, we are undergoing a pictorial turn, where the era of language is being swept aside by images. At issue here is how we conceive of film and cinema: when we conceptualize film as representation there is an assumed sensory understanding that privileges vision and immobility, a heterology.

A heterological viewer, or voyeur, separates the subject (the viewer) from the object (the film). Rather than conceiving the spectatorial event as a segregation between subject and object, in *Atlas of Emotion* (2002) Bruno argues for a haptic mobilization that turns the voyeur into a voyageur; the spectator is no longer chained in Plato’s cave, but free to wander. Haptics focuses on corporeality and the porous boundary between inside and outside, the skin, thereby repositioning our attention to the sense of touching and being touched. This redirection occurs not merely as an add-on to vision, but as an emotional resonance affecting the body. Etymologically, emotion can be traced to both feelings
and movement. A focus on optics positions the viewing subject as occupying a reel or real space, which produces an indexical relationship between image and reality. The move from optics to haptics mobilizes the spectator and shifts the attention from sightseeing to site-seeing. The focus on site is not about a real signified grounding the reel, but rather is about a reconfiguration of place through embodied movement.

Finance and the financial system are key components in the workings of a capitalist market economy and of capitalist firms. The absence of finance or an inefficient financial system may be detrimental to economic growth and development (Levine 1997). This is relevant to economies across the income spectrum from poor to rich. Over the last few decades, developing countries have undergone considerable financial development, which includes establishing securities markets and growing the banking system, often at the behest of multilateral agencies like the World Bank and the International Monetary Fund. While such development has had positive effects, it has also brought problems due to inadequate institutional supports (e.g., supervisory capabilities). Keeping in line with the removal of borders to international trade in goods and services, developing countries have become more integrated in global financial markets, opening themselves to greater flows of foreign capital and allowing greater provision of financial services by foreign financial institutions. Again, while some of this integration has brought positive benefits to developing countries, often to the urban middle classes and economic elites, it has also brought growth-reducing crises, which affect the poor the most. Microfinance has grown exponentially in the last decade, but many of the world’s poorest still experience financial exclusion, and whether the access that is provided produces better developmental outcomes is debatable.

This entry first considers debates over the direction of causality of finance in driving economic growth and development, or rather, if finance leads or follows entrepreneurial activity. The second section discusses global financial integration and convergence of financial systems and the implications for economic growth and development, while covering the rise of Islamic finance and sovereign wealth funds. The entry concludes with a discussion of finance and the poor, and issues of financial exclusion.

Does finance lead or follow development?

That finance and the financial system is an important component of any developed market economy is not a question of debate. Yet, at what point in the chain of development finance and the financial system enter is debatable. For some, finance leads development. For others, finance follows development. The former point of view, often attributed to Joseph Schumpeter, contends that financial intermediaries, such as investment banks, identify and finance entrepreneurs and technological changes that lead to economic growth and development. In that respect, the quality and sophistication of the financial services industry as a real sector is important. Financial intermediaries emerge in advance of the demand for their services, assets, and liabilities. The industry is hence an active participant in economic growth and change, as it researches, identifies, and finances the most promising sectors, firms, and managers, while providing
the critical functions of savings mobilization, risk management (e.g., portfolio diversification), and monitoring and control. In effect, this view assumes that finance is supply-leading.

The latter point of view, often attributed to the post-Keynesian economist Joan Robinson, contends that the financial system simply follows in the wake of enterprising firms, providing a conduit through which savings can be transferred from slow-growth sectors to high-growth sectors. Put simply, the financial system is responsive to the demand for its services. As entrepreneurs and firms identify new opportunities, which cannot be financed with their own internal resources, the financial system responds by providing services to see these opportunities to fruition. In comparison to the supply-leading view, this demand-following view sees a much less important role for the financial services industry as a real sector. It is much less critical to the growth and development process. The industry is a passive actor. This does not mean the financial system and financial intermediaries are not important, however. Absent a functioning financial system and financial intermediaries, growth and development could be constrained, as entrepreneurs and firms are unable to realize promising opportunities.

In reality, it is unlikely that financial systems, particularly in more developed economies, are either characteristically supply-leading or characteristically demand-following (Patrick 1966). More developed financial systems are likely to demonstrate characteristics of both, where their interaction drives and sustains development. For example, consider that supply-leading finance may identify promising but untried opportunities that once they take hold are sustained by demand-following finance. The latter is crucial in channeling resources from slow-growth sectors to the new higher-growth sector, or from economically mature regions and countries to high-growth emerging regions and countries. Even if demand-following finance continues as a passive vector sustaining economic growth and development, this does not mean that supply-leading finance is not looking for new opportunities and growth industries it can support.

In no case on the spectrum of supply-leading to demand-following finance is growth and development guaranteed, however. On the supply-leading side of finance, intermediaries may not be very good at identifying the most promising sectors, firms, and entrepreneurs. Just like any other real sector in an economy, they may underperform. This may be due to any number of reasons, from the expertise and experience of individuals working in the sector, to excessive risk aversion or excessive risk-taking. On the demand-following side of finance, an underdeveloped financial system may have high transaction costs, and asymmetric information problems may not be sufficiently mitigated and managed such that savers may be reluctant to provide resources to borrowers. In other words, savers may not trust the system to operate effectively and efficiently enough to part with their savings.

Even if this dichotomy is not so strict in practice, especially in developed regions of the world, the causal significance of finance as an initiator of growth and development remains uncertain. As the above argument suggests, supply-leading and demand-following finance work in parallel in cumulative causation reinforcing the economy’s growth and development. But for developing countries and regions with undeveloped financial systems and capital scarcity (or unaccounted for economic resources), it is not clear if finance should be a leading vector of development, or if it is, in what form, and with what supports. In other words, financial development may in theory boost growth and development, but such development may require progress elsewhere in
a country or region’s institutional development (McKinnon 1991).

For example, a stock market may affect economic development through liquidity creation; investors can buy and sell shares of companies, as and when they require their savings, yet the companies benefit from the permanent access to the capital raised through the issuance of those shares. This may be the case in developed countries, where markets are underwritten by strong regulations and the rule of law. Indeed, the largest and most liquid capital markets, such as in the United States, have very strong legal protections for minority shareholders. Firms and other entities, such as governments, that issue debt or equity securities are required to disclose regular information on their activities, and management and the directors of companies are subject to particular legally defined fiduciary duties or codes of conduct to ensure they act in the best interests of the company. Although malfeasance and misfeasance may still occur and do occur, the existence of strong investor protections underwrites market efficiency, building trust among participants and therefore liquidity. Consequently for firms, the cost of capital is likely to be lower, making investment opportunities and projects more feasible.

In a developing country or region, however, this beneficial dynamic may not hold, as regulations and enforcement mechanisms that underwrite an efficient stock market may not be well developed. The stock market may therefore be more of a casino rather than a mechanism for transferring economic resources across space and time. Because of weak institutions, firms may face a higher cost of capital and investors may shun only but the most seasoned and well-known firms. Hence, stock market development does not produce widespread development, but rather supports existing concentrations of capital and power. Moreover, weak institutions may lead to greater market volatility and asset price bubbles that inflict macroeconomic harm on the real economy once they burst. In effect, financial development, particularly when not accompanied by wider institutional development, may be detrimental to development, causing more harm than good. While not applicable to all, this was the experience of many developing countries in the 1980s and 1990s, as governments heeded the advice at the core of the so-called Washington Consensus that market-based financial development and liberalization would boost growth. Yet, insufficient development of lending expertise, mechanisms for monitoring, and regulatory and supervisory capabilities eroded the potential benefits of financial development. If premature financial development at home has clear domestic consequences, the liberalization of cross-border capital movements during the period brought further problems for the unprepared.

The globalization of finance

Since the early 1990s cross-border capital flows have grown increasingly large, particularly among advanced economies but also including emerging market economies (Lane and Milesi-Ferretti 2008). For the former, much of this growth is attributable to European integration. For the latter, this is a reflection of the removal of barriers to cross-border capital, as emerging markets become increasingly integrated into the global economy and multilateral agreements on trade and capital movements. In effect, the growth of global financial relations reflects the expansion of global trade and economic integration. As such, capital markets have become increasingly global in scope, offering opportunities, in particular, to large multinational firms and other large capital users, but also increasing opportunities for diversification for savers. But even if the benefits are
clear for some, particularly those in more developed economies, most of the world’s poor remain excluded and in some cases adversely affected.

The removal of barriers to the flow of international capital has also coincided with the removal of operational barriers for the financial services industry. Large investment and commercial banks can more freely operate in other jurisdictions, establishing subsidiaries that bring greater competition to previously protected financial services providers. In some countries, such as many of the postsocialist countries of Eastern Europe, foreign banks dominate the local retail and wholesale provision of financial services. For these countries, the entrance of foreign financial services providers and foreign capital beginning in the 1990s helped spur local economic development, as accessing capital became easier. But problems have arisen, particularly at the retail level, where consumers took out mortgages denominated in foreign currencies (e.g., Swiss franc, euro). A collapse of local currencies has constrained the ability to repay foreign-denominated mortgages, undermining the developmental outcomes from increased foreign capital and access to foreign financial services providers.

With the globalization of the financial services industry, common financial practices have become normalized across countries, thus lessening previous national distinctiveness in the provision of financial services. National distinctiveness has further eroded as banking and accounting standards have become increasingly harmonized at the international level. The most prominent being the Basel Accords on banking regulation and the International Financial Reporting Standards, which are required or permitted in over 100 countries worldwide. The latter facilitate international investment, as investors are better able to compare firms from different jurisdictions.

Despite such harmonization, there are important pockets of dissenting activity. Although representing a very small portion of global financial assets (less than 1%), Islamic banking and finance (IBF) has grown in recent years. IBF involves various restrictions on usury, speculation, excessive uncertainty, and activities inconsistent with Shari’a law (e.g., alcohol consumption). Moreover, there is an emphasis on sharing risks and benefits, and on procedural and contractual transparency (Pollard and Samers 2013). If small, IBF, like other nonconventional yet comparably small financial activity (e.g., socially responsible investment, ethical investment), signals alternative possibilities for how and through which means economic resources are managed and transferred across time and space. Put slightly differently, such nonconventional modes of finance emphasize that finance should be socially useful – a point that was laid bare in the recent global financial crisis.

In theory, the removal of barriers to cross-border capital flows and the globalization of the financial services industry, all underwritten by multilateral agreements and the normalization of financial and corporate accounting practices, are supposed to facilitate the transfer of economic resources across space and time, where capital flows to those regions that are growing and need it most, while increasing opportunities for diversification and thus risk management globally. As such, the integration and convergence of financial systems is supposed to facilitate growth and development, igniting opportunities through supply-leading finance and providing needed capital and demand-following financial services to rapidly growing emerging market economies. It would be inaccurate to contend that this has not occurred, but the increasing liberalization of global capital flows has not been without negative consequences. Capital has not necessarily flowed to areas where it is most
needed; many low-income developing countries have not derived many benefits, and crises have resulted. It has also facilitated the growth of offshore tax havens, which deprive governments, rich and poor, of tax revenues that could go to supporting economic development (Sarre 2007).

What has been learned through increasing liberalization at the global level and the liberalization of financial systems locally, particularly in developing countries, is that growth and development is not necessarily guaranteed. The deepening of credit provision and access to financial intermediation in developing countries does spur development, but it must be underwritten by adequate regulatory oversight, effective private sector credit evaluation capabilities, and a robust legal system and accounting infrastructure. Rapid or excessive financial deepening weakened banking systems and brought inflationary pressures, which contributed to growth-inhibiting financial crises (Rousseau and Wachtel 2011). In effect, without well-developed institutions the finance-growth nexus is weakened significantly. The global financial crisis of 2008, which was a developed world financial crisis, demonstrated that this principle applies to developed economies as well. Although the causes are numerous, the crisis occurred arguably because of institutional weakening and a passive attitude to financial regulation in the largest capital markets of the world.

For developing economies, the liberalization of global capital flows has posed problems because of so-called hot money. Hot money refers to short-term speculative capital flows from low interest rate yielding countries to high interest rate yielding countries. As this money can move quickly in or out of a country, it can cause instability and ultimately harm to a country’s economy. For example, if hot money leads to a rapid increase in a country’s currency in foreign exchange markets, this can have a negative impact on a country’s ability to export. Hot money can also contribute to an asset boom, by supplying excess liquidity. Once the hot money begins to flow outward, the asset boom collapses, which can lead to a widespread financial crisis. This is what happened, for example, in the 1997 East Asian Financial Crisis.

In response to that crisis, many countries in the region have accumulated vast foreign exchange reserves, partly reflecting active management of their currencies to support export-led growth, and an effort to insure against future balance of payments crises. While much of these reserves is held at central banks, governments have increasingly funneled capital into separate government investment management agencies, which now are referred to as sovereign wealth funds (SWF). One partial reason many countries have established stabilization funds, a form of SWF, is to limit the need to access external help, in the event of a macroeconomic shock or crisis, from multilateral institutions such as the International Monetary Fund, as such external intervention comes with conditionalities requiring macroeconomic and fiscal reforms that may be overly harsh, potentially unsuitable for local conditions, or politically undesirable. Importantly, these government-owned or parastatal investment funds are increasingly taking a seat at the table, making acquisitions in major Western firms, buying resource assets in other countries, or financing important infrastructure projects. They are doing this in part to earn much higher investment returns than are possible by holding cash or government bonds, usually US dollars and US Treasuries. Many of these SWFs have set up offices in the world’s major financial centers and they are employing experienced asset managers. Some SWFs – particularly the more sophisticated of them – cannot be thought of as yet another government agency or just a department in a country’s central bank. There are now more
than 60 SWFs in operation around the world, with more than 6 trillion dollars in assets under management (Clark, Dixon, and Monk 2013).

Although some SWFs are created from the surpluses of export-led growth, most are based on commodity revenues. The largest of these are associated with oil and gas producers in the Middle East and Norway. As commodity prices have boomed over the last decade, more and more resource-rich developing countries are establishing SWFs. For instance, in the coming decade, Africa may become the largest sponsor of SWFs on the planet. Estimates vary, but the number of funds in Africa alone range from the low to mid-teens, with sponsors from Algeria and Botswana to São Tomé & Príncipe and Sudan. Add to that the number of countries considering or constructing new SWFs, such as Angola, Ghana, Mauritius, Mozambique, Nigeria, Rwanda, South Africa, and Zimbabwe, and Africa could soon be home to upwards of 20 or more SWFs. Given the financial resources that SWFs have, and that many come from emerging and developing economies, the pressure to focus on development (broadly speaking) is undoubtedly high. On the one hand, an SWF can facilitate development within its home country by investing in infrastructure projects, investing in industrial development to help diversify the economy, and smoothing the effects of economic crises by acting as a lender of last resort. For resource-rich countries, in particular, the SWF can help provide stability to the often volatile revenue streams that the government receives from natural resource rents.

Nonetheless, SWFs are not a panacea for the myriad challenges facing resource-rich developing countries. While these special-purpose vehicles may provide some optimism to the resource wealthy, as a means of mitigating the so-called resource curse (see Ross 2012) by managing the volatility of government spending or even directing dividends to individual citizens, SWFs are not a replacement for broader institutional development. Such optimism for the potential of SWFs in resource management should be tempered, moreover, because implementing and sustaining the SWF solution itself is inherently complex. On the one hand, governing, managing, and operating an SWF as an institutional investor or as an agency charged with delegating asset management to external private sector fund managers requires expertise and organizational capabilities not necessarily readily available in many developing countries. Even if such challenges were overcome, an SWF, reflecting existing structures of political authority in a country, may serve the interests of the economic and political elite, providing little by way of social and economic progress to the wider citizenry. Instead of overcoming the resource curse, the SWF simply reinforces it.

Financial exclusion and microfinance

Even if finance appears to have a ubiquitous presence in developed economies and urban life in particular, there are still serious issues of financial exclusion (Leyshon, French, and Signoretta 2008). For many of the world’s poor, basic financial services such as savings accounts or access to credit do not exist. As a result, the poor are forced to rely on informal means of financing, which can often be exploitative or have excessively high costs. According to the World Bank Global Financial Inclusion Database, roughly 2.5 billion adults are without access to a formal bank account. Even though most of these are in developing countries, financial exclusion does exist in high-income countries as well. Financial exclusion often occurs in rural areas, where provision of financial services may be sparse. But many urban poor can face financial exclusion, even though there is likely to be greater provision
of banking and other financial services. Likewise, there are disparities with age and gender, where older individuals make use of formal finance, partly as a function of having greater income and wealth, and men have greater access than women by 6–9% (Demirguc-Kunt and Klapper 2012).

The causes of financial exclusion are largely structural. Banking for the poor runs up against issues of scale. For banks, servicing the poor may not be cost effective, as the savings and loans involved are small and the number of individuals large. In the case of the rural poor, there is the added cost of branch banking, which explains an urban bias in the availability of financial services to the poor. As formal finance has been unavailable to the poor, particularly in developing countries, the poor typically have relied on informal financial arrangements, which can be classed as either autonomous or reactive. The autonomous sector includes pawnbrokers, indigenous bankers, and mutual, or club-based, arrangements like ROSCAS (rotating savings and credit associations), where a group of individuals comes together for a fixed period of time to save or borrow together. The reactive sector arises in reaction to deficiencies in and control over formal finance. This sector includes private finance companies, urban curb markets, and other fringe entities. Despite the apparent dichotomy between formal and informal finance, the line between the two is actually blurred, as informal arrangements have become institutionalized in developing countries, not least because informal finance often accounts for a large share of outstanding household debt.

The revolution in microfinance, which is reaching more and more of the world’s poor, is in part attributable to the work of Muhammad Yunus, an economics professor in Bangladesh who began making small loans to villagers in the 1970s. From this experience Yunus founded Grameen Bank, which works on the principle that making loans to the poor is preferable to charity as a means of disrupting poverty. The Grameen model has been replicated around the world, and even in developed economies (Armendariz and Morduch 2010). Different and comparable models have also developed, such as Kiva, a nonprofit organization that leverages the Internet and a worldwide network of microfinance institutions. Mobile phone banking, such as M-Pesa in Kenya, has helped open up access for the financially excluded in some countries where mobile phone ownership is high. The latter example is evidence of the formal sector making greater efforts to reach the poor. Although microfinance has grown in popularity around the world, it is not without its critics. Some see microfinance as another neoliberal fantasy. Typical arguments are that microfinance institutions are not self-financing; free of any charity as claimed; that loans are taken to cover consumption rather than to make investments in productive activities; and, that the small enterprises financed through microlending are not successful over the long term (Bateman and Chang 2012).

Despite the structural causes of financial exclusion relating to the cost of provision, the political and institutional causes are significant. Financial exclusion reflects wider social and economic exclusion. Irregular work and below-subsistence income, for example, reduce demand for financial services. Likewise, illiteracy and inadequate formal education are further barriers to accessing and understanding financial products and services. This does not mean that financial inclusion is a worthless effort. Rather, financial inclusion is likely only to be successful in the context of wider social and economic inclusion.

Today, the existence and management of the natural environment are increasingly integrated into the systems of financial capital. Finance refers both to money (lent and/or invested, i.e., “capital”) and to the allocation of assets and liabilities over time. Finance plays a significant role in sustaining the global economy by mobilizing capital for energy, infrastructure, manufacturing, and technological innovation. As a consequence, patterns of capital investment amongst governments, companies, and consumers influence the environmental consequences of economic life.

Christopher Wright (2013) provides an excellent summary of the conventional ways in which the natural environment and financial capital are intertwined. The globalization of finance coupled with innovations in securitization (the financial practice of pooling various types of contractual debt, such as mortgages or credit card debt obligations, and selling their related cash flows to third-party investors as securities) and technology has given rise to new forms of environmental investment as well as increased financial instability and short-term investing. Derivatives (financial contracts which derive value from the performance of an asset or commodity) have the potential to undermine sustainable land and resource use by distancing shareholders of capital from environmental impacts. While corporate environmental reporting and dedicated environmental investment practices help mitigate the negative impacts of financial transactions on the environment, these developments have created an uncertain and unstable condition in which governments, companies, and investors struggle to make long-term decisions and plan for the future (Wright 2013).

A relatively recent trend in the relationship between finance and the environment is the practice of using the environment as a means or medium of financialization. For the sake of clarity, financialization is defined here as the process of translating value that is exchanged (whether tangible or intangible) into financial instruments or derivatives of financial instruments. As such, financialization can be considered a process of wealth accumulation that derives profit from financial channels (the circulation and exchange of capital) in addition to commerce or commodity production. The financialization of the natural environment is commonly referred to as environmental finance, wherein the existence and quality of natural resources are priced and exchanged as instruments in financial systems.

Economic productivity and value in relation to environmental finance

The contemporary role of finance in marshaling capital for the material transformation of the natural environment – and thus the use of the environment to generate economic growth and productivity – raises the question of the ultimate source of value in economic productivity. This is a widely debated topic between several streams of thought from neo-Marxist political ecology
to environmental history (studies of human and environment history coming predominantly from environmental sociology and social studies of science). An overview of some of these debates can be found elsewhere (Mol and Spaargaren 2000). Because value plays a central role in Marxist economic thinking, it serves as a useful starting point to consider the issue of the relationship between the environment and value. Scholars following from Marx assert that the source of value in economic productivity is labor (i.e., the fruits of workers’ activities for their employers). From this simple premise three important points of departure regarding the relationship between Marxist thinking on value and the environment can be derived: historical materialism, the general laws of production, and the issue of metabolic rift.

Historical materialism is the idea that human history is the story of the evolution of the “means of production” (the physical, nonhuman inputs used in production, such as machinery, tools, factories, infrastructure, and natural capital) and the “relations of production” (relations between the owners of the means of production and the laborers). Specifically, with the concept “historical materialism” Marx argued that the means of production (the development of new technologies and greater productive capacity) eventually advance to the point where they revolutionize the relations of production, transforming societies from slavery to serfdom, to capitalism (Marx 1993; Marx and Engels 1965). The materiality of changing infrastructure, technologies, and even natural capital such as source of energy, transforms the relationship between owners of capital and laborers and the system of production, all the while advancing the privatization of the means of production (land, labor, and capital). The history of the evolution of production from serfdom to capitalism is not linear but, rather, results from the interaction and evolution of the means and relations of production. From Marx’s perspective, a historical understanding of the evolution of political economy therefore requires an understanding of the transformation of the social relations of production, particularly the power relationships between the owners of the means of production and the suppliers of labor (Marx 1993). Surplus accumulation accrues from the transformation of commodities according to the formula M–C–M′: money (M) transformed into commodities (C) transformed (through the labor of the proletariat) into surplus value (M′) (Marx 1867). The wealth of capitalism, and for that matter every other system of production, is, therefore, built through social labor. For this reason, a primary focus in Marx’s later works (Capital) is the social relations of production.

Political ecologists and environmental scholars argue against this overemphasis on social relations, pointing out there is an underlying metabolism of natural resources in production that is also essential to the generation of profit – an issue Marx himself acknowledged. For one thing, commodities are themselves derived from natural resources. Although Marx rejected natural determinism as an explanation for the function of capitalism (Harvey 2011), he did directly address the decline of the natural environment with concepts like “the metabolic rift” – the idea that increasing the productivity of large-scale agriculture and industry ultimately leads to a decline of the long-term fertility and productivity of the soil (Foster 1999). However, the ways in which ecological conditions impact the evolution of the forces and relations of production, as well as the implications of production on environmental decline, were secondary to the concerns and issues of the social relations of production in Marx’s scholarship.
Environmental historians such as William Cronon (1990, 1993) take issue with the overemphasis on labor in neo-Marxist conceptions of the production of value and seek instead to integrate both the natural environment and cultures of ecological interaction into the understanding of production and consumption decisions at various points in time. Cronon (1993), in particular, highlights the ways societies make production decisions based on both the ecology of the environment in which they live and culturally driven perceptions of society–environment relations. He argues that the evolution of social history can be understood from the standpoint of “modes of consumption” (the varied ways things are consumed) rather than modes of production (the varied ways things are produced). The value of economic processes is a product of both socioeconomic relations of production and socio–natural relations of consumption (Cronon 1990).

While neo-Marxists tend to focus on the social nature of value and ecologists on natural and physical manifestations of value, both describe elements of a common material phenomenon: the cycling of value through various economic spheres and processes. Additionally, both are concerned with value creation and the ways in which capitalism and financialization transform social and natural materiality. The two different views of materialism can be perhaps reconciled with the introduction of a typology that considers the space and time of production and consumption processes as well as their material constitution (Figure 1).

The matrix in Figure 1 represents the spatial and temporal dynamics of four distinct types of value (use, exchange, derived, and external). On the horizontal access time is divided between the present and the future. The vertical axis divides space into socioeconomic – symbolizing social interaction and economic structuring or sociomateriality – and socioenvironmental – symbolizing the interaction of human and environmental systems or physical materiality (a detailed overview of the two concepts is given by Bansal and Knox–Hayes (2013)). The horizontal axis divides time into present (symbolic of realized economy) and future (symbolic of potential economy). The lower left quadrant, socioeconomic transaction in the present time, is where use value is created and consumption takes place. The upper left quadrant, present socioeconomic transaction, is where exchange value is created and commerce takes place. The upper right quadrant, future or potential socioeconomic transaction, is where derived value (value derived from goods and services, e.g., derivatives such as wheat options or mortgage-backed securities) is created and where finance exists. Finance derives its value from underlying resources and services (or commodities and social relations). Finally, the lower right quadrant, future or potential socioenvironmental transactions, is where external value (the value of externalities, or value “external” to present use and exchange) is created and where environmental finance is being created.

In the center of the diagram the transition of value according to the cycle of financial production is represented with black arrows (M–D–C–M′) as money (M) leveraged through derivative finance (D) to generate commodities (C) and sell these for surplus capital (M′). A new inverse cycle of the “internalization” of externalities (M–E–C–M′) leverages money (M) through the priced externality (E) to invest in commodities (C) and generate profit. Internalization is generated through environmental finance and is considered here as the process of pricing externalities to change production decisions. For example, accounting for the priced externality of carbon dioxide released from the burning of fossil fuels might lead to the production of solar
panels due to new relative price competitiveness of solar energy over conventional thermal energy combined with a carbon price. The externality (E) is introduced to represent certificates and other commodities, such as carbon credits, that are used to price externalities.

The model is useful for situating the debates between neo-Marxist scholars and environmental historians over the source of value. Although the neo-Marxian scholarship first conceptualizes the cycle of production, its concern with respect to the generation of value is fundamentally with labor relations within commerce and finance, and the attendant creation of exchange value from social labor. Put in the context of the framework outlined above, the theories from neo-Marxian scholarship fundamentally engage with the creation and cycling of exchange value. In contrast, although environmental historians are also concerned with the broader cycles of production, by emphasizing the human–environment interaction they describe the use of natural resources and the impact of consumption on the natural environment. In so doing, environmental historians primarily engage with the generation and cycling of use value, and particularly with concepts such as “modes of consumption.” Therefore, rather than being a dispute about the ultimate source of value, the debate between these scholars is about the role of different but interconnected sources of value related to different but parallel economies.

The notion of parallel economies indicates several issues at play. First, parallel economies refer to the creation of systems of externality pricing intended to balance the environmental impact of economic production. Production either in the form of \( M-C-M' \) or with the use of financial derivatives \( M-D-C-M' \) can arguably be short-circuited (as with some forms of derivatives trading) and money can be used to directly generate surplus value without ever mobilizing physical commodities \( M-D-M' \). Nevertheless, the ultimate goal is to accumulate value in finance. This surplus value is extracted from both natural resources and social labor. As Marx acknowledged with concepts like “metabolic rift,” the production cycle by its very nature depletes the natural resources and social systems upon which it relies.

The pricing of externalities is designed to balance this circuit by forcing value from finance through externalities into the creation of environmentally beneficial technologies like renewable energy. In theory the circuit of internalization should close the loop and return value from finance or surplus accumulation to improve the quality of the natural environment or at the least to improve socioenvironmental relations. In this framework, environmental finance generates a parallel economy (parallel to the economy of production) that internalizes externalities and transforms production decisions to return value to the natural environment.

The notion of parallel economies also represents the ability to extend the value of physical
resources from their present objective spatial and temporal connotation across space and time. Figure 1 illustrates both present and future or potential value with individual columns. While present value is singular (commodities and services exist in particular places and have value either in use or exchange at any given moment), future or potential value is unlimited. Figure 1 could, therefore, illustrate future value with innumerable columns moving to the right across time. Because future or potential value is subjective, within finance (and indeed even environmental finance) there exists the potential to create numerous layers of value from singular physical resources through the structuring of potential value (Knox-Hayes 2013). For example, consider a commodity such as a bushel of wheat. It can be used through consumption to generate use value (lower left quadrant). It can also be first exchanged (upper left quadrant) and then consumed to generate use value. However, as long as the value of the bushel of wheat is located with its physical existence it generates single sources of value (it can be either used or exchanged), but its value is very much in its present place and time. In contrast, the subjective value of the bushel of wheat can exist in numerous places and times. For example, finance can derive value from the wheat through the creation of a variety of “options” to buy or sell the wheat at a specified price at various points in time. Multiple options (derivatives) for the single bushel of wheat can exist simultaneously because they represent future or potential sources of value spread across time. But the options instruments themselves have financial value that can be traded in the present.

The subjective nature of future and potential value creates concerns for the accounting of financial value and, particularly, for the ways in which financial value becomes represented in present time. Modern economic systems recognize all types of value as commensurate through pricing, regardless of qualifications regarding how, when, and where value actually exists. A wheat option might generate a quantitatively similar price to a bushel of wheat, but the quality of value contained within the two as well as the consequences of that valuation is considerably different. The bushel of wheat can feed hungry people. The wheat option merely provides the opportunity for a potentially advantageous economic transaction in the future. This is not to say that a financial option is without value, but rather that its value is fundamentally different from the value of a commodity itself. Therefore, in addition to offering an understanding of the relations of various economic spheres and processes, the topology in Figure 1 also suggests that the spatial and temporal nature of value is significant. In practice, there are several challenges with the ability of externality pricing to balance the social and environmental detriments of production.

To operate effectively, environmental finance must create a truly parallel economy, of similar scale and scope to the productive economy, that internalizes the externalities of production and operates according to the specified pathway of finance with an aim toward generating environmentally beneficial commodities. The problem is that just as finance can short-circuit the cycle of production by creating paths for money to generate surplus value irrespective of underlying physical commodities, so too can environmental finance shortcut the cycle of externality pricing that should generate new technologies. Environmental finance can, instead, derive surplus value solely from the circulation of environmental externalities through financial transactions. In the subsequent sections, the structure of environmental finance is further detailed and some of the concerns for accounting the value of environmental assets are outlined.
Development of environmental finance

While natural resources have always been incorporated as productive inputs in economic systems, environmental finance has the potential to transform the way in which natural resources are valued in economic systems. Environmental finance manages natural resources through the pricing and trading of positive and negative externalities – environmental benefits or costs accrued from economic activities that are not accounted in economic transactions. For example, the burning of fossil fuels results in the emission of carbon dioxide and other greenhouse gases; these are not accounted for in the price of energy unless a carbon-pricing scheme is put in place. To price externalities, the value of environmental resources is shifted from use value – the value of using a good or service grounded in objective space and time – to external value derived from the good or service, which is value liberated in subjective space and time. The conversion of the use value of the natural environment (which is deeply embedded in physical materiality) to financial or external value (value external to the consumption or exchange of the resource) through the pricing of the externalities presents some concerns that environmental finance will ultimately serve to devalue and destabilize – rather than preserve – natural environmental systems (Knox-Hayes 2013). These concerns primarily stem from the mismatch between the scale of financial productivity that markets achieve and the material impacts they generate for natural resources. Environmental finance will undoubtedly have profound implications for energy and environment use in coming decades, particularly as financial markets are adapted to manage new sets of environmental asset classes.

Negative externalities

The idea that market mechanisms utilizing well-defined property rights could be used to price and overcome the problem of negative externalities is a theory derived from Ronald Coase (1960). Early applications of Coase’s theory of externalities, particularly the EPA’s acid rain trading program in the United States, demonstrated the ability of markets to successfully control levels of pollution from sulfur (SO$_x$) and nitrogen (NO$_x$) oxides. Under the EPA program, yearly caps on SO$_x$ and NO$_x$ were established and heavy emitters were allocated a limited set of allowances to emit of SO$_x$ and NO$_x$ (also called permits). The emitters could meet the cap either by reducing their emissions of SO$_x$ and NO$_x$ in line with the permits they had been allocated or by buying additional permits from more efficient emitters who had reduced their levels of pollution below their established targets. The acid rain trading program was seen by many to be a success in the United States because SO$_x$ levels fell. The perhaps unintended consequence of the program, however, was the rise in coal use (since scrubbers were introduced to remove SO$_x$ and NO$_x$) as electricity generation demands increased.

The general success of the acid rain trading program established the viability of using market-based approaches for addressing negative externalities. The precedent the program set established the foundations for treaties addressing climate change under the United Nations Framework Convention on Climate Change (UNFCCC). Climate change is framed as first and foremost an economic problem rooted in the failure to correctly price environmental externalities. The 1998 Kyoto Protocol introduced market mechanisms through which countries could cooperate to meet their national emissions reduction targets. Emissions trading in the Kyoto Protocol functions was along lines similar to
the trading systems set up under the acid rain trading program, wherein economic actors can buy and sell emissions permits under an overall emissions cap.

Both within and without the framework of the Kyoto Protocol, the capping and trading of emissions has become a common policy response around the globe to mitigating climate change. This policy response is designed to create parallel economic activity that internalizes the cost of externalities through the creation and transaction of priced externalities such as a carbon emissions credits (Knox-Hayes 2010; Bumpus 2011). Emissions trading systems have been set up in the European Union, in California and the northeastern United States, in Australia (although the system was repealed a few years after initiation), China, Japan, and South Korea. Additional systems are planned in the Ukraine, Turkey, Brazil, and Thailand. A comprehensive overview in the development of emissions trading schemes is given in the World Bank’s annual State and Trends of Carbon Pricing Report (Kossoy et al. 2014).

Positive externalities

In addition to mitigating greenhouse gases, carbon emissions markets also serve as demonstration markets: if greenhouse gases can be successfully regulated through market mechanisms, then so too can virtually every positive and negative externality. Pilot programs have been trialed to manage other negative externalities, including water pollution. Additionally, a series of markets to manage positive externalities such as forestry and biodiversity are being created. For example, the reducing emissions from deforestation and degradation (REDD) program is being negotiated under the UNFCCC. This program would finance the positive externalities (including carbon syncing and biodiversity preservation) of the world’s forests (particularly rainforests) with funding from emissions trading programs and private and public environmental funds. The establishment of markets to trade carbon emissions, forestry, and biodiversity demonstrate the widespread belief in the potential of environmental finance to manage positive and negative externalities.

Gretchen Daily and her colleagues (1997) coined the term ecosystem services to describe the ways in which the positive externalities generated by the world’s ecosystems are capital assets. The logic of pricing environmental externalities can be extended to suggest that the function of the biosphere itself could be priced. Ecosystems can be priced to manage the flow of vital services, including the production of goods (such as seafood and timber), and life support processes (such as water filtration and pollination) (Daily et al. 2000). Moreover, ecosystems have value in terms of the conservation of future use options (such as preserving genetic diversity for future medicinal use). Despite these potential benefits, it is challenging to directly price ecosystems. Relative to other forms of capital, ecosystems are poorly understood, scarcely monitored, and (in many cases) undergoing rapid degradation and depletion. Market prices often do not reflect the full social costs of production and most ecosystem services are presently not traded on markets. Additionally, methods of indirect revealed preference (for example, valuing clean air by comparing land rents in clean versus polluted areas) are not relevant to setting a value on the existence of certain assets (such as the satisfaction derived from contemplating the existence of a tropical rainforest or essential functions like pollination). Finally, measuring the value of ecosystem services based on avoidance of costs provides only partial indications of value, especially for services without adequate substitute.
Undeterred by these challenges, Robert Costanza and his colleagues (1997) have estimated the financial worth of the biosphere to be in the range of US$16–54 trillion per year. To put this in perspective, Costanza and his colleague highlight the fact that the global gross national product in 1997 was US$18 trillion. In other words, the unaccounted economic functions of the biosphere (the sum of positive externalities) are on a yearly average twice the size of the global economy. The pricing of ecosystem services suggests that there is tremendous untapped value to be gained from the pricing of the functions of the ecosphere. In combination with programs such as sulfur trading and carbon trading that value the avoidance of negative externalities, these efforts to price the value of ecosystem services demonstrate the scale and potential at which environmental finance could operate.

Nevertheless, the productivity arising from integrating ecosystem services is not really based on the creation of new resources but rather is based on the valuation of existing environmental resources in parallel ways (Figure 1). First, natural resources are valued in the conventional sense of economic inputs (lower left quadrant in Figure 1); second, the generation of positive and negative externalities from the environmental resources are valued (lower right quadrant in Figure 1). In other words, the valuation and integration of ecosystems services into financial systems has the potential to create parallel economies (economies of use and economies of quality of natural resources), increasing not only the scope but also the scale of financial incursion into socioenvironmental relations. For environmental finance to achieve its full potential, however, it must transform the natural environment into a new source of assets. Ecosystem service pricing demonstrates the value of environmental positive externalities and the potential for the marketization of externalities to create parallel economies that magnify financial value.

Creation of environmental assets and liabilities

The creation of environmental finance requires that the interactions of human industry with the natural environment (as either positive or negative externalities) must be accounted for as assets and liabilities. The principle of environmental finance is based on the creation of parallel economies, which generate economic activity not from the pricing of resources but rather from the pricing of positive and negative impacts on/from the existence of environmental resources. Take, for example, forestry. The first layer of financial value generated from the forest is the collection and consumption of environmental resources directly from the forest: fruit, sap, and timber (lower left quadrant in Figure 1). The second layer of financial value is derived not directly from the use of forest resources, but rather from the preservation of the future quality of the natural resources and the services they provide through the pricing of externalities (lower right quadrant Figure 1). This second layer is primarily where environmental finance operates, through the extraction of the financial value of positive and negative externalities from the forest.

Continuing with the example, leaving the trees standing rather than harvesting them for timber avoids negative externalities, such as carbon dioxide emissions from the burning of the trees, as well as soil degradation from the denuded forest floor. The standing forest also creates positive externalities, or provides ecosystem services, by sinking excess greenhouse gases, protecting the biodiversity, and maintaining the integrity of the hydrological balance within the ecosystem. In order to financially account for these positive
and negative environmental services, a complex infrastructure of governance and economic accountability must be created. The first step is to privatize – define property rights or titles for the ecosystem services and environmental liabilities – in order to commodify the existence of the natural environment (Castree 2003). The next step is to make environmental assets and liabilities internally and externally commensurate with other financial instruments. Finally, the exchange of environmental goods and services must be integrated into the operation of financial services through intermediaries and exchanges.

Privatization

Privatization is the assignment of the legal title of a specific thing to a named individual, group of individuals, or an institution. The property right or title grants the owner exclusive rights to utilize the resources of title however they choose. Privatization is essential for financialization: without it, resources cannot be freely exchanged in a market system. The establishment of titles and environmental property rights begins with the privatization of land, water, and air, and progresses to the privatization of finer aspects of land, water, air, and organic materials. Privatization of land, for example, has progressed from title to the use of the surface of the land, to the minerals contained in the land, to the species, and perhaps even genes of species, living on the land.

Privatization proceeds through several steps. First, the resource itself must be legally defined by establishing spatial and temporal boundaries. For example, the parameters of ownership of a forest must be defined spatially on the basis of the landmass on which a forest exists. Ownership of the forest may be distinguished from ownership of the land and other associated resources (minerals, water, etc.). Defining the time frame over which the forest is owned is also essential, particularly if the forest is disassociated from the land upon which it exists. The property right itself relies on social convention: the established means by which the property comes to be understood to exist and the legal infrastructure through which the right can be represented in the form of a title (MacKenzie 2009).

Once the parameters of ownership are set around an asset, the value can be defined. However, the financial value of an asset exists only in exchange or through the potential for exchange (Knox-Hayes 2013). For these reasons, Castree (2003) suggests that alienability is a critical aspect of the creation of assets and liabilities. The resources, or the facets of resources that are privatized, must in some way be alienable – isolatable – so they can be exchanged. The title that grants ownership of a certain number of hectares of forest in a specific place assumes that the hectares of forest are alienable from the broader ecosystem (land, species, hydrology) within which they exist. Specifically, the owner of the forest has the right to cut it down for timber or to extract the minerals in the soil beneath the timber because – in line with resource disaggregation – doing so is understood to have little or no impact on neighboring resources.

The process of defining environmental property rights with respect to positive and negative externalities becomes more problematic because the rights must often define something intangible beyond the environmental resource itself. For example, leaving a forest standing avoids the release of greenhouse gas emissions into the atmosphere. Emissions reduction credits can then be generated from the existence of a forest and defined as property rights. The ownership of the carbon credits is derived from the existence of a market that values the absence of the negative externality (emissions) and from the event of avoiding emissions by leaving the forest standing.
for a certain period of time. The ownership is tied into a certificate, which defines the avoided externality in terms of tons of carbon not emitted into the atmosphere (carbon emissions credits).

The credits are anchored in the spatial and temporal context of an extent forest but their value can easily be moved to another spatial and temporal frame, where they can be retired or cancelled against carbon productive activities. For example, the owner of one ton of CO₂ equivalent produced by a forest standing in Peru can exchange the credit for one ton of carbon dioxide produced by a thermal power plant in Germany (Bansal and Knox-Hayes 2013). Avoiding the negative externality (cutting down the forest) is represented by the credit, which is issued to an original owner, who then holds the right to a defined unit of emission. The carbon credit allows the owner to move the generation of a negative externality to any time or place because the carbon credit represents the capture of the reduction of an emission.

Critically, the value generated from the exchange of the emissions credit does not guarantee the preservation of the forest. Its financial value is generated from a parallel economic activity distinct from the use of the forest as a resource in and of itself. As with the forest, the value of the credit must likewise be defined and is established through a contract of exchange. The contract allows the credits to be valued as a source of exchange in advance of their production. The exchange value of the credits is derived from the establishment of a title over current and future potential activities. For example, carbon credits allow for the exchange of the positive externalities embodied in standing forests (carbon sinks) for the negative externalities embodied in productive activities (emissions from a power plant).

The privatization of externalities of environmental resources has tremendous repercussions for the use and exchange of those resources. Scholars have raised concerns that the value derived from the use of a resource (harvesting of the forest) cannot be reconciled with value derived from positive externalities of the forest left standing (Altvater 1993; Miles and Kapos 2008). There are inevitably sources of conflict from the two types of property rights. The standing forest requires that the land not be used for purposes other than to hold the forest. As such, financial value tied to the use of the land will conflict with the financial value derived from the property rights tied to positive externalities of a standing forest.

Commensuration

Commensuration is the process through which resources are made accountable by defining the resource according to a common metric (Callon 2009). Financialization requires the creation of a standard against which the resources can be compared. Castree (2003) identifies two processes of commensuration: individuation and abstraction. Individuation refers to the representation and physical act of separating a specific thing or entity from its supporting context: establishing the forest as a legally owned entity. This involves putting legal and material boundaries around the forest so that it can be bought, sold, and used. Abstraction is a process whereby the specificity of any individualized thing (an oak forest or an oak tree) is assimilated to the homogeneity of a broader type of things (a “forest” or a “tree”). Abstraction is both functional – a pine forest becomes abstracted as a “forest” – and spatial – a forest in Peru is abstracted as equivalent to a forest in any other location (Robertson 2000). The goal of commensuration is to make the commodities uniquely identifiable (individuation) but completely fungible (abstracted).
Commensuration enhances the scale at which assets and liabilities can be marketed as well as the rate at which they can be exchanged. Commensuration is achieved through the standardization of resource metrics or of the information contained in representation of the resource (such as a carbon credit or other financial certificate) (Lohmann 2009). Standardization requires agreements on the format and content of the commodities, as well as for the contracts of trade. Here the critical objective is to determine which pieces of information are included in the representation of an asset, and which pieces are not. For a pine forest to be made commensurate with an oak forest the common metrics of evaluation might be the number of hectares of land covered by the forest, the weight of the biomass, or even a metric that evaluates the capacity to sink carbon dioxide emissions. Note that equally important to what is included in the metric of evaluation is what is left out. From the standpoint of standardization in the context of climate change policy, the role of the oak forest as a habitat for particular bird species is immaterial, and thus that characteristic is stripped from the metric. Assets are made homogenous through this process of standardizing and reducing information content.

For positive and negative externalities, commensuration similarly requires the definition of metrics of evaluation and variables of equivalency. With respect to carbon credits, all of the information of the process of reducing emissions (the maintenance of a forest or the installation of a scrubber on a thermal power plant) is reduced to the metric of one ton of carbon dioxide equivalent. In this respect an oak forest can be made commensurate with a pine forest by considering the relative amount of CO2 equivalent it absorbs every year. The credits are indistinguishable from their counterparts and erase the specificity of other qualities of the forests from which they were derived.

Finally, the creation of financial instruments enhances the spatial and temporal liquidity of environmental assets (both direct and derived from externalities) by enabling them to be treated as commensurate with any other financial instrument. Environmental assets acquire a financial value that makes them exchangeable with any other financial asset. The metric is their financial value. The final stage of creating environmental assets is integrating them into financial infrastructure through intermediaries and exchanges.

Intermediation and the infrastructure of environmental finance

Intermediation is the process of transferring the value and liability associated with a good or service between two places and two individuals, a service which is usually provided by banks, brokers, and other financial service providers. Intermediation is a crucial element of the integration of environmental assets into financial services. This is accomplished through the construction of new standards and conventions, the establishment of infrastructure and systems of trade, and the creation of new intermediary firms (Knox-Hayes 2013; Labatt and White 2003). Intermediaries provide custodial services, transferring environmental assets from their origination source to the end buyer.

The valuation and trade of assets and liabilities constructed from environmental externalities require considerable social standardization and connectivity. Several types of firms and organization are essential to building services and infrastructure of environmental finance, including legal and accounting firms, aggregators, development funds, registries, banks, brokerages, and exchanges (Knox-Hayes 2009). Legal firms define environmental assets as legal commodities and tradable instruments, and are often
consulted in writing new regulatory frameworks to provide legal scope and a market for the exchange of environmental assets and liabilities. Accounting firms develop the standards and metrics through which environmental assets and liabilities are measured and accounted for. Environmental asset aggregators originate the environmental projects in partnership with leading legal firms, and aggregate the credits from these projects for use in developed countries. Development funds facilitate the implementation of environmental projects.

Additionally, a range of private intermediaries have become involved in environmental finance, particularly investment banks, which provide most of the finance to develop environmental projects. Banks hold portfolios of carbon credits and other environmental assets, which they sell to their clients and bring to market through carbon brokerages and exchanges. Environmental brokerages link buyers and sellers of the environmental assets. Environmental exchanges provide a forum for buyers and sellers to meet, but also hedge the delivery risk associated with the creation of financial assets from externalities. Registries enhance the mobility of financial assets and liabilities created from externalities, such as carbon credits, by digitally connecting producers and consumers of the credits.

As initiators, custodians and mobilizers of environmental assets, banks and other intermediaries occupy a critical junction point in the process of environmental financialization and are able to shape it in profound ways. In particular, intermediaries enable environmental assets to be structured in the same format as other financial assets, regardless of the unique characteristics of the material environment from which the environmental assets were drawn. This creates the ability to securitize environmental assets like carbon, forestry or biodiversity credits and to exchange them for other financial assets or environmental liabilities as bankers seek to accelerate the rate at which the credits produce financial value.

Avenues of investigating environmental finance

Sitting at the interface of human and environment interaction, and socio-natural and socio-economic productivity across time, scholarship on the structure and function of environmental finance is of increasing importance to the discipline of geography. Scholars approach the subject through a range of lenses, critiquing issues of valuation and accounting, the integrity of financialized environmental resources, and the hybrid nature of socioenvironmental and socio-economic systems. In addition, analysis of the spatial and temporal dynamics and interactions of finance and the environment offers the potential for new insights.

Economic geographers like Neil Smith (2008) and David Harvey (1996) criticize the production of nature, arguing that environmental commodities become a means to the end of accumulation for accumulation’s sake irrespective of the qualitative particularities of environmental commodities. Similarly, John O’Neill suggests that “the neoclassical project of attempting to cost all environmental goods in monetary terms becomes an instance of a larger expansion of market boundaries” (O’Neill 2007, 21). These studies are complemented by work from scholars that challenges the ways in which environmental resources become transformed through the process of commodification. Scholars such as Bakker (2004) have studied the demise of water as a “public good” as it is privatized and transformed into a salable commodity. Similarly, Ralph Kloppenburg (2005) demonstrates how the privatization of crop varieties limits diversity and
vitality of crops as companies gained proprietary access to hybrid crop varieties.

In general, these studies illustrate the ways in which the natural environment has been transformed from open access public goods to a set of private resources. William Boyd (2001) demonstrates this through his investigation of the poultry industry: chickens as natural entities become physically altered to suit the profitability requirements of the agri-food companies that manufacture them. Gavin Bridge (2008) highlights the ways in which economic and political institutions of commodity production and consumption shape the ecology and society of resource production, particularly the processes and cultural practices through which natural environments become enacted as resources. The work of these and other scholars suggests a need to understand the transformative capacity of environmental finance.

Additionally, there is a growing interest and need within geography to evaluate the spatial and temporal dynamics of environmental finance. One of the strengths of geography as a discipline is its ability to bring scale into analysis. There is an organic connection between space and time within capitalism, which in turn means that space–time plays an important role in the dynamics of financialization (Castree 2009). Finance is predominately motivated to accelerate the production of financial value from physical or intangible assets. Environmental finance is about the integration of natural systems into economic systems, and the acceleration of the production of value from environmental assets. It does not guarantee, or even necessarily strive towards, the protection or preservation of the natural environment. The inability of financial actors and institutions to make long-term decisions and plan for the future is critical to the challenges of environmental finance. Space and time are, therefore, central to understanding the intersection between environmental finance and other spheres and processes of economic productivity (as in Figure 1) but also critical lenses for understanding the broader function of environmental finance.

The application of financial markets to the management of environmental systems suggests dangers of distortion. Because markets account for neither information complexity nor spatial scale and temporal duration under which environmental systems operate, they produce, at best, a very partial picture of the real world value of environmental assets and can introduce temporal mismatches as natural and economic processes move at very different speeds. For example, the financial value of forests under REDD is assessed by measuring the amount of CO₂ reduced per area of forest standing (Miles and Kapos 2008). Yet, the age and diversity of the forest area do not factor into the credit. Monocultures, new growth, and old growth forests can be considered comparable in their ability to reduce carbon if they are of similar density and size. Furthermore, in reducing the forests to this commensurable metric, their history, vitality, and diversity become irrelevant to calculations of their value.

The creation of parallel economies removes the material context of the forest resource, including its use value, from the calculation of the exchange value of the financial instrument. Consideration of the spatial and temporal nature of value highlights the danger that financial products create the illusion that socially meaningful value exists without context. Financialization transforms the intrinsic and even instrumental value of the forest to financial or external value. There is a real potential for the financial product to leave the forest and its spatial and temporal complexity behind. Environmental finance creates the sense that a forest that took 10 000 years to evolve in a particular geography can be
exchanged for a forest of similar size and density that was grown in 30 years in a location of choice. Distortions in spatial and temporal scale heighten the demand for accelerated rates of resource production. While socioeconomic systems can to some extent adjust to the demands of accelerated production, the function of socioenvironmental systems is deeply embedded in space and time, and cannot easily accommodate temporal acceleration and spatial compression (Bansal and Knox-Hayes 2013). Spatial and temporal dynamics are essential to environmental finance and offer promising avenues of investigation.

Financial geography

Karen P.Y. Lai
National University of Singapore

Financial geography is concerned with the roles of finance, money, and markets in the restructuring of contemporary capitalism. Research focuses on how such restructuring has uneven impacts across space, and also on the ways in which space and place are mobilized in the production of financial markets and processes. Some examples of the spatialities of finance include financial exclusion, regional inequalities due to financial activities, differential connectivity of global and local financial flows and networks, and the rise of new onshore and offshore financial centers. More than acting as a neutral lubricant in the economic system, financial markets, actors, and instruments shape the development and life chances of people and communities across regions and localities. While some have argued that globalization and new information and communication technologies (ICT) have rendered geography irrelevant, financial geographers contest that space and place remain crucial to the financial system in shaping financial decisions, allocation of capital, regulatory frameworks of global financial markets, and their unequal outcomes.

Economic geographers and regional scientists have long been preoccupied with industrial landscapes, especially in terms of industrial development and agglomeration. Little consideration has been given to the impact of money and finance on spatial processes and impacts. The late 1980s, however, saw a wave of studies on the spatial dimensions of money, establishing the theoretical and empirical importance of finance in shaping the economy, regional development, and place-making at different spatial scales. This partly reflected a broader research interest in service sectors in the 1980s and 1990s, following deindustrialization in many developed economies and increased attention to the role of finance and other advanced producer services in driving economic growth in cities and regions. The impetus for financial geography also arose from a critical inquiry into how financial flows and structures shape and contribute to uneven development and instability, following the excesses of the high-rolling 1980s in the financial centers of London and New York.

Initial attention was given to the regulation and governance of the international financial system and debates around the dynamic relationships between finance capital and nation-states. This political economy approach is complemented by more social and cultural explanations for analyzing the persistent and increasing importance of international financial centers (IFCs) as strategic basing points for global capital. The territorial embeddedness of specific localities in the production and reproduction of global finance is explained by particular social and cultural constructions of people and places. While initial studies analyzed individual cities, relational economic approaches became more important in explaining how and why such financial centers develop or maintain their roles and prominence as IFC networks. More in-depth studies examined the workings of specific financial markets, the influence of global financial markets on corporate governance and national policies, and broader implications of financial logics for
governing economic and social lives. More recently, financial geographers are paying more attention to emerging economies and alternative financial networks as a critical response to the domination of Anglo-American economies in financial geography research.

**Political economy approach**

Early research in financial geography explores the changing spatial structures of the international financial system and the financial industry. The role of money and finance is given center stage in examining the circulation, accumulation, and regulation of capital and their spatial implications. While advancements in transportation and ICT technologies have reduced the relative distance between places, this “shrinking” of the world is also part of the general process of capitalist commodity production and capital accumulation, as capitalist producers are locked into a perpetual race to exploit new markets and to reduce the turnover time of capital (Harvey 1982). This time–space compression reshapes relationships between space and capital, and presents new regulatory challenges with the international monetary and financial system constituting a kind of regulatory space holding together broader processes of accumulation. This perspective draws attention to geographical and structural shifts in power between states and markets in the regulation and operation of markets as the globalization of capital and ideas disrupted traditional forms of sovereignty and international regulation. Studies examine how regulatory changes, technological innovations, and the globalization of markets and monetary flows are remapping the financial landscape towards increasing deterritorialization, but states remain important arbiters in determining the shape and speed of such processes, both within their national space economy and on the international arena.

An important theme in this area of research is the notion of hegemonic stability – the idea that one powerful state will impose order on the international financial system such that it provides a platform upon which more general processes of capital accumulation follow. Studies on earlier systems of international regulation in the nineteenth and twentieth centuries largely focus on British financial capitalism and the pivotal role of the City of London in the construction of the gold standard in the nineteenth century, and the rise and fall of US financial hegemony during the postwar period. The construction and subsequent collapse of the US-led Bretton Woods system demonstrate the limits of national markets for accumulation strategies as economic activity becomes increasingly internationalized. The development of Eurodollar markets, for example, threatens the control that national governments exercised over national space–economies and symbolizes the emerging power and international mobility of private capital. This gives rise to the concept of posthegemony, whereby different state actors linked into different policy communities increasingly operate within transnational networks that comprise counterparts abroad as well as global financial institutions. In this sense, hegemonic power resides not with one territorial state but in a number of nodal points or flows. While this decentered hegemonic core is more spatially diffused than before, modes of regulation are still anchored by various actors, including supranational organizations such as the World Bank and the International Monetary Fund (IMF), large private capital, and particular communities (be they policy, finance, or other interest groups) located primarily in the United States, Europe, and Japan.

Another systemic concern is that of regulatory arbitrage. The spatially bounded nature of
regulation (often organized according to political-territorial boundaries) makes it possible, particularly with the aid of advances in ICT, for economic agents to move between different “regulatory spaces” in order to circumvent constraints associated with a particular regulatory regime. Regulatory arbitrage and reregulation are key themes as scholars analyze changing power relations between states and markets and their implications for the global financial system. With this practice of spatial-regulatory arbitrage, national economic policies become increasingly sensitive to the power of international money and orientated to the pursuit of low inflation and relative price stability in the constant bid to retain such “hot money.” State regulatory functions are further challenged by the inherent tendency of financial institutions for financial innovation, as new financial instruments open up new areas of financial activity and profits as yet unconstrained by regulatory control. The power of finance capital thus pressures national and local governments to accommodate global capital in ever more earnest ways through deregulation of financial markets and institutions. The winners of this process have been particular global cities that have become attuned to the rhythms of the global economy and adept at pinning down hypermobile capital through deregulation and specific forms of urban and economic development policies. A related strand of work explores the transformation of financial space through the growth of “offshore” financial centers (OFCs), where more permissive regulatory environments serve as havens from the restrictions that national governments place on financial activities. The linkages between onshore and offshore regulatory spaces are important in understanding the broader financial system, such as the development of international banking facilities in the United States and its relationship to offshore financial activities in the Bahamas and the Cayman Islands.

Even as the shift in power from states to markets is a key research theme, others point to the continued relevance of the regulatory role of the state in the international financial system. The state is clearly vital for creating and maintaining the physical infrastructure that is necessary for a city’s high standing within the network of global cities, but national and local state agents are also highly implicated through their contributions to the institutional infrastructure of these cities. State regulation, in particular, is an important part of “institutional thickness” – a product of the interaction and collective strategies of institutions of all kinds, including firms, financial institutions, trade associations, non- or intergovernmental organizations, and economic development agencies, as well as state and local governments – that appears to differentiate successful places and regions in the global economy. The growing importance of supranational organizations and international forums of monetary and economic coordination, such as the G7 and G20 country groups or the IMF, is also noted. Conventional understandings of state power and economic boundaries are blurred and works on geographies of money and finance become more concerned with flux, fluidity, and the geography of flows.

International financial centers and networks

The persistence, and increasing importance, of particular localities (in the form of IFCs and OFCs) as strategic basing points for global capital features prominently in research on the geographical relationships, processes, and impacts of finance. The role of economic centrality in the development of IFCs is prominent in global cities research. The transformation of the world economy since the 1980s is connected to an economic
shift towards services and finance, which has consolidated the importance of major cities as sites for certain types of activities and functions. These global cities are centers of command in the organization of the world economy, as key locations, marketplaces, and major sites of production and innovation for finance and specialized services. Localities such as New York, London, and Tokyo are leading examples of cities that have evolved into strategic sites for the development, production, and supply of innovative financial and business services. Some of the work illustrating this could be categorized as social constructivist in approach, inspired by the work of sociologists and anthropologists who treat money as a contingent and socialized phenomenon. This rejects the idea of a single, centered model of money in favor of viewing money as constituted through different networks of human practices. In order to explain why IFCs have not simply melted into a generalized and electronic “space of flows,” research highlights the influence of a wide range of social and cultural factors that contribute to their success and survival. This departs from a more abstract political economic perspective by conceptualizing financial centers as active and dynamic ensembles of networks – of institutions, individuals, machines, concepts, interpretations, and information.

Information is particularly important as the role of a financial center is to generate, capture, and interpret the vast amounts of monetary information that flows through every day. Rather than merely being physical locations of financial markets and institutions for the global finance industry, IFCs are centers of representation and chief points of surveillance, centers of expertise where product innovation and marketing are conducted, and centers of social interaction amongst finance workers. Stepping outside such networks and localities could be extremely costly in a financial world that has become increasingly complex and hypermobile. Studies of trust show how the business of finance still thrives on close interfirm and interpersonal relationships, such that physical proximity within an IFC is integral to the operation and reproduction of the financial system itself. Although formal institutions and mechanisms, such as credit rating agencies, exist to underwrite trust in finance, informal and personal relationships continue to be vital in lubricating the wheels of international finance. As the financial system becomes increasingly complex, trust relationships have also become central strategies for reducing risk through the development and maintenance of interpersonal relationships, which are more easily performed in relatively circumscribed spaces such as IFCs.

Attention to such social and cultural constructions of IFCs has important implications for understanding urban and regional development. Active branding exercises conducted by state actors and institutions have become critical to the imaging of particular global cities as having the right credentials and expertise to claim the status of IFC. The City of London, for example, consciously plays to the role of cultural authority and expertise in global financial services through a rediscovery of tradition. Such branding exercises are more than symbolic reconstruction; they have material consequences for the reconfiguration of city centers to meet the demands of capital. The developments of the London Docklands, Battery Park City in New York, and Shanghai Pudong New Area are the material expressions of a shift from organizing the city as an assortment of concrete production spaces towards visualizing it as a coherent space of financial processes, consumption, and political ideology. Studies in this vein range from the iconography of the City of London’s built environment, to analyses of media representations of financial crises, and issues of gender and
embodiment in understanding the practices and spatialities of finance.

Even as particular cities (such as London and New York) are seen as top-ranking global cities and preeminent IFCs far ahead of other competing centers, global cities must inevitably engage one another in fulfilling their functions of economic coordination and control, as their very success is sustained by their roles within a network of cities. Earlier studies divide cities into different tiers of importance according to their degree of integration into the global economy, and their roles as basing points in the spatial articulation of global production, finance, and consumption. IFCs are ranked according to variables such as number of financial headquarters and branches or volumes of financial transactions. The roles of producer services in supporting IFC growth are also noted, whereby particular cities function as sites of production for services and financial products that coordinate global economic activities. Since the early 2000s, geographers have highlighted the value of a network approach. Studies of IFCs and financial services explore more complementary forms of relations and alliances alongside the notion of hierarchy and competition between global cities. The theorization of a network of global cities inspired geographers to analyze intercity networks based upon flows and connections with the establishment of the Globalization and World Cities (GaWC) research network based at Loughborough University in the United Kingdom. These relational approaches highlight the roles of “lesser” IFCs in sustaining the overall global financial architecture, such as Frankfurt’s growth as a complementary financial center to London, the IFC network of Hong Kong, Shanghai and Beijing in Greater China, and the consistent flows of capital, labor, and knowledge that have sustained both New York and London as pre- eminent global centers (often referred to as the NY-LON connection).

An IFC network approach has further developed in recent years through connecting developments between IFCs and OFCs. This problematizes the divide between what is seen as legitimate onshore financial activities in major financial centers (located within global cities) and less regulated and slightly shady transactions handled by offshore jurisdictions (often depicted as small island economies). Such offshore jurisdictions are more important to global economic transformations and regional development than previously recognized; they have become a vital component of business and financial practice for firms, individuals, and other institutions (Coe, Lai, and Wójcik 2014). Concomitantly, offshore functions in the interest of regulatory arbitrage are also widely practiced in many IFCs, with the rise of so-called midshore financial centers that have both onshore traits (sophisticated financial markets, strong legal and regulatory systems) and offshore features (low taxes and secrecy), such as Singapore and Hong Kong.

Financial markets and financialization

The workings of specific financial markets, the influence of global financial markets on corporate governance and national policies, and the broader implications of financial logics for governing economic and social lives have become more important in the past decade. With the scaling back of state welfare functions in Anglo-American economies, the privatization of pension funds, growth of unit trusts and other investment vehicles, and their management and investments have become significant topics of research into how these institutional investors impact financial markets development, national development, and firm strategies. This is related
FINANCIAL GEOGRAPHY

to the spatialities of stock markets and how different national market structures and regulatory systems (such as in the United States, the United Kingdom, France, and Germany) have evolved in response to global financial imperatives. These strands of research highlight the increased importance of global financial markets for corporate governance, as accounting strategies have changed in response to the interests of global portfolio managers, leading, in turn, to the transformation of European corporate governance. The rise of stock markets and the changing relationship between bank financing and capital markets financing also have an important influence on corporate governance, regional development, and global production networks. As long as financial decision-making and the allocation of capital remain concentrated in major IFCs, regions and locations that lack such centers are disadvantaged in terms of access to finance, particularly in areas such as venture capital. The risky nature of the sector, and the trust-based and relational nature of venture capital investment, could lead to clustering of funding to firms and individuals located near to IFCs. This could account for spatial variations in the levels of success shown by innovative enterprises.

This leads to a more recent topic termed “financialization.” This refers to the increasing importance of financial logics in different aspects of economic, political, and social life. This diverse and rapidly expanding literature ranges from regulation theory and critical social accountancy approaches to more sociocultural perspectives. Coverage ranges from the growing and systemic nature of finance and financial engineering and their impacts on global governance, through national and firm level analyses that examine patterns of accumulation through financial channels rather than through trade or commodity production, to more individual and household level analyses of the transformation of everyday habits of savings and borrowing. Financial geographers have focused mainly on analyses of the processes and impacts of financialization on firms and regions, and have been particularly influential with respect to culturally inflected sociological research on how finance shapes everyday life within contemporary capitalist societies. Individuals are being conditioned to take on greater financial responsibilities and risks as Keynesian-style state social support is replaced by private sector variants such as personal pensions, private insurance, and investments. The transformation of everyday practices of borrowing and saving is also seen in the rise of credit card and other debts, and savings being channeled into various forms of investment products rather than conventional bank deposits. While some view this as a democratization of finance and investment to a broader public, others see it as the creation and extension of new risks with spatially uneven impacts. Instead of an abstract and monolithic entity, the financial system is reframed as a coalition of smaller constitutive ecologies, such that distinctive groupings of financial knowledge, practices, and subjectivities emerge in different places with uneven connectivity and material outcomes. This financial ecologies approach shows how households and individuals are changing their savings/investment practices and are being drawn into different financial relationships delineated by distinctive sociocultural demographics, and with unequal outcomes. The overall impact of financialization is a decisive shift in the way that financial futures and risks are conceptualized and managed by individuals and households. There is an engagement with, and acceptance of, investment in capital markets in order to secure individual financial futures. As global finance becomes increasingly influential in driving state policies, firm practices, and individual actions,
money is being made not just from efficient allocation of funds to profitable ventures in the “real economy” but by buying and selling of financial instruments. Such trends increase the vulnerability of the real economy to financial crises, and also raise questions about conceptualization of “real” and virtual/fictitious/financial economies.

**Alternative financial networks**

While research approaches and topics in financial geography have diversified over the past few decades, the geographical focus has been largely dominated by Anglo-American economies, with some attempts at incorporating certain financial markets in Europe and Japan. The scrutiny of financial markets and activities in US and UK financial centers is perhaps unsurprising given the importance of service sectors (and advanced producer services in particular) in those economies, following deindustrialization since the 1970s. However, as relational approaches to urbanization and capital accumulation become popular in studies of global city networks and IFC development, the geographical scope of financial geography begins to incorporate new nodes and networks in the global economy beyond the premier centers of London, New York, and Tokyo. With cycles of economic crises and recovery, financial markets and regions that used to be deemed unsuitable for investments are reframed as investment alternatives, offering opportunities for higher returns or as strategic assets for risk management. Such studies of “emerging markets” critically examine their discursive construction and mobilization by fund managers, analysts, rating agencies, and even nation-states as they seek ever higher returns on capital, especially when faced with recessionary pressures or slow growth environments in developed markets. The growing significance of IFCs and financial markets in East and Southeast Asia, the Middle East, and Eastern Europe has important implications for understanding the geographical scope of global finance, the entanglement of different types of financial markets and financial centers in strategies of capital accumulation, and how dominant discourses about the world economy have real impact on capital flows and their uneven distribution across countries and regions.

The worldwide rise of sovereign wealth funds (SWFs) also has important implications for understanding the complex entanglement of nation-states, geopolitics, development, and global finance. While their motives, intentions, and operations may vary, wealthy economies in East Asia and the Gulf states using SWFs share common goals of managing rates of return on accumulated financial assets through investment in a broad range of asset classes and regions around the world. Research explores how these SWFs act as strategic instruments of states in maintaining legitimacy and furthering geopolitical interests, which combine both domestic concerns and international relations. As a result of these global investment footprints, even small countries with large and globally oriented SWFs can wield significant influence in the global political economy.

Analyses of the constructions and practices of financial logics based on Islamic religious principles and ethical guidelines have also been incorporated in order to better understand so-called mainstream finance. They reveal the use of different types of economic theories beyond the orthodox financial economics that dominate “Western” economic systems and a suite of different financial centers and networks previously unaccounted for. The growth of Islamic banking and finance in Muslim-dominated countries in the Middle East, Southeast Asia, and parts of Africa, as well as in non-Muslim countries (with London being an important global center for
Islamic financial products), also points to the entangled nature of “alternative” and “Western” financial systems. This is particularly significant as even conventional financial institutions are now looking to “alternative” financial products and markets in the incessant search for returns on capital, be they emerging markets, Islamic finance, or carbon trading markets. This underscores the importance of engaging in more intensive research on financial geographies beyond established financial centers, in ways that are sensitive to geographically variegated systems and practices, as well as on the ways in which different circuits of financial knowledge and practices are entangled and mutually constituted along uneven power geometries.

Further reading

Geographers often need to make a systematic model that describes some phenomenon of interest. These models frequently involve numerical values, and give relationships between those values as a set of equations to solve. In many cases these solutions are not available in analytic form, and instead require a computational approximation to find an answer. Offered here is a brief overview of how such answers may be obtained; more detailed specialist texts are indicated in the section “Further reading.” After a short introduction, the basic ideas of using finite differences to find approximate solutions to differential equations are described. There follows an illustrative example of using finite elements, which can deal with more complex geometries and capture a range of geographic phenomena that can be represented as spatially continuous. A final section illustrates how granular systems (or those better approximated using discrete entities) can be approached using the discrete element method.

The spatial distributions or temporal evolution of some geographical systems often have some aspects that are, to a good approximation, continuous, in time or space, or both. Physical examples are fluid flows in the atmosphere or ocean, surface flows in lakes and rivers, coastal phenomena including tides, storm surges or tsunami, and subsurface water fluxes including both near surface saturated and unsaturated layers, or deeper groundwater flows. Volcanic plumes or lava flows, or in colder areas snow-avalanches and, at longer time-scales, flow of glaciers may also be included. Surface deformation such as soil creep or, over geological timescales, the movement and deformation of the crust of the Earth may also fall into this category. Although, ultimately, the flowing materials are atomic in nature, at scales of geographical interest the material may be treatable as essentially smooth and continuous. However, even in systems of a noticeably discrete nature, if numbers are sufficiently large and space scales sufficiently great, it may be appropriate to treat ecological and human systems as having some nearly continuous properties. Examples include population growth, predator–prey interactions (Gurney and Nisbet 1998), spread of disease (Keeling and Rohani 2008), physiology of trees and animals, demographic and economic “Limits to Growth” (Meadows, Randers, and Meadows 2005), or diffusion processes in cities, such as suburbanization or intraurban migration (Batty 2007). Conversely, in granular systems comprising many discrete individual particles, interactions may be treated as continuous, even when contacts between particles are discontinuous both temporally and spatially (Munjiza 2004). In all these cases the most natural way to formulate a dynamic mathematical model of the continuous system is to use differential equations. Unfortunately, while it might be possible to write these equations down, they are often sufficiently difficult that they cannot be solved analytically (i.e., using exact mathematical techniques) but instead must be solved by other means, including numerical and computational approximations. In Box 1 a few
Finite-element and finite-difference modeling

Box 1 Some simple illustrative equations

**Exponential growth/decay**

Population $N$ with birth rate $b$ and death rate $d$:

$$\frac{dN}{dt} = (b - d)N = \lambda N$$

**The logistic equation – bounded growth**

Population $N$ with birth rate $r$ and “carrying capacity” $K$:

$$\frac{dN}{dt} = rN \left(1 - \frac{N}{K}\right)$$

**Nonlinear oscillations – the Lotka–Volterra predator–prey equations**

Prey species $p$ born at rate $\alpha$, is eaten by predators, $e$, at rate per capita $\beta$, leading to predator births at rate per capita $\gamma$. Otherwise predators die at rate $\delta$:

$$\frac{\partial p}{\partial t} = \alpha p - \beta pe$$

$$\frac{\partial e}{\partial t} = \gamma pe - \delta e$$

**Compartmental model of disease spread – the “SIR” equations**

Susceptible population fraction $S$, Infected $I$, Recovered (or dead) $R$, with infection rate $\beta$ and recovery rate $\gamma$:

$$\frac{\partial S}{\partial t} = -\beta SI$$

$$\frac{\partial I}{\partial t} = \beta SI - \gamma I$$

$$\frac{\partial R}{\partial t} = \gamma I$$

**Diffusion in one space dimension**

Quantity $S$ diffuses over space $x$ with time $t$ with diffusion constant $k$:

$$\frac{\partial S}{\partial t} = k \frac{\partial^2 S}{\partial x^2}$$

**Shallow water equations in one space dimension – conservative form, no friction or viscosity**

$H$ is the water depth and $h$ the height of the water surface level (above the horizontal), velocity $u$, time $t$, space $x$, acceleration due to gravity $g$:

$$\frac{\partial h}{\partial t} + \frac{\partial (Hu)}{\partial x} = 0$$

$$\frac{\partial (Hu)}{\partial t} + \frac{\partial (Hu^2)}{\partial x} = -gH \frac{\partial h}{\partial x}$$

Illustrative examples are shown, from the simplest one-dimensional forms where we have access to the closed-form solution, to those cases where a small degree of nonlinearity leads to complex dynamics that must instead be approximated. These examples will prove useful in illustrating computational ways forward.

Finite differences

Solving sets of equations has a long history. The volume “Institutionum Calculi Integralis” (Foundations of Integral Calculus), published in 1768 by Leonhard Euler, offers methods for obtaining approximate integrals of differential
equations. Fortunately these techniques have been elaborated sufficiently often since then that we do not have to resort to the primary text. The basic idea is that starting from a known point, and assuming that rates of change are constant over a small interval, neighboring values of variables can be approximated by moving forward a finite step. In doing so it is hoped that an accurate estimate is made by choosing a step that is sufficiently small. Essentially this reverts to the original way the derivative is defined using a straight line to approach a tangent to a curve (Figure 1).

Given some function $S$ for which we know the rate of change, $F$, as a function of $S$ itself and a coordinate $q$, and a starting value $S_0$ at $q_0$, that is:

$$\frac{dS}{dq} = F(S, q), \ S = S_0 \text{ at } q = q_0 \quad (1)$$

a new value of $S$ at $(q_0 + dq)$ can be estimated by using the rate of change $F(S_0, q_0)$ thus:

$$S(q_0 + dq) \approx S(q_0) + F(S_0, q_0) dq \quad (2)$$

which is generally known as the forward Euler method. So our differential equation is replaced with an approximate algebraic expression that is easier to evaluate. Subsequent values of $S$ at \{q_0 + dq, q_0 + 2dq, q_0 + 3dq \ldots \} can be found sequentially, stepping forward to find the new values of $S(q)$ and thus $F(S,q)$, so that we can find a complete estimate of the behavior of $S$ over some range (Figure 2).

Even in a simple case this procedure is tedious and error prone to carry out by hand, although as pointed out by Richardson (quoted in Hunt 1998) such methods are often simpler, more systematic and easier to check than many analytic methods. Richardson’s own pioneering attempt at a numerical weather forecast in the early twentieth century (Richardson 1922), based on finite differences, laid the groundwork for later development of weather forecast models in the 1940s and 1950s. His own first attempt lacked accuracy because the initial conditions for the forecast needed to be filtered to match the timescales present in the numerical scheme – otherwise errors in the initial data can trigger large-amplitude high-frequency gravity waves that are usually suppressed in the real atmosphere (Lynch 2006). However, the practicality of this approach lay in doubt because of the effort required – Richardson’s own vision of a room filled with people each tasked with the calculation of part of the forecast needed 64,000 people to keep pace with the global weather (presaging the modern method of using many parallel computational cores). An automatic method is needed to make finite-difference calculations realistically possible.

As early as the 1800s the need for mechanization to improve reliability of finite-difference methods was recognized, leading to Babbage’s design for the difference engine, essentially a mechanical computer. The target was, in that

Figure 1 The rate of change of $S$ at $q_0$, $F(S_0, q_0)$, is given by the red tangent line. For a finite change $dq$, the actual change in $S$ is shown by the green dotted line. Extrapolating $S(q_0)$ to an estimate of $S(q_0 + dq)$ using the tangent at $q_0$ we make the error relative to the exact value shown by the blue dashed line, which, for a sufficiently smooth function, we can make as small as we please by reducing the size of $dq$. 

Figure 2  Successive approximations to $S$ starting from $S(q_0)$ at each of the points $\{q_0+dq, q_0+2dq, q_0+3dq \ldots \}$ using the forward Euler method. Notice that the error in each step accumulates to give a global error after many steps that is larger than each individual error, although in the case illustrated the error per step is decreasing as $q$ increases.

case, the calculation of series approximations, dependent on the idea (due to Newton) that successive differences of a polynomial sequence become constant once the number of differenc- ings matches the polynomial order. Although such automation was not realized until the advent of the digital computer in the mid-twentieth century, the mechanical nature of the difference engine makes it clear that the calculation has finite precision. Digital computers, being by their very nature finite, lend themselves to finite-difference approaches almost by default. While it is possible, with modern machinery, to evaluate arithmetic expressions to arbitrary precision, the time required increases with the number of significant digits, and at some point a truncation in the representation of numbers is needed. So every numerical quantity in a computation usually has a fixed fractional precision: a typical value would be about 15 places of decimals. Multiplication of two such numbers cannot have better precision, and extra digits that might be present in an exact calculation get discarded. This rounding error is independent of the above errors made using a finite-difference scheme, but may be important, as these small imperfections can be amplified by unstable numerical methods.

Desirable properties for numerical solution schemes

The three main desiderata of finite-difference methods are consistency, stability, and convergence. For a method to be consistent, the error in making a single step from any starting point should reduce to zero as the step size reduces. The rate at which this local error reduces, expressed as a power of the step size, determines the order of the method – the forward Euler method is linear (i.e., first order) and will give exact answers only for linear functions. For numerical efficiency it is advantageous to have a faster reduction of local error with step size, either quadratic (second order) or better, although the great effort needed to work with order higher than five usually means that very high order methods are not often used. However, this by itself is not sufficient to ensure that the global error be controlled – for this the method has to also be stable. In general, if the method is both consistent and stable, then it will also be convergent, in the sense that the global error will reduce to zero as the step size is reduced, and the numerical solution converges to the solution of the original differential equation.

To look at this more closely, consider some of the example equations from Box 1. The conditions of consistency and stability demand that the global error decrease with step size $dq$, so that in the limit the exact answer is recovered.
For exponential decay this can be shown to be the case by solving the finite-difference equation from the forward Euler method directly. The original equation is shown in equation (A):

\[
\frac{dN}{dt} = (b - d)N = \lambda N \Rightarrow N = N(0) \exp(\lambda t)
\]  

(3)

where \(N\) is a population number, \(b\) the birth rate, \(d\) the death rate, and \(\lambda = b - d\), so that for deaths exceeding births we get exponential decay. Using the forward Euler method with timestep \(h\) gives equation (4):

\[
\frac{N(t + h) - N(t)}{h} \approx \lambda N(t)
\]

\[
\Rightarrow N(t + h) = N(t)(1 + \lambda h)
\]

\[
\Rightarrow N(nh) = (1 + \lambda h)^n N(0) = \left(1 + \frac{\lambda t}{n}\right)^n N(0)
\]

(4)

where \(t = nh\) denotes the total time represented by \(n\) steps of length \(h\). If \(t\) is kept constant by letting \(h \to 0\) and \(n \to \infty\), the final discrete expression of equation (4) reduces to the exponential function. Hence, the solution converges to the solution of the original equation in the limit of small \(h\). However, something different happens when \(h\) becomes large. Whereas for \(-1 < \lambda h < 0\) a monotonic decreasing behavior is obtained, in \(-2 < \lambda h < -1\) the solution still decreases, but oscillates, and once \(\lambda h < -2\) the oscillations grow geometrically and there is no possibility of a solution. This kind of rapid unwanted growth is typical of unstable numerical methods – usually there is a threshold step value, beyond which instability sets in and the algorithm “blows up,” often crashing the program that tries to implement it. Some methods, however, can be unstable for any timestep value. For example, we can try to increase the order of the method by using the so called “leap-frog” scheme. Suppose a Taylor expansion of \(N(t + h)\) and \(N(t - h)\) is written (equation (5)):

\[
N(t + h) = N(t) + \frac{dN}{dt} \bigg|_t \bigg(h + \frac{1}{2} \frac{d^2 N}{dt^2} \bigg) h^2 + O(h^3) \ldots
\]

\[
N(t - h) = N(t) - \frac{dN}{dt} \bigg|_t \bigg(h + \frac{1}{2} \frac{d^2 N}{dt^2} \bigg) h^2 - O(h^3) \ldots
\]

(5)

Subtracting the two expressions in equation (5), the terms in \(N(t)\) and those proportional to \(h^2\) cancel to give:

\[
\frac{dN}{dt} \bigg|_t = \frac{N(t + h) - N(t - h)}{2h} + O(h^2) \ldots
\]

(6)

This result is exact at point \(t\) for both linear and quadratic curves, and, therefore, the single-step error should reduce more quickly as \(h\) is reduced. Using this approximation in the exponential equation gives:

\[
N(t + h) = N(t - h) + 2\lambda h N(t)
\]

(7)

Note that two starting values are now needed: if \(N\) is known at \(t = 0\) and \(t = h\), then \(N\) can be found at \(t = 2h\). Usually a first-order step (e.g., forward Euler) is used to acquire \(N(t + h)\) as part of the process of solution. Initially the result is more accurate than the Euler method (Figure 3), but after a while initial small oscillations (kicked off by the first step!) begin to grow and shortly are well out of control. Reducing the timestep just postpones the inevitable failure to find a solution.

For this reason, many alternative schemes have been developed for higher order accuracy. Runge-Kutta schemes are often employed for their relative simplicity and robustness, although multistep (or predictor-corrector) schemes may give high order with good stability (Press et al. 2007). Often, though, in more complex
Figure 3  Trying to solve the exponential decay equation using a leap-frog scheme. The exact solution is the black curve, and the numerical scheme is in red. After a while exponentially growing oscillations set in: the solution is unconditionally unstable.

cases, finding the right timestep can require some experimentation. Careful analysis of the expected errors and their rate of growth may give a condition on the timestep controlling the solution. Using a Taylor series expansion to analyze growth of errors can help, for example, although a Fourier analysis is often more informative (Morton and Mayers 2005). In nonlinear cases this typically means first making a linear approximation to the equations to make the analysis tractable – even so, for nonlinear problems it can be necessary to introduce some artificial damping terms that control the error growth even though they are not strictly implied by the original equations.

As noted above, the attempted solution with the leap-frog method is also oscillatory, a behavior that is not evident at all in the original solution – such spurious “numerical modes” can be present even when the method is otherwise stable, and can be quite difficult to suppress. For example, the SIR equations (per Box 1, a model of disease spread) can have such oscillatory errors for a range of different numerical schemes (Keeling and Rohani 2008). Here the logistic equation is looked at as a slightly different example. This equation has often been used to describe a population initially growing exponentially, but limited as to resource so that it has maximum carrying capacity $K$ – the solution can be found analytically with a little algebra (Gurney and Nisbet 1998), as shown in equation (8):

$$\frac{dN}{dt} = rN \left(1 - \frac{N}{K}\right) \Rightarrow N = \frac{KN(0)}{N(0) + (K - N(0)) \exp(-rt)}$$

(8)

which has the rather smooth behavior shown in Figure 4. Note that for an ordinary differential equation of this kind it can be shown that the solution is unique for given $N(0)$, $r$, and $K$.

In finite-difference form, using the forward Euler method gives:

$$N(t + h) = N(t)(1 + rh) - N(t)^2 rh/K$$

(9)

For small timesteps this reproduces the analytic form reasonably well. However, as the timestep increases, bounded oscillations appear: the solution alternates about the final analytic value without growing. Increase the timestep still more and the oscillation begins to vary in size and become unpredictable, in the sense that a small change in the initial condition leads to a large difference in the solution. The difference equation shows deterministic chaos (Ott 2002). Here the point is to illustrate that the differential equation and the finite-difference version can have completely different behavior, and for nonlinear cases it may be difficult to anticipate the parameter ranges over which such phenomena might appear. The issue of chaotic nonlinear behavior, which renders significant forward prediction in time impossible, is a frequent problem.
Figure 4 Solution of the logistic equation with $N(0) = 1$, $K = 100$, $r = 3$ (black) and the discrete version from equation (9) with $h = 0.975$. For $h > 1$ the solution is unstable and plunges off toward $-\infty$.

Typically such a form leads to more stable expressions for the difference equation, but now it is necessary to solve for $S(q)$ at each timestep, since on the right-hand side there are terms that are evaluated at the forward point $q + dq$. In cases where $F$ is nonlinear this may be nontrivial: typically it at least requires solution of a set of linear equations to find the value of $S(q + dq)$. Hence, these methods are usually called implicit schemes, as opposed to the more straightforward explicit schemes that have been looked at above. For these reasons it may not be worth the expense of using an implicit method in order to gain stability – a shorter timestep may be easier and may possibly suffice. However, for certain types of equations, particularly those that are known as stiff, where the existence of a wide range of timescales in the solution makes a stable scheme difficult to achieve (Acton 1970), implicit schemes may be a necessity. In simple cases, it may be possible to find a solution directly – for exponential growth the solution is shown in equation (11):

$$\frac{N(t + h) - N(t)}{h} = \lambda N(t + h)$$

$$\Rightarrow N(t + h) = N(t) \frac{1}{1 - \lambda h}$$

yielding the backward Euler method, which is stable for any step size $h$ when $\lambda < 0$, although large values of $h$ will give large errors. Further elaborations are possible using semi-implicit schemes that use a linear combination of forward and backward differences, as shown in equation (12):

$$\frac{S(q + dq) - S(q)}{dq} = \theta F(S, q + dq) + (1 - \theta) F(S, q)$$

where $0 < \theta < 1$. These do not imply less work than a strictly implicit scheme, but it may be possible to obtain a higher order method than either a strictly explicit or implicit method alone, whilst also giving improved stability.

Including space

In order to solve initial value problems that involve both time and space it is necessary to difference the spatial part of the system. As an example consider the one-dimensional diffusion equation:

$$\frac{\partial S}{\partial t} = k \frac{\partial^2 S}{\partial x^2}$$

Notice that an approximation is now needed for the second derivative, which can be obtained from the Taylor expansions of equation (5),
written for space coordinate $x$ rather than time $t$. Adding rather than differencing the two, the first order derivatives cancel to give:

$$\frac{\partial^2 S}{\partial x^2} \approx \frac{S(t, x + \delta x) - 2S(t, x) + S(t, x - \delta x)}{\delta x^2}$$  
(14)

for small spatial difference $\delta x$. For time differencing the Euler method can be used (the leap-frog method would, in this case, be unstable for all $\delta t$ again), as shown in equation (15):

$$S(t + \delta t, x) = S(t, x) + \frac{2k\delta t}{\delta x^2}(0.5(S(t, x + \delta x) + S(t, x - \delta x)) - S(t, x))$$  
(15)

On the right-hand side of equation (15), the second term shows that some fraction of the value at point $x$ is replaced with the average of the values to either side: a smoothing of the spatial values is obtained as time advances, as expected from a diffusive process. Note that this term is now weighted by a ratio of the timestep to the square of the spatial step – the stability of the scheme depends on this ratio being sufficiently small: a tiny difference in $\delta t$ can again lead from a stable solution to exponentially growing oscillations. Implicit or semi-implicit schemes are typically therefore preferred in this case. Notice also that information is needed across the entire boundary in $x$ in order to start the solution off. This includes the edge points where the above approximation for the second derivative cannot be used, and the behavior must be prescribed at all times. The dependence of the solution on the entire initial boundary is characteristic of this type of parabolic equation.

By contrast hyperbolic equations, such as the shallow water equations, used to model fluid systems where the horizontal scale is much larger than the vertical, have associated with them a finite propagation speed. This means that the domain of dependence for any spatial point at a given time includes only those other spatial points that are close enough for a signal to have traversed the intervening distance since $t = 0$. Here, for stability, the ratio $\delta t/\delta x$ needs to be small enough that the numerical domain of dependence includes that of the original equation – this corresponds roughly to the notion that no propagating disturbance should be able to travel more than $\delta x$ in under a single timestep.

To extend the method to two space dimensions, a regular rectangular grid of cells extending in the $x$ and $y$ directions can be used. Since the axes are orthogonal we can introduce independent differences in each space dimension. For example, for the diffusion operator in 2-D taking differences separately in $x$ and $y$ is shown in equation (16):

$$\nabla^2 S = \frac{\partial^2 S}{\partial x^2} + \frac{\partial^2 S}{\partial y^2} \approx \frac{S(t, x + \delta x, y) - 2S(t, x, y) + S(t, x - \delta x, y)}{\delta x^2} + \frac{S(t, x, y + \delta y) - 2S(t, x, y) + S(t, x, y - \delta y)}{\delta y^2}$$  
(16)

Numerical stability now depends on which of the two spatial dimensions has the more restrictive condition on the timestep. Spatial considerations can lead to new kinds of instability, however – for example, centered spatial schemes (similar to leap-frog, but now for spatial differences) can lead to a decoupling of solutions between alternating spatial cells and lead to a characteristic “checkerboard” pattern that may, again, grow exponentially with time.

These spatial finite-difference approximations are closely related to cellular automata (CA), the main difference being that here there is the specific goal of approximating a continuous equation. In the abstract, cellular automata do
not normally need to impose stability or convergence criteria on changes between steps, unless the intent is to model a real physical process such as fluid flow. On the other hand, the set of allowable states in a cellular model is typically smaller, but the range of phenomena covered draws on a broader class than that which is usually thought to be covered by differential equations. However, it is useful to bear the connection in mind, as the large body of literature that has grown up around finite-difference methods may be informative for CA models.

**Finite volumes and finite elements**

One difficulty with the use of orthogonal grids for spatial differences is that the grid may not fit complex geometries. In such cases it may be appropriate to allow for other cell shapes. While it is common to write cellular automata models on a hexagonal rather than a rectangular grid, solution of differential equations typically needs more flexibility. Geographers are familiar with the idea that triangulated networks are useful for tiling domains with irregularly spaced points, and this can be exploited in creating a mesh that can efficiently cover complex boundaries. The problem is to find schemes that can deal with arbitrary geometry in a well-controlled way. A whole area of research has developed around generation of meshes that have sufficient smoothness and regularity to be stable for a given solution scheme.

For flow problems, where it is possible to write the governing equations in conservative form, that is, where time derivatives depend on spatial fluxes (e.g., the shallow water equations, Box 1), finite volume methods can be used. The discretized equations are written in terms of cell-average values, with fluxes between cells specified on cell boundaries. This has the advantage that the cells can have any shape, and that the conservation properties of the system are good, since fluxes subtracted from one cell are guaranteed to be added to neighboring cells and vice versa (subject, of course, to some rounding error). This method is frequently used for shock-capturing schemes in fluids, since the conservative flux-form of the equations gives better accuracy in following moving discontinuities.

*Finite-element* techniques are an alternative set of methods arising originally from the need to solve boundary value problems in engineering: in these cases, rather than the initial value problems that have been dealt with above, the values of a function are specified along an entire boundary, and the solution has to be found everywhere in the interior of the bounded domain simultaneously. Equations of *elliptic* type fall into this category, an example being the steady-state version of the diffusion equation, with zero time derivative, leading to the Laplace equation, \( \nabla^2 S = 0 \). However, finite-element schemes can also cope with time dependency. To deal with irregular cell shapes, the fact that any function can be expanded in a series of linearly independent basis functions is used. By choosing these basis functions to be nonzero only outside some small spatial range around each cell, an integral form of the differential equation can be converted to a set of algebraic equations (Figure 5). For simple cases this often reduces to an equivalent finite-difference method, but the ability to handle arbitrary cell shapes, and to use relatively high order polynomials as basis functions, makes the extra effort required to set up the method worthwhile when boundaries have a lot of structure that needs to be captured. For example, where the boundary has sharp edges or rapidly changing properties, mesh refinement can be used, covering areas that have more rapidly changing properties with a larger number of smaller cells.
Finite-element and finite-difference modeling

Figure 5 Linear finite elements \(e_1, e_2\) and \(e_3\) defined on range \(x_0\) to \(x_4\), \(e_2\), shown in red, has the form:

\[
\begin{align*}
  e_1(x) &= \frac{x-x_1}{x_2-x_1} \quad x_1 < x < x_2 \\
  e_2(x) &= \frac{x-x_3}{x_2-x_3} \quad x_2 < x < x_3 \\
  e_3(x) &= 0 \quad \text{otherwise}
\end{align*}
\]

And similarly for \(e_1\) and \(e_3\), so products of \(e_1\) and \(e_2\) will only be nonzero when \(x_1 < x < x_2\).

An example of one version of the finite-element method is shown in Box 2. This simple case can be generalized to more space dimensions, and adjusted to accommodate more complex equations and more general boundary conditions, while maintaining the sparse matrix form, so that solutions are computationally efficient.

Discrete elements

The methods described so far are helpful when the behavior of a system is well approximated by aggregate or averaged values as continuously varying functions over space and time. For some cases this may be an inadequate description, or it may not be clear how to construct such aggregate equations in a way that is known to be consistent with the underlying dynamics.

As an example, rock fall or granular flow, such as sand grains moving against each other, can be considered. Here there are a large number of discrete particles distributed over a range of sizes, and possibly made from different materials, that may only interact fleetingly. Although it may be possible to write linear equations to describe the elastic interactions between the particles when they are in contact, the nonlinear nature of contact–changes over time can give rise to complex emergent behavior for the whole system that might not be anticipated from the individual interactions. One approach to this problem is to try to model every individual particle, allowing those not in contact with each other to move freely (possibly accelerating under body forces such as gravity), but solving the elastic equations when particles are in contact. Thus, a set of equations is obtained as shown in equation (17):

\[
\begin{align*}
  m_i \frac{d^2 r_i}{dt^2} &= \sum_j F_{ij} + B_i \\
  I_i \frac{d\omega_i}{dt} &= \sum_j \Gamma_{ij} + \tau_i
\end{align*}
\]  

(17)

where \(m_i\) is the mass of particle \(i\), \(r_i\) is a three dimensional vector giving the position of the particle center of mass, \(F_{ij}\) are the forces acting between particle \(i\) and \(j\), and \(B_i\) are the other forces acting on the particle, including gravity. \(I_i\) is the particle moment of inertia, \(\omega_i\) the angular velocity, \(\Gamma_{ij}\) the torque between particle \(i\) and \(j\), and \(\tau_i\) any torque acting other than those due to particle interactions, and this equation is written rotated into the principle axes of body \(i\). The difficulties now lie in efficiently tracking particle contacts, and in finding and specifying the force laws that govern the particle interactions. The force equations can then be solved at each contact point using finite differences. To find contacts the simplest method is again to use a regular grid.
Box 2 Finite-element example

Assume we wish to find $S$ as a sum over a set of functions $e$ so that:

$$S = \sum \alpha_j e_j$$

where the values $\alpha_j$ are values to be determined. The $e_j$ need to form a complete set over our domain. Usually it is sufficient to use polynomials in the coordinates for this purpose, but we have to truncate the set in order to make a usable approximation – so, for example, linear, quadratic or cubic polynomials might be used, depending on the degree of accuracy required.

Suppose we want to solve:

$$\frac{\partial^2 S}{\partial x^2} = F(x)$$

with some boundary conditions, say $S = 0$ over the whole of the boundary of the domain.

First we write our equation in the weak form, using some set of functions $\nu(x)$:

$$\int \frac{\partial^2 S}{\partial x^2} \nu(x) dx = \int F\nu(x) dx$$

which will generally be satisfied, given the original equation.

Assuming that we can choose $e_j$ to satisfy the same boundary conditions as $S$, and that we can also use the $e_j$ as our functions $\nu(x)$ (this sometimes being known as the Galerkin method):

$$\int \frac{\partial^2 \sum \alpha_j e_j}{\partial x^2} \nu_i dx = \int \frac{\partial \sum \alpha_j e_j}{\partial x} \frac{\partial \nu_i}{\partial x} dx = \int F\nu_i dx$$

where we have integrated by parts and used the fact that the $e_j$ are zero at the boundary. Interchanging the sum and integral we can now write a set of linear equations for $\alpha_j$:

$$\sum_j K_{ij} \alpha_j = f_i$$

where the stiffness matrix

$$K_{ij} = \int \frac{\partial e_j}{\partial x} \frac{\partial e_i}{\partial x} dx$$

and

$$f_i = \int F e_i dx$$

By choosing $e_j$ carefully so that they are only nonzero in a small range near to a given grid-point $j$, the matrix $K_{ij}$ can be made sparse, which is to say only a few of the elements are nonzero, typically mostly those close to the leading diagonal.

Particles can then be searched for contacts with those that lie in neighboring cells, rather than having to search the entire domain. The simplest model represents all particles as rigid spheres, but approximates contact forces using linear springs, where the particles are allowed to overlap by a small amount to represent spring compression at the surface. Forces producing rotational torques reduce to tangential friction in this case, and can be represented by a spring that stretches over time up to some limiting length beyond which slip occurs. Thus:
with normal force $F_{i,j}$, where $k_{i,j}$ is the stiffness of the spring acting to repel the two particles, and $\Delta r_{i,j}$ the particle overlap. $u_{i,j}$ is the normal component of the relative velocity, leading to a damping term $C_u_{i,j}$. Similarly, $k^T_{i,j}$ is the tangential spring stiffness and $Dv_{i,j}$ damps the tangential motion given tangential relative velocity $v_{i,j}$. $F^T_{i,j}$ is the tangential force, $\mu$ is a friction coefficient and $\hat{t}$ is a unit vector along the direction of the tangential spring (Cleary and Prakash 2004). The timestep for stability now depends on the factor

$$\sqrt{\frac{k}{m}}$$

as the spring constant for real rocks is extremely large (and as we would also like to limit the particle overlap to a small fraction of the radius) this necessitates a very small timestep – typically microseconds. Because any real system comprises many billions of particles, the method is very computationally expensive: usually only a small fraction of the material can be dealt with, either by using a very small domain, or neglecting most of the smaller particles. However, spheres typically flow more easily than irregular shapes, and using nonround particles may be required. This can be done by bonding together groups of spheres and treating these groups as a single rigid body, but this may leave artificially lumpy particle boundaries. At the other extreme, each particle can be modeled as an elastic solid, using finite elements, and the internal propagation of elastic waves and shear deformation can then be added to the solution. This combined finite-discrete element should then give a more accurate representation of the bulk properties that can emerge from individual particle-scale interactions (Munjiza 2004). Either way, the solution of the contact problem for nonspherical particles is even more expensive, especially if particles are nonconvex and can have multiple contact points with each other.

Challenges

This brief examination of discrete methods has touched upon a range of problem domains, each with their own challenges for future development. Even where a good solution method is known for a well-established set of equations, we often have poor knowledge both of the appropriate parameters and of the relevant boundary conditions for an unambiguous solution. In hydraulic models, for example, the subsurface conditions are typically not known, and models will only give reasonable results once calibrated to flow data – this can mean several different set of parameters might fit the surface flow data equally well (the “equifinality problem”) (Beven 2006). In the atmosphere nonlinear processes that occur at microscopic scales cannot be resolved by a grid that can cover the global domain, yet can have a significant effect on the solution (cloud processes and surface hydrology being examples). These subgrid processes have to be modeled independently (usually referred to as a “parameterization”) to try to approximate effects of the unresolved dynamics. Even so, fluid advection tends to produce narrow structures that move downscale and cross the boundaries of fixed grids, leading to their being artificially diffused away by the numerical scheme. This is particularly a problem for traces gases or pollutants that are being carried along by the fluid and can add to the difficulties of simulating atmospheric chemistry (which often has “stiff” numerical
behavior, in that solutions require implicit methods). One possible way of dealing with these issues is using adaptive mesh refinement, adding extra resolution dynamically to the model where needed. As a further difficulty, the initial conditions are often poorly known, and the equations chaotic, so that current practice is to produce not just one model output from given initial data, but an ensemble that covers plausible variations in the initial state that are consistent with the discrete model setup, and therefore produces a range of possible future atmospheric conditions.

At smaller scales, free surfaces in complex domains with moving boundaries are a challenge for fixed-grid methods. As of the time of writing, for example, in flood models, stage-dependent flow of water past arbitrarily shaped flexible vegetation is just beginning to be addressed. The case where the fluid is filled with floating debris, as is typical for any real flood, has yet to be approached effectively. When suspended and moving sediments are included then modeling becomes still more difficult, especially where a discrete element model of sediment is to be combined with the fluid flow. The large size range that typically occurs in such situations, from fine sand and silt up to cobbles and boulders, represents a further challenge, although recent advances in the use of methods based on parallel graphics-processing-units (GPU) make the treatment of large numbers of particles and the solution of the contact problem over large size ranges more accessible.

Moving to the ecological and human realm, the use of aggregate population–based equations has its own problems. Unrealistic results can come from the assumption that population densities are continuous down to the accuracy of the computational representation – for example, a continuous model of the spread of rabies in foxes allowed for the resurgence of the disease in areas where the population density suggested only $10^{-18}$ of a fox could be present (hence referred to as the atto-fox problem) (Mollison 1991). It might be questioned whether the differential equation approach is really appropriate for this kind of case. As the logistic equation example shows, discrete and continuous approximations can have quite distinct dynamical results – it may be that in these kinds of cases an explicitly discrete approach that takes into account the “graininess” of the real system is more appropriate and realistic. For granular flows the discrete element method is one step in this direction, and the equivalent for ecosystems (individual-based models) and social systems (agent-based models) may be better suited to addressing the full complexity that these systems can display.

Description and purpose

Suomen Maantieteellinen Seura is a group of geographers and those interested in geography. The official languages are Finnish and Swedish. The purpose of the society is to promote research in geography and related sciences at home and abroad. It also promotes the use and visibility of geographical knowledge and understanding in tackling societal and environmental challenges. The society also makes statements on topical issues and processes related on, for example, research and education politics and regional planning. Through its activities the society promotes interaction between geographers nationally and internationally.

Current activities or projects

Geography Days are twice-yearly meetings of geographers and geography enthusiasts organized in collaboration with university geography and regional studies units. They are open to all society members; five to six board meetings are held in a year.

The society organizes international collaboration and meetings with other geographical societies especially from neighboring countries (for example, the biannual Nordic Geographers Meeting (NGM)). The society prepares statements on topical processes in the society (e.g., related to science politics and geography education in national school curriculums).

Brief history

The Geographical Society of Finland (founded 1888) and Finnish Geographical Association (founded 1887) were united in 1921 into a single organization, the Geographical Society of Finland. One of the cornerstones of the society’s publishing has been the National Atlas of Finland. The first edition of the Atlas was the first of its kind in the world and raised international interest (e.g., achieved a gold medal in the Exposition Universelle of 1900 held in Paris, France). Since then, cartographic communication and map-making methods have changed drastically. The maps of the previous editions are currently available in the geography.fi web pages for everyone to use and enjoy.

Firm foundation and growth

Godfrey Yeung
National University of Singapore

The firm acts as an intermediate agent to reduce the transaction costs incurred in dealing with individual economic actors. It also acts as a nexus of contracts to allow transactions to be internalized and coordinated efficiently in the circular flow of production and consumption, where trust between economic agents could become institutionalized within the economic system.

Firm foundation is about how to govern the operation of a firm, ranging from official rules and regulations to unofficial norms, customs, and practices. Firm growth is about the development of a firm, including the expansion of its spatial reach through mergers and acquisitions and/or greenfield investment in local and overseas markets. An understanding of the firm, its foundation, and its growth is crucial to comprehend how economic agents and actors are interrelated and contribute to economic development across space.

Economic geographers highlight the interlinked relationships between institutions (the formal rules and regulations and informal norms) and the best practices of industrial sectors and how these shape firm behavior. Institutions not only regulate industrial best practices and conventions regarding the organization of work and labor-management relations in the workplace, but also shape the values, expectations, and even the decisions of economic actors through the functioning of labor markets, regimes of industrial relations, and corporate governance. Economic geographers therefore contribute to the debate about globalization by providing solid empirical evidence that it is generating heterogeneous rather than homogeneous processes (or outcomes) of firm foundation and growth. As clearly illustrated by the two case examples of law firms and staffing agencies in this entry, the world is not “flat” and there is no convergence of best practices across space as the transnational corporations (TNCs) cannot just adopt their operational templates from home countries in their subsidiaries without adjusting their corporate cultures to the national laws and regulations and the specific local culture and practices in host countries. Geography does matter for producer service sectors, notably consultancy, accountancy, banking, and finance, as partly illustrated by the high-profile global advertising campaign slogan of the banking giant HSBC: “The world’s local bank.” In other words, diverse national institutions create heterogeneous industrial practices across space, and their reproduction and modification results in distinctive national/regional modes of governance and trajectories of growth in firms rather than their global convergence.

An overview of the theory of the firm proposed by Ronald H. Coase will be followed by a brief outline of various perspectives on firms, including the crucial contribution of Oliver E. Williamson on the importance of interfirm (market) and intrafirm (hierarchical) transactions in the functioning of the market economy. A detailed explanation of Meric Gertler’s concept of the formal rules and regulations and informal value and norms which contribute to the formu-
FIRM FOUNDATION AND GROWTH

Firm

Ronald H. Coase, a Nobel laureate in economics, initially developed the theory of the firm. In his classic article, Coase (1937) introduced the concept of transaction costs to explain the nature and limits of firms. He asked why, instead of economic actors trading with each other directly, economic transactions have to be channeled through firms in a presumably efficient market economy. The crux of the issue is that the functioning of the price mechanisms is not cost-free, as almost every transaction involves some information costs (for example, finding out the prices of raw materials to make a commodity) and coordination and agency costs, including the negotiation and conclusion of a separate contract for each exchange transaction, for example, from the purchasing of raw materials to measuring the separate contribution of individual workers in the production line, and so on. All the information and enforcement costs involved in the execution of economic transactions are called transaction costs.

Instead of dealing with every individual economic actor in each transaction and incurring the corresponding high transaction costs, Coase (1937) argued that the firm acts as an intermediate agent – between employer and employees on the production side, and wholesale/retail on the consumption side – to internalize the production of goods and services within a circular flow of production and consumption in an economy. The employment contract regulates the relationship between employers and employees: for a specified remuneration (which may be fixed in the case of monthly salary or vary according to certain predetermined parameters, such as piece rate wages), one agrees to obey the instructions of an entrepreneur within certain limits. In other words, firms exist to reduce the transaction costs of economic transactions in a market economy.

Various views of the firm

Coase’s pioneering work laid the foundations for our understanding of firms. A number of scholars have further elaborated the concept of the firm and the five most important interpretations are outlined below.

Resource-based: The firm is an administrative organization that aims to make profitable use of its resources. The differences in how resources and services are utilized explain the heterogeneity of firms with a similar level of endowments.

Knowledge-based: The firm is an efficient mechanism for the creation and transformation of knowledge into economically viable products and services. Temporary geographical proximity is vital for economic actors to exchange business information. Smaller firms in the same sector tend to agglomerate in industrial clusters, given their limited financial or human resources do not allow frequent commuting. Larger firms, in contrast, tend to locate themselves near subcontractors or research laboratories operating at different stages of the production processes. They are more “footloose” in their location and could find it easier to relocate in areas with better endowments and preferential policies offered by local governments.

Entrepreneurial: This approach focuses on the role of entrepreneurship where judgmental decisions concerning the mobilization of resources by opportunistic risk-takers are crucial for
the establishment and development of firms. Schumpeter argued that the “creative destructive” nature of entrepreneurship is illustrated through the introduction of (i) a new good or the new quality of a good, (ii) a new method of production, (iii) a new market, (iv) a new source of supply of raw materials or components, or (v) the new organization of any industry.

Evolutionary: Firms are seen as systems of distributed knowledge whereby established ones have developed a set of routine procedures and processes from their past successes. These routines could be modified or even replaced as a response to competition from new market opportunities and/or product solutions. Evolutionary economic geographers, notably Ron Boschma and his associates, have adopted such an analytical approach by emphasizing the importance of path dependency and technological lock-in to explain spatial variations in the formation and development of industrial clusters.

Governance-based: Coase’s pioneering work laid the foundation for the later important contribution of Oliver E. Williamson, another Nobel laureate in economics, on transaction costs and the firm. In his seminal work, Markets and Hierarchies (1975), Williamson further elaborated Coase’s ideas on transaction costs by showing how intrafirm (hierarchical) transactions could mitigate imperfections in the market economy. He argued that transaction costs accompany both interfirm (market) and intrafirm (hierarchical) transactions, and both markets and hierarchies are important coordinating mechanisms for economic transactions.

Due to the specific nature of human beings as economic agents, Williamson (1975) emphasized that in reality the market economy may not function effectively. He pointed out that economic actors would behave opportunistically and in their own self-interest (called opportunism, such as shirking their responsibilities and free-riding on the back of others’ work) or even by making irrational decisions due to lack of access to information (bounded rationality due to informational asymmetry). Instead of relying on market mechanisms to minimize the costs of interfirm transactions, a firm as a nexus of contracts can allow entrepreneurs to organize business transactions between employers and employees in a vertical hierarchical organizational structure to reduce transaction costs. Only by so doing can individual firms survive market competition from various other firms conducting their transactions through the market. Moreover, firms can allow transactions to be internalized and coordinated efficiently where trust between economic agents can become institutionalized within the economic system: that is, the economy can function efficiently when employment contracts are the norm and where both employers and employees know their obligations and rights. Therefore, the creation of hierarchical organizations and institutions is a rational response to the transaction costs problems caused partly by human nature (bounded rationality and opportunist) in a pure market economy.

The institutional turn in new economic geography

Two important perspectives in the development of new economic geography arose in the 1990s. In addition to the organizational dimension, economic geographers examined the impact of globalization on regional economic development, arguing that relational or organizational proximity is at least as important as geographical proximity. Other economic geographers
have focused on the supporting regional social and institutional contexts when examining the organization of production. One of the most notable contributors to the latter is an institutional approach as part of the new economic geography initiated by Meric S. Gertler.

Adding to the earlier work of Douglass C. North on new institutional economics, Gertler (2004) proposed a new conceptualization of industrial practices and the behavior of firms. He argued that the institution is the main driving force behind the organization of production through examining the influence of cultures on the practices of firms and the trajectories of regional and national economies.

Like North (1990, 3), who argued that institutions embody “the rules of the game in a society” and shape and constrain the behavior of individual economic agents, Gertler (2004) defined institutions as the formal rules and regulations and the informal norms that regulate the behavior and shape the values and expectations of individual economic actors (firms, managers, investors, and workers) through the labor and capital markets, corporate governance, and education and training systems, among others.

For the interlinked relationships between institutions and industrial practices, Gertler emphasizes the importance of maintaining a clear distinction between institutions at the societal level, attitudes and values at the individual level, and economic behavior as expressed in the industrial practices of firms (Figure 1).

Institutions have a twofold impact on industrial practices. On the one hand, they regulate industrial best practices and conventions regarding the organization of work and labor: that is, management relations in the workplace. On the other hand, institutions also shape the values, expectations, and even the decisions of individual economic actors (unconsciously) through the functioning of the labor market, industrial relations regimes, and corporate governance. These interactive relationships between institutions and industrial practices could have an impact on their own reproduction and modification over time. Thus, all firms are embedded within the matrix of their institutional environment, which incorporates formal rules and regulations, and informal customs and social norms in the context of a specific region or country.

In common with North (1990), Gertler (2004, 2010) also argues that market mechanisms play an important role in the continuation of industrial best practices and their further refinement. Economic actors in a competitive market could phase out inefficient industrial practices. Nonetheless, the scope and pace of any change in industrial practices is constrained by the existing institutional framework in the specific national context and the locally embedded formal and informal rules that have been reproduced over time. This is especially the case if changes in industrial practices have involved changes in the institutional environment that have had an impact on local, regional, or global politics. It is one of the reasons why institutional change is a path-dependent process and involves considerable transaction costs.

Using a comparison of the practices, norms, and expectations of German and North
American advanced machinery users, Gertler (2004) demonstrated that the industry-specific shared routines and industrial best practices – including the internal and interfirm organization of production, the adoption of technologies, and their affiliated knowledge and skills – in each region are strongly influenced by its corresponding institutional matrix (regional-specific social and industrial contexts). The subsequent development of industrial best practices and economic activities can, in turn, influence institutional development. Through these case studies, he demonstrated that it is essential to understand the way that place-specific institutions in the form of regulations and norms can define the corresponding values and attitudes. A detailed understanding of the relationship between local institutions and work cultures or industrial practices can demonstrate how workers should behave and how firms could be organized and operate. This in turn informs best practices for people in the workplace: that is, the industrial practices of workers in specific industries and in specific regions.

Instead of a convergence of best practices across space, as suggested by the leading proponents of globalization such as Francis Fukuyama and Kenichi Ohmae, Gertler (2010) and other economic geographers’ work has demonstrated that the distinct local institutional environment at various levels interacts with individual actors, organizations, and institutions, and regional institutions impact on the structure and operation of firms. This creates heterogeneous industrial practices across space. In other words, differences in local institutional settings affect industrial best practices, including differences in knowing how to work in specific professions in different regions. Due to the resistance to change from vested and dominant interests, and the existence of dominant social mores and traditions, the specific setting of each institutional environment in a region is a combination of elements that could both promote and hinder industrial and regional development. Consequently, the existence of institutional inertia (path dependency) supports the existence of distinctive national “models” rather than the global convergence of mode of governance and trajectory of growth in firms (as argued by the conventional thesis of globalization, in which geography no longer matters).

Two service sectors as illustrative examples

The implications for research into new economic geography are that the diversity of institutional regimes across regions accounts for significant variations in work practices. Instead of implementing the same business model and adopting an identical corporate culture all over the world, TNCs may therefore have to allow their local subsidiaries to adopt their own sets of best practices and corporate cultures in order to function effectively. In other words, TNCs are effectively not only dealing with differences in best practices, but also differences in corporate identity over space, as corporate culture is a set of social conventions, norms, and standards that underlie the social interactions within a firm.

Using a data reduction analysis (principal components analysis) of office networks, Taylor et al. (2013) documented the overlapping and permeable regional geographies of 175 leading advanced producer service firms in 138 cities in 2010. These major producer service firms extended their market reach via global cities in order to serve major clients in manufacturing sectors. The internationalization of law firms and staffing agencies are just two examples that are often used to illustrate how diverse national institutions can shape the development strategies of transnational service firms: that is, they show
FIRM FOUNDATION AND GROWTH

the importance of regional differences in the institutional environment and how transnational firms have to work with local management in overseas subsidiaries.

Law firms

Law firms provide interesting case studies of how regional institutions can have an impact on local work practices, partly because of the restrictive nature of a profession where professional associations play a key role in the establishment and enforcement of barriers to entry, and partly because of governance whereby legal firms are effectively co-owned and managed by (senior and managing) partners. Such de-equitization is an increasingly widespread trend in transnational law firms, especially after the bankruptcy of Dewey & LeBoeuf (New York) in 2012. Some partners in these law firms are called “service” partners, who are de facto employees as they are nonequity holders and have no clients they can claim as their own. It has been suggested that Americanization of legal services would be a feature of the globalizing era, including the spread of adversarial legalism. However, instead of the automatic transplantation of Anglo-American mega-law firms’ culture through American and British law firms, some studies show how their arrival in Germany, for example, in fact led to the development of German-type corporate mega-law firms which transformed the legal service sectors that had been dominated by small firms and individual lawyers.

As with other professions where educational institutions and professional associations have played a significant role in training and regulation, both the legal profession (lawyers and solicitors) and law firms are highly regulated at national and even regional levels. National (and regional) educational institutions, especially professional associations, thus have a profound effect on the establishment and development of specific cultures of professional practice through various entrance qualifications, examinations and licensing, in-house and/or often mandatory training (as interns or trainees) after graduation, and so on.

The independence of lawyers and the remuneration structures are two major areas of difference in the legal profession across space. The autonomy of lawyers is partly determined by local legal traditions: common law versus civil law. In the traditional Anglo-American common law jurisdictions, lawyers work in teams to deal with the complexities of regulation. American lawyers, however, have long been independent from the state, promoting their clients’ interests through the judicial process, and large corporate law firms were established in the early 1900s. British lawyers have been following this trend since the 1960s, and large law firms with more than 25 partners have been allowed since 1967. In continental European civil law jurisdictions, lawyers work as autonomous technical experts advising their clients of the relevant law and its specific requirements rather than using the law (and its potential loopholes) to defend or promote their client’s interests through the judicial process. In Germany, large corporate law firms (with more than 10 lawyers) have only been allowed since 1989. Law schools also instill specific local cultures in their graduates. For instance, individualism and competition are integral to American law schools, where their year group ranks graduates, while their British counterparts are not ranked. The Law Society in England stipulates that every law school graduate must complete a two-year training program with a law firm under the mentorship of a partner before she or he can be registered as a licensed lawyer, while their counterparts in the United States only have to pass the bar examination in their local state, and there is relatively little
interaction between partners and new recruits. In Germany, potential lawyers have to undergo a five-year degree program, pass the first state examination, undergo two years’ training in a law firm, and then pass the second state examination before finally being allowed to register as a lawyer (see Faulconbridge 2008).

In terms of the remuneration structure, it is largely about profit-sharing (or “lockstep”: all the partners share the firm’s revenue, with the specific percentage of their share determined by their seniority within the firm) versus the merit-based model (an individual lawyer’s income is based on the revenues she or he generates for the firm). In England and Australia, lawyers in the same firm normally work as a team to defend or advise a client, and the profit-sharing model of remuneration is adopted. Merit-based remuneration is normally used in the United States as an individual lawyer defends or promotes the client’s case to a judge through the judicial process. For instance, Clifford Chance and Linklaters, two of the largest British-based law firms, have adopted the profit-sharing model of remuneration, while American counterparts such as Skadden, Arps, Slate, Meagher & Flom or Jones Day use the merit-based model of remuneration (Faulconbridge 2008, 505). To maintain an integrated partnership across different offices, certain transnational law firms have adopted a hybrid model of remuneration that incorporates elements of both models, but uses the merit-based model for exceptional performance by individual lawyers. Latham & Watkins and White & Case, both US-based leading law firms, have adopted this hybrid mode of remuneration.

There can be diverse practices among the legal profession within the same country, partly to address the needs of their clients and partly as a reflection of their specific corporate cultures. In the interests of their brand and reputation, transnational law firms have an incentive to standardize their practices across space. Spatial heterogeneity in the culture of work between different regional offices could impact on the financial performance and even reputation of transnational law firms; their TNC clients expect the same standards as they enjoy in their home countries. This is especially the case for mergers and acquisitions deals across several jurisdictions, say from the United States or Europe to either Asia or Latin America. Senior partners at the headquarters normally develop and adopt certain “gold standards” in their internal training manuals so that new recruits (and junior partners) know what is expected as best practice. Moreover, transnational law firms will assemble a legal team across different jurisdictions to address the expectations of their clients. Practice groups, where all lawyers with the same legal specialization in different jurisdictions gather together, are the main strategy deployed by transnational law firms to address the need for teamwork and to form a common corporate culture. As a partial reflection of their legal work, each practice group within the same law firm will have its own subculture. For example, corporate lawyers tend to be involved in negotiation and debate, while litigators tend to have more ruthless work styles (and sometimes, attitudes) (see Beaverstock 2004).

Institutionalization of work cultures across different offices requires senior partners in global law firms to act as cultural entrepreneurs who impose their standards upon new recruits in regional offices. The common strategies range from mentoring trainees, forming communities of practices and being role models, enrolling in in-house and external professional development programs (such as enrolling in Master of Business Administration (MBA) programs), and specifying the criteria for promotion (especially for becoming a partner), to selective recruitment.
FIRM FOUNDATION AND GROWTH

(by recruiting lawyers with similar educational and/or work experience). A typical example of recruiting lawyers with similar educational background is the Tokyo office of Clifford Chance, where all but one partner has qualifications gained in countries other than Japan, with English and American law or MBAs being the most common (Faulconbridge 2008, 508). The international bent of the lawyer profile is partly a reflection of the profile of their major clients, many being TNCs based in Europe or North America. Lawyers trained in Anglo-American educational institutions have a closer cultural distance and are likely to be more effective in communicating and understanding the expectations of clients with similar backgrounds.

As the commercial success of transnational law firms is closely linked to their long-term business relationships with major clients, the expectations and demands of TNCs have an impact on shaping the cultures of practice in transnational legal firms and even the legal profession itself: that is, in defining the norms of the profession. There is a counterargument that the best practices of transnational law firms are increasingly influenced by the rise of emerging economies and their specific demands. Non-Anglo-American legal systems may place importance on proficiency in foreign (local) languages, and the specific relationships between the legal profession and local states. For example, lawyers normally have a more passive role when advising their clients on the interpretation of local commercial law in China than their counterparts in the United States.

Tension between the headquarters and regional offices of transnational law firms can occur if they have to recruit local lawyers for their local offices. These local lawyers have already been molded or socialized into certain work practices and thus have their own forms of territorial and societal embeddedness, either through formal training at (local) educational institutions or on-the-job training (see Faulconbridge 2008). The resultant best work practices are therefore a reflection of the symbiotic relationships between the senior partners and the managing partners in the home and host countries, who have to negotiate and resolve potential conflicts and tensions between the different cultures of work. This is especially the case when the remuneration systems adopted in different offices (e.g., the merit-based model in the New York office but the profit-sharing model in the London office) and the recruitment of star lawyers from rival legal firms cause tension.

Staffing agencies

The staffing industry is another case illustrating the importance of institutions for cultures of work. The staffing industry is inherently geographical, as physical proximity, local knowledge of the labor market, and an institutional environment are crucial to the delivery of its core services. Staffing agencies are (largely) privately owned companies acting as economic intermediaries that recruit permanent and/or contract workers for their clients for a fee. The involvement of professional staffing agencies in the recruitment of (senior) permanent executives can defuse potential accusations of nepotism or the influence of “old-boy networks,” especially at listed companies where the governance of senior management is under public scrutiny (see Beaverstock, Faulconbridge, and Hall 2010). In the case of contracted staff, the employment relationship exists between the staffing agencies and the workers, but the clients determine the work relationship— the staffing agencies pay workers. The highly flexible arrangements for contracted staff allow firms to more easily cover seasonal fluctuations in market demand. This contributes to the popularity of staffing
agencies; for example, the US-based Manpower, one of the major players in the staffing industry, increased the number of countries in which it has offices from 52 to 82 countries between 2000 and 2009 (Coe, Johns, and Ward 2011).

Staffing agencies can be classified into two main categories: general and specialist. The former are largely traditional staffing agencies providing temporary contract staff to their clients, while the latter specialize in recruiting temporary and permanent staff in specific sectors, especially information and communication technology and the financial service sectors. Examples of major general staffing agencies are Adecco (Switzerland), Manpower (United States), and Vedior (Netherlands), while Hays (United Kingdom), Michael Page (United States), and Robert Half International (United States) are the leading international specialist staffing agencies. As a partial reflection of their businesses, general staffing agencies normally have a greater level of geographical presence than specialist staffing agencies. For instance, Adecco has 6600 offices worldwide while Robert Walters, a specialist staffing agency, has only 38 offices, mostly in the global cities where its potential clients are located.

Due to the specific nature of the staffing industry, a decentralized mode of operation is commonly adopted. Marketing, information and communication technology, and human resources (providing the “matching” service to clients) are the key departments in local offices. Some of these offices can be larger than the headquarters of transnational staffing agencies: for example, one of the top five transnational staffing agencies has only 80 staff in its global headquarters (Coe, Johns, and Ward 2011, 64). There are, however, variations among the major players. Vedior is one of the most decentralized staffing agencies; its managers have a high level of autonomy to deal with changing market demands (some of them even adopt a multibrand approach to cater for different market segments). Manpower, meanwhile, has a greater degree of centralization of its management structure, branding, and marketing strategies.

As with the law firms, practices in the staffing industry are shaped by market demand and the institutional environment in the host countries. This includes their regulatory authorities and corresponding welfare regimes (including medical and work insurance), the role of labor unions and industry-wide codes of conduct, as well as the lobbying efforts by relevant actors concerning the regulation of work hours and the work environment, special regulations for short-term employment, and so on.

Variations in national welfare and labor regimes shape the development of the staffing industry in different countries. An understanding of the local job market and institutional environment, including the work culture, is therefore vital. The local regulatory and welfare regimes range from the liberal labor markets of the United States and the United Kingdom, the liberal but still regulated market of Australia, and the highly regulated markets in Sweden and Japan, to the liberalizing former socialist markets in the Czech Republic and Poland (see Coe, Johns, and Ward 2011). For instance, the labor market in Australia is normally regarded as neoliberal. However, it cannot be assumed that the labor market, and thus the staffing industry, is the same as in the United States or the United Kingdom, partly due to its legacy of a relatively egalitarian wage arbitration system for male employees (breadwinners) and the crucial role of the labor unions in collective bargaining and subsequent wage resolutions. Despite the liberalization of the labor market since the 1980s, provisions for certain welfare conditions in employment contracts, such as tea breaks, sick leave, and holiday leave, are still common in Australia.
In Sweden, the development of the staffing industry is heavily influenced by the social democratic welfare state regime and the roles played by different actors. Although the regulation of the industry is liberal, the Swedish labor market is still highly regulated, with its legacy of full employment, the active role of labor unions in collective bargaining, and the resources committed by the state to achieve such goals, from the provision and promotion of full employment to staff training and retaining. These labor market regulations actually facilitate the development of the staffing industry whereby the demand for temporary staff provides a higher level of flexibility for employers in their management of human resources (because of the rigidity of the redundancy processes) and yet fulfills the labor regulations that require, for example, cover for the maternity leave of permanent staff. Instead of lifetime employment (for males) in Japan, the deregulation of employment relations by the developmental state regime and the decades-long economic recession, plus partisan lobbying from labor unions and local agencies, have played important roles in the development of staffing agencies.

In the Czech Republic and Poland, wide-ranging deregulation prior to accession to the European Union (EU) has had a profound impact on the development of various industries and subsequent economic restructuring. Development of the staffing industry has been shaped by the liberalized labor market and the norms, expectations, and economic structure of their respective economies. While both countries have allowed the establishment of transnational staffing agencies – either through greenfield investment or mergers and acquisitions – there are strategic differences in their deregulation. The Czech Republic has adopted the Dutch model for the regulation of the staffing industry, but Poland has liberalized the industry without reference to the experience of any one country.

The territorial embeddedness of the staffing industry is demonstrated by its resistance to the standardization of practices across space and the centralization of control. As staffing agencies need to respond to sector- and region-specific market demands, those operating in transnational markets cannot always use the same operational template everywhere in the world (Coe, Johns, and Ward 2011). This explains the entry of transnational staffing agencies into the Czech Republic and Poland via mergers and acquisitions. While local managers are allowed a high level of autonomy to reflect the importance of local expertise, there is a tension between this and the importance of the global strategic presence of a brand in newly established markets, in that certain aspects of the headquarters’ corporate cultures and practices central to the brand name may not always be adequately represented.

Conclusion

The understanding of the importance of firms has improved significantly since the seminal work of Ronald H. Coase on the theory of the firm. He characterized the firm as an intermediate agent for reducing the transaction costs incurred in dealing with individual economic actors. Oliver E. Williamson emphasized the importance of interfirm (market) and intrafirm (hierarchical) transactions for the functioning of the market economy, and Douglass C. North introduced the new institutional economics.

Based on these significant theoretical foundations, economic geographers such as Meric Gertler have highlighted the interlinked relationships between institutions (formal rules and regulations and informal norms) and industrial
practices. The former not only regulate industrial best practices and conventions regarding the organization of work and labor-management relations in the workplace, but also shape the values, expectations, and even the decisions of economic actors through the functioning of labor markets, regimes of industrial relations, and corporate governance. These diverse institutions create heterogeneous industrial practices across national space, and their reproduction and modification illustrates the existence of distinctive national modes of governance and trajectories of growth in firms rather than any globally convergent world.

The cases of law firms and staff agencies clearly illustrate the central argument made by economic geographers, namely that diverse national formal and informal institutions create a heterogeneous culture of work across space. In so doing, economic geographers have contributed to the ongoing debates about the impact of globalized forces and varieties of capitalism in general, and corporate cultures and regional development in particular, on the issue of whether globalization does or does not lead to uniform patterns of firm foundation and growth.

Firm migration

Jouke van Dijk
Piet H. Pellenbarg
University of Groningen, Netherlands

The location decisions of firms are crucial for the economic development of countries and regions. Therefore, insights into the determinants of firm migration are very important for policy purposes. However, although firm migration occurs frequently worldwide, it is only a minor field of study in the research practice of economic geography and spatial economics. This is surprising because determining the optimum firm location is a key issue for these disciplines, and a firm migration can be understood as a relocation, following a new decision about the best place to establish the firm’s activities when location conditions change over time (the terms “firm relocation” and “firm migration” are used synonymously in this entry). Relocation decisions might even be considered as the most interesting type of firm location decision. In the initial stages of new firm formation, many location choices are hardly felt as real choices. New entrepreneurs often take their hometown as a natural start-up location. In a relocation, the situation is usually completely different. For whatever reason (firm growth, lease expiration, new infrastructure conditions, shifting spatial patterns of demand and supply, labor costs, or labor shortages), the existing location is now the main problem, and the thinking about where to find new and better location conditions is of prime concern. An interesting question is why in the literature other firm demographic events such as firm start-ups and closures, firm growth and decline, and firm spin-offs and spin-outs receive much more attention. Part of the answer is that, in the systematic exploration of the effects of firm demography factors, new firms are assumed to have a larger impact on local and regional economies than migrations.

Yet another weighty reason is the complexity of the subject. The complexity is in the multitude of possible interpretations of locational changes as proper relocations. A lock, stock, and barrel move of the whole firm to another location is easily understood as a proper firm migration; and, when only a part of the original operations is moved to a new location while other parts stay at the existing site, this can be understood as a partial migration. But what about situations where the transfer of parts of the production to another place is framed as contracting out to another independent firm? Or where two firms from two locations merge and restart in a third place? Or where a firm closes down in one location and opens up a new plant making the same product in a different location under a different firm name? In all such cases, part or all of the initial firm’s activities move to another location, but it is more difficult to label them as real firm migrations. The next problem is the relative scarcity of sufficient and reliable data. Firm registration systems tend to be different in type and quality between countries, and sometimes even between regions and cities, which is a problem for comparative research in firm demography. But the more serious problem is that many firm registration systems aim at
Firm migration, spatial scale, and spatial theories

Spatial moves by firms can be classified into three broad categories: intraregional, interregional, and international (Pellenbarg, Van Wissen, and Van Dijk 2002). Intraregional moves mainly concern the industrial suburbanization around the larger urban agglomerations, while interregional migration involves industrial decentralization from the economic core areas to peripheral areas. Intraregional moves can be related to the incubator hypothesis developed by Leone and Struyck, which describes the process of firm birth in central urban areas, with a “natural” follow-up of firm migrations from these central areas to urban peripheries, where the surviving and then growing start-ups seek space for their expansion at a location that is more accessible for their clients and suppliers. Firms moving over smaller distances within urban areas tend to be young and small, and the migrations are not partial but integral. Interregional moves may also be integral if firms move to areas with lower land and/or labor costs, but often take the form of partial moves when subsidiaries are opened in other parts of the country. International migration can be integral or partial for small and medium-sized firms that are undergoing an internationalization process similar to that of multinational (MNL) enterprises. The spatial behavior of large companies is more complicated. They try to realize ownership, location, and/or internationalization advantages according to the OLI framework developed by Dunning by means of export, foreign direct investment, or relocation, or a combination of them. Their relocation behavior is driven either by their search for new international markets and the acquisition of new technological, financial, and marketing competences, or by their continual search for low operating cost locations, especially low labor cost locations. Low labor cost definitely links the international long-distance firm migration story to Gunnar Myrdal’s classic theory of cumulative causation.

On reflection, the juxtaposition between long (international) and short (local and regional) distance moves is not an absolute one. From Table 1 it is clear that there is a gradual transition between the extreme spatial types of global and local firm migration, which can be correlated to the various organizational types of migration: integral move, partial move, setting up of branch plant and joint ventures, and contracting out.

The range of spatial theories that may be linked to the phenomenon of firm migration is much broader than the theories of Myrdal, Dunning, and Leone and Struyck. Investigators seeking to describe, explain, and predict firm migration processes at the different spatial levels have been using neoclassical, behavioral, institutional, evolutionary, and organizational network approaches, more or less in that order. A more detailed description of these five theoretical approaches to firm migration can be found in the elaborate surveys of firm relocation literature by Pellenbarg, Van Wissen, and Van Dijk (2002) and Pellenbarg and Knoben (2012). A relative new approach is followed by Baldwin and Okubo (2014) who introduce firm migration into a combination of the heterogeneous firm trade (HFT) models and the new economic geography (NEG) models introduced by Krugman, where increasing returns to scale create forces...

that foster spatial agglomeration. In a recent survey paper Arauzo-Card, Liviano-Solis, and Manjón-Antolin (2010) argue that, although most studies relate the choice of the explanatory variables to neoclassical, behavioral, and/or institutional factors, the link with the associated theories is usually weak. They conclude that the analytical framework has remained very much the same since the early 1980s, but that the studies of relocations lack specific theoretical foundations and are essentially empirically driven.

Origin and development of firm migration research

An extensive survey of progress in firm migration research since the 1950s can be found in Pellenbarg and Knoben (2012). This section presents an adapted and abridged version of this survey.
FIRM MIGRATION

Research projects of the 1950s and 1960s in the United States and the United Kingdom

McLaughlin and Robock’s (1949) study Why Industry Moves South was the earliest published study on firm relocation. It describes the mid-century migration flow of manufacturing industry in the United States from the northeastern to the southeastern states, where labor costs were lower and trade unions less active. Several classical firm migration studies concerning the United Kingdom were published in the 1950s and 1960s as well (e.g., Keeble 1968). In these studies, external relocation factors dominate the explanation of the phenomenon, although some attention is given to firm-internal relocation forces, especially the push impulse resulting from output growth. A core interest of the researchers in this period was the impact of firm relocation on local and regional economic growth and decline, and the possibility of influencing firm moves with local and regional policy instruments. Firm relocation was regarded as a means to transfer work and prosperity to lagging regions while at the same time easing the congestion, labor market, and space capacity problems in core regions. Instead of reducing regional disparities by means of a “workers to the work” policy, firm relocation was welcomed to facilitate a “work-to-the-workers” policy. Summing up, the early studies shared a prime interest in the external causes of relocation (push and pull) and the impact of relocation on local and regional economies, including the policy options to stimulate these economies. Several of the early studies also tried to evaluate such policy measures, with mixed results (e.g., Cameron and Clark 1966).

British research dominance in the 1970s

In the 1970s most international publications on firm relocation were British-based. The interest of British researchers in firm relocation coincides with the heydays of British regional policy, which relied heavily on guiding manufacturing firms to assisted areas and using location controls, capital subsidies, and labor subsidies. These firm relocation studies are part of a bigger research wave in this period which sought to measure the effect of regional policy instruments on the economy of the assisted areas. Naturally, the focus of the analyses in this period remained on external relocation factors. The availability of reliable (national) data on firm relocation in the United Kingdom was a great stimulus for firm migration research. Using these national data, Keeble (1976) argued that earlier research had underestimated the importance of firm relocation. In terms of employment, one-third of all industrial movement in the late 1960s in the United Kingdom as a whole is categorized by Keeble as short-distance “spillover” from the large conurbations and 50% as long-distance “between regions” moves to the periphery (Keeble 1976). Keeble also concluded that “regional policy was the single most important variable influencing the sub-regional pattern of migrant industries between 1966 and 1971,” a conclusion that contradicts Cameron and Clark’s (1966) more cautious conclusion about the same issue for the previous decade. Later in the 1970s, Townroe (1979) added to the abundant information about industrial firm migration in the United Kingdom new information about the United States. Interestingly, Townroe was the first to analyze firm relocation from a behavioral theoretical perspective. His study was a first attempt to present a general descriptive model of the location decision-making process. Furthermore, he was the first to suggest that firm relocation research should be integrated with studies of the birth, growth, decline, and death of firms to form a so-called components-of-change
approach, later to be labeled the “demography of firms” approach.

Firm migration research in other European countries

The second half of the 1970s witnessed firm migration studies from many more European countries. Both policymakers and regional scientists were reflecting the same curiosity as their colleagues in the United States and the United Kingdom about the nature of the process of spatial–economic change and the possible results of regional policies, which in the post-war period were revived all over Europe. The late 1970s may be considered the florescence of classical firm relocation research. In the Netherlands an early industrial relocation report was published by SISWO (1967), followed by a national survey study by Pellenbarg (1985). Information regarding France, Italy, Ireland, Belgium, Denmark, and Greece became available as well (for references see Pellenbarg and Knoben 2012). An interesting result of the European survey by Klaassen and Molle (1983) is that in all countries there is a short-distance “industrial sub-urbanization” around the larger urban agglomerations on the one hand, and a longer-distance “industrial decentralization” from economic core areas to peripheral and/or development areas on the other. Most of the European research projects of the late 1970s were still concentrated on the manufacturing sector, which was apparently the most mobile sector of the 1960s and 1970s and, at the same time, the main target sector for regional development policies in most countries. All European studies of this period agree about the nature of the driving forces behind the firm relocation processes. These are lack of space, transport issues, and labor market problems. The first two are the main causes for short-distance moves in and around the urban agglomerations, while the third is the dominant motive for long-distance movements to development areas in national peripheries. So, in line with UK and US studies from the 1970s, external factors were still found to be the main drivers of spatial firm mobility. However, in the course of the 1970s the importance of the labor market push motive gradually decreased. The economic recession of the mid-1970s caused higher unemployment levels, and labor shortages disappeared in many core regions. After this, the magnitude of long-distance relocation decreased.

The 1980s: from the regional to the urban level

In the 1980s international publications on firm migration decreased and the interest of migration research switched to the urban level. Policies such as environmental policies, urban renewal policies, and local development policies were expected to result in firm relocations as well (Pen 2002). For most of these new policies, the urban agglomeration was the most relevant playing field. Despite the change in the spatial level of analysis, the focus of the analyses from this period remained on external relocation factors. The new interest in the urban (i.e., local) level of analysis in this period coincided with a strong increase in short-distance firm relocation. This can be related to the process of the suburbanization of firms, propelled by space shortage and increasing land prices in large cities, parking problems, and growing congestion on city roads and beltways. The urban firm exodus consequently grew, and city governments worried about the erosion of urban employment. Some of the government’s own policies, especially environmental policy and urban renewal policy, reinforced the pressure on firms to leave urban locations. In this context, it was easily understood that firm relocation
FIRM MIGRATION

studies from the 1980s onward concentrated more heavily on urban agglomerations. In the meantime, the majority of firms which left the city during this time were no longer industrial or wholesale firms, but business services.

The 1990s to the present: new approaches and perspectives

In the 1990s and 2000s a few more regional and national studies appeared that repeat the approach of the classics in firm migration studies, that is, monitoring regional or national (manufacturing) firm migration patterns and explaining these on the basis of external factor-oriented interview programs or regression analyses. After the 1980s the interest in firm relocation as a direct remedy for regional development and/or labor market problems disappeared in most countries. Modern regional policy views now start from the premise that regions should independently create the conditions for economic growth and innovation based on their own strengths; regional subsidies should be given to develop these strengths. Key concepts underlying the new policy agenda are regional agglomeration effects, endogenous growth, regional knowledge networks, learning regions, sustained economic growth, and place-based smart specialization.

Firm demography

According to current views, firm relocation is still a relevant issue, as the interesting consequence of the coming of age of generations of new firms developing various locational strategies for coping with sustained growth. Consequently firm relocation is no longer treated as a separate event, but incorporated in what Townroe labeled the “components-of-change approach.” This is in fact a demographic approach to firm dynamics, which gradually gained popularity among regional scientists during the 1990s (Van Dijk and Pellenbarg 2000a). The approach, which is followed by geographers, sociologists, and economists, is variously termed “industrial demography,” “demography of the firm or enterprise,” or “economic demography” (Van Wissen 2002).

Firm-internal factors

Another new research theme that emerged in the 2000s is the focus on the role of firm-internal characteristics as a cause of firm relocation. In this approach, micro-level models are estimated that try to explain firm relocation by incorporating various firm-internal, locational, and firm-external variables (Van Dijk and Pellenbarg 2000b; Brouwer, Mariotti, and Van Ommeren 2004; Knoeben and Oerlemans 2008). Van Dijk and Pellenbarg (2000b) were the first to econometrically show, using firm-level data from the Netherlands, that firm-internal variables, such as firm size, economic sector and migration history/age, locations stress at the present location, and ownership of the building are better predictors of firm relocation than locational and other external factors. Brouwer, Mariotti, and Van Ommeren (2004) performed a similar analysis but included more firm-internal variables and utilized data from more countries. Their results also indicate that firm-internal variables are the most important cause of firm relocation. Besides size and age, they find in particular that changes in the size of the firm (both positive and negative), as well as mergers and takeovers, are strongly associated with firm relocation. De Bok and Van Oort (2011) confirm from an analysis of the Dutch province of South-Holland that firm relocation behavior is affected much more by firm-level attributes (size, age, and growth
rate) than by agglomeration and accessibility attributes.

Impact of firm migration

In recent years studies of the possible impact of firm migration as one of the factors (in addition to, for example, new firm formation) influencing regional economic performance have become more important. The focus is no longer on the migration of manufacturing firms to lagging regions, but on a broader policy perspective of promoting regions as attractive locations, including environmental policies that aim to influence the location decisions of a polluting firm. Cabus, Horemans, and Van Haverbeke (2008) conduct a comprehensive study of the location behavior of firms in Belgium. They start with a traditional investigation of the location determinants, taking into account the characteristics of both the firm and the region. They then investigate the implications of this behavior for the firm and for the region, and end with a series of policy recommendations. Van Oort et al. (2007) analyze how spatial dynamics in firm behavior affect local and regional employment in the Netherlands. They show that the contributions to employment growth from new firm formation and from firm migration are of a comparable magnitude. Furthermore, migrating firms show employment growth that is almost twice as high as nonmigrating firms. In contrast to this, Neumark, Zhang, and Kolko (2006) find that, in the United States, new firm formation is a much more important generator of new employment on a regional scale than the interstate relocation of firms. The difference in spatial scale may cause this difference, because interstate moves in the United States may be comparable to migration between countries in Europe. Daunfeldt, Elert, and Rudholm (2013) analyze the differences between start-ups and firm in-migration using Swedish data on wholesale industries in the period 2000–2004, and conclude that the determining factors are largely the same but that the magnitude differs. Manjón-Antolín and Arauzo-Carod (2011), using data for Catalonia, find that most factors affecting start-up rates are different from those affecting relocation rates, while those that affect both rates do so with different intensities. In addition, start-ups and relocations are positive but are asymmetrically related.

International firm migration

In a study about international relocations of Belgian firms Sleuwaegen and Pennings (2006) find that wages and the market potential of host regions are important determinants for the location choice. With regard to firm characteristics, they show that large firms more often relocate to remote countries. Public aid only plays a decisive role for relocations to adjacent countries with similar factor conditions. This suggests that this type of relocation aid is only distorting competition instead of investing in facilities that improve a region’s attractiveness. Baldwin and Okubo (2014) argue that, until now, international firm migration has been ignored in trade models. In a theoretical model that combines the HFT model and the NEG model, they show that, by allowing firm migration whereby the most efficient firms move to the larger countries, both the large and the small countries are better off. International firm migration also becomes relevant in a world of outsourcing and offshoring, and more recently also reshoring, where firms are looking for optimal locations all over the globe in order to maximize the contribution to the global value chain (Contractor et al. 2010). In addition, climate change and more frequent extreme weather conditions may create the need for firms to relocate away from highly affected regions (Linnenluecke, Stathakis, and Griffiths 2011).
The relocation decision process

As a consequence of the new conception of firm relocation as a specific locational strategy, firm migration research shifted from its long-term one-sided focus on the external causes of firm relocation to the study of the internal causes of firm relocation, and also developed an interest in the structure of the relocation decision process. The new interest in the process of decision-making in firm relocation situations was an important renewal. The identification of external push, pull, and keep factors, which was customary in pre-1990 research, provided only a superficial explanation of firm relocations. In the 1990s there was a desire for a deeper explanation. Earlier interest in decision processes was already observable in the behavioral approach to firm migration. As early as the 1970s Townroe, representing this approach, developed a model with five successive decision stages: (i) stimulus; (ii) problem definition; (iii) search; (iv) formulation and comparison of alternatives; and (v) choice and action. There was little application of his scheme in empirical research, but the 1990s saw a revival of interest in the process of firm relocation decisions. Louw (1996), for example, empirically studied the location choice behavior of (relocating) large offices in the Netherlands. He conceptualized the decision-making process as a sequence of three phases: an orientation phase, a selection phase, and a negotiation phase. His findings indicate that spatial factors (i.e., geographical position, accessibility, parking possibilities, proximity of facilities, public transport, and quality of the spatial surroundings) play an important part in the first two phases, whereas financial and contractual factors are more important in the third phase, when it comes to negotiating a result. Louw’s process-oriented approach of firm relocation decisions has been followed up by Pen (2002). In a study based on an extensive inquiry among over 1000 individual firms, Pen considers relocation as one of six types of location strategies. The average length of the decision-making process proves to be much longer than is often assumed (on average two years) and shows that the number of stages in the decision process varies from a minimum of three to a maximum of seven. Greenhalgh (2008) analyses the firm relocation decision process based on interviews in Tyne and Wear, in the northeast of England, from the perspective of the property market using a three-stage decision model: (i) trigger (stimuli or catalyst provoking initiation of process); (ii) analysis (pursuit; influence of people and factors on process); (iii) outcome (decision made and process concluded). They find that organizations adopt varying degrees of sophistication when making relocation decisions; small firms are more inclined to make decisions based on constrained information whereas larger organizations adopt a more complex approach. Regardless of firm size, key individuals exert considerable influence over the decision-making process and its outcome. In a recent study based on various data sources for the Tokyo Metropolitan Area, Nguyen et al. (2013) study the firm relocation process using a model that also consists of three levels: (i) moving probability; (ii) region choice probability; and (iii) zone choice probability. The results indicate that large firms and older firms have a lower probability of relocation and that migrating firms are more attracted to regions with high accessibility. Finally, spatial factors and land prices in a given zone strongly affect the zone choice decision-making process of all firms. Using individual business surveys for 2006, Hu et al. (2008) examine US firms’ decisions to relocate or expand in the past as well as their intention to relocate or expand in the future. The results indicate that factors related to firms’ internal characteristics, features of location sites, and
the general economic environment may affect firms’ past and future decisions. These factors are found to be generally consistent in their impact on past and future decisions with several noticeable differences. The hypothesis that firms that have moved once will move again in the future (footloose firms) is supported by this study.

Recent new developments

A more specific new strand of research deals with firm relocation at the neighborhood level because the out-migration rates of firms show large differences between regions. However, based on Dutch data for 2010, Sleutjes and Völker (2012) find that neighborhood characteristics only play a modest role, while growth ambitions and the size and quality of the business premises are most important. In line also with Greenhalgh (2008), this indicates that the real estate market is likely to be an important factor for firm relocation. Risselada, Schutjens, and Van Oort (2013) focus especially on the role of real estate and conclude that real estate factors are important determinants of the likelihood of firms relocating. Like Van Dijk and Pellenbarg (2000b), they find that property ownership has a negative effect on relocation. Residing in high age and large property sizes also limits firm relocation.

With regard to the international migration of MNL enterprises, Lampón, González-Benito, and García-Vázquez (2015) analyze relocation processes in the Spanish automobile components industry for the period 2001–2008. While acknowledging that location advantages play a relevant role, they show that international relocation changes in production geography can, to a great extent, be explained by corporate strategies, other decision-making mechanisms, and firms’ characteristics. Knoben and Oerlemans (2008) add to other studies, like Van Dijk and Pellenbarg (2000b), by explicitly taking into account the relations between a firm and other organizations in its environment (i.e., relational variables). They show that, compared to a baseline model including internal, external, and locational variables, adding relational variables significantly enhances the explanatory power of the models, and that this varies according to the strength and geographical distance of their relationships. Bodenmann and Axhausen (2012) show that local taxes have a very positive pull effect on firm relocation for the St Gallen region in Switzerland over the period 1996–2006. Their findings also confirm the role of distance, and they find significant differences by sector. Weterings and Knoben (2013) analyze Dutch data for 1996–2006 and confirm the classic distinction between short-distance moves caused by lack of space and that long-distance relocations are mainly influenced by regional characteristics. They also find that the spatial concentration of similar or related firms, a higher level of urbanization, and research and development (R&D) intensity keep firms in a region, but that firms leave regions with a higher share of innovative firms. A recent study by the City of London Corporation (2014) on the effects of the current economic crisis shows that firm migration is acting as the key component of change, compensating to a large extent for the negative effects of job losses due to layoffs and the bankruptcy of existing firms in the City.

Theory and methods

The location decisions of firms are crucial for the economic development of countries and regions and, therefore for policy purposes, insights into the determinants of firm migration are very important. In a recent survey paper Arauzo-Cardó, Liviano-Solis, and Manjón-Antolín (2010) try to shed light on this in a critical assessment of the methods and empirical
Firm migration results of about 50 studies on location behavior, including relocations. They conclude that for policymakers there is room for action in areas such as education, infrastructure, and taxation. Future research is needed, especially in the analysis of behavioral factors as underpinning for the theoretical foundations for firm relocations and of the impact of public policies. They also argue that more sophisticated econometric specifications, using different levels of geographically aggregated (panel) data and/or spatial econometric techniques, are needed to provide further insights.

Conclusion and research frontier

Firm migration or relocation is a very important determinant of regional economic dynamics. This entry provides an overview of the present theories and empirical findings on this topic. The spatial scale is important because the causes and effects differ substantially for firm relocations within urban areas and between regions within countries, and for international relocations between countries or even continents. Over time the research focus shifted between the spatial scales. Firm migration research started in the 1950s and 1960s by studying the relocation of manufacturing firms in the context of the regional development policies. Early on, firm-external factors were the main explanatory factors, but later on the role of firm-internal factors and the phases in the decision-making process became more important as better data and methods were available. In addition, firms in other industries were analyzed and the differences in the determinants and effects of new firms compared to relocating firms were the subject of study. Most recently, external factors like neighborhoods, real estate, and the variety in the regional economy have been linked to firm migration. With regard to the methodology, there has been a shift from purely descriptive studies to the use of sophisticated econometric methods.

The location decisions of firms are crucial for the economic development of countries and regions and, therefore for policy purposes, insights in the determinants of firm migration are very important for developing effective policy measures for regional economic development, but also for decision-makers in firms who have to survive in an increasing competitive world market. Although substantial progress has been made since the mid-1950s, there is still room for further development. Firm migration is now studied in different fields and by researchers from different disciplines. The theoretical foundations of firm relocation could be enhanced by greater integration of traditional location theory and regional development theory, and by insights from behavioral and evolutionary theories the organizational network approach, trade theories, and management science. Empirical questions like the effects of firm migration on firm growth, its impact on regional economic development (such as the employment), a firm’s territorial embeddedness in a location, further firm growth after migrating, corporate strategies of MNEs and so on, deserve further study. More attention is also needed on the interaction with other firms and the real estate market, and the impact on regional development in the context of new policy concepts like place-based smart specialization. This can be facilitated by the increasing availability of employer–employee linked micro-data and big data to apply more sophisticated methods like spatial and panel econometric methods, GIS, and methods for network analysis.

Business firms in their infinite variety are situated at the heart of the modern economy. They are the creators and destroyers of products, services, jobs, and markets. As the pivotal economic actors driving the rise and fall of cities, regions, and nations, firms are a core interest of economic geographers. A general understanding of the firm includes that of its existence, boundaries, organization, and competence. Geographers are interested in the spatial dimensions of these issues. The focus on place, space, and scale is a key difference between geography and the other social sciences in the way the firm is theorized (see Taylor and Oinas 2006). Economic geography has emphasized location decision-making, the value added of co-location, localized collective learning and knowledge spillover, interfirm networks and local–global dynamics, and the impacts of formal and informal institutions at multiple geographic scales as they shape business transactions, organizations, and performance. However, a comprehensive, consistent, geographic conceptualization of the firm that integrates key insights from the various theories of the firm has yet to be established.

Every firm has its unique geography of creation, expansion, integration, and differentiation. Geographers see firms as intrinsically spatial and territorial, and are deeply concerned by the firm–territory nexus. As human–devised mechanisms for coordinating and motivating the activities of individuals and groups, firms are internally diverse, complex, multidimensional, and spatially variegated. A business firm is generally characterized by: (i) an ownership structure, an employer–employee relationship, and a management hierarchy; (ii) market-oriented, for-profit production; (iii) product or market specialization and internal division of labor and tasks; (iv) durable association and interaction of a group of people; (v) embeddedness in the network of suppliers and customers; and (vi) a life cycle from birth to death. Relatedly, indispensable functions of the firm include acquiring and processing information, discovering knowledge, allocating resources, eliciting efforts, coordinating tasks, evaluating performances, settling disputes, and governing conflicts (Dosi and Marengo 2007). Broadly conceived, a business firm’s core functions can be categorized as either incentive alignment (motivational governance) or problem-solving (cognitive competence), both of which are geographically mediated.

Surprisingly, interest in the firm in economics and the social sciences in general has been relatively new, partly because the mainstream has, for a long time, adopted a rational choice perspective based on the *Homo economicus* assumption: that humans are hyperrational and narrowly self-interested actors who have complete knowledge and the ability to make instant and perfect judgments. Accordingly, the firm has been viewed from a production function perspective, as a “black box” that transforms inputs into outputs. Similarly, a “complete contracts” approach has dominated, which assumes that all economically significant contingencies can be foreseen and incorporated into enforceable contracts.
The emphasis on rationality and de-emphasis on uncertainty are two sides of the same coin. The *Homo economicus* assumption rules out the relationship of the limited human mind to the complex environment. When there is ubiquitous uncertainty, imperfect information, and cognitive inadequacy, the heterogeneity of firm–environment interplays comes to the fore, and the firm-specific centralization of decision-making – a process termed “cephalization” by Knight (1921) – becomes imperative and inevitable. Knight drew attention to the role of the entrepreneur in attempting to reduce uncertainty. The entrepreneurship-based view of the firm focuses on the firm’s entrepreneurial, judgmental decision-making under conditions of uncertainty for opportunity recognition and resource mobilization. Because markets for entrepreneurial judgment are closed, one must first start a firm before one can exercise judgment; moreover, judgment implies asset ownership and organizational control. Economic geography still underplays the significance of entrepreneurship processes, especially how firms are first created, thus missing the first crucial point in the development of a firm and cluster.

The transaction cost approach pioneered by Ron Coase (1937) and elaborated by Oliver Williamson (1975) also attempts to leaven the rationalist, maximizing assumptions of the complete contracts model by introducing the concept of bounded rationality, wherein firms do not have all the necessary information and calculative ability with which to make decisions, especially given behavioral opportunism. In this view, the use of the price mechanism can be costly, and transactions that are recursive and associated with substantial uncertainty and transaction-specific investments are more likely to take place within hierarchically organized firms rather than spontaneously coordinated markets. The transaction costs model implies that contracts can never be complete, because it is either impossible or too costly to specify all the unforeseen contingencies in a transaction. Geographers have generally emphasized the role of spatial proximity and social networks in reducing transaction costs, but the precise mechanism and causality have yet to be further specified. The transaction cost approach places exclusive emphasis on incentive alignment; thus, it has also been termed the governance-based view of the firm. Even with a relaxed assumption of rationality, the focus is on the moral rather than cognitive aspect of uncertainty, and the firm is still assumed to be striving solely for profit maximization and productivity optimization.

In contrast, the behavioral theory of the firm, popularized by Cyert and March (1963), drops the assumptions of profit maximization and perfect knowledge, and focuses on the internal decision-making structure in firms. The firm is seen as a coalition sitting within a network of relationships and a site of decision-making in the face of uncertainty, conflict, problem-driven search, learning, and adaptation. It is argued that the decision-makers of firms are satisfiers rather than maximizers. The firm’s decision-makers often have diverse and conflicting goals, expectations, and opinions under uncertainty. When goals are not met, search behavior is instigated, initiating learning and adaptation. The behavior approach was introduced into economic geography in the 1960s by Alan Pred, who regarded firms as locational decision-makers constrained by their access to, and their capacity for processing, information. But there is as yet no systematic framework integrating behavioral factors into economic geography.

The evolutionary view of the firm is inspired by the behavioral perspective, but it has the dynamics of knowledge generation at its core, along with Darwinian notions of variety, inheritance, retention, and selection. The emphasis
is on firm-specific knowledge that is complex, tacit, distributed, and context-dependent. The analytical entry point is the variety arising from the microbehaviors of firms, directed by durable, inheritable, selectable, quasi-genetic routines. Drawing on the behavioral approach, the evolutionary view conceptualizes firms as satisficers rather than maximizers: a “search” for new routines and technologies is triggered when performance falls below the satisfactory level. It holds that superior routines are selected through market competition. Evolutionary economic geography, developed on the basis of an evolutionary view, argues that largely localized processes of search, learning, spinoffs, and labor mobility are prime vehicles for routine replication and the formation and persistence of clusters (Boschma and Frenken 2006).

From a different angle, the resource-based view (RBV) of the firm seeks to account for the creation, maintenance, and renewal of firm-specific competencies by emphasizing the resources of firms (Penrose 1959). In contrast to the knowledge-centric view, access to and adaptive accumulation of key pecuniary assets is seen as being just as important as the knowledge used to deploy them in production. Although RBV is criticized for its tautology, it does remind geographers of the importance of control over and access to nonorganizational, nonknowledge, and location-specific resources.

The dynamic capabilities framework synthesizes RBV and the evolutionary view of the firm. It defines the firm as an ecosystem for sensing, seizing, and managing market and technological opportunities. In this view, market competition is centered on control over firm-specific resources in a dynamic setting, emphasizing dynamic competencies based in “layer upon layer” of path-dependent development involving complex interactions between resources, strategies, and routines (Teece 2007, 1327). In addition to efficient routines, privileged access to and control over strategic, complementary, and pecuniary resources that have been inherited from the past and/or are aided by corporate and state power can be at least as important. Geographically, this means that, to a certain extent, the facilities, assets, and human capital created by previous rounds of politically mediated investment and development in a region constitute a suitable basis for subsequent production, innovation, and profit-making. How conflicts are triggered and mediated, and mitigated by territory-specific institutions, is an important subject for future research.

Regardless of the focus on problem-solving or incentive alignment, geographers increasingly take a relational embeddedness perspective, seeing the firm as a constellation of socially constructed networks controlled by social actors with activities spread across space but embedded in particular places. The network ties are theorized, vaguely, as conducive to the building of mutual trust and understanding, thus helping to reduce both communication and transaction costs, while making the firms’ boundaries open and porous. The emerging literature on global production networks takes these networks further as the foundational unit of analysis for understanding the global economy.

However, when the boundaries of the firm are seen as fuzzy, permeable, and multiple, it risks making the firm an awkward if not irrelevant analytical category, notwithstanding the legal/contractual structures that embrace and surround it. As an economic institution grounded in the laws and regulations of its particular institutional environment, the firm has boundaries that are delineated and precise. Firms are not only the creation of social relations and networks, but also the creation of government and politics. It is up to the state to create stable and reliable conditions under
which firms organize, compete, cooperate, and exchange. How property rights as social relations are defined, enforced, and contested is a geographic variable and needs to be explored. The size of the risk premium associated with each transaction varies in accordance with the territorial-specific characteristics of the contract enforcement mechanism. A particular institutional context offers a unique payoff structure and gives rise to a particular kind of demand structure for different kinds of knowledge and skills. The kinds of information and knowledge required by the entrepreneurs and managers are in good part a consequence of a particular institutional context. Given the distributed nature of knowledge, firms need not only to develop a better absorptive capacity internally but also to build and maintain an increasing number of external “knowledge nodes” with user communities, public and private universities, technical service institutes, and partnering firms, whose generation and interaction are shaped by state-engineered institutions. The question of how the microbehavior and evolution of firms are shaped by and coevolve with macro, multisclar societal institutions, structures, and relations has yet to be answered by geographers.

Flexible labor markets

Tara Vinodrai
University of Waterloo, Canada

The rise in flexible labor markets is an outcome of globalization, deregulation, technological change, and the transition toward a knowledge-based economy which encompasses new forms of work and organizational practices. Characteristic of the rise of flexible labor markets are higher turnover or churn rates, decreased union densities, eroded worker protections, and the increased use of subcontracting and temporary, part-time, and casual work arrangements. Workers who are exposed to these practices represent a growing pool of contingent labor that endures high levels of precariousness and risk. This contingent labor pool is composed primarily of people in marginal groups, including women, visible minorities, immigrants, and migrant workers. However, the precise nature of flexibility in local, national, and global labor markets is a product of the actions of, and the negotiations and struggles between, firms, workers, and other actors, which in turn are also shaped and constrained by institutions organized at a variety of geographic scales.

Theoretical perspectives on the study of flexible labor markets have evolved over time. Initial work on flexible labor markets drew on early theories of labor market segmentation, highlighting the dual nature of the labor market, which included primary and secondary labor market segments. In the dual labor market model, the primary labor market segment was generally characterized by good employment and working conditions, high wages, and stability achieved through well-defined rules and structures for advancement. The secondary labor market included lower-wage workers, with fewer prospects for advancement, less job security, and poor working conditions. Under the dual labor market model, the secondary labor market was characterized by flexibility, in contrast to the more rigid and stable structures of the primary labor market.

However, as scholars began to study and document the transition from a Fordist economy toward an economy labeled as “flexible specialization,” “post-Fordism,” or other monikers, it became clear that flexibility was increasingly pervasive throughout the labor market. In other words, both high- and low-skilled workers faced flexible labor market conditions. Moreover, scholars also observed that the degree of flexibility and the nature of labor markets varied geographically and by industrial sector. Thus, throughout the late 1980s and 1990s, economic geographers and other scholars contributed to our understanding of how restructuring in various industries affected labor markets at the national, regional, and community levels. Most of this work grounded the shift in the desire of firms to achieve flexibility in their production processes, as well as the concurrent responses of governments to enable and support business competitiveness under globalization. This work highlighted the array of organizational practices used by firms, including subcontracting arrangements, flattened organizational structures, teamwork, as well as the use of automation and other technologies to become flexible in their responses to changing market conditions. Moreover, earlier theoretical work tended to
be informed by the experiences of advanced, Western economies. Subsequent work noted the important shifts in the social regulation of labor markets and, therefore, the markedly differential effects felt by different groups of workers. Indeed, some observers have suggested that flexibility has always been a characteristic of labor markets, but its reach has extended beyond marginal groups (e.g., women, visible minorities, etc.) to affect those most often privileged in the labor market. Thus, while there continues to be an emphasis on the structural elements of labor market flexibility, more recent work also highlights the experiences of workers in the labor market and their role as active geographical agents that shape and rework labor market structures and employment relations in an effort to improve wages and working conditions. Recent work also has been more sensitive to the commonalities, differences, and relationships between the Global North and the Global South, as well as reflecting a greater awareness of social differences.

As a result of this evolution in how flexible labor markets are conceptualized, the contemporary geographic literature on employment and flexible labor markets emphasizes several important dimensions from both a theoretical and a research standpoint: (i) the role of deregulation and the pervasive influence of institutions; (ii) the organizational practices of the firm; (iii) the emergence of new forms of work; and (iv) the growing importance of intermediaries as agents for labor market change. Each of these is discussed in detail.

First, scholars emphasize that labor market flexibility is shaped by institutions and government policies organized at a variety of geographic scales, as well as by employment regulations and standards that govern how labor markets operate. In response to competitive pressures under globalization, governments and businesses have attempted to remove rigidities in the labor markets. Underlying the motivation toward deregulation is a belief that this will improve competitiveness and reduce costs for business by allowing firms to easily respond to changing marketing conditions and reduce their overhead costs. This is often achieved through weakening the power of labor organizations such as unions, reducing broader welfare provisions, and changing (un)employment policies, often involving workfare schemes. However, the nature and degree of flexibility in labor markets is both historically and geographically contingent. For example, the erosion of social welfare provisions and protections afforded to workers in earlier periods toward workfare arrangements is particularly prominent in the United States. Moreover, even within the United States, state-level legislation, such as right-to-work laws, results in unevenness in terms of how flexibility can be achieved. In this latter case, right-to-work legislation effectively limits the formation of unions, leaving power primarily in the hands of the employer. At the other end of the spectrum, in Scandinavian countries where there have been long-standing social welfare traditions, “flexicurity” arrangements enable the state to provide security to individual workers if they become unemployed while simultaneously allowing firms to achieve flexibility. In many countries in the Global South, where historically workers’ rights have been weaker, the ability of unions and other labor organizations to improve conditions has been greatly influenced by regional and national policies and institutional arrangements. Overall, these observations emphasize that institutions organized at a variety of geographic scales shape the nature of flexible labor markets.

Accompanying these shifts in governance and (de)regulation has been the decline of permanent, stable full-time jobs with benefits, as firms engage in a variety of organizational practices,
including outsourcing and subcontracting, as well as adopt and implement technologies intended to reduce labor costs and achieve production efficiencies. For this reason, scholars have often examined labor market flexibility through the lens of the firm. Indeed, the main advantages of a flexible labor market are realized by firms that are able to achieve both functional and numerical flexibility as a means to reduce costs and improve efficiency. Functional flexibility refers to the ability of firms to deploy workers to meet particular demands. It is often associated with teamwork, multiskilling, and other practices that allow firms to adjust their workforce internally based on their current needs. At the same time, numerical flexibility allows firms to adjust the size of their workforce through the use of a number of employment practices including the use of short-term contracts; subcontracting arrangements; casual, temporary, or part-time employees; and other arrangements. While the use of these nonstandard forms of employment can confer benefits on firms, there are clear disadvantages for workers themselves, who are exposed to high levels of personal risk. In aggregate this has led to the rise of a contingent workforce that collectively has little job security and access to few benefits. Overall, the prognosis is that the contemporary flexible labor market is highly unequal and segmented, leaving both high- and low-skilled workers in a precarious position.

While an assumption in earlier work was that it was primarily low-skilled workers who were exposed to the risks of the flexible labor market, the contemporary reality that flexibility is a common characteristic throughout the economy brings with it other observations. The transition to a knowledge-based economy has meant that new forms of work are emerging, including occupations where rules, standards, and norms are not well established. For instance, work in relatively new creative industries such as digital media is often precarious and exposes individuals to high levels of economic risk, involving nonstandard forms of work including self-employment, freelancing, and short-term contracts. Work in digital media and other creative industries is often project-based. However, it should be noted that project-based work has become widespread across other sectors of the economy. As an organizational form, it is inherently flexible as it allows the assembly of teams with different skill sets on an as-needed or temporary basis, and often involves the regular movement of workers between projects and employers. This is highly beneficial from the point of view of innovation and learning as it allows for experimentation and the ongoing creation of novelty. However, it also confers considerable risk on individual workers and their long-term career development, as this type of work is not stable and comes with neither long-term security nor collectivized health and pension benefits. Moreover, project-based work often relies on participation in social and professional networks that allow individual workers to gain access to important knowledge about upcoming projects and opportunities, as well as to learn various trade secrets and industry-specific practices. As such, project-based work often requires that workers trade on their personal identity characteristics, in addition to skill. As scholars have noted, the social orientation of these emerging flexible labor markets means that they are deeply imbued with power relations, have a higher chance of being exclusionary, and lead to unequal access to opportunities, depending on who you know rather than what you know. The emerging evidence suggests that these power relations reinforce exclusions based on gender, race, class, and ethnicity.

Finally, the shift toward flexibility in both high- and low-skill employment has led to
the growth of labor market intermediaries, organizations that help to mitigate labor market risk by matching employers and employees. While this means new and expanding roles for traditional intermediaries such as unions, guilds, and professional associations, it has also meant the growth and emergence of new forms of intermediaries ranging from temporary staffing agencies to online job clearinghouses to various community-driven worker collectives. In addition to intermediaries that directly broker the employer–employee or job seeker–employer relation, emerging intermediaries may also provide services, assist in skills and career development, facilitate networking activities, monitor changes in practice, and engage in advocacy. However, these intermediaries are not always benign. Certainly, the immense growth of the global temporary staffing industry is a symptom of an increasingly flexible labor market; but, as profit-seeking organizations, they often actively reinforce labor market conditions that leave workers facing precarity and risk in their everyday lives. Moreover, these organizations mediate supply and demand in local, national, and global markets, thereby shaping global migration flows and networked relations between places in the Global North and Global South.

Overall, current research accepts flexibility as a core feature of the contemporary labor market. However, there remain open questions about how these processes differentially affect particular groups with shared identities based on race, gender, ethnicity, class, and other markers of difference; how different social groups organize at and across different geographic scales to change their circumstances; what new or different intermediaries, networks, and governance arrangements are emerging that either mitigate or reinforce the risks and issues associated with flexible labor markets and produce new geographies and networks spanning the Global North and Global South; and how these are embedded within and vary between different geographic and institutional contexts.

Flexible specialization

Godfrey Yeung
National University of Singapore

Flexible specialization refers to the phenomenon of a closely linked network of firms, from suppliers to distributors, that engage in the production and distribution of nonstandard, specialized products to cater for ever-changing consumer demands. It is a partial reemergence of the craft model of production, which consists of flexible, specialist firms, based on flexible technologies, skilled workers, and a supporting industrial community. The transformation from the mass production of standardized products under Fordism to the volume production of nonstandardized products under flexible specialization illustrates how different forms of production organization can shape the characteristics of regional economic activities over time.

Fordism and post-Fordism

Fordism is the notion of a modern economic and social system based on the mass production of standardized products in large volume using purpose-built machinery and unskilled/semiskilled labor, a form of production initially developed by Henry Ford for the production of the Model T automobile in the Ford Motor Company in 1908. By utilizing purpose-built machinery to break down complex manufacturing processes into simpler, repetitive, and routine tasks that could be performed efficiently by unskilled/semiskilled workers along assembly lines driven by conveyor belts, the Ford Motor Company enjoyed economy of scale in the production of standardized products in large volumes—all Model Ts were black—and marketed Model Ts as the first affordable passenger vehicle by undercutting other automobile manufactures through a (much) lower retail price.

When parts and components are delivered in large and infrequent batches from suppliers, some of which could be located far away from the assembly plant, the assembly plant has to build large warehouses nearby to hold a large inventory of parts and components under the “just-in-case” supply distribution system to support large-scale production and avoid potential downtime in assembly lines. The firm normally keeps a distant working relationship with its large number of suppliers, and procurement is largely based on pricing: that is, there may be no long-term working relationship with suppliers (Dicken 2011, 147).

The dominance of the Fordist mode of production came to an end during the mid-1970s, when the developed economies ground to a halt due to rising inflation and growing unemployment after the 1973 oil crisis. During the recession, producers were left with plenty of unsold and out-of-fashion products, especially products with short product life cycles, such as consumer electronics. Neo-Marxists (including regulation theorists) argue that Fordism is based on the unsustainable regime of the accumulation of domestic mass production and mass consumption that drove post-World War II economic growth in capitalist countries (Jessop 1992).

Distinct from the neo-Marxist emphasis on the intrinsic crisis of the regime of accumulation, Michael J. Piore and Charles F. Sabel (1984),
among others, argued that the forms of the organization of production have shaped the characteristics of regional economic activities and their performance. The move away from the mass production of Fordism to a flexible form of organization of production was a direct response to the change in consumer demand for differentiated and “trendy” products in an increasingly globalized world (Scott 1988; Storper and Scott 1989). Moreover, manufacturers in developed countries were no longer able to compete on cost alone, as generic products were readily available from emerging economies at even lower costs.

Flexible specialization

The debate on regional modes of production was largely triggered by the publication of Piore and Sabel’s (1984) modern classic, *The Second Industrial Divide: Possibilities for Prosperity*. They described the second industrial divide as characterized by a transition from the technological paradigm of Fordism to flexible specialization. The economic slowdown was associated with the crisis of the Fordist production system, as the mass production of standardized products with dedicated machines and unskilled workers was unable to meet consumer demand for specialized and distinctive goods in the globalized economy.

The reemergence of some forms of the craft model of production occurred as a result of a demand and supply-side response in the changing global economy, whereby producers employed skilled workers and installed highly adaptable machinery to cater for consumer preference for customized products in various forms of product mix. Piore and Sabel (1984) termed this new mode of production *flexible specialization*: a network of flexible, specialist firms, with flexible technologies, skilled workers, and a supporting local industrial community. In the twentieth century, the Fordist mass production era signaled the end of small-scale craft production. Piore and Sabel (1984) argued that abandoning the mass production of standardized products and the return to craft methods of specialized production in the 1980s represented a second industrial divide (which is also the title of their book) in industrial societies.

The main distinctive features of flexible specialization in industrial districts compared to the Fordist mode of production are (Dicken 2011, 101) as follows.

- While the Fordist mode of production used complex purpose-built machinery to produce standardized products in large volumes, flexible specialization is characterized by highly flexible production methods using modular component systems deployed by a number of independent small-scale family-owned and craft-based firms, each of which tends to cover an individual phase of production and is normally coordinated by a larger (sometimes trading) firm to produce economy of scope, rather than of scale.
- Instead of using largely unskilled or semiskilled workers to perform specific, repetitive, routine tasks as in Fordism, workers (or workers-cum-owners in the case of small-scale family businesses) in flexible specialization have multiple production and practical skills, including the skills to maintain their machines. The highly flexible modular production system allows the local network of firms to adjust its product specifications, or even shift to new products without the costly retooling of machinery, to produce a wide range of different products of the volume required to meet effectively the ever-changing market demand.
- Rather than keeping a large inventory at warehouses near the assembly plant under
FLEXIBLE SPECIALIZATION

the “just-in-case” supply system of Fordism, firms in industrial districts are connected by specialized transaction networks of trusted suppliers and distributors. Local suppliers are crucial in the “just-in-time” delivery system, whereby specialized and quality parts and components have to be delivered in frequent, small-volume batches to the assembly plant to minimize the inventory and its associated costs (hence, the costs of switching to new products or specifications is lowered). The firm also has a close working relationship with its suppliers. The significant advancements in information communication technologies, especially the adoption of ERP (Enterprise Resource Planning), have facilitated logistical management by the provision of real-time demand information for supply and distribution chains.

Critics of flexible specialization have pointed out that the empirical foundation of research into this new organization of production is largely based on West European industrial districts, typically textiles in Prato and the engineering and ceramics sectors in Emilia Romagna of the Third Italy, according, for example, to Piore and Sabel (1984), and Russo (1985).

Indeed, the practicality of the flexible specialization mode of production is now in question due to the recent economic crisis in the Third Italy. In addition to the wider economic crisis in the European Union and rising production and other miscellaneous costs in Italy, the decline of industrial districts in Italy is partly due to the apparent revival of mass production (hence, lower costs) in emerging economies. This is especially the case in the “fast fashion” industry, as Chinese manufacturers can produce (very) similar products as quickly as Italian artisans/designers and at much lower costs (fast and large-scale production), partly through imitation or even counterfeiting originals.

Fluvial depositional processes and landforms

Paul F. Hudson
LUC The Hague, Leiden University, Netherlands

Fluvial deposits and landforms constitute a broad and diverse range of Earth surface processes, and are intricately related to human interests and influences. Fluvial sediments are deposited by overbank or lateral accretion processes which result in a complex assemblage of deposits organized within a floodplain mosaic. The dominance of specific types of depositional processes depends greatly upon the fluvial sediment and discharge regime, which should be considered from a drainage basin perspective. Knowledge of fluvial sedimentary processes and their depositional landforms is important to a variety of disciplines, especially sedimentology and geomorphology, engineering, hydrology, ecology, and archaeology.

Earth scientists study fluvial deposits to gain insights into patterns of flood sedimentation and relations with climatic or anthropogenic forcings. Recognition of distinct types of fluvial deposits is essential to understanding the evolution of river valleys and their adjustment to sea level fluctuation. Geotechnical properties of fluvial deposits are essential for engineers to consider, such as in the management of storm runoff and the design of flood control systems, as well as in transportation infrastructure. Fluvial depositional processes also create significant floodplain topography, which is important from the standpoint of flooding. Fluvial landforms, such as natural levees, have been utilized for millennia by ancient and prehistoric civilizations for settlement and agriculture, and archaeologists are interested in active and relict fluvial deposits in view of their geoarchaeological potential. Because overbank fluvial landforms are created from numerous individual flood events, they represent a climate- and landscape-sensitive archive with great promise for furthering our understanding of watershed-scale hydrologic variation in response to climate and anthropogenic change.

There are a variety of ways to classify fluvial depositional landforms, including mechanisms of sediment transport, morphology, hydraulics, and whether sedimentary deposits are cohesive or noncohesive. But fluvial deposits should always be viewed from the perspective of the drainage basin in which they have been constructed. Here the important watershed characteristics that influence fluvial deposits include scale (basin area), discharge regime (magnitude, frequency, seasonality), sediment load (suspended, bedload dominated), lithology (crystalline, calcareous), land use and land cover, and drainage basin morphometry (slope, shape, relief). An important drainage basin control is stream power, and specific (or unit) stream power has been shown to be an effective means to discriminate general styles of fluvial deposits (Nanson and Croke 1992). Similar to other components of fluvial systems, specific fluvial deposits are scale dependent and increase in size with drainage area due to mutual increases in sediment load and streamflow (energy). The scale dependence of fluvial deposits suggests that the concept of effective discharge applies to different types of fluvial landforms, especially point bars, crevasses,
and natural levees because of their relation to channel morphology.

From the perspective of a methodological framework, fluvial sedimentology and geomorphology provide useful approaches for examining the processes controlling the development of floodplain deposits and landforms, and in relating them to the broader topic of river metamorphosis and evolution. The science of fluvial sedimentology is mainly conducted by geomorphologists and sedimentologists within university physical geography and geology programs, with government agencies having an important role for much primary data collection (e.g., deep cores, soil mapping, geospatial data, hydrologic data). Understanding active sedimentary processes requires fieldwork and instrumentation, such as the measurement and description of bedforms, topographic surveying, coring, and the mapping and collection of flood deposits. Laboratory work includes chemical and physical characterization of field samples, with the latter utilizing the modified Wentworth scale to formally classify the particle size of sedimentary deposits. The use of color-infrared imagery, combined with the increasing availability of high resolution LiDAR digital elevation models (DEM), greatly facilitates the identification and mapping of fluvial depositional features such as crevasses, old channel belts, and terraces. Establishing the chronology of fluvial deposition and landform evolution requires a combination of relative and absolute dating techniques, with the latter most commonly including radiometric approaches or field-based instrumentation. Finally, indices of the above noted data types are commonly analyzed by mathematical and statistical approaches using computer-based hydraulic models (e.g., Hydrologic Engineering Center – River Analysis System (HEC-RAS)) within the framework of a geographic information system (GIS).

**Form and process**

Conventionally, fluvial landforms are created by two major sets of depositional processes: lateral accretion and overbank sedimentation. Within these broad categories, however, are a range of specific processes and depositional features. Sediment sorting during overbank conditions results in a lateral fining of flood deposits whereas sediment sorting associated with channel migration and bar formation results in a vertical fining-up sedimentary sequence.

**Lateral accretion processes**

In laterally migrating channels, coarse-grained (noncohesive) bedload is deposited along channel margins, and bedforms are the key sedimentary signature where median particle size ranges from coarse silt to gravel. Deposition occurs when the critical shear stress required to entrain particles of a specific size exceeds boundary shear stress. As such, the pattern of channel deposits approximates that of the distribution of channel boundary shear stress (Gomez 2006). Thus, the coarsest channel sediments are deposited within the channel thalweg, with sequentially finer sediments deposited outwards towards the channel margins as channel depth and velocity decrease. A typical sequence along an asymmetric channel cross-section (alternate bar or point bar) is that coarse gravel or cobbles are deposited within the channel thalweg at the cutbank, with sand to coarse silts deposited within shallow reaches towards the channel margins (inside of bend). Lower flow regime (Froude number <1) bedforms include ripples and dunes, which are commonly well preserved in the sedimentary record. The spacing and height of dune crests are proportional to flow depth, and therefore of keen interest to sedimentologists and geomorphologists to analyze the flow conditions.
during the moment of deposition. The transition to upper flow regime (Froude number >1) includes upstream migrating antidunes, which are rarely preserved in the sedimentary record (Bridge 2003). Between low and high flow stage, ripples and dunes provide sedimentologic evidence of recent events and the hydraulics of sedimentation. Phases of point bar deposition can often be distinguished by thin (≈1–3 mm) “clay drapes,” consisting of fine-grained cohesive wash load sediments deposited during slackwater conditions during the waning stage of the discharge hydrograph.

Channel bars

Channel bars develop as ripples and dunes are successively deposited along the flanks of shallow channel margins, resulting in lateral accretion. The process of lateral channel bar aggradation results in a distinctive fining-up trend in particle size, and is consistent with the concept of helical flow and a laterally migrating channel, which is a key sedimentary signature to identify past fluvial processes. The development of point bars within meandering rivers is among the most studied sedimentary features. Under an assumption of equilibrium, alternating channel bars and point bars adjust in association with lateral migration and maintain a consistent size and morphology. Bar deposits represent the largest percentage of overall accommodation space within a river valley. The recognition of floodplains infilled with channel bar deposits is an important indication of former channel activity, which may provide evidence for prior hydroclimatic conditions. Coarse-grained floodplain deposits are important natural resources which are heavily exploited by humans. Within dry regions, floodplain agriculture is often dependent upon alluvial aquifers for irrigation, particularly during extended low-flow conditions. Channel bar deposits are heavily exploited for aggregate, especially for construction of urban areas and associated transportation infrastructure.

Overbank sedimentary processes

Overbank sedimentation is an important mechanism for floodplain creation. Overbank deposits bury coarse-grained channel bar deposits, and in especially wide valleys cohesive fine-grained backswamp deposits constitute a considerable proportion of overall accommodation space. In addition to backswamps, other fluvial sedimentary features formed by overbank processes include natural levees, crevasses, and infilled channels (Bridge 2003).

Overbank sedimentation includes coarse sediment (sand/coarse silt) transported as bedload and fine-grained sediment transported in suspension, especially wash load (clay/fine silt). Although large floods receive a great deal of attention from the standpoint of hydrology, sedimentologically there is no relationship between flood magnitude and the rate of floodplain sedimentation. Individual flood deposits vary in thickness from millimeters to as much as half a meter, exhibiting pronounced lateral fining in thickness and particle size with distance from the active channel. Overbank flow velocity rapidly decreases upon exiting the channel. This causes sand and coarse silt to fall out of suspension and to be deposited along the channel margins, or transported across the floodplain as bedload, which may then be preserved as dunes and ripples as flow conditions transition from upper to lower flow regime (Bridge 2003). The distance that coarser sediments are transported across the floodplain surface as bedload is controlled by local floodplain hydraulics, which are influenced by the floodplain topography, the growth of vegetation, and floodplain hydrology. The overbank sedimentation process can be further considered...
FLUVIAL DEPOSITIONAL PROCESSES AND LANDFORMS

Based on whether advective or turbulent diffusive processes are dominant (Pizzuto 1987). Turbulent diffusive processes occur when floodplain basins (e.g., backswamps) are inundated prior to the river being overbank. This produces a steep suspended sediment concentration gradient across the floodplain, and induces abrupt sedimentation and high amounts of coarse sediment to be deposited along the channel margins. Advective sedimentation occurs when the river floods an otherwise dry floodplain, and enables coarser suspended sediment to be transported further from the channel margins. Along the distant margins of natural levees and in backswamps, slackwater deposition of clay is the dominant mode of sedimentation and results in thin clay laminations perhaps a millimeter in thickness (Aalto et al. 2003).

**Natural levees**

Natural levees represent the aggregate construction of numerous individual sedimentation events and require hundreds of years to form. Natural levees form along channel-floodplain margins and slope towards floodplain bottoms. Natural levees are located along meandering, braided, anastomosing, estuarine, crevasse, and distributary channels of alluvial fans and deltas. They are especially associated with flood-prone rivers dominated by suspended sediment transport, and coastal plain meandering rivers in particular. The size (height and width) of natural levees is related to flood stage variability and the available sediment for construction (Cazanacli and Smith 1996). The stratigraphy of natural levees at cutbanks includes individual strata commonly ranging from 1 cm to 10 cm in thickness, decreasing in thickness with distance from the active channel bank.

The slopes of natural levees between the channel and flood basins are related to sediment size, with coarse sediments associated with steep natural levees while fine-grained sediments are more associated with broad low sloping natural levees (Cazanacli and Smith 1996). Along a given river reach, the largest natural levees are located at the outside of meander bends, suggesting the reworking of floodplain deposits during large events, but also that crevasse mechanisms are important to natural levee development. In the case of laterally stable channels, minor natural levees may form on the inside of meander bends (burying point bar deposits). Along a river, the size of natural levees increases downstream of tributaries, especially with a large increase in discharge and sediment load. Natural levees are largest towards the lower reaches of large coastal plain alluvial valleys, but then decrease in size as they flow within deltaic settings and sediment load is exhausted (Hudson and Heitmuller 2003). From the standpoint of humans, natural levees are among the most important landforms within an active floodplain, as their higher surface and permeable soils permit settlement and, especially, agricultural activities with minimal flood risk.

**Crevasse splays**

A crevasse is formed during overbank conditions because of flood waters scouring a trough into the channel bank. A crevasse splay is a fan-shaped deposit with an axial scour channel extending at a tangent from the main river channel and natural levee crest, along the outside of a meander bend (Bridge 2003). Crevasses have a dendritic pattern because of smaller bifurcating channels, which are primarily depositional. Sediment is deposited mainly by sheet wash, and includes minor natural levees formed along the banks of the larger secondary channels (Cazanacli and Smith 1996). Crevasses are important mechanisms for distributing coarse sediments from high-energy settings to low-energy settings, which are
FLUVIAL DEPOSITIONAL PROCESSES AND LANDFORMS

otherwise dominated by fine-grained cohesive deposits. The formation of crevasses is especially associated with flood duration, although flood frequency is also important.

Crevase splays provide an indication of the flood activity of a river, and in remote locations should be seen as a good indicator of flood hazards. In regions with considerable economic and human welfare interests, river management agencies are tasked with managing crevasses. Restoration of floodplain ecosystem services along some lowland rivers includes the explicit breaching of river dikes during flood events to simulate crevasse processes. The ensuing hydrologic and topographic variability restores important elements of a river’s geodiversity, stimulating biogeographic complexity (Florsheim and Mount 2003). The recognition of distal floodplain sedimentation by crevasse-like processes is especially important in rivers with a high flood duration, such as humid tropical rivers which undergo an extended season of floodplain inundation. In such cases, crevasses continue to deliver large amounts of coarse silts to flood basins within a network of interconnected floodplain channels (e.g., Aalto et al. 2003).

Infilled channels

Many floodplains contain evidence of past river channel dynamics in the form of old channels, including abandoned river courses, meander cutoffs, and sloughs. Old channels become infilled with overbank deposits, primarily fine-grained cohesive deposits. Sedimentologically, these are often termed “clay plugs,” especially infilled oxbow lakes. This is somewhat of an oversimplification, however, as most infilled channels also contain lenses of coarser deposits (fine sand and coarse silt) which provide an indication of the frequency of prior flood events, especially large floods. Radiocarbon dating organic material obtained from field coring is a common approach to identifying the timing of past river channel changes, as well as paleoflood history.

Infilled channels exist within active meander belts, but are also preserved in abandoned meander belts. The timescales for channel infilling depend greatly on the main-stem sediment load and flood regime, as well as on the floodplain topography and distance of the old channel from the active channel. Over long periods (10^−3 years) infilled deposits become compacted and dense, and form clay plugs. Old clay plugs, however, have contemporary relevance because of being resistant to bank erosion, which thereby influences subsequent patterns of river meandering. The presence of hard clay plugs is especially common where an active channel is reworking an older channel belt, and should be considered in the development of channel engineering and bank protection management plans.

Backswamps

Beyond the limits of coarse sediment delivery, overbank flooding results in the transport and accumulation of thick fine-grained cohesive deposits. Backswamps are usually associated with larger river valleys which have sufficient accommodation space to store old deposits, and which are distal enough from the active channel that they are dominated by low-energy conditions and fine-grained sedimentation for extended periods (10^−3 years). Sedimentation is dominated by the deposition of wash load sediments (fine silt/clay) within a slackwater environment. The presence of “stringers” of coarser sediments (silt/fine sand) transported by prior large flood events is occasionally noted in deep floodplain corings. The thickness of backswamp deposits varies mainly according to the size (depth and width) of the river valley, but commonly exceeds 10 m (Bridge 2003).
Alluvial fans

Alluvial fans are formed where fluvial sediments are deposited as a fan-shaped landform. The essence of the feature is that multiple distributary channels extend outwards in a dendritic pattern from the fan apex, which is located where the longitudinal profile exhibits an abrupt reduction in slope. The channels deposit sediment at widely different rates because of being in different stages of formation and function. Two important controls on alluvial fan formation include an abrupt reduction in stream gradient and an increase in the zone of deposition. These boundary conditions occur where a narrow river valley enters a larger valley along bluff lines or fault-controlled mountain flanks. Several additional drainage basin controls on the formation and morphology of alluvial fans include (i) sediment load, (ii) hydrologic regime, (iii) gradient, and (iv) drainage area. Alluvial fans are located across all climatic regions, although a common misconception is that they are mainly associated with dry climates. This is likely because the morphology and vegetation pattern of alluvial fans is more discernible and distinctive within dry environments. The groundwater within coarse alluvial fan deposits often represents an important aquifer to small communities, and especially for irrigation of associated agriculture.

Sedimentary deposits associated with alluvial fan formation include a combination of channel and overbank deposits, with the latter being dominant under the influence of extensive sheet flow conditions during flood events, as well as debris flow deposits. As such, the coarse particle size of alluvial fans exhibits a distinctive fining trend with distance away from the fan apex, and sediment sorting also increases. The timing of alluvial fan sedimentation should be sensitive to exogenic controls, although linking their activity to climate change can be problematic in tectonically active regions because of base-level changes (Harvey 2002). Where alluvial fans are closely spaced they may coalesce, resulting in a larger depositional landform termed a “bajada.”

Fluvial terraces

Fluvial terraces are relict fluvial landforms situated above the active floodplain surface. Their morphology consists of distinctive elongated flat surfaces (treads) defined by erosional bluffs (risers). Terraces are formed when channel incision hydrologically disconnects the floodplain surface from active fluvial processes. Relict fluvial deposits then undergo reworking and modification by other types of surficial processes, including eolian, runoff, weathering, and pedogenic processes. Many river valleys are defined by specific terrace sequences, with progressively higher (and older) terraces displaying evidence of a greater degree of reworking and pedogenesis. In relation to humans, fluvial terraces are among Earth’s most productive lands. River terraces have a variety of qualities that lend themselves to human exploitation, including (i) freedom from flood risk, (ii) deep fertile soils, (iii) level surfaces, and (iv) proximity to water resources, making them invaluable for occupation and agricultural activities.

The study of river terraces has a long tradition within physical geography and geomorphology, and the mapping of river valleys into active Holocene surface bounded by fleets of relict Pleistocene terraces (i.e., $t_0$, $t_1$, $t_2$, $t_3$, etc.) is among the earliest traditions in landform mapping. Unfortunately, this rather simplistic perspective does not recognize geomorphic variability during the Holocene and the formation of low Holocene terraces, or effective terraces created during the Anthropocene. Earlier – and
persistent – ideas concerning the origin of terraces attempted to “fit” each specific fluvial terrace to a glacial cycle, an idea that originated in central Europe with the study of Rhine River terraces in relation to glaciation in the Alps. This conceptual framework was also applied in North America, especially in relation to continental ice sheets, sea level fluctuation, and Mississippi River terraces. Modern ideas concerning the origin of river terraces recognize a greater range of climatic variability across the oxygen isotope record, changes in sediment load, and especially tectonic controls.

**Fluvial deltas**

Deltas form at the terminus of a watershed where a river discharges into a standing body of water, and result in coastal environments with considerable geomorphic and biological diversity. The classification of deltas is based upon their morphology, which primarily relates to their planform geometry. The shape of a delta is determined by the style of deltaic sedimentation, with three controls on sedimentation being tides, waves, and fluvial regime, with the latter control being defined by river discharge and sediment load. Fluvial deltas are located within lakes and marine settings having low wave energy or tidal range relative to fluvial inputs. Fluvial deltas are characterized by an elongated channel, which is formed as a prograding river mouth advances into a receiving basin. Fluvial delta evolution occurs in association with river mouth progradation, and especially includes river mouth bifurcation and the formation of distributary branches and subdeltas created by crevasse events during flooding, which collectively form a delta lobe.

The process of delta lobe formation is initiated upon the debouching of sediment at a river mouth, which abruptly results in sediment sorting and deposition. Sediment sorting at the river mouth produces deltaic sedimentary facies comprising three distinctive depositional units: (i) bottom-set – horizontal bedding consisting of soft fine-grained cohesive deposits derived from the suspended load; (ii) fore-set – inclined bedding consisting of coarse-grained deposits derived from bedload; and (iii) top-set – horizontal bedding consisting of medium- to fine-grained deposits derived from overbank processes with organic material representative of wetland and marsh environments (Bridge 2003). Continued river mouth progradation results in dense coarse-grained fore-set bedding burying and compacting soft bottom-set bedding, producing a distinctive coarsening-up vertical sedimentary sequence which defines deltaic facies.

**Floodplain deposits and pedogenesis**

Understanding the development of floodplain soils in relation to sedimentary parent material requires consideration of sediment structure, floodplain hydrology, weathering, and bioturbation. The length of time for which sedimentary structure is preserved depends not only on primary sedimentology, particle size, and bedding, but also on pedogenic regime. Floodplains are often considered a single depositional environment, but pedogenic characteristics vary spatially, away from the channel. A soil catena, for example, may occur along the natural levee profile, which represents a systemic topographic transition from higher well-drained channel bank margin to lower and poorly drained backswamps. Sandy sediment structure is usually preserved longer than fine-grained muddy bedding, with individual sedimentary laminae possibly
destroyed after a year or so because of bio-
turbation by plants and burrowing organisms, 
especially in the humid tropics. Soils developing 
on thicker, sandier, and well-drained surfaces 
of channel bars and natural levee crests fre-
quently have oxidized and leached horizons with 
abundant manganese nodules and iron oxide 
stains. These soils may have medium to stiff, 
mottled gray, tan, and brown silty clay, sandy 
clay, or silty sand, and overlay darker fine-grained 
soils with considerable organic matter, devel-
oped in floodplain bottoms. The most common 
soil profile along a channel cutbank is an A–C 
horizon, which occurs because of insufficient 
time for eluvial (E) or illuvial (B) horizons to 
develop. High rates of overbank sedimentation 
result in floodplain topsoil typically lacking dark 
organic matter. With increasing distance from 
the active channel, however, the maturity of 
soils increases, as does bioturbation. Soils within 
poorly drained flood basins typically lack strat-
ification and have better developed illuvial (Bt) 
horizons. Backswamp soils are frequently gleyed 
(iron reduction) because of a persistent high 
water table. In the case of a high water table, 
the plant root zone is near the surface, whereas 
in floodplains with high seasonal fluctuation 
in the water table the root zone extends much 
deeper, which reduces the preservation of thinly 
laminated sedimentary structure.

Conclusions

Fluvial deposits are associated with a diverse 
range of surficial environments and have been 
important to humans for millennia for settle-
ment, agriculture, and natural resources. Because 
of their sensitivity to climatic and anthropogenic 
influences, in an era of global environmental 
change it remains essential to understand the 
fundamental controls influencing Earth’s fluvial 
sedimentary processes.

Fluvial erosional processes and landforms

Ross H. Martin  
Texas State University, USA

Fluvial erosion can be found in varying forms and rates throughout a watershed. From raindrop-impact erosion and upland denudation to undercutting and mass wasting, fluvial processes are responsible for moving large amounts of sediment across landscapes. Fluxes of sediment create various physical signatures on the landscape. River planform and morphology, and other landforms associated with fluvial processes are determined by the characteristics of fluid flow and the properties of the erodible material (Knighton 1998). The interaction of fluid flow with the Earth’s surface leads to an understanding of how sediments are initially entrained. Erodible material varies greatly, from fine-grained cohesive sediments to bedrock to loosely consolidated alluvial material.

The scale of assessment of fluvial erosion spans from understanding the physics of how a single particle is entrained to mass wasting events along river banks to landscape evolution. Fluvial processes occur from the top of the watershed to the bottom, beginning as rain falls on a landscape. Rain-splash erosion occurs as rain falls on bare ground. In upland areas, overland flow can denude hillslopes. As surface water flows down a watershed it accumulates into streams, then rivers, creating potential for the erosion and transport of sediment.

For the purpose of general understanding, the watershed can be divided into three areas based on the dominant process – erosion, transport, and deposition (Schumm 1977). Erosion is dominant at the upstream most portion of the watershed, where steep slopes provide greater potential energy for sediment mobility. The middle zone is dominated by transport. In the transport zone, sediment deposition from upstream acts in quasi-equilibrium with erosion. The most downstream portion of a watershed can be characterized by deposition; here, the slope decreases and the stream’s ability to move sediment is reduced. In reality, geomorphic response is a system of complex responses depending on many variables at many scales.

Flow dynamics

The flow of water in open channels is primarily dependent on the interaction of two factors, the force of gravity acting in the downslope direction and friction (Knighton 1998). This relationship can be approximated by the Reynolds number (Re):

\[ Re = \frac{VR}{v} \]

where \( V \) is equal to velocity (m s\(^{-1}\)), \( R \) is the hydraulic radius of the flow (m), and \( v \) is the kinematic viscosity (m\(^2\) s\(^{-1}\)).

The velocity profile of flow in a stream shows that the velocity decreases as it approaches the boundary layer. In systems with a low Reynolds number the flow is laminar, which means that the velocity of each “layer” of water is constant and there is little mixing between the layers. In these cases, the amount of shear stress available to transport sediments is proportional to the velocity difference between the “layers” of flow.
(Petts and Foster 1985). On the other side of the spectrum, systems with a high Reynolds number are characterized by turbulent flow. Turbulent flow results in eddies and diffusion of water particles, which provides an additional viscosity factor to the system, termed eddy viscosity (Petts and Foster 1985). This results in greater shear stress available to transport and erode sediment. In reality, Reynolds numbers of typical stream channels are somewhere in the middle of the two extremes (laminar and turbulent flow).

Large rocks, large woody debris, weirs, dams or other features can create momentary or singular disruption to the flow and, thereby, can create irregular erosive patterns. A hydraulic drop in the stream’s path can create a transition from subcritical to supercritical flow. Most streams with gradually varied flow exhibit subcritical flow, where the gravitational force dominates. Supercritical flows occur where inertial forces dominate, move rapidly, can overshoot bends in the channel, and, therefore, have the potential to be highly erosive (Charlton 2007). The Froude number \( Fr \) is the ratio of the gravitational and inertial forces. Where the Froude number is \( Fr > 1 \) the flow is supercritical, where it is \( Fr < 1 \) it is subcritical, and if it is equal to one it is considered transitional:

\[
Fr = \frac{v}{\sqrt{gd}}
\]

where \( Fr \) is the Froude number, \( v \) is velocity \( (m s^{-1}) \), \( g \) is the gravitation constant \( (9.8 \text{ m s}^{-2}) \), and \( d \) is depth \( (m) \).

The surface of the channel provides resistance to flow, in varying degrees, depending on the roughness of the channel bed and walls. The flow exerts a shearing action on the channel boundary (bed and walls). Therefore, the flow in the channel is slower near the boundary and faster in the middle of the channel, where there is little resistance. It is typical to measure average water depth at 0.6 of the water depth in the center of the channel (Petts and Foster 1985). Several equations have been formulated to approximate the velocity of a flow. The velocity is dependent on channel roughness or resistance to flow, slope, and cross-sectional form. The Chezy equation, Manning’s equation, and the Darcy–Weisbach equation relate flow velocity to bed roughness. In general, roughness and flow resistance are greater where the ratio of sediment size to flow depth is greater.

### Thresholds for initial motion of sediments

Erosion of material by fluvial processes begins with the movement of sediment. Sediment resting on a stream bed or hill slope requires force to be coaxed to move. Work is done when a force moves an object over a given distance. Power is defined as the rate at which work is done. Bagnold (1966) suggested that stream power be used to evaluate the capacity of a flow to mobilize sediments:

\[
\Omega = \rho g Q S
\]

where \( \Omega \) = stream power \( (\text{wattsm}^{-1}) \), \( \rho \) = density of water \( (\text{kgm}^{-3}) \), \( g \) = gravity constant, \( Q \) = discharge \( (\text{m}^3 \text{s}^{-1}) \) and \( S \) = slope \( (\text{m/m}) \).

Stream power can also be expressed as specific stream power \( (\omega) \):

\[
\omega = \frac{\Omega}{w}
\]

where \( w \) = width. Specific stream power \( (\omega) \) can also be related to bed shear stress \( (t) \):

\[
\omega = \frac{t}{v}
\]

where \( t \) = bed shear stress and \( v \) = average flow velocity. Bed shear stress \( (t) \) is the amount of shearing force placed on the bed surface by the flow of the water. It can also be written as:
\[ t = \rho ghS \]

where \( \rho \) = density of water (kg m\(^{-3}\)), \( g \) = gravity constant, \( h \) = height or depth of water (m) and \( S \) = slope (m m\(^{-1}\)).

Sediments are mobilized when the shear stress induced by the flow of water overcomes the forces that are keeping the particles in place. Larger particles require more energy and, therefore, flows of a greater discharge to be mobilized. The amount of surface area that is exposed to the flow is proportional to the drag force (or shear force) the grain endures. The degree to which a particle protrudes into the flow plays a major role in how much force it takes to dislodge and mobilize that sediment. On a stream bed with similar sized sediments individual grains will be equally sheltered from flow; whereas larger grains lying on a fine-grained bed will protrude into the flow and shelter smaller grain sizes downstream.

Wiberg and Smith (1987) showed that a major component of initial motion is the pivot angle, which is how much a grain must rotate to roll over the next downstream grain. The degree of bed grain size homogeneity plays an important role. It takes more force to pivot a large grain from between other large grains, whereas a larger grain resting on a fine-grained bed will have a very small pivot angle.

Critical shear stresses for mobility are related to the force of gravity, the size and weight of the grain in relation to the shear stress on the bed, and the kinematic viscosity. Shields (1936) plotted critical shear stresses against Reynolds number. This relationship is known as the Shields function or parameter. Once rearranged, this function becomes a dimensionless critical shear stress that is equated to the ratio of shear stress exerted on the bed to the submerged weight of bed surface particles:

\[ \theta_{cr} = \frac{t_{cr}}{g(\rho_s - \rho)D} \]

where \( \theta_{cr} \) is the Shields parameter (dimensionless shear stress), \( t_{cr} \) is the critical bed shear stress, \( g \) is the gravitational constant, \( \rho_s \) and \( \rho \) are the densities of sediment and water, and \( D \) is grain size.

The Shields parameter is used in many sediment transport equations. A commonly cited threshold value of the Shields stress is 0.03 (Buffington and Montgomery 1997) and Bagnold (1980) used a critical Shields value of 0.04. Many studies have related critical shear stress with relative grain size. In these power relationships, the range of the coefficients and exponents is determined by bed sorting, methodology used, and other factors inherent in natural streams or flumes.

**Sediment sources and erosion**

Sediment sources for alluvial streams include predominantly bed incision and bank erosion. The makeup of the substrate that underlies the stream bed will, to a large extent, determine the sediment size distribution of grains on a stream bed. Low to moderate flows may only entrain some of the sediment that is already resting on the stream bed; however, a larger flow, which can entrain most or all of the sediment on the stream bed, may erode or incise the underlying substrate. Bank erosion is complicated by root systems that hold sediment together. Thus, riparian vegetation is an important factor in fluvial erosion. Bank failures induced by direct action of the water include mass wasting and weakening of bank material. Mass wasting on banks includes slumping, rotational failures, and undercutting failures, which are the result of particle entrainment from the bank. Processes such as frost action and ice wedging can weaken the bank, making it more susceptible to failure and erosion. Slaking occurs when dry sediments
are rapidly inundated and air gets trapped in the sediment, which results in buoyancy forces dislodging sediments.

Bedrock channels are eroded by quarrying, abrasion and corrosion. Quarrying includes the breaking apart and movement of blocks or aggregates of bedrock. Blocks can be broken off by wedging, where fine grain particles enter a crevasse during a high flow and over time the crevasse enlarges, similar to ice wedging. Cavitation occurs only during high flows, when shock waves are generated by high flows with large pressure difference (Knighton 1998). Abrasion occurs when fine-grained sediments suspended in the flow scour, scratch, and abrade the bedrock surface. Abrasion becomes concentrated in weak areas, and acts in a positive feedback loop. Once abrasion scours a weak area a pothole or pit can form, which results in an eddy within the pothole. Sediments can become trapped, which then increases the rate of abrasive scouring (Charlton 2007). Corrosion of bedrock material is the result of dissolution of soluble bedrock, commonly along fracture planes.

Transport

The transport of sediment can be divided into three categories: bedload, suspended load, and dissolved load. Bedload is defined as the sediment that moves by rolling, sliding or saltation (bouncing) along the bed during transport. It generally contains the coarsest size fraction of mobile particles. This portion of sediment transport is primarily dependent on flow competency, and the largest particles are likely just beyond their thresholds for mobility. The bedload material can also protect the underlying substrate from erosion. Flows can winnow smaller grain size fractions, leaving only coarser gravels behind.

This condition, known as armoring, results in a protective layer that can withstand moderately high flows. If the armor layer is entrained, the river will experience a sudden and dramatic flux of sediment, as all of the grain sizes, including the smaller once protected grains, mobilize at once. Estimates of bedload transport rates are varied and complicated. Armoring is one of many factors that make empirically estimating bedload difficult. Log jams and large woody debris can also interfere with flow regimes. Cohesive sediments make estimating bed load difficult, too, as they tend to erode as aggregates instead of as individual particles. Bedload transport is primarily dependent on flow competency, so there are many transport equations that relate volume of bedload transport to discharge.

Suspended load comprises the sand and silt-sized sediments that are suspended in the flow, which will settle as soon as the discharge decreases. The size, shape, and density of a particle and the fluid density of a flow will determine the fall velocity for that particle (Charlton 2007). Slow fall velocities (smaller grains) and a turbulent flow result in the suspension of sediment. Since this sediment remains in suspension, it is able to be transported over long distances. The amount of sediment transported as suspended load is often determined by the availability of sediment in the watershed and is sourced from hillslope erosion, bank erosion, and, to a lesser extent, the stream bed. Since suspended load discharge varies with sediment availability, it often exhibits hysteresis, in which there are different quantities of sediment transported for a similar discharge. Because of the variability of suspended load it is difficult to estimate. Sediment rating curves that relate suspended load to discharge can be created but, as suspended load is dependent on vegetation cover, soil properties, and topography, among other factors, those rating curves are typically calibrated for a watershed or region. Often,
the suspended load comprises the majority of the total sediment yield from a basin. Very fine grained clays and silts, and biogenic sediments are included in suspended load. Turbidity, a common water quality parameter, is a measure of water cloudiness, and suspended sediment by proxy.

Dissolved load includes solutes from chemical weathering, atmospheric inputs, and anthropogenic sources (Knighton 1998). Dissolved load transport is not confined to surface water flow and is not a contributor to the mechanics of river adjustment and migration. However, chemical denudation of rock by surface water is a source of dissolved load and an appreciable factor of geomorphic change in some environments, such as karst. Chemical denudation is complex and dependent on water chemistry, among other factors (Petts and Foster 1985).

**Bedforms**

The flow dynamics and availability of certain sizes of sediment will dictate bed forms. In homogenous sand channels, as the Froude number and velocity vary the channel bed will exhibit different formations on the bed surface. At lower velocities and Froude number, ripple patterns will be dominant on the bed surface. As both the Froude number and velocity increase, dunes will begin to form and boils may appear in the water surface. Both dunes and ripples form when the upstream face is eroded and sediment is deposited on the downstream slope face. As the Froude number increases to one, the bed surface will flatten, with no ripples or dunes, as the flow velocity is too high to allow sediments to be deposited on the downstream slope face. Further increasing the Froude number and supercritical flow will result in standing waves, and the formation of anti-dunes on the bed channel.

Channel beds with mixed sediment sizes will exhibit sediment sorting. Pebble clusters may form when a large particle extends into the flow, and because it locally interrupts the flow, it initiates deposition on the upstream side of the large clast. Often pebble clusters can exhibit imbricated structures (Charlton 2007). Smaller sediments are deposited in the sheltered area downstream of the large clast. Shear stress variations on the bed surface sort the available grains. In pool-riffle sequences, coarser grains are found in the riffles and finer grains are found in the pools, where they are allowed to settle. In meandering channels, particles are sorted through the meander bend (Clayton 2010). Gravel bed channels tend to form armor layers where finer sediments are winnowed away, leaving a layer of coarse-grained sediments on the surface of the bed.

In some channels, especially after high flow events, erosion creates zones of high bed slope. These local increases in gradient are known as nickpoints. Nickpoints can occur in both bedrock and alluvial single thread channels, and migrate upstream because of shear stress increases associated with localized increase in stream gradient. Layers of more and less resistant rock or soils can also create nickpoints as the underlying less resistant rock erodes.

**Channel planform**

There is a continuum between a handful of dominant variables that will dictate channel planform. Those include sediment supply and grain size, slope, discharge, flood frequency, riparian vegetation, and geologic setting. The most obvious distinction is that channels are either single thread or braided. Schumm (1977) showed that slope and sediment load correspond to channel planform. A simplistic model is
that low sediment loads and low slopes result in straight channels, high sediment loads and high slopes result in braided channels, and meandering channels exist with intermediate slopes and sediment loads. A stream’s energy can be linked to channel planform and plays a major role in determining the size of sediment that can be mobilized. Potential and kinetic energy perform work via fluid flow, which results in turbulence and associated viscosity, a flow’s ability to overcome friction at the boundary layer, erosional shear, and capacity to transport sediment (Knighton 1998).

Higher-energy systems tend to be bedload dominant and can be characterized by braided planforms and large mid-channel bars. Braided planforms are associated with abundant bedload sediment, erodible banks, and highly variable discharge, conditions which are often present in proglacial environments. The abundance of bed material can be the result of aggradation, in which the river cannot transport the material. Braiding is an adjustment so that the river can transport the bed material. According to the stream power theory of sediment transport suggested by Bagnold (1977), bedload transport is more efficient in channels with higher width to depth ratios (Knighton 1998), such as braided channels. Single-thread streams in high slope environments may form cascades or steps and pools as a mechanism to dissipate energy. The energy is dissipated because of the increase in boundary roughness as the water flows over the large rocks or logs that make the steps and falls to the pool below.

With only moderate energy and mixed loads, the stream may begin to meander. Single thread channels can be described by their degree of sinuosity, which is equal to channel length divided by valley length. Flume studies have shown any degree of sinuosity can be accomplished by varying slope, discharge, and sediment supply (Knighton 1998). Meanders, functionally, provide a mechanism for the dissipation of a stream’s energy by reducing the stream’s slope. Meandering is the result of the feedback processes that cause cut banks to erode and point bars to aggrade. Cut banks are found on the outside of the meander bends. In these areas, as the name implies, lateral erosion of the bank material is occurring. This results in the meander bend migrating. Point bars are locations of deposition that act in quasi-equilibrium with the cut banks. High sinuosity and undeterred meanders result in meander bends being cut off as two meanders migrate together. This results in oxbow lakes and scarred landscapes. Streams with coarse grain availability and with varying degrees of sinuosity will form pool and riffle sequences. Riffles are typically coarser grained with shallower, faster moving water and pools are deeper with slower flow over finer grains.

Lower energy streams dominated by suspended load will vary from meandering channels with tortuous sinuosity to anabranching channels. Anabranching channels are associated with very low slopes and energy. The anabranching nature of these channels is caused by avulsions during peak flows. Avulsions are erosional episodes where high flows jump established banks and incise new channels. Wandering gravel channels and anastomosing channels are the primary types of anabranching channels documented. Anastomosing channels are characterized by very low gradients and very low rates of bedload transport. They are similar in appearance to braided channels, except that they are usually more stable and have clayey or silty banks. Wandering gravel channels are characterized by coarse sediment input but lower transport rates than braided channels (Charlton 2007). Wandering gravel channels tend to be more stable than braided channels because often the mid-channel bars are vegetated.
Hillslopes and interfluvies

Fluvial processes are not confined to channels. As rain falls, the impact of the rain drop can mobilize sediments, known as rain-splash erosion. Overland flow of water is also responsible for eroding and transporting sediments on slopes. Both of these processes act as sediment sources to streams.

Raindrops fall and accelerate to terminal velocity, which is dependent on drop size. The sediment particle size that can be mobilized by a falling rain drop is dependent on momentum. On a flat surface, raindrop impact results in a random distribution of sediment. As the slope increases, more of the mobilized sediment is displaced down the slope. Rain-splash erosion is complicated by vegetation canopy, which can intercept rain, reducing total volume, and can prevent rain drops from reaching terminal velocity (Petts and Foster 1985). Root systems and ground cover also play an important role in determining the amount of sediment available for mobilization.

Once the rain has fallen, it collects and flows over the surface, a process termed Hortonian overland flow. Hortonian flow can entrain sediments after critical shear stresses are overcome. Sediment is mobilized, which results in changes in the microtopography of the hillslope. Rill formation is dependent on the vegetation cover and soil or sediment type. Water flow concentrates in the depression, where erosion is accentuated, resulting in rills. Gullies are similar to rills but are larger and tend to be permanent channels for ephemeral flow. However, gullies are distinctly different from stream channels, with lower width:depth ratios. Gullies, like rills, are highly dependent on the lack of vegetation cover and tend to form in arid environments. Gullies enlarge and deepen as headcuts or nickpoints concentrate the erosion and migrate upslope.

Arroyos are gully-like features that form in arid environments with abundant sediment.

Focus groups

Peter Hopkins
Newcastle University, UK

Focus groups are now an established qualitative research method in the discipline of geography and are regularly used within many subfields of human geography including environmental geography, social and cultural geographies, population studies, and children’s geographies (Burgess 1996; Hyams 2004; Skop 2006). As a method, focus groups are about producing data based on a one-off group discussion on a specific topic that is provided by the researcher, who often takes on the role of the moderator (Hennink 2014; Morgan 1998). The main idea behind focus groups is, therefore, to generate group interaction and contestation over ideas and opinions that cannot readily be found in individual interviews (Krueger 1994; 1998). Key factors to consider about focus groups include group interaction, the topic, the role of the moderator, and the size of the group (Hopkins 2007).

Focus groups can be used in a self-contained manner as the main source of data. They can also supplement another method such as interviews, or be used in a multimethod study alongside a host of other research methods. Focus groups can work usefully alongside interviews, ethnography, questionnaire surveys, as well as participatory action research approaches. It can also be useful to consider the potential benefits of using focus groups at different stages of a research project. For example, focus groups may be used at the start of a research project to orient the researcher to a new field, to generate ideas and themes for further exploration later in the study, or to generate hypotheses that can be systematically tested through further research. Focus groups may also be used later on in a study to discuss research outcomes in groups or to verify the findings of the researcher.

The increasing use of focus groups is largely due to the many benefits they can bring to research (Barbour and Kitzinger 1999; Goss 1996). As well as being helpful for those who want to orient themselves to a new field, focus groups can be particularly useful for providing insights into how groups develop, challenge issues, and focus their arguments around particular points. This can often lead to the generation of new ideas, the evolution of a creative process, and a dynamic research agenda that may encourage researchers to be reflexive about their perspectives and approach. Indeed, the group dynamic may be pertinent to the research content. Focus groups can also be more inclusive, offering participants safety in numbers and perhaps even recruiting those who are “hard to reach”; some would therefore see focus groups as being more democratic and empowering to the participants and less threatening and power-laden compared to individual interviews. Focus groups can arguably also be cathartic experiences for participants, allowing and enabling them to raise and debate issues that they rarely have the opportunity to discuss (Johnson 1996), thus contributing toward social change and transformation.

That being said, focus groups are not without their weaknesses and potential pitfalls. Those who participate in focus groups may give “public” accounts as they present themselves to other group members. Certain types of participants
FOCUS GROUPS

may also dominate the discussion and silence those who are less verbal or confident, or, worse still, there may be saboteurs who are determined to refocus the discussion around their ideas and agenda, thereby overlooking the wishes of the moderator. Furthermore, focus groups can be hard to recruit beyond the usual suspects. One of the most significant criticisms levied at focus groups is that they are difficult to run and, therefore, rely very heavily on skilled moderators (Krueger 1998).

The development of focus groups as an established qualitative research method is somewhat contested, however. Focus groups are often linked with interviews (and, in particular, group interviews) and most strongly associated with market research where a group of people are consulted about a product, event, or issue. It is important to differentiate between focus groups – which are one-off group meetings – with in-depth groups that meet on more than one occasion (and often on many occasions over a period of time) and have their origins in training, educational, and therapeutic contexts. Generally, the intentions of both methods are very different. Focus groups aim to gain one-off insights into a particular issue in a group; although this may also be one of the aims of an in-depth group, it is likely that in-depth groups will have additional primary aims such as training people in a particular skill or technique, or acting as a therapeutic context in which people can improve their wellbeing over a period of time. As such, comparing focus groups to university tutorial or seminar groups is unhelpful, as often these are not one-off and the overall aim is to improve students’ knowledge and understanding over a period of time rather than having only a one-off group discussion.

Given the significance of the role of the person who moderates a focus group, much of the literature often focuses on the skills required to be a good moderator (e.g., Krueger 1998). Issues here include how to gain the consent of and other information from each person, as well as how to facilitate the introduction of group members to each other and how to generate the initial discussion. With some focus groups, it may not be clear how many people will actually turn up, so the moderator may need to be prepared for different sizes of groups and the different skills required. During the focus group discussion, the moderator also needs to balance how often they intervene to steer the discussion and how they manage group members who are either very quiet or who dominate the group. Furthermore, unless the moderator is working with another researcher who observes the discussion and takes notes, they will need to try to keep track of who says what to facilitate the process of transcribing the focus group and correctly allocating statements to participants.

There are a number of methodological considerations to take into account when employing focus groups as a method of data collection. These can include, but are by no means limited to, the number of participants in the group; the composition of group members; location, timing, and context; as well as other factors including the sensitivity of the topic, the age of the participants, and the positionalities of the researcher and the participants. The main factors that often determine the success of a focus group are the focus of the researcher/moderator and the interaction of the group. These additional considerations are important for those aiming to conduct rigorous and ethical research.

Most definitions of focus groups include some reference to the number of people needed for the group and these tend to range from as low as 4 to as high as 12. However, the most important aspect of the focus group method is group interaction in discussing a particular topic rather than the number of participants.
Depending on the particular topic and the social group participating, the optimum number of focus group members will vary. For some topics, it will be very challenging to moderate a focus group discussion with 12 people, whereas for others it may be challenging to generate a discussion with only four people. A useful example that challenges the focus on numbers is research about pregnant women’s experiences of public spaces in New Zealand, in which Longhurst (1996) conducted three focus groups, to which only two women turned up. These ended up being a useful form of data collection and offered the researcher insights into the research topic despite their having been initially categorized as “failed” focus groups. In a second example, Hopkins (2007) found that, in working with Muslim young men, larger groups were more difficult to moderate compared to those with only three or four participants, because the smaller groups provided the opportunity for each participant to voice their opinion, which was not always offered by the larger groups.

In terms of group composition, some of the focus group literature claims that focus group participants should have shared characteristics in terms of the criteria for selection (e.g., gender, age, ethnicity, location) but should not know each other (Tonkiss 2004). This is problematic as it is based on the principles of survey logic and makes assumptions about who does and does not know each other. Holbrook and Jackson (1996) observed that focus groups with people who already know each other and group discussions with people who have never met before have different strengths and weaknesses. Focus groups where participants are unknown to each other may require more work from the moderator to facilitate introductions and generate initial discussion compared to focus groups with people who already know each other. On the other hand, focus groups with those unknown to each other may result in people being more considered about their opinions, whereas focus groups with people who know each other well may be informed by subtle power struggles that may shape the discussion in particular ways and that remain undisclosed to the moderator. Researchers using focus groups as a method of data collection should therefore consider these important methodological issues when recruiting and moderating focus groups.

Location, timing, and context are also important considerations when planning and conducting focus groups and when analyzing the data that emerge from them (Hennink 2014). The physical location of the focus group discussion often requires careful consideration to ensure that participants feel comfortable and able to discuss the topic. Related to this, the timing of the focus group needs to be thought through. For example, office workers who regularly work from 9 to 5 are unlikely to turn up at an afternoon focus group, and some older people may not want to attend a focus group that takes place late in the evening when it is dark. Finally, there may be significant contextual matters to consider such as political events or local activities that might shape the focus group discussion. This may include issues such as local or national elections, protests, strikes, or community events that may limit focus group participation or result in the focus of the discussion being shaped by specific events that are happening at the time (Hopkins 2007).

There are a range of additional issues that human geographers should consider when conducting focus groups, many of which are related to the points already raised. One factor to consider is the sensitivity of the topic. While some topics may be so sensitive that it would be ethically inappropriate to discuss them in a group setting, others may usefully be explored in a focus group; sensitivity should be demonstrated
FOCUS GROUPS

in the choice of the size and composition of the group, as well as the location and context of the group discussion. For example, the small size of the group may be one of the reasons why the focus groups that Longhurst (1996) conducted with pregnant women were so successful. This is a very personal topic and some of the participants may not have been as comfortable sharing their experiences in a large group. Related to this, the age of the participants and the positionalities of the researcher in relation to the research participants may also be important considerations (Hopkins 2007).

Food security

Colin Sage
University College Cork, Ireland

The origins of the term “food security” are often traced to the 1974 World Food Conference. This was called in the wake of a series of humanitarian disasters affecting the Horn of Africa, South Asia, and the Sahel (1972–1973); the Soviet Union’s secret emergency purchase of US grain following its own harvest failures; and the escalating global increase in cereal prices between 1971 and 1974. The conference gave rise to the first widely adopted definition of food security as the “availability at all times of adequate world food supplies of basic food stuffs … to sustain a steady expansion of food consumption … and to offset fluctuations in production and prices.” Yet, despite an apparent consensus by scholars as to this origin, it has been argued that food security can be traced back to Europe and World War I. Edelman (2014) asserts that the term was strongly linked to concern for national security and to the capacity of each country to produce its own food such that it would reduce its political and military vulnerability. This framing resonates strongly with contemporary discussions of the related concept of food sovereignty, to which this entry will return. It is clear that food security does have a longer history than many acknowledge and, indeed, featured in statements made during the 1943 Hot Springs Conference of allied governments which was regarded as the first step in founding the Food and Agriculture Organization of the United Nations (FAO).

The 1974 definition was naturally a consequence of its time and is clearly framed by the imperative of production and supply that strongly resonated with the prevailing agricultural modernization discourses of the era, best exemplified by the Green Revolution model of technology transfer. The development and dissemination of high-yielding varieties of wheat and rice as part of a “package” of technologies that sought to increase scale, levels of mechanization, and market orientation while successfully increasing “output” were to have enormous unanticipated consequences for rural societies. While aggregate output rose in those regions endowed with the necessary resources (soils, water, and infrastructure) required for the technology (principally Southeast Asia, the Punjab, parts of Latin America), other regions (especially in sub-Saharan Africa) were marked by deepening hunger, malnutrition, and disease. Understanding of the complexities of food insecurity and vulnerability was aided by local and regional studies conducted by geographers and other rural development specialists.

However, probably the single most important contribution to shifting the prevailing view of food insecurity was the publication of Amartya Sen’s Poverty and Famines (Sen 1981). Here Sen forcefully demonstrated that hunger and starvation are not an inevitable consequence of a decline in the availability of food, but rather reflect the circumstances of people not being able to secure access to food. For Sen, this can be explained by understanding people’s entitlement relations, which might derive from endowments in land, other assets, or their labor power and which provide the basis for survival under “normal” conditions.
Changing circumstances, such as the occurrence of drought, may reconfigure entitlements as the abandonment of agricultural production in the absence of rainfall, for example, renders rural wage laborers vulnerable to unemployment and hunger. Livestock owners face a similar predicament as, in the absence of adequate grazing, animals weaken and their value drops, while grain prices invariably soar. Entitlement theory consequently contributed to a shift in food security thinking away from the macroscale and toward the individual and household level.

Food security was, moreover, once synonymous with the supply of high-calorie staples such as cereals and tubers to resolve problems of protein-energy malnutrition. The logic of the Green Revolution was to deliver increased calories above all. But calorie intake says little about nutritional status, and by the late 1980s health and nutrition research better understood that minerals, vitamins, and trace elements – including iron, iodine, folate, and vitamins A, B complex, and C – play a critical role in human wellbeing. Globally, today, “over 165 million children are stunted and two billion people lack vitamins and minerals for good health” (Khoury et al. 2014). Indeed it has been estimated that 2 billion people are anemic – over 30% of the world’s population – making it the most widespread nutritional disorder in the world.

By the time of the World Food Summit in 1996 the definition of food security had evolved to reflect issues of access and the variety of analytical scales from the household to the global level, as well as social and cultural influences over food preferences. Thus food security is said to be achieved when “all people, at all times, have physical and economic access to sufficient, safe, and nutritious food to meet their dietary needs and food preferences for an active and healthy life.”

Clearly, then, the notion of food security is a storied term for which it has been estimated there are more than 200 definitions and 450 indicators. In part, the multiplicity of meanings attached to food security can be attributed to the boundary nature of the concept: it has crossed many academic disciplines besides geography, and been a focus for applied work in the agricultural, environmental, and health sciences. Yet, if there is one pillar that has anchored food security discourse over the past half-century or more, it is the central role of technology-led production as the key to food availability.

**Food security and productivism**

From the second half of the twentieth century, astonishing increases in agricultural productivity were achieved as a consequence of a series of interconnected technological developments, which Mazoyer and Roudart (2006) conceptualize as:

- motorization: the development of increasingly powerful tractors and engines fueled by oil, substituting capital for labor;
- mechanization: increasingly complex and effective machinery streamlining production throughout the food chain; and
- chemicalization: the deployment of growing volumes of synthetic fertilizers and pesticides, as well as associated developments in plant and animal genetics.

This model, which has come to be labeled *productivism* for its singular focus on output, has enabled the world today to produce sufficient food by volume of crops to meet the needs of the world’s growing population. Of course, there are an estimated 870 million malnourished people whose present state of food insecurity is a consequence not so much of output as of a failure
of access, compounded by locally contingent variables such as affordability or conflict. Yet productivism, together with the development and intensification of global trade, has proven the axiomatic principle promoted by international organizations and national governments by which food security would be achieved.

The development of the global food system since the 1980s has witnessed the emergence of new trading patterns that have had huge repercussions for some of the poorest and least food-secure countries. For example, the rise of the new agricultural exporting countries such as Kenya has led to their engagement with nontraditional, high-value fruit, flower, and vegetable contract production for major supermarket chains in the North. Meanwhile other countries have witnessed extensive cereal and oil seed cultivation in response to the rising global demand for livestock feed and biofuels. Such large-scale commercial developments have often served to marginalize millions of small farmers through dispossession of land, depletion of water resources, or loss of local market share. At the same time, closer economic integration leads to increased exposure to international market forces for hundreds of millions more.

During the first decade of the twenty-first century, cereal prices rose to their highest levels in real terms since the early 1970s, reaching a peak in 2008, which was followed by significant price volatility. Such dramatic increases triggered violent protests and widespread civil unrest across the world as household budgets could no longer meet basic dietary needs and the number of food-insecure people reached 1 billion. Unsurprisingly, attention turned to identifying the drivers of these price rises, and their continuing volatility. Among the drivers for which analytical models demonstrated a link with food prices were: financial speculation on global commodity markets; extreme weather events and potential climate perturbations; declining grain stocks, possibly linked to falling public investment in agriculture over two decades; and rising consumer demand, as a consequence of demographic increase and also of changing dietary composition. However, the clearest correlation with the behavior of food commodity prices was that of hydrocarbon energy prices which rose steadily through the decade, reaching a peak in July 2008 before falling back. For many analysts it is higher oil prices and the associated expansion of the biofuels sector that has been most responsible for undermining food security worldwide.

A consequence of tightening oil markets as demand outstrips supply capacity has resulted in a huge boom for biofuel crops capable of being converted to either ethanol or biodiesel. By 2010, the combined amount of maize and sugarcane from the United States and Brazil respectively used as feedstock for ethanol amounted to 460 million tonnes, or 6% of global crop production by mass (Cassidy et al. 2013). It has been estimated that the volume of maize currently diverted to ethanol distillation in the United States would be sufficient to feed 400 million people for one year. The setting of mandatory targets for utilization of renewable energy sources in the transport sector by the European Union, the United States, and other countries has driven the expansion of maize and sugarcane, as well as palm and other vegetable oils, for conversion to biodiesel, across arable land. The essential fungibility of agri-commodities like these suggests that the food needs of the poor are subordinate to the energy requirements of the more powerful. This is best illustrated by the appropriation of land currently underway throughout the poorest countries of the Global South as powerful states and corporations engage in deals to acquire land and water resources. It has been estimated that up to 227 million ha – an area equivalent to the
total arable land of Western Europe – has been identified as suitable for occupation by foreign investors. Two-thirds of this land grabbing is in Africa, and 60% is destined for biofuel crops.

The logic of productivism, then, is to raise output and trust in the power of markets to enable people to get access to food. Yet the multiplicity of challenges – such as those regarded as drivers of the food price spikes of 2008 and beyond – demonstrate the increasing vulnerability of the food system. Indeed, there are particular anxieties around the impacts of climate change, freshwater depletion, impairment of ecological services, and the consequences of tightening energy markets that are leading many to believe that we need to move away from the productivist model. While policy analysts may argue over the rank ordering of drivers, it is clear to many that the global food system has become increasingly sensitive to a variety of short-term episodic shocks and lacks the resilience to cope effectively with such events. The task now facing us, therefore, is to optimize production across a far more complex landscape involving environmental sustainability, social justice, and nutritional security.

**Sustainability, sovereignty, security**

The first decade of the twenty-first century has consequently witnessed a reinvigorated global debate about food security, such that it has been said to constitute one of the key master frames of public policy. Rising and volatile food prices and associated political instability, together with projections over future needs, have raised the stakes in formulating legitimate solutions to food security. In particular, framing the problem as one of pressing future demand emerged from the 2008 Rome Summit on World Food Security. Here, two key projections were presented that have since become central pillars of global food security discourse: (i) that food production needs to increase by 50% by 2030 to meet rising demand; and (ii) that it needs to double by 2050 to feed a world population of 9 billion (Maye and Kirwan 2013).

Focusing on these projections has been a particular feature of those who favor treating food security as a scientific problem requiring technical solutions and where agricultural biotechnology and genetically modified (GM) seeds are regarded as the most effective way to feed the poor in developing countries. Proponents of this approach most often focus on the low yields of indigenous farming systems and argue that modern technologies through a new Green/Gene Revolution could do much to achieve food security across the poorest countries. Critics, on the other hand, have argued that not only does this emphasis on untried, imported technologies smack of a neocolonial attitude that undervalues the knowledge and adaptability of small farmers, but it runs the risk of deepening vulnerability to distant input markets as well as conspicuously failing to appreciate changing local environmental circumstances. Perhaps the most comprehensive case for a change of direction from high-tech productivism was set out by the International Assessment of Agricultural Knowledge, Science and Technology for Development (IAASTD 2009), which argued that industrial agriculture alone will not resolve the problems of hunger and poverty, and that it is incapable of adapting to the environmental challenges that lie immediately ahead.

A more pragmatic approach emerged in the wake of the 2008 crisis from a UK Government Foresight exercise that served to advance the concept of sustainable intensification (SI). Essentially, SI means producing more food from the same amount of land but with less environmental impact, a notion that has led its critics...
to suggest that SI means we can have our cake and eat it too. However, SI is concerned with halting and even reversing the continued expansion of agricultural land, recognizing the “new fundamentals” associated with climate change, freshwater depletion, and other resource limits. Hence its emphasis rests on the intensification of existing agricultural land, although this should not be pursued without due regard for other multifunctional benefits such as carbon sequestration and biodiversity conservation. Nevertheless, it is a concept that remains largely focused on the two Rome Summit key projections and that promotes a largely technology-centered approach where bioscience, nanotechnology, and information and communication technology (ICT) are regarded as keys to future food security.

If the development of a reinvigorated global debate about food security has revealed a sharply fractured consensus, it has also enabled a strong counterhegemonic discourse to be heard. Emerging from a highly heterogeneous constituency – from peasant movements in the South to food activists in the North, together with some very eminent global policy experts and leaders – this alternative discourse encompasses many divergent aspirations but shares a rejection of the technology-centered, business-as-usual approach in favor of an overarching goal of making agri-food systems more resilient. Questions of social justice, the cultural value of food, public health, and sustainability also crowd in to this alternative conceptualization of food security in an environmentally uncertain and changing world.

Among the most important claims proposed by this broad movement is that of food sovereignty. This is a term that also has a more obscure origin than is generally acknowledged, but it is most commonly associated with the international peasant movement Via Campesina, and is rooted in a rights-based framework that insists on food being treated as a basic human right. Food sovereignty has been widely proclaimed and reaffirmed, and in 2012 the FAO’s Committee on World Food Security agreed to its adoption. Indeed, the ascendency of food sovereignty as a potential policy proposition has helped it to move from being considered an entirely oppositional term associated with an antiglobalization agenda to one that is now entangled with food security. By insisting on the relational and rights dimensions of food, the notion of food sovereignty has begun to establish not only the human right to eat but also the right to produce. In this regard it challenges the existing food system built on the disembedded production of tradable commodities and transformed by large-scale manufacturing into cheap, processed, global brands. For, as diets worldwide become more homogeneous, they also appear to be less healthful, with a higher consumption of processed and convenience foods rich in saturated fats, sodium, and sugar. It is these growing dietary practices (malconsumption) that appear to account for an estimated 2 billion people worldwide being considered overweight and obese and susceptible to a host of medical problems that are thought to cost the global economy up to $2 trillion.

Food security, then, has become an increasingly contested term and one that is challenged by more intractable and interconnected threats than “simply” global hunger. The interlocking of food and energy markets; climate change and freshwater depletion; and diet-related ill-health all serve to make the solution a great deal more complex than one of “doubling output” (Sage 2013). Reframing food security in relation to food sovereignty may serve to demonstrate the vital importance of policy measures at all levels – from local to global – that will be required if we are to find ways to enable everyone to eat sustainably, healthily, equitably, and securely into the future.

Fordism/post-Fordism

Tu Lan
University of New Hampshire, USA

Fordism was a model of economic development characterized by mass production and mass consumption in the United States and Western Europe between the 1930s and 1970s. Post-Fordism includes a number of alternative development models flourishing after the crisis of Fordism in the 1970s. Both concepts have been widely used by geographers, particularly of the Marxist tradition, to study changing labor relations and associated social formations in major capitalist economies.

The term “Fordism” was originally used by Antonio Gramsci (1971, 277–316) to describe the forms of production pioneered by Henry Ford’s automobile industry. Gramsci attributed the higher productivity and relatively more stable labor relations in the United States to Frederick Taylor’s reinvention of assembly lines, a rational demographic composition, a higher wage, and “a specific mode of living and of thinking and feeling life” (1971, 302).

On the basis of Gramsci’s work, the French regulation school developed a conceptual framework to analyze Fordism. It argues that capitalism has no permanent solution for its inherent contradictions of overproduction and falling rate of profit, and that any stable period of capitalist accumulation is therefore historically contingent on a regime of accumulation and a mode of regulation.

According to Alain Lipietz (1987) and Bob Jessop (1991, 136–137), Fordism has four major dimensions. First, Fordism was made possible by the labor process of Taylorism, in which unskilled labor specializing in simple, repetitive work on the assembly lines was separated from skilled and engineering labor at the managerial level. Taylorism, together with rapid mechanization, significantly raised the productivity of standardized commodities, such as Ford’s automobiles. It was the precondition for mass production.

Second, Fordism needs a regime of accumulation which concerns the allocation of social resources between different departments of production and between production and consumption. In order to maintain the rate of profit, increasing mechanization needs to be balanced out by the rising productivity of equal rate, while the rising productivity has to be absorbed by the rising purchasing power. Therefore in Fordism, mass production necessarily leads to mass consumption.

Third, the Fordist regime of accumulation requires a specific mode of regulation of wage relations. In particular, it must ensure a rising wage level for the working class to buy the commodities that are put out by mass production. Regulationists believe that Fordist wage relations are based on an institutional arrangement which is a result of a consensus within the ruling bloc of the individual states. Consequences of the consensus include the welfare state, nationalized trade unions, and a centralized banking system based on the gold standard of the US dollar.

Finally, Fordism also had widespread consequences in the broader society, such as a lifestyle of nuclear families who consume standardized goods, which Jessop called “a general pattern of social organization” (1991, 137).
Fordism went into a crisis signaled by the end of Bretton Woods system in 1971. The crisis was due to three main reasons. First, productivity failed to catch up with the rate of mechanization, leading to the rising organic composition of capital since the 1960s. Therefore, the overall rates of profit in major capitalist economies continually fell, making mass production untenable. Second, multinationals started to outsource manufacturing jobs to newly industrialized countries (NICs), leading to the stagnation of the wages of the working class in the United States, which made mass consumption unsustainable. Finally, short-term incidents such as the oil embargo by Arab countries in the 1960s and 1970s also severely halted the capitalist accumulation of major capitalist economies.

There have been multiple post-Fordisms, that is, alternative development models in response to the Fordist crisis (Amin 1994). In geography, by far the most influential has been flexible production or flexible specialization. This work is closely related to the literature on Italian industrial districts. In contrast to the mass production of vertically integrated corporations in the United States and Western Europe, industrial districts in Italy were renowned for their just-in-time production of small and medium-sized enterprises (SMEs). It is argued that changes on the demand side from standardized to diversified goods in Western consumer markets necessitated the transition from Fordism to flexible production (Piore and Sabel 1986).

For geographers, the transition to flexible production in each of the regions has always been specific. For example, Allen Scott (1988) and Michael Storper (1997) showed the importance of territorial embeddedness in just-in-time production. Focusing on the cultural dimension of Fordism, David Harvey (1991) argued that the flexibilization of labor led to the fragmentation of postmodern cultures in the West. Lipietz (1997) observed that, in certain capitalist economies such as Germany and Japan, the main response was a “negotiated involvement of the workers,” whereas in the United States the primary response was neo-Taylorism, in which flexible production was achieved by labor outsourcing and a rollback of social welfare. More recently, Jessop (2013) summarized two post-Fordist regimes of accumulation as the knowledge-based model in Europe and the finance-dominated model in the United States and the United Kingdom, both of which have been discredited after the global financial crisis in 2008.

Many features of post-Fordism, such as flexible specialization of labor and the cutting of the social welfare, have been articulated into the broader project of neoliberalism. However, for Marxist geographers, none of the alternative models is likely to permanently solve the inherent contradictions of capitalism.

In a seemingly unassuming article published in *Science* in 1967, Mandelbrot (1967) posted a question that geographers and cartographers had been puzzling about: How long is the coast of Britain? The answer to this coastline measurement problem, as most geographers had known, would depend on the length of the divider used to traverse the zigzagging coastline on the map, and the total coastline length would be the product of the number of divider steps needed to traverse the line multiplied by the divider length. The intriguing part of this measurement problem is that, given a contorted coastline, the smaller the divider length used, the longer the coastline is. Further, the more contorted the coastline, the more drastic the difference in the resultant length measurements from using varying divider lengths. This phenomenon, also called the Steinhaus paradox, has long been observed by geographers and researchers alike. But Mandelbrot was able to capture and quantify the relationship between coastline length, its measurement scale (divider length), and the complexity of the line by using a new concept called fractals.

The coastline measurement problem was just one of the phenomena that prompted the development of fractals. Through observation of real-world objects, Mandelbrot found that most spatial patterns of nature, such as clouds, terrains, forests, and mountains, look so irregular and fragmented that classical geometry is not efficient in describing and quantifying their complexity. In classical (Euclidean) geometry, the objects are defined by an integer dimension, which is also called the topological dimension. A point has a topological dimension of zero, a line is one-dimensional, a plane has two dimensions, and a cube three dimensions. In Mandelbrot’s fractal geometry, objects have fractional dimensions called the fractal dimension \( D \). A point can have a fractal dimension ranging from zero to one, a line from one to two, and an area from two to three. The higher the fractal dimension of the object, the more complex is the geometry of the object. Real-world coastlines have fractal dimension values typically around 1.2–1.3, and topographic landscapes around 2.2–2.3. Dimension values for satellite image surfaces have been reported to be much higher; depending on the type of landscape examined, they can be as high as 2.7–2.9 (Lam 1990). This major paradigm shift in geometry thinking was further elaborated and crystallized in Mandelbrot’s subsequent publications, which led to many followers and applications.

Since Mandelbrot’s first book *Fractals: Form, Chance, and Dimension* published in French in 1975 and translated in English in 1977, fractal analysis has blossomed and dominated the scientific literature for over two decades (Mandelbrot 1977, 1983). During the 1980s and 1990s, studies on fractals can be found literally in every major discipline, ranging from physics, chemistry, biology, engineering, and geography to music and arts. Scientists found fractals and fractal geometry an attractive concept that could be used to explain the complexity of the world. The movie and video game industry (such as “Star Wars”) utilized the fractal technique to
enhance the simulation and visualization, and this helped popularize fractal analysis to the non-science communities and the public during those years. The significance of the fractal concept has been said to be comparable to the concepts of entropy, chaos, or Gaussian distribution. It was once proclaimed that no one would be considered scientifically literate if the meaning and scope of fractals was not understood (Batty 1985; Lam 2009).

Fractal analysis has a long tradition in geography. Geographers started examining the fractal concept and its potential applications as early as the 1980s (Goodchild 1980; Lam 1980; Arlinghaus 1985; Batty 1985; Clarke 1986; Goodchild and Mark 1987). The fractal concept addresses fundamental issues that have long plagued geographers and spatial scientists, such as the issues of scale, map generalization, and landscape measurement and characterization. While fractal analysis has generated many successful applications and valuable findings, there are also major misunderstandings, problems, and misuses of fractals. Literature on fractals and fractal analysis is abundant across disciplines. This entry focuses on fractals as applied in geography. The goal is to provide a better understanding and appreciation of fractal analysis in geography. The basic concept of fractals is first explained and some key methods for computing fractal dimension and simulation are introduced. Then, a number of fractal applications are highlighted, with issues related to fractal analysis summarized. The entry concludes with remarks on issues and future development of fractal analysis.

Fractal measurement

In defining the fractal dimension, Mandelbrot employed a concept called self-similarity. Many spatial forms such as curves and surfaces are self-similar, meaning that each portion can be considered as a reduced-scale of the whole. The degree of self-similarity, expressed as a similarity ratio, is used to define the theoretical fractal dimension $D$ (equation 1):

$$D = \log N/ \log (1/r) \quad (1)$$

where $r$ is a similarity ratio (i.e., a scale reduction factor) and $N$ is the number of steps needed to traverse a curve. To illustrate how to determine the fractal dimension of a curve, consider a straight line and a divider step size of 1/4 of the line length (i.e., $r = 1/4$), it will take four steps ($N$) to traverse the straight line. Applying equation 1, $D = \log 4/ \log (1/(1/4)) = 1.0$. If the complexity of the line increases such that it takes six steps to traverse the line, then $D = \log 6/ \log (1/(1/4)) = 1.29$. As the complexity of the line increases, the fractal dimension increases, until it reaches a theoretical maximum fractal dimension of 2.0 for a line.

Since most natural forms, curves, and surfaces are not strictly self-similar but rather statistically self-similar, the fractal dimension will need to be estimated statistically through the regression technique. Regardless of the difference among different fractal measurement algorithms, the regression technique often involves three steps: (i) measure an attribute of the object (e.g., length, area) using various step sizes; (ii) plot the logarithm of the attribute of the object against the logarithm of the step size, also called the fractal plot, and fit a linear least-square regression line through the data points; (iii) estimate the slope of the regression line, which is used to determine the fractal dimension. For a curve, the fractal dimension is determined by equations 2 and 3:

$$\log L = K + B \log S \quad (2)$$

$$D = 1 - B \quad (3)$$

where $L$ is the length of the curve, $S$ is the step size, $B$ is the slope of the regression, and $K$ is a
constant. These equations show that the more irregular the curve, the greater the increase in length as step size decreases, hence the steeper the negative slope, leading to a higher fractal dimension. The $D$ value of a surface can be estimated in a similar fashion, but using equation 4 instead of equation 3:

$$D = 2 - B$$  \hspace{1cm} (4)$$

For a reliable regression estimate, at least five step sizes should be used. This means that in a logarithmic scale, if the initial step size is 2, then the subsequent step sizes would be 4, 8, 16, 32, and so on, which can quickly reach the limit of the line length. Therefore, in reality, the fractal plot seldom has a lot of data points for regression. The goodness-of-fit of the regression, the $r^2$ value, is used to indicate if the estimated $D$ value is reliable. Table 1 compares the estimated and theoretical $D$ values for three curves using the walking-divider method described above. The circle and the Koch curve were generated by computer routines, whereas the Louisiana coastline was digitized from a 1:1,350,000-scale map that resulted in 485 digitized $x,y$ coordinate pairs.

As can be seen from Table 1, the measured $D$ values are very similar to the theoretical $D$ values. However, it is also observed that the $r^2$ value of the circle measurement is very low ($r^2 = 0.489$), implying that the fractal plot is not linear. In fact, a number of studies have already found that fractal plots of empirical curves are seldom linear for all step sizes, indicating that true fractals with self-similarity at all scales are uncommon. This observation shows that fractals and “scale,” another central concept in geography, are intimately related. Instead of including all the data points to create a single regression line when they do not behave linearly, breakpoints can be used to delineate a specific range of scales at which the fractal dimension is measured. In other words, the fact that self-similarity exists only over a limited range of scales could be utilized to summarize the scale changes of an object or a pattern (Lam and Quattrochi 1992). This scale issue subsequently leads to an extension of basic fractal analysis into multifractal analysis to examine multiscale objects and patterns and local fractals to capture local variations.

Measuring the fractal dimension of curves is relatively straightforward, even though a number of arbitrary decisions have to be made, such as the choice of the initial step size, the number of step sizes used, and the range of scales (i.e., breakpoints) used to derive the slope of the regression. Extending the fractal dimension measurement to surfaces, however, is not straightforward, and many more arbitrary decisions are needed to be made. Numerous methods have been developed to calculate the fractal dimension of a surface, which unfortunately often lead to very different results. Fractal dimension is defined differently in different algorithms by different

FRACTAL ANALYSIS

researchers. Some algorithms use only a single measurement instead of multiple step sizes and regression analysis to derive the dimension. For example, FRAGSTATS, a free software package to compute landscape indices, defines the fractal dimension as the ratio between the perimeter and its area of a patch, which is different from many other fractal surface measurement algorithms. Previous research compared several algorithms, such as box-counting, variogram, isarithm, and triangular prism, and found that the latter two methods are more accurate. These two algorithms are briefly described here to illustrate their different approaches, so that a better understanding of the fractal surface measurement can be gained (Lam 1990; Lam et al. 2002).

The isarithm method for measuring the surface dimension is intuitively simple; it can be considered as a direct extension of the walking-divider method, except that the curves measured are now isarithms derived from the surface (e.g., contours in relief surface). In extending the method from curve to surface estimation, two additional considerations are needed – how many isarithms should be used to represent the surface and how should these isarithms be averaged to derive a composite $D$ value? Because of these ambiguities, another method, the triangular prism method, is often preferred.

The triangular prism method follows the same logic but uses a different strategy. It defines the surface by a mesh of grids and measures the area of the surface at different grid step sizes. The surface area at each step is the sum of the surface area of the triangular prisms constructed by connecting the height (i.e., $z$ values) of the four corners of each grid step and its center. The logarithm of total surface area is then regressed against the logarithm of step size (not step size squared as documented in Clarke 1986), and the fractal dimension is calculated as two minus the slope of the regression line as in equation 4.

The triangular prism method has been improved over the years and previous research found the method robust and accurate. A version of the improved triangular algorithm, plus several other fractal measurement algorithms, can be found in a software package called ICAMS (image characterization and modeling systems), which was developed by the authors and collaborators and is available for the public to download (www.rsgis.envs.lsu.edu/icams.asp) (Lam et al. 2002).

Fractal simulation

Another hallmark contribution of fractal analysis is its ability to simulate real-world objects and patterns. Enhanced with computer graphics color rendering, images generated from the fractal technique are often so striking and compelling that filmmakers, artists, and musicians use the method to produce extraterrestrial landscapes, fractal music, and design patterns (Peitgen and Richter 1986; Peitgen and Saupe 1988). The Mandelbrot set was reportedly the most complex mathematical set in the literature and has since become an icon of fractals. In geographic analysis, measurement using the fractal dimension is the first step towards scientific understanding of complex forms and processes, whereas simulation that mimics reality often leads to further understanding of spatial processes.

In searching for a stochastic model that can simulate fractal patterns closely, Mandelbrot employed the Brownian motion model in physics. Brownian motion refers to the irregular movements of small particles, the time series of which often shows a highly autocorrelated sequence, indicating a long-time dependence on previous movements. Brownian trails are fractal sets, with a fractal dimension of 1.5 for a Brownian curve and a fractal dimension of
2.5 for a Brownian surface. Mandelbrot combined Brownian functions with the concept of self-similarity and developed a new model called the fractional Brownian motion (fBm) functions. From these functions, curves and surfaces of other dimensions can be generated, hence they are also called the fractional Brownian motion (fBm) curves and surfaces. Several algorithms can be used to generate fractal curves and surfaces, including the shear displacement method, the modified Markov method, the inverse Fourier transform method, and the recursive subdivision method. Figure 1 displays three simulated surfaces in 3-D and the corresponding 2-D images generated by the shear-displacement method, which shows clearly that as \( D \) increases, the complexity of the surface increases (Goodchild 1980; Lam et al. 2002). The algorithm is also available in the ICAMS software previously mentioned.

Fractal applications

Fractal applications in geography generally fall into two groups. The first group uses fractals to generate real-world objects and patterns for both analytical and visualization purposes. The second group uses the fractal dimension or the power function as an aid in describing the complexity of spatial forms and patterns. Such applications can be further classified into three categories: applications in geospatial analysis, analysis of physical processes, and analysis of human phenomena. Each type of application is briefly described here.

In simulation applications, the fractal model provides a theoretically sound approach to simulate curves and surfaces for scientific analysis. The range of surfaces and curves simulated with a prescribed fractal dimension value is an ideal test-bed for evaluating geographical models and algorithms. For example, simulated fractal surfaces have been used as test datasets to examine the performance of various spatial interpolation methods and the efficiency of different spatial data structures. Another major type of applications is to use the fractal simulation technique as an interpolation method to generate coastlines and curves based on a few sample points. This curve generation process is, in fact, an inverse of curve generalization, and such algorithms could be implemented in a geographic information system for automated map displays at varying levels of cartographic generalization. In physical and environmental applications, researchers developed elaborated algorithms for deriving river networks from simulated fractal surfaces to help understand the various properties of geomorphic processes. In human geography, a number of studies applied the fractal model to simulate central place hierarchy, urban morphology, and urban growth. Last but not the least, researchers have used simulated fractal surfaces as a null-hypothesis terrain or norm, whereby further simulation of various geomorphic processes can be made to investigate the effects of different landform processes.

There are numerous applications of the fractal model in measuring and evaluating spatial phenomena. In the subfield of geographic information science and remote sensing, Goodchild (1980) in a pioneer article demonstrated that the fractal dimension can be used to predict the effects of cartographic generalization and spatial sampling on some common measures such as length, area, and point estimation. The dimensionality of the object or pattern can be input into an equation to estimate the relative benefit of using finer grid cells or denser sampling. This finding helps in determining the optimum resolution of pixels and polygons used in remote sensing and GIS studies.
Figure 1  Three simulated surfaces and corresponding images; from top to bottom, $D = 2.1$, 2.5, and 2.9. Adapted from Lam et al. (2002). Reprinted by permission of Taylor & Francis (http://www.tandfonline.com).
Fractal analysis of physical processes takes many forms. Researchers have used the fractal dimensions computed for different parts of a coastline to infer the underlying coastal processes that shape the coastline. A smooth coastline suggests the dominance of large-scale marine process such as ocean currents, whereas a contorted coastline is likely a result of local deltaic deposition and land subsidence. Other studies use the fractal plots to describe the power function relationships between physical variables, such as the power function between stream length and basin area and the time series of river bedload transport. In the latter case, the fractal structure of the time-series data of river bedload transport offers insight into the underlying mechanics of bedload movement and provides information that can be used to establish guidelines for bedload sampling (Lam and De Cola 1993). In ecological applications, the fractal dimension has been used together with other spatial indices to characterize the different tree types as manifested in remote sensing images. The fractal dimension has also been found useful to indicate the degree of human disturbance in natural landscapes; the higher the fractal dimension yielded, the least disturbed the landscape by humans.

Many human-dominated processes exhibit fractal patterns. The city’s rank–size rule is a well-known example of the fractal power function. Also, researchers have linked the classical Christaller’s central-place hierarchy in urban geography with fractals and found that a $K = 3$ central place hierarchy has $D = 1.26$, whereas $D = 1.13$ for a $K = 7$ hierarchy. For a $K = 4$ hierarchy, which is the most complicated boundary configuration, $D = 1.58$. It has been suggested that if two urban areas have the same fractal dimensions, it may mean that similar planning actions could be applied (Arlinghaus 1985; Lam and De Cola 1993). Batty and his collaborators have conducted extensive research on fractal cities (Batty and Longley 1994). Their research suggests that urban growth follows a form of fractal process, called the diffusion-limited aggregation (DLA) process, and that it is possible to classify a city’s development history based on the fractal dimension.

Issues and development

After the first wave of fractal applications in the 1980s–1990s, a number of problems associated with fractal analysis arose; further development of the fractal model and technique has since been made. First, the fractal model has been criticized by some researchers because self-similarity across all scales rarely exists in natural phenomena and reducing the complexity of spatial patterns into a single dimension runs the danger of oversimplification. The subsequent development of multifractals and local fractals has made the fractal analysis more flexible and applicable. Furthermore, instead of regarding the scale–dependency of fractals as a shortcoming, researchers have utilized the information on the changes of the fractal dimension with scale to help interpret the underlying spatial processes at specific scale ranges.

The second problem of fractal analysis refers to the inconsistency of measurement. Different researchers employ different algorithms and their measurement results often differ, sometimes substantially. How to determine which computed value is the most accurate one? And how do we know when a computed fractal dimension value is statistically significant? Consider two surfaces, one with a $D$ value of 2.2 and the other with a value of 2.3, are they statistically the same or different? Associated with the measurement problem is that most fractal curve and surface measurement algorithms have not been tested systematically. Also, these algorithms were seldom designed for general use or made available
FRACTAL ANALYSIS

to researchers. The difficulties and time involved in programming their own algorithms have prevented more geographical studies from using fractals.

Subsequent advances in the fractal studies have led to more algorithms and software being made available for use by the public. The development of a software package called the image characterization and modeling system (ICAMS) is one example (Lam et al. 2002). Funded by US federal agencies such as the National Aeronautics and Space Administration (NASA), ICAMS was developed to provide algorithms for computing fractal dimensions for surfaces and images, generating fractal surfaces, as well as computing a number of related spatial/textural statistics such as wavelets, lacunarity, spatial autocorrelation, and variograms. Benchmark studies comparing the fractal measurement algorithms implemented in ICAMS have also been conducted, which led to further improvement of the algorithms. The modified triangular prism method previously described is an improved algorithm in ICAMS. It was a direct outcome of making the software available for many researchers to use so that they can focus on better analysis rather than spending time to program the algorithms from scratch.

Significant advances have been made recently in applying the fractal model in image processing and remote sensing. The medical community increasingly uses fractal and multifractal analyses to characterize a wide range of images and signals, including electrocardiogram (ECG) and electroencephalogram (EEG) signals, brain imaging, mammography, and bone imaging. In geographical image processing, the fractal dimensions computed for local moving windows have been used as a texture layer for better image classification and change detection. This new local fractal approach is designed to overcome the problems of using a single fractal dimension to represent an entire study area. By applying the calculation in a small window area, the variations and complexity at fine scales can be better captured. Including the local fractal dimensions in image classification has resulted in a dramatic increase in classification accuracy. Moreover, unlike many spatial indices used in landscape ecology, fractal dimension can be computed directly from unclassified images. This property makes fractal analysis a very useful tool for change detection, which then paves the way for future automation in image classification and change detection.

Finally, recent studies have advocated using the fractal dimension as part of the metadata for spatial data such as remote sensing images. The argument is that if means and standard deviations are basic nonspatial descriptors for spatial data, then why not add the fractal dimension as an index of spatial complexity to fill in the missing basic spatial information that conventional nonspatial statistics do not provide? Such information should help speed up the mining of large image databases and the selection of appropriate imagery for many applications.

Conclusions

Fractals were literally everywhere in the 1980s and 1990s. Studies utilizing the fractal model and techniques have made tremendous impacts on many aspects of science, art, and technology, including advancing geographical sciences. However, the explosive number of studies in the first two decades is in marked contrast with the relatively few studies in recent years. This significant decline in the number of studies involving fractals can be seen as a natural life cycle of any academic research topic and may indicate that the study topic has now reached a certain level of maturity. Given the tremendous potential of the fractal model, it is useful here
to identify the research gaps and suggest future research using fractals that will help further our understanding of spatial phenomena.

At least four future research directions can be identified. First, more research is needed to develop the confidence limits and statistical significance of the fractal dimension measured. Second, the fractal dimension is a useful and competent index, but the fractal dimension alone is not sufficient to represent all aspects of spatial complexity; additional spatial indices such as wavelets, lacunarity, and spatial autocorrelation are needed to help in describing complex systems. Thus, the complementarities among these various indices should further be explored. Third, future studies should focus more on the validity of the research design and the interpretation of the fractal analysis results. Many previous fractal studies used complicated algorithms and data to generate results but stopped short in making a full and useful interpretation of how the patterns could be related to the underlying processes and how fractals have helped in explaining such patterns. Fourth, existing geographical applications of the fractal model have been mostly confined to explaining the present forms and patterns; its use in predictive process modeling has seldom been explored. The fractal model would seem to be a useful analytical addition to current research frontiers, including research on modeling the complex interactions between natural and human processes, agent-based modeling, big data mining, and system resilience and sustainability. The fractal model is a fantastic model of complexity; its use in explaining and modeling complexities is very promising and should be further explored.

FRACTAL ANALYSIS

The term “fragmentation of production” describes the distribution of the production process across different countries. It is an important feature of globalization. Products become internationalized; national markets are more closely linked to markets abroad; economy-wide behavior patterns converge; and the domain of overlapping policy interests expands (Arndt 2010).

The nature of fragmentation

The term “fragmentation” was first used in this context by Jones and Kierzkowski (1990) to explain the growth of service sectors related to the increase of intraindustrial international trade. They introduced two key concepts in their explanation: “production blocks” and “service links.”

The production blocks refer to the technical possibility of a production line being “fragmented” into small parts, so as to be carried out in different locations. The development of transportation and communication technologies significantly decreases the cost of coordination between production blocks that are dispersed in terms of distance. It becomes not only feasible but also rational to involve producers operating in different countries or even different continents in supply chains for certain products because the firm can take advantage of location-specific advantages in production such as proximity to resource supply, easy access to market, and convenient transportation. For example, an airplane may have its wings manufactured in Japan, its doors in France, and its seats in the United Kingdom. All the components are shipped to the United States, where they are assembled and sold as the final product.

In order to coordinate all the activities scattered in different locations, service links are crucial to facilitate the exchange of information between different blocks. Jones and Kierzkowski (1990) provided a framework to analyze the process of fragmentation (see Figure 1). In a traditional production process, inputs are organized and combined to generate final outputs. All aspects of production are conducted in one place, the proximity helping to reduce the cost of communication. As production becomes increasingly fragmented, the coordination is more involved and complex, and calls for more service links between the production blocks. A service link consists of activities such as transportation, insurance, telecommunication, quality control, and management coordination to ensure that the production blocks interact in the proper manner. The higher the speed and efficiency of the service link, the better the capability for production to take advantage of location-specific resources through fragmentation.

Fragmentation of production enables manufacturers to exploit component-specific economies of scale through vertical specialization. If the producer of a component can serve competing producers of final products, they may expand production for greater economy of scale, which in turn contributes to the growth of international
production sharing. With the establishment of service links, the specialized component producer will invest in technological innovation for fragmented production; this is not likely to take place in an integrated production system (Arndt and Kierzkowski 2001).

Beside the technical feasibility of international fragmentation, the separability of ownership, or controllability, can also affect the organizational structure. The firm has to make a choice of fragmenting production across both geographic and organizational boundaries, and may trade off fragmentation along one dimension for integration on the other (Kimura and Ando 2003). In order to organize the production blocks dispersed in different locations smoothly, firms provide service links for communication and coordination to facilitate the efficient and on-time transportation of parts and components within the network. Therefore, fragmentation will take place only when savings in production cost exceed the costs associated with service links. Besides economic concerns, the choice of ownership arrangement also depends on legal and institutional considerations especially when dealing with cross-border business; it involves trust, enforceability of contracts, and protection of intellectual property (Navaretti and Venables 2004).

The fragmentation of production used to be limited to within a country because domestic service links were easier to establish and

---

cheaper to operate. However, in recent years, technological innovations, the liberalization of international trade in services, convergence in legal and regulatory systems, and increased freedom of establishment have significantly reduced international coordination costs. As cross-border service links have become cheaper, more reliable, and more accessible, the locational options for production blocks have become global in scope (Arndt and Kierzkowski 2001). As mentioned earlier, multinational companies (MNCs) trade off between integration and fragmentation along both geographical and organization dimensions. Their decisions have impacts on the global pattern of international trade and foreign direct investment (FDI).

The analytical issues of fragmentation

Fragmentation developed well between advanced and emerging economies. It has grown fast in industries such as electronics, machinery, and textiles and apparel. In developing countries, the domestic value added to a country’s exports is often significantly less than the value of those exports. What factors determine the role of different countries in the division of labor in international production sharing? The phenomenon of cross-border fragmentation may be explained from a variety of theoretical perspectives related to international trade and FDI (Deardorff 2001).

First, the Ricardian classical theory of international trade provides a simple model based on absolute difference in technological capability between countries to explain cross-border fragmentation. According to this model, countries have different capabilities in technology, which determine intraproduct specialization among countries. Countries with limited technological development will engage in low-tech production, while more advanced components and assembly will be produced in countries with more sophisticated technologies. With advantages in technologies, FDI will move from technologically advanced to technologically emerging economies. But this theory cannot explain how the differences in location-specific technologies among different countries came to be.

Second, the Heckscher–Ohlin (H–O) framework attributes the basis for specialization to the differences in factor endowments of each country. Countries will specialize in activities that make intensive use of locally abundant factors of production. That is, other things being equal, labor-intensive component production and assembly will be carried out in labor-abundant countries, while skill- and capital-intensive activities will be performed in more advanced countries. This factor-proportions view provides a good explanation for vertical intraindustrial specialization, and predicts that FDI will tend to flow from capital- and skill-abundant, labor-scarce countries to labor-abundant economies. However, the H–O model cannot explain the dynamics of country-specific factor endowment. The shifting of FDI from developed to developing countries can help provide up-front capital for an industrial facility and technological capability in some developing countries, which could increase the skill and capital intensity of the local industrial base through the multiplier effects of industrial localization and human capital investment.

Neither the Ricardo nor the H–O framework is capable of handling scale economies and externalities related to the localization of industrial investment, which is important in the development of fragmentation. The imperfect competition literature provides important insights: that consumers value variety, and that monopolistically competitive firms specialize in producing variety. There is increasing return
to scale: economies of scale come into play on both the production side and in the provision of service links between production blocks. The concentration of production of each part or component in one location permits firms to exploit internal economies of scale at each location. Meanwhile, the agglomeration and clustering of producers generate economies that are external to the plant and firm.

The imperfect competition model provides a micro-economic mechanism for the fragmentation of the global production network. However, it simplifies most of the location-specific factors that can shape the production network in various ways. The factor endowments are only one type of location advantage, and therefore cannot fully explain the pattern of international trade and movements of FDI. The gravity model offers a way of accounting for additional location-specific considerations – including distance, country size, border effects, and various institutional and policy-related factors. It has been employed in the context of production networks to test the effects of distance on the trade and FDI in terms of both horizontal and vertical specialization. It suggests that FDI responds positively to distance. In horizontal specialization FDI is the substitute for exports. As distance and cost increase, exports are replaced by on-site production for the local market and hence FDI flow rises. At the same time, vertical FDI moves to support production sharing. When distance raises the cost of service links, the production sharing becomes unprofitable and FDI declines (Kimura, Takahashi, and Hayakawa 2007).

The effects of fragmentation

MNCs have played a key role in the evolution of cross-production networks. They reshape the local industrial structure through direct investment and purchasing activities. The initial organizational structure follows a hub-and-spoke pattern, with affiliates in several countries trading directly with the parent company and less with one another. As interactions become more sophisticated and infrastructure is developed, networks evolve in which trade takes place between affiliates located in various countries, as well as between affiliates and local firms. This pattern is exemplified by Japanese multinationals operating in Southeast Asia (Kimura and Ando 2003; Cheng and Kierzkowski 2001) and MNCs based in Singapore (Yeung 2001).

The geographical agglomeration of certain fragmented stages of production can generate positive externalities. The expanding market helps to develop specialized local industrial clusters, which attract and train workers, improve access to finance and other services, and generate knowledge spillovers that raise productivity and reduce costs. The local government can help the development of such agglomerations with supportive public policies and investment in infrastructure. Local producers can enter the industry as suppliers of goods and services to the multinationals, which opens the path to industrialization for developing countries.

The provision of service links can significantly benefit from economies of scale, too. Larger numbers of units and firms can share the fixed costs associated with establishing a communications network as more and more local participating entities join the network. Cooperative policies between countries to reduce the barriers in service sectors will benefit the development of agglomeration. Some empirical studies also show that production sharing tends to reduce the sensitivity of trade flows to financial fluctuation (Okubo, Kimura, and Teshima 2014) or exchange rate change (Arndt and Huemer 2007).
Anxieties about the spread of fragmentation relate to its impacts on jobs and wages in advanced countries, as a result of the offshoring of manufacturing, as well as services like call centers, help desks, programming, and ticketing operations. Production sharing with low-wage countries may increase competition for lower wages in a “race to the bottom.” It affects low-skilled workers more than the skilled workers. However, the real effects could be complex. Although jobs directly attached to shift industries have been lost, the cross-border sourcing of components could raise competitiveness and lower the prices of final products or services, thereby increasing sales and thus output. Thus, more jobs could be created elsewhere in the industry or more generally in the economy. And even unskilled workers in developed countries can enjoy price decreases as consumers. Empirical studies show mixed results in different sectors in relation to the skill ratios in affected industries, and the relationship between labor and capital. There is a trade adjustment problem related to fragmentation, for jobs lost in one sector must be balanced against jobs gained in others. Some policy interventions are needed to match unemployed workers with emerging jobs (Feenstra 1998).

Regional trade agreements can affect the development of fragmentation of production. Free trade agreements within preferential trade areas (PTAs) can help the development of production sharing in member countries, while rules of origin restricting the use of components from outside the PTA can significantly divert trade flows. At the same time, fragmentation of production is changing the nature of regional integration. It requires deeper integration beyond the removal of tariffs and other restrictions on the flow of goods and services. It calls for liberalization of investment and for the cross-border movement of persons, as well as the harmonization of technical standards, regulatory policies, and dispute settlement procedures. Cross-border coordination of production networks promotes convergence of business cycles and requires greater regional cooperation, including on monetary policy and market governance.

France: Association de Géographes Français (AGF) (Association of French Geographers)

Founded: 1920
Location of headquarters: Paris
Membership: 220 (as of March 2015)
President: Roland Pourtier
Contact: nrpourtier@wanadoo.fr

Description and purpose

The Association of French Geographers (AGF) organizes four full-day public research seminars per year. Most meetings take place in Paris but sometimes they take place in other cities as well. Peer-reviewed proceedings are published in the bulletin, which also welcomes articles on any number of themes or topics. All PhD students are strongly encouraged to participate in AGF activities.

Paper sessions may focus on any aspect of our discipline, from geomorphology to cultural geography, regional to epistemology. Recent themes include global warming, heritage and territory, peri-urban agriculture, geography of the high seas, the United States, hazards in tropical environments, city dynamics in Southeast Asia, geography’s turning points, and re-industrialization in France.

Journals or major publication series

Bulletin de l’Association de Géographes Français

Current activities or projects

The association is a partner with the CNFG (French National Committee for Geography–IGU) and has organized joint seminars with specialized commissions of the CNFG. It is also a partner of the APHG (Association of History and Geography Teachers).

The board of the association is made up of 15 elected members (elected for three years, with an annual turnover of five members).

Brief history

The AGF was created in 1920 by Emmanuel de Martonne, who later became president of the International Geographical Union. Its headquarters are at the Institute of Geography, located in Paris’ Quartier Latin.

France: Comité National Français de Géographie (CNFG) (French National Committee of Geography)

Founded: 1920
Location of headquarters: Paris
Website: www.cnfg.fr
Membership: 350 (as of 2014)
President: Richard Laganier
Contact: president@cnfg.fr

Description and purpose

The main aim of the CNFG is the coordination of French geographical activities (i.e., it launches or directs research which it deems needed or useful). It also serves as the French representative organization to the International Geographical Union (IGU) and mediates the communication between the IGU and French geographers. The CNFG also maintains communications with other international geographical organizations. Its 24 subcommittees pursue research and collaborations in various subdisciplines of geography. The CNFG also publishes a newsletter, issues awards and prizes on an annual basis, and organizes meetings and conferences throughout the year.

Journals or major publication series

Current activities or projects

The committee organizes and participates in a range of meetings, seminars, and conferences. It publishes the newsletter and represents French geography at the IGU meetings.

Brief history

The CNFG was created in 1920 under an initiative of the French Academy of Science. The association is now a member of the French Committee of International Scientific Unions (COFUSI) and represents French geography at the International Geographical Union, where it has a vote in the general assembly.

The CNFG has been a major actor in geography in France and abroad, notably for the French-speaking geography outside of France. It has organized the 1984 IGU Congress in Paris, and is planning to organize the IGU’s Centennial Congress in 2022, also in Paris.

Recently, the association has been trying to open up to new generations of geographers and to new methods and developing ideas in geography by creating new subcommissions and relaxing its membership conditions.

The CNFG maintains strong links with other French geographical associations and international events.

France: Société de Géographie (Society of Geography)

Founded: 1821
Location of headquarters: Paris
Website: www.socgeo.org
Membership: 914 (as of December 31, 2013)
President: Jean-Robert Pitte
Contact: jean-robert.pitte@wanadoo.fr

Description and purpose

The Société de Géographie, established by royal decree on December 14, 1827, is a scientific and cultural nonprofit organization. The society's mission is to promote the knowledge and popularity of geography. The organization also aims to appeal to specialists as well as the general public by promoting the understanding and use of geography in all its diversity.

Journals or major publication series

La Géographie
Bulletin de liaison des members de la Société de Géographie

Current activities or projects

The society pursues multiple activities: it organizes monthly conferences, alternating them with those of the Explorers’ Society, which it hosts and with which it actively collaborates. The society also organizes one or two round tables each year and publishes edited papers from these events. It also serves its members through two publications: the journal La Géographie, intended to more widely disseminate the work of university academics or writers concerned with the larger contemporary questions in geography; and the Bulletin for society members, which publish information on the life of the society and its members’ activities. The two publications share a review of other works or publications that contribute to the advancement of geographic knowledge. The society's valuable photography collection is well-illustrated in a collection of albums, co-published with éditions Glénat. The society also organizes expeditions and voyages. The most recent such trips include a crossing of the Morvan, a cruise on the Saône, a long journey through Uzbekistan, a cruise in the Venetian Lagoon, and an educational field trip to northern Cotentin, following an address by Barneville-Carteret. Lastly, once annually, at the end of November, a Day of Geography allows the society to gather a large number of members who come to listen to presentations, join in debates, see films, and more. The society's awards are distributed at the close of this special day.

Brief history

Founded on December 15, 1821, the Société de Géographie is the oldest in the world. It was founded 7 days before its counterpart in Berlin and 9 years before the Royal Geographical Society in London.

Its first bulletin was published in 1822 and it was declared a public service by Charles X in 1827. Geographers and cartographers of this period were mostly dedicated to the creation of maps, atlases, and geographical dictionaries. They did not possess a monopoly on the description of the world regions that were published by navigators, the military, religious orders,
and natural scientists. The first president of the society, the Marquis Pierre-Simon de Laplace was a mathematician, physicist, and astronomer, a member of the Académie des Sciences since 1773 and of the Académie française since 1816. He never authored documents related to geography, but he was a respected scientist who legitimized the creation of an organization dedicated to this branch of human knowledge.

The society encouraged numerous explorers, contributed financially to their travels, and also remunerated them upon their return home. The society has one of the most important specialized libraries in the world, collecting manuscripts, archives, and photographs. Since World War II the collection is hosted at the Department of Maps in the Bibliothèque nationale de France, which ensures its conservation and access for the public.

Today, the society has approximately 1000 members and about 100 honorary members residing on all the world's continents. Among these are Prince Albert II of Monaco and Prince Charles of England, both passionate promoters of environmental and natural resources management.

Submitted by Jean-Robert Pitte
Free trade zones (FTZs), also known as commercial free zones and free commercial zones, are geographically delimited, usually physically secured (fenced-in), duty-free areas, offering warehousing, storage, separate customs, streamlined procedures and distribution facilities for trade, trans-shipment, and re-export operations. They are defined spaces where laws and regulations, especially those related to trade, are more liberal than in the rest of a country. Typically, the territory set aside is considered outside a country’s customs regime. Normal trade barriers such as tariffs and quotas are eliminated and bureaucratic requirements are lowered to attract new business and foreign investments. FTZs are often located at or near a port of entry to facilitate import and export or an underdeveloped part of the host country to boost employment and economic growth.

In FTZs, trade-related activities have become increasingly integrated with manufacturing activities. FTZs of the United States, for example, are import- and trade-oriented, but they also permit manufacturing. Most export processing zones of the world have also incorporated the functions of FTZs but are primarily export- and manufacturing-oriented. Here a broad conceptualization is adopted and FTZ treated as a generic term that may (partially) encompass many practical variants in the name of free export zones, duty-free zones, industrial free zones, export processing zones, special economic zones, industrial export zones, free ports, enterprise zones, bonded warehouses, and so on. The different terms over time and space often reflect the specific activities carried out within a particular zone.

While nation-states have developed “exceptional” spaces of economic activity for over a century, the recent phenomenon and proliferation of FTZs refer to a period beginning in the late 1960s, when developing countries sought to attract investment through territory-based concessionary incentives. The typical FTZ policy package includes: (i) partial or complete exemption from export taxes, duties on imports of raw materials or intermediate goods; (ii) exemption from direct taxes such as profits taxes, municipal and property taxes; (iii) exemption or deferral from payment of indirect taxes such as value-added tax and goods and services tax on domestic purchases; (iv) exemption from national foreign exchange controls; (v) free profit repatriation for foreign companies; (vi) provision of streamlined administrative services with less bureaucracy and red tape; (vii) free or subsidized provision of enhanced physical infrastructure for office space, utilities, production, transport, logistics, and business services; and (viii) other incentives (often offered by regional/local governments) to attract jobs and investment.

Free trade zones in a broad sense have existed for centuries. They were originally established to encourage entrepôt trade, and mostly took the form of citywide zones located on international trade routes, for example, Gibraltar (1704), Singapore (1819), Hong Kong (1848), and Hamburg (1888). An entrepôt was a central...
point where goods were assembled and physically traded before being exported to final destinations. Closely related to the entrepôt function is re-export and trans-shipment trade.

The development of the US foreign trade zone program in 1934 was the next major milestone in the history of free zones. At the time tariffs were as high as 60% for goods entering the United States, so the foreign trade zone program was perceived as a counterweight to offset the harmful effects of trade protectionism. The program was also expected to create and retain jobs and investments, and to help major US trade centers to compete against their international rivals such as London.

The first modern industrial free zone was the Shannon Free Zone (SFZ), established in Ireland in 1959. A further extension of the free zone concept, known as the export processing zone (EPZ), was developed in Kaohsiung, Taiwan, in 1965, and subsequently became the role model in many developing countries. The EPZ is a combination of old customs areas and export-oriented manufacturing. EPZs combine tax-free holidays with other incentives for foreign investors to set up factories that were expected to attract foreign direct investment, produce export goods, train low-skilled workers, and facilitate technology transfer. Before the 1970s, most zones were clustered in industrialized countries, primarily in Western Europe. Inspired by the role model of Shannon and Kaohsiung, EPZs subsequently proliferated throughout Asia, as well as in Latin America and in the Middle East. In the 1980s the pace of zone development increased and expanded to new regions, including South Asia, South America, and sub-Saharan Africa. The number of zones – especially EPZs – has grown dramatically, particularly since the mid-1990s.

Overall, enhancing trade efficiency and manufacturing competitiveness is the principal rationale behind free zone programs in most industrialized countries. Revitalization of economically distressed urban and rural areas is the motivation behind the many free zone programs in developed countries. The main rationale for the Shannon Free Zone in Ireland was to establish a “growth pole” in the economically distressed southern part of the country. For developing countries, free zones have traditionally had both a policy and an infrastructure rationale. The policy rationale is associated with the expected economic benefits from FTZs, which commonly include: attracting foreign direct investment, creating employment and generating income, earning foreign exchange, developing and diversifying exports while maintaining protective barriers, piloting new policies and approaches, transferring knowledge to local firms through backward linkages, and catalyzing entrepreneurship and innovation in the local community. The infrastructure rationale is aimed at enhancing the competitiveness of manufacturers and service providers through fully serviced sites with purpose-built facilities for sale or lease. It is also intended to realize agglomeration economies and more efficient environmental controls from concentrating industries in one locality.

Today, a relatively small number of countries account for the majority of worldwide zone activity. Zones are concentrated in Asia and the Pacific (mainly China), Latin America, and Central and Eastern Europe and Central Asia. The Asia–Pacific region has been at the forefront of zone development over the last three decades, led by the “Asian Tigers” and China. The development of free zones has been the epitome of China’s market-oriented reforms and opening up since 1979, as well as a major catalyst of this process. The opening of China and its market reform policies have relied heavily on all kinds of zoning technologies and the production of new spaces of exception (Ong 2006). This strategy allows the authoritarian Chinese party-state
to create and accommodate islands of distinct governing regimes, or laboratories of capitalism, within the broader landscape of at least nominal, enduring socialist rule.

Traditional free zones have played a key role in the process of industrialization, especially the development of export sectors. Newly industrialized Asian economies are often pointed to as models in utilizing their zones to both promote and diversify their export bases. These economies have to a certain extent succeeded in moving up the value chains and encouraging exports in a wide range of industries. Nevertheless, most zone enterprises worldwide are still engaged in labor-intensive, assembly-oriented activities in low value-added sectors such as apparel, textiles, toys, footwear, electronics, and auto parts. African FTZs are generally marked by low levels of investment and exports, marginal employment impact, limited attraction of FDI, and an absence of linkages with the domestic economy. Widespread failure has raised serious doubts about the desirability of the free zone programs.

FTZs have frequently been criticized for negative socioeconomic impacts, for example, exploitation of women, suppression of labor standards and core labor rights including trade unionization, low wage levels and poor employment conditions (work hours, health, and safety), and lax environmental standards. The attraction of the FTZs to foreign investors is frequently the ready availability of cheap but disciplined labor. FTZs have often been characterized by a lack of social dialogue between employers and the representatives of workers, many of whom are migrants or working in industry for the first time. Foreign enterprises often take advantage of the weak enforcement of safety, health, and environmental regulations in the zones.

Many have also cautioned against a race to the bottom in relation to social and environmental standards, and of a race to the top in terms of incentives to investors of the FTZs. The package of fiscal incentives offered by FTZs is increasingly similar and more generous around the world. These incentives have imposed significant costs on government budgets but are increasingly finding it difficult to live up to public expectations. The long-term success of EPZ-led development rests on the ability of nation-states to seize foreign demand and continuously direct resources to higher-productivity areas. To a great extent, the likelihood that FTZs will contribute to wider economic and social development hinges on their embeddedness in the host country’s economy, through forward and backward linkages between zone enterprises and local suppliers of goods and services. Linkages are usually dependent on the host economy having an existing industrial base to produce the necessary absorptive capacity. Some countries lack the fundamental investments in human capital necessary to enable the FTZ to be a positive experience. Poor education and health problems are certainly fetters on the likelihood of expanding the career potential and job satisfaction of workers that lead to improved productivity and stability. Others face strong political barriers to building free, strong, and representative workers’ organizations that can play a major role in improving working conditions and increasing productivity and competitiveness. These are usually larger societal challenges that are difficult to rectify in the short run.

Freshwater resources: past, present, future

Definition, facts, and figures

Freshwater, also called sweet water in contrast to saltwater, is defined as water having a concentration of less than 500 ppm (parts per million) dissolved salts. Of all the water on Earth, 97.5% (approximately 1.41 billion km³) is saltwater and only 2.5% is freshwater – but this is of great importance and plays a crucial role in human activities and natural ecosystems (see the next section). Freshwater comprises all natural water on the Earth’s surface in the form of lakes, rivers, ponds, glaciers, ice and ice sheets, and other wetlands and beneath the surface in the form of groundwater and soil moisture as well as the water contained in the atmosphere. Almost 70% of the freshwater is stored in the icecaps and as soil moisture or is present as groundwater in deep aquifers not accessible for human use. Less than 1% of the global freshwater (which corresponds to roughly 0.007% of all water on Earth) is accessible for direct human use. This is the water of lakes, rivers, reservoirs and aquifers shallow enough to be tapped. This water is renewed by precipitation on a regular basis and therefore available for sustainable use. Groundwater is by far the most abundant and readily available source of freshwater, followed by lakes, reservoirs, rivers, and wetlands (UNEP 2008). The sources of freshwater and the corresponding amounts are summarized in Figure 1 (WWAP 2006, based on data from Shiklomanov and Rodda 2003). As with most estimates at this scale, there is some uncertainty associated with them, especially for the estimate of fresh groundwater resources.

Freshwater amounts vary considerably in space and time. In space, its availability is unevenly distributed. The global freshwater resources as volume per continent are shown in Figure 2. Most freshwater is stored in the ice caps, with Antarctica containing by far the largest amount. For all continents, the major amount of freshwater is groundwater and nearly all of it is fossil, thus not suitable for renewable water consumption. Only very little freshwater is readily available and can be used in a sustainable way. This is significantly less in the Southern Hemisphere (Africa, South America, and Australia) than in the Northern Hemisphere.

The hydrosphere is all of the Earth’s water, including surface water (water in oceans, lakes, and rivers), groundwater (water in soil and beneath the Earth’s surface), snowcover, ice, and water in the atmosphere, including water vapor. In time, the amount of water in the hydrosphere varies due to the exchange between ocean,
land, and atmosphere, the so-called hydrological cycle. The water cycle plays manifold roles in the climate, chemistry, and biology of the Earth and freshwater ecosystems, being of great importance to maintain freshwater. Figure 3 shows the scheme of this cycle. The water moves from one reservoir to another, for example, from river to ocean or from the ocean to the atmosphere, by the physical processes of evaporation, transpiration, sublimation, condensation, precipitation, infiltration, runoff, and subsurface flow, thus going through the different phases of liquid (water), solid (ice), and gas (vapor). The main driver of these processes is the radiative energy from the sun, which heats water in oceans, lakes, and wet soils. Water evaporates as water vapor into the air. Ice and snow can sublimate directly into vapor. Evapotranspiration is water transpired from plants and evaporated from the soil. Rising air currents take the vapor up into the atmosphere where cooler temperatures cause it to condense into clouds. Air currents move water vapor around the globe, cloud particles collide, grow, and fall out of the upper atmospheric layers as precipitation. Some precipitation falls as snow, hail, or sleet and can accumulate as ice caps and glaciers, which can store frozen water for thousands of years. Thus mountains, glaciers, and ice caps play an important role in many areas of the globe as they store water and release it through melting during the warmest seasons. Most water falls back into the oceans or onto land as rain where the water flows over the ground as surface runoff. A portion of runoff enters rivers with stream flow moving water toward the oceans whereas some water infiltrates into the ground and into aquifers. Runoff and water emerging from the ground (groundwater) may be stored as fresh water in lakes. In river valleys and floodplains there is often continuous
water exchange between surface and groundwater beneath and alongside a stream bed. Over time, the water returns to the ocean continuing the water cycle.

Vörösmarty and Sahagian (2000) estimate the total renewable water supply to 39,600 km³ with about 75% accessible to humans, the majority coming from forests and mountains. The global fraction of total runoff accessible to humans shrinks to 53% if uncaptured flood flow is not considered. About 80% of the global population live downstream of renewable freshwater services while 20% remain without sustainable supply (UNEP 2005) and rely on unsustainable water resources. Forest and mountain ecosystems serve as source area for the largest amount of (renewable) freshwater supply. With 57% of the total, and 28% of the renewable runoff, they supply at least 4 billion people with freshwater (UNEP 2005). More than 90% of a river’s flow may be derived from catchment headwaters and the hydrology of downstream areas depends directly on the water coming from upstream. The connection of upstream and downstream areas is very important and threatened by many factors. The transmittance of upstream hydrology to downstream is crucial for the functioning of the ecosystem and thus the maintenance of ecosystem services. Global surveys like the Millennium Ecosystem Assessment (UNEP 2005) or the Global Biodiversity Outlook identify freshwater ecosystems as having suffered from greater degradation than any other global ecosystem (see below).
Freshwater ecosystem services – why do we need freshwater

Water is essential to all forms of life and is needed in almost all human activities, from basic drinking water to food production and health, from energy production to industrial development, from sustainable management of natural resources to conservation of the environment. Water also has a cultural and religious value. Together with energy and nutrients, water is a core piece for the delivery of all ecosystem services to humankind. All species on Earth, including humans, depend on clean freshwater from freshwater ecosystems, which in turn depend on healthy rivers and basins. Maintaining healthy ecosystems is thus crucial for the maintenance of the services they provide. Scientists have discussed ecosystem services implicitly for decades but the ecosystem services concept was popularized by the Millennium Ecosystem Assessment (UNEP 2005) and is since then widely used, even though it is still subject to criticism, especially for the concept of cultural ecosystem services. The ecosystem services literature focuses on the benefits for humans but discussions about the intrinsic value of nature are persistent, arguing along the lines that nature has a value beyond money and beyond direct human services. Also the value as a resource base beyond attaching ecosystem services to it should be considered. However, estimates have been made in attaching a monetary value to ecosystem services,

reporting an amount of US$6.5 trillion per year as the value attached to freshwater ecosystems (Costanza et al. 1997). The concept of attaching a monetary value to ecosystem services is also subject to ongoing discussions and criticism. Table 1 summarizes the ecosystem services of freshwater divided into provisioning services (products obtained from ecosystems), regulating services (benefits obtained from regulation of ecosystem processes), and cultural services (nonmaterial benefits obtained from ecosystems). In the Millennium Ecosystem Assessment (UNEP 2005) freshwater is mainly classified as provisioning service referring to the domestic, agricultural, and industrial use as well as for power generation and transportation.

A main service considered in many studies is the use of freshwater by humans for domestic, agricultural, and industrial purposes and geographic distribution of human settlement can be directly linked to the availability of freshwater. The annual global freshwater use is reported to be approximately 3600 km$^3$ corresponding to 25% of the annual total runoff of the total accessible runoff of 53% (Shiklomanov and Rodda 2003). Nearly half of the global total is used in Asia and a third in OECD (UNEP 2005). As freshwater availability varies in space and time, overuse,
resources depletion, and water scarcity are important subjects related to freshwater use. The related problems are mainly aquifer depletion, soil salinization, and competition for water. The nonrenewable use is affected by large uncertainties and is reported to lie between 5% and 25% (UNEP 2005). All continents record overuse, predominantly the arid regions of North Africa and the Middle East and 20% of the global population remains without enough water, thus relying completely on unsustainable water resources. Impacts of unsustainable water use can directly be linked to food security. Globally the major part (70%) is used in agriculture, followed by industrial use (22%) and domestic use (8%). These figures differ significantly for high-income countries, which use the greatest amount for industrial purposes, and low/middle-income countries, using an even higher percentage for agriculture. The use in the agricultural sector is mainly defined by irrigation and leads to an irretrievable loss of a third of the global water use (UNEP 2005). The efficiency of agricultural irrigation varies greatly and losses through evapotranspiration over irrigated cropland are reported to be on average 50%. Water stress or water scarcity is the lack of sufficient accessible water to meet the demands within a region. Two common indicators are the amount of water available per person and the ratio of volume of water withdrawn to volume of renewable water available. According to the Falkenmark Water Stress Indicator (Falkenmark and Lindh 1976) values between 1000 and 1700 m³/annum per capita indicate water stress and values less than 1000 m³/annum per capita indicate extreme water stress. Figure 4 shows water stress per country calculated as the ratio of water withdrawal and potential renewable supply. However, these indicators give only partial indications of water resources pressures in a country or region because the consequences of water stress also depend on how water is managed. Another approach therefore divides the water scarcity into physical and economic

Figure 4 Water stress (ratio of water withdrawal and renewable supply) per country. Graphic: Martin Heynen.
water scarcity. Physical water scarcity indicates that the water resources are approaching or have exceeded sustainable limits whereas economic water scarcity indicates that malnutrition exists because human, institutional, and financial capital limit access to water even though water in nature is available locally to meet human demands (International Water Management Institute 2007). The Human Development Report (Watkins 2006) states that water scarcity already affects every continent. Around 1.2 billion people, or almost one-fifth of the world’s population, live in areas of physical scarcity, and 500 million people are approaching this situation. Another 1.6 billion people, or almost one-quarter of the world’s population, face economic water shortage.

Worldwide 1–2 billion people are reported to live under water scarcity conditions, and the problems associated with water stress and scarcity are expansive in the areas of human health, food production, and economic development. Also, the water scarcity coping capacity varies significantly with the level of economic development, education, and governance (also see UNEP 2005).

Past, present, future – how is freshwater changing?

Past

Since Antiquity, drainage, irrigation, and impoundment have been the major human activities impacting water. Since at least 5000 years ago, most water has been used for irrigated agriculture. L’vovich and White (1990) report a fifteenfold increase in global water withdrawal between 1800 and 1980 and the overall increase since 1900 is reported to have been sixfold (WMO 1997). In the late nineteenth century and early twentieth century dams became a popular water management tool and to date around 45 000 bigger dams were built, most between 1950 and the early 1980s associated with an increase in global water withdrawal since the 1950s due to economic development and industrial water consumption as well as an expansion of irrigated areas. Freshwater withdrawals have almost doubled since 1960 and more than half of all accessible freshwater runoff is currently used by humans. As a result, the dynamics in time and the spatial distribution of water are no longer determined only by natural climate variations (Shiklomanov in Gleick et al. 1993). Together with anthropogenic changes of the hydrological cycles alteration of the water quality also occurs, which is severely affected by industrial and agricultural chemicals. It was not before the Clean Water Act (first federal law governing water pollution in the US) in 1972 that humans officially and globally recognized the need to protect water. The index of health of freshwater ecosystems shows a decline of 50% between 1970 and 1995 and extinction rates of freshwater species are reported to be much higher than those of other species (terrestrial, coastal marine). Rivers and their floodplains, lakes, and wetlands have undergone more dramatic changes than any other type of ecosystem in the recent decades due to multiple human activities.

Present

The greatest present and future challenge to freshwater systems is the management of human and ecosystem needs. The biggest threats to freshwater ecosystems are land-use disturbances, hydrological alterations, and the introduction of non-native species. The first two can be closely linked to population growth and economic development. Land-use practices and changes (e.g., deforestation, expansion of agricultural
and irrigated land) affect freshwaters by modification of nutrient and sediment loads, changes in water temperature, and increased pollution due to fertilizers, pesticides, and waste. Land gets degraded leading to water stress and increased water scarcity. The main drivers of hydrological alterations are dam constructions for hydropower use, diversion of water for multipurpose use, the draining of wetlands, and constructions for flood control and agriculture. Potential changes in the hydrological regime due to impoundment, channelization, water withdrawal, or catchment conversion have an influence on key environmental parameters: water quality (water temperature, oxygen level, nutrients), energy sources, and also the physical habitat structure. They can also lead to fragmentation of aquatic habitat and groundwater depletion. A river’s natural flow dynamics maintain and support key ecological processes and vital life-cycle stages, thus alterations can significantly change an ecosystem or its functioning (Poff et al. 1997). As the flow regime influences all other key environmental factors such as water chemistry, physical habitat, and biological composition and interaction, “flow regime” has been described as the “master variable” by scientists (e.g., Poff et al. 1997) and the primary determinant of freshwater ecosystem functioning. Excessive changes to the natural flow regime can cause river ecosystems to degrade with high costs for both biodiversity and society (Richter et al. 2003). The five components of the natural flow regime defined by Poff et al. (1997) are magnitude, timing, frequency, duration, and rate of change. Maintaining the full range of variation in natural hydrological regimes is vital to sustain the integrity of aquatic ecosystems. As the ecosystems’ need for water competes with the human needs, they require protection in order to maintain their capability to provide goods and services to people, now and for future generations. An understanding of freshwater ecosystem integrity is therefore essential to maintain the range of goods and services that underpin livelihoods and communities, especially in developing countries (Le Quesne et al. 2010).

Humans now capture more than 50% of freshwater runoff, river systems have been fragmented by approximately 1 million dams globally and reservoirs trap 25% of the global sediment load before it reaches the oceans (Vörösmarty and Sahagian 2000). The Flowing Forward report by Le Quesne et al. (2010) concludes that by 2020 there will be few, if any, untouched ecosystems and that there are many water bodies likely to be profoundly transformed in their key ecological characteristics. These will inevitably have crucial impact on livelihoods and human development.

Future

Climate and freshwater are interconnected in complex ways and climate change should be seen as part of a broad set of pressures on freshwater systems. Observational records and climate change projections provide evidence of freshwater resources being vulnerable and having the potential to be severely impacted by climate change with wide-ranging consequences on human societies and ecosystems. Most impacts on freshwater are expected to occur as a result of climate change with other anthropogenic pressures, such as changes in population, lifestyle, economy, and technology and climate change is not necessarily the predominant driver of freshwater ecosystem degradation. However, it will endanger human use of freshwater and freshwater species, driving engineering responses such as new dams, dredging, levees, and water diversion to improve water security that will further threaten freshwater ecosystems and the human responses to climate change could cause effects as large or larger than the effects of climate change itself. As climate change is not a
smooth and gradual process, but very complex and affected by large uncertainties, so will be the impacts of it on freshwater ecosystems. But they will lead to changes in quantity, quality, and timing of water and thus to the entire freshwater flow regime. Not all freshwater ecosystems will be affected in the same way due to the variability of climate change in space and time leading to diverse degrees of vulnerability and resilience. Particular elements of the ecological (freshwater) system will be at risk at particular points in time and space, and to particular kinds of changes and stressors (Le Quesne et al. 2010). Significant changes in water availability and use or the hydrological cycle (affecting water supply and floods) require adaptation in the management of water resources. Most impacts are expected in the most vulnerable regions of the world and already sensitive ecosystems. The key variables for change (following Le Quesne et al. 2010) are as follows.

- **Temperature**: increased temperatures, especially over land, leading to changes in volume and timing of water availability and changes in water temperature.
- **Precipitation**: increased global precipitation highly variable in space and time leading to changes in timing and amount of precipitation, increase in number of extreme events and thus an increase in droughts and floods.
- **Evapotranspiration and sublimation**: increased evapotranspiration as a function of humidity, radiation, wind and temperature as well as increased sublimation from ice and snow can be seen as direct loss of water in the basin.
- **Runoff**: as a combination of precipitation and evapotranspiration also changes in runoff such as increased low-flow episodes and associated water stress or shifts in amount and timing of floods will occur, which are geographically highly variable. Also changes in seasonality occur, especially in mountainous regions where less solid precipitation is falling due to higher temperatures. Sediment and pollution load will change following the runoff.

Gradual changes (changes around mean values, e.g., increase of extreme events) are significant for ecosystems (species and people) and hardest to predict, but there are also modal changes (e.g., periods of rapid shifts like glacial melting). IPCC has concluded that the atmosphere holds more water vapor and that global precipitation seems to be increasing. However, this is not uniform over the globe, but unevenly distributed in space and time. The main impacts of climate change can be summarized as follows (compare to Le Quesne et al. 2010).

- **Altering timing/availability of freshwater**: fast melting of glaciers, changing precipitation patterns, changes in groundwater recharge pattern, changes in amount of solid precipitation and timing of melt, increased evaporative losses.
- **Increase/shift in timing of extreme events**: not enough water (droughts, food crisis) versus too much water (floods, storms, water-borne diseases), changes of habitat structures.
- **Loss of biodiversity due to decline in habitats**: increasing temperatures, increasing pollution, changes in sediment load, water temperature, and so forth.
- **Increased water stress**: longer low-flow periods (reduced habitats, increased temperature, and pollution).

Water requirements for agriculture could double by 2050 without even considering climate change (International Water Management Institute 2007). Traditional pressures with
uncertain future trajectories are expected to be superimposed by climate change pressures, which are hard to predict. Attempts of human societies and economies to adapt to climate change may decrease the ability of ecosystems to adapt (Le Quesne et al. 2010).

With anticipated population growth and economic development and associated phenomena, a further increase of water stress and scarcity is very likely. UN reports that projections of water use are to increase by 50% for developing and 18% for developed countries and that by 2025, 1800 million people will be living in countries with absolute water scarcity and two-thirds of the world’s population will be affected by water stress conditions.

The future rate of freshwater species’ extinction is predicted to be almost five times greater than for terrestrial animals and three times greater than for coastal marine species. Conservation strategies need to focus on hydrologic and water chemistry regimes linked to species diversity, population dynamics, and habitat quality.

Outlook

Freshwater ecosystems are currently under severe threat. In order to maintain healthy freshwater systems that are able to serve as resource base and provide the necessary services to livelihoods, the reduction of the existent pressures and the protection of freshwater ecosystems are crucial. The reduction of existing pressures and thus the maintenance of ecosystem functions, while still allowing development, is a key challenge. A focus point of sustainable resources management remains the tradeoff between water used to satisfy human demand and the water needed for sustaining aquatic ecosystems. A good definition of the goal of sustainable water management is given by Richter et al. (2003): “Ecologically sustainable water management protects the ecological integrity of affected ecosystems while meeting intergenerational human needs for water and sustaining the full array of other products and services provided by natural freshwater ecosystems. Ecological integrity is protected when the compositional and structural diversity and natural functioning of affected ecosystems is maintained.” Sustainable management of freshwater resources has gained importance at the regional and global scale and “integrated water resources management” (IWRM) has become the corresponding scientific paradigm. The integrated basin-wide planning considers the whole catchment as management unit and respects the interdependences of the freshwater system (upstream–downstream, groundwater–river, etc.). It tries to involve all stakeholders in the management process and decisions, thus being an iterative approach to water management. The key to translate the latest knowledge into action is institutional capacity and good stewardship. Frameworks and institutions need to be enabled and policies and laws at the international and national level in the water sector as well as general environmental programs need to be strongly formulated.

Friendship, geographies of

Tim Bunnell
National University of Singapore

Friendship refers to a broad range of interpersonal relations that are entered into and may be left voluntarily. The voluntary character of friendship distinguishes it conceptually from kinship ties (that exist and persist regardless of personal choice) and marital bonds (that require legal and/or religious procedures to be broken), although in practice the distinction between friends and kin is often blurred and people may also regard their spouses as friends. Geography is implicated in different ways in friendship formation, maintenance, and dissolution. Advances in technologies of communication are extending possibilities for people to maintain and even to forge friendships at a distance, yet sites of schooling, work, and other physically copresent activities continue to be important spaces of friendship. As is also the case when marital relations end, the dissolution of friendships can have profound implications for personal geographies, reconfiguring the kinds of social spaces and networks that a person is able to or wishes to access.

The sheer diversity of relations to which the term “friend” can refer – ranging from a recent acquaintance to a lifelong confidante – poses a significant challenge to generalization of its geographies, as does contextual variability in the meaning and scope of “friendship.”

Although Western thinking and writing on friendship can be traced back to the classical scholarship of Aristotle and Plato, until recently the term had attracted only sporadic interest in geography and most other social science disciplines. In part, this lack reflects a tendency to trivialize the interpersonal and informal character of friendships. In sociology, for example, friendships have often been perceived as being of merely (inter)personal significance and, correspondingly, as having little in the way of wider social or structural consequence. Anthropology, meanwhile, has tended to focus on consanguinity (relation through kinship) and formalized affinity (e.g., relationship through marriage) to the neglect of non- or more-than-kin relationships, particularly in studies of traditional societies. The most established and sustained interest in work on friendship is to be found in social psychology. Interpersonal attraction, including but not limited to issues of friendship formation, has been analyzed by social psychologists since the 1960s; however, while geographical dimensions such as the significance of residential propinquity have often been incorporated into such studies, they have had little resonance in academic geography.

Growing interest in friendship among geographers has been bound up with a shifting evaluation of its significance in disciplines such as sociology and anthropology, where the concept has not traditionally been a focus of attention, rather than a reflection of any strengthening of geography’s engagement with social psychology. In particular, it has increasingly been recognized that friendship is shaped by and, in turn, (re)shapes wider conditions of social, economic, and political life. The rise to prominence of work on social capital, for example, not only highlights the importance of social networks for individual wellbeing, but has also meant that friendship and other informal social relations evoke alternative imaginings of social structure.
and organization. Highly influential sociological work has characterized social networks in terms of “status homophily,” meaning that friendships may actively reinforce and reproduce wider structural distinctions rather than merely reflect them. Conversely, it has been recognized that friendships can generate or sustain alternative subjectivities and hidden solidarities that challenge existing social and/or political formations. In her geographical ethnography of leaf-collecting work by girls in the Indian Himalayas, Jane Dyson (2010) showed how friendship was a medium for the reproduction of dominant gender norms and ideologies, but also allowed experimentation with identities that did not necessarily conform to adult expectations. In geographical terms, it is significant that Dyson emphasized the physical location of girls’ work and play – the forest as “a space figuratively and physically remote from the adult domain of the village” (2010, 493) – in her description of their irreverent and mischievous behavior. While sociologists have written about the “context” or “backcloth” of friendship formation, geographic scholarship is distinguished by its emphasis on “places and spaces of friendship” (Bowlby 2011, 612) and associated spatial practices.

While speaking to sociological debates about the social, political, and even structural significance of what was once considered to be “merely” personal, geographers’ interest in friendship also reflects disciplinary recognition of the intimate as important in its own right. Friendship is a means by which people across the world maintain intimate relations both proximate and, increasingly, at a distance. Examination of such intimate human geographies positions work on friendship in humanistic, feminist, and poststructuralist strands of the discipline, in contrast to the more positivist or behaviorist approaches conventionally favored by social psychologists. There is considerable potential for research connecting geographies of friendship to the wider growth of disciplinary interest in issues of human emotion and affect (Bunnell et al. 2012). More so than forms of intimacy associated with kinship or civic unions, friendship requires ongoing and reciprocal emotional work by virtue of not being based on blood ties or formal contracts. The production and reproduction of, for example, mutual trust, fondness, and emotional solidarities through friendship implies both geography and affect: the social geographies of embodied encounters and the performative aspects of friendships that have often been overlooked in categorical accounts of human identity (as being classed, racialized, sexed, gendered, etc.); and the precognitive and often inexpressible affective “substratum” or “bedrock” that circulates between and connects bodies. While existing geographical work has referred to “affective structures” (Valentine 2008) that underpin intimate ties, the term “structure” arguably sits rather uneasily in studies of the relational and fluid “doing” of friendships. The affective dimensions of friendship and its geographies thus form part of a wider questioning of the ontology of the social in human geography.

Although the inter- or transpersonal may be conceptualized in a variety of ways, voluntary relations such as friendships are widely understood to be assuming increased importance in contemporary life. The concept of friendship may be said to reconcile imaginings of late modernity in which individuals have historically unprecedented freedom to enter and leave relationships, on the one hand, with recognition of the continued significance of intimacy, on the other. Friendship is a form of intimacy that appears increasingly important in our urbanizing, mobile, and interconnected world. For purposes of review, it is possible to disentangle three main strands of geographical work that attend to friendship as part of historically shifting social
and spatial relations. The first has to do with geographies of intimacy in contemporary urban life. Geographers such as Nigel Thrift have highlighted the role of friendship and conviviality in “keeping cities resilient and caring” in the twenty-first century (Thrift 2005, 146). In the face of the supposed demise of sociality in alienated Western cities, Thrift considers the institution of friendship to be widespread and even “thriving.” Furthermore, in contrast to loving or romantic couple relationships, friendship, according to Thrift, offers a “light-touch” model of intimacy and compassion that is realistic and achievable today.

Second, friendship is arguably assuming greater social significance in the context of increasing human mobility and long-distance connections that characterize lives in the twenty-first century. Existing practices of connection, community, and intimacy that have been sustained primarily through geographies of stasis are thrown into flux under contemporary conditions of globalization and transnationalism. While this flux has implications for a range of intimate social relations, friendship has gained particular prominence in recent geographical research on migration and mobility. Katie Walsh’s work on British expatriates in Dubai, for example, begins by examining transient heterosexual intimacy but concludes by noting the prevalence of platonic (friendship) ties (Walsh 2007). The young migrant women in Walsh’s study often found (mainly same-sex) friendships to be more meaningful and dependable forms of intimate attachment than those with their sexual partners. Friendship may assume even greater importance for migrant populations at the other end of the socioeconomic spectrum, in the lives of men and women whose social geographies tend to be much more restricted, whose sexual relations are often policed and regulated, and who are unlikely to be able to afford to pay for professional help in dealing with personal or psychological problems. Friendship networks can serve as resources for such migrant men and women in terms ranging from day-to-day practical support (e.g., wayfinding in new environments) to emotional support and care (e.g., for those suffering from depression or struggling with alcohol addiction).

Third, and relatedly, friendship is bound up with shifting geographies of care. In addition to the ways in which migration and transnationalism have reconfigured geographies of caregiving among kin relations, sociological literature has made much of a wider shift from “families of fate” to more voluntarily formed and individualized “personal communities.” Geographer Sophie Bowlby (2011) has highlighted the need for greater attention to be given to the role of friendship in research on care, while resisting notions of a wholesale shift away from “traditional” family-based relations and associated caring practices. Empirical evidence for such a shift is inconclusive at best, with family and other kin members continuing to be important caregivers in at least some life stages, including in those Western contexts on which sociological generalizations have mostly been based. In addition, however, Bowlby (2011, 610–611) points to a blurring of the distinction between family and friends, including situations in which “some family relationships take on many of the attributes of friendships and a few friends may become more like ‘family members.’” The different combinations of friends and/or family implied in “caring for” and “caring about” people, and the ways in which these vary across life stages, make for a rich vein of potential future scholarship in human geography.

Running across all three of these intertwined strands of research are wider geographic issues concerning the significance of bodily copresence for friendships, the extent to which friendship practices and spatialities are being reconfigured
with advances in information and communications technologies, and whether extended possibilities for real-time interaction with distant others are making friendship more or less important compared to other forms of social relations. Do the “light-touch” forms of urban intimacy in which Nigel Thrift has expressed hope require face-to-face interaction, or can they be mediated through technologies of communication? Does messaging with mobile phones and Internet technologies negate the need for convivial spaces of association among migrant friends, or is the coordination of such association among their most important functions? What variation is there in the relative importance of friendship in forms of care that are provided in situ versus those provided at a distance through technologies of communication? Much more empirical work is needed to answer such questions in different social and spatial contexts. The prevailing consensus is that the maintenance of most friendships requires at least occasional copresence (Bowlby 2011), and highly influential research on the Internet-based social media network Facebook has shown that online “friends” mostly emerge from prior offline relations (Ellison, Steinfield, and Lampe 2007). The pace of technological change renders any such conclusions tentative at best, however, and emerging technologies of friendship may form the basis for a transdisciplinary field of research in itself. At the same time, it is important not to presume that technologies of friendship at a distance are new to a twenty-first-century world of high-speed Internet connectivity. Work by historical geographers has highlighted letter-writing and correspondence as technologies of friendship at the turn of the twentieth century (Thomas 2004). As that century progressed, letter-writing became a technology of long-distance social relations that extended beyond political or aristocratic elites. Through the emergence of phenomena such as “pen pals,” it became possible for “friendships” to develop in the space of correspondence between people who had never met face to face.

One established area of geographic research on friendship that is being impacted profoundly by technologies such as Facebook is geographies of children and young people. Not only is friendship conventionally assumed to be of particular importance to children and young people, but they are also often the most enthusiastic adopters of new social networking technologies. To what extent does access to specific technologies exacerbate the impact of socioeconomic status on children’s identities and the friendship groups in which they can participate? Does the use of such technologies mean that moving house or moving school no longer spells the end of friendship networks and associated senses of belonging? Existing research points to the importance of human mobility as a motivation for the formation and maintenance of online networks, with social network sites (SNS) often serving to offset the “friendsickness” associated with moves away from old friends (Ellison, Steinfield, and Lampe 2007). It is important to note, however, that work addressing friendship in geographies of children and young people has certainly not been entirely subsumed by issues of information and communication technologies. Helen Wilson’s (2013) recent ethnographic work on playground encounters, for example, extends established geographic themes concerning how, where, and with whom children forge friendships.

Work on children and young people is also a key field of geographic research in which the positive valence of friendship has been subjected to critical scrutiny. While friendship is generally considered a positive form of sociality, it also has a dark side. Existing work has noted how friendships among children and young people can be important sources of self-esteem and collective identity, but also that bullying and
the production of spaces of fear can be carried out through gangs of friends. Similarly, although friendships can provide opportunities for mutual learning and the broadening of children’s lived spatialities, expectations of conformity among friends can result in children being “led astray.” Such issues arguably apply to the lives of adults as well as to those of children and young people, although they are particularly noteworthy among the latter group precisely because of the way in which childhood friendships can shape opportunities into adulthood. Research that is more specifically concerned with friendship among adults, meanwhile, has included consideration of how the institution reinforces social and spatial inequalities. Although it is possible for friendships to form and be maintained across sociospatial difference, the tendency toward status homophily means that friendship is bound up with ways in which geographies of social inequality are reproduced. In addition, the power associated with trust between friends is clearly open to abuse and may be cast in terms of vulnerability. The informal labor recruitment industry that forms part of a wider migration industry from the Philippines, for example, rests in large part on appropriations – and misuse – of trust in friendships. Sallie Yea’s interviewees who migrated to Singapore for work opportunities as waitresses or hostesses had often been deceived by trusted friends about the nature and conditions of their employment, and this placed them in situations of debt bondage and lack of choice in performing sexual labor (see Bunnell et al. 2012).

Issues of interpersonal trust and power compel many geographers and other social scientists to reflect critically on friendships in their research practice. Clearly, this reflection applies to research that is not explicitly concerned with friendship in either empirical or theoretical terms (and it is worth noting that the terms “friend” and “friendship” appear more commonly in the preface or acknowledgments sections of books and journal articles than in the main body of social science publications); however, even limiting consideration here to scholarship in which friendship does feature as a central concept, the role of friends in carrying out one’s research varies according to methodological choices and preferences. In work that aims to make statistical generalizations about friendship patterns and preferences, or that seeks to map friendship patterns rather than examining the meanings of sociospatial linkages for the individuals concerned, friendships between researcher and researched are unlikely to assume methodological significance (indeed, they are perhaps unlikely to form at all). In other methodological approaches to geographic research, such as in forms of ethnography, not only is it likely that friendships will form during fieldwork, but friends and friendship can become central to the research process. In feminist and postcolonial geographic scholarship, friendships can be vital to research solidarities and collaborative praxis (Sangtin Writers and Nagar 2006).

Finally, there is a pressing need for forms of postcolonially inflected research that takes seriously contextual variation in the meanings and practices of friendship. Such variation expresses perhaps the most straightforward geography of friendship. To date, however, geographers and other scholars working on friendship have largely focused their attention on experiences in the West and the wider anglophone world. If sociological generalizations about shifting social relations, in particular, are notoriously Western- or even US-centric, then an important contribution that geographers can make is to provincialize such generalizations through comparative consideration of friendship in other regions of the world. Commonly cited attributes of friendlike relations in the West, such as the absence of instrumentality in friendship making
and maintenance, do not necessarily apply in other sociocultural contexts. Importantly, such contexts should not be viewed merely in terms of “traditional” cultures or as societies that are undergoing transformations (such as industrialization and urbanization) that have already occurred in the West. One example of how such teleological thinking can be avoided or even inverted concerns the role of friendship in informal networks of care. If these are expanding in many Western societies to compensate for diminishing levels of care provided by the state, perhaps emergent geographies of friendship and care in such contexts are becoming more like societies that have never had extensive state welfare provision. Thus, in addition to being important in their own right, studies of “friendship” in non-Western regions of the world – quotation marks here denote the fact that most people in most regions of the world would not use the English-language term – compel definitional rethinking of the concept and its wider social or structural dimensions. Similarly, critical engagement with terms in languages other than English could help to identify specific forms of friendship. While adjectival differentiations such as “best friend” or “true friend” have been noted in English, for example, other languages (such as Korean) have specific terms for forms of human relations that are conventionally given the generic label of “friendship” in English.

The frontier is one of the most anarchic, unstable, liberating, fertile, and, because of this bewildering ambiguity, also one of the most contested concepts in geography. Within classical border typology, a frontier is a particular kind of border and thus, in its most basic aspect, a criterion for spatial differentiation, both material and ideological. A primary and crucial distinction is the one made by the Polish geographer Ladis Kristof (1959) in his seminal work on the nature of boundaries and frontiers. He scrutinized frontiers through the revealing method of contrasting them to their most antagonizing opposite: unlike the boundary, which summons images of well-defined lines and limits aimed at fixing and disciplining bodies and minds, the frontier is a blurred area of “variable width” (see also Semple 1911, 208) whose moving contours remain beyond anyone’s control, open to all kinds of either friendly or violent encounters. While the boundary is a manifestation of the state’s “centripetal forces,” the frontier is not the imprint of a political project’s claim over space but a “phenomenon of the ‘facts of life,’” “a manifestation of centrifugal forces,” a decentralizing circumstance and thus a challenge to the nation-state (Kristof 1959, 270, 273).

The frontier is what lies “in front” and thus a world yet unknown (Kristof 1959, 269–270). As the vision of what lies ahead, the frontier is precisely the antithesis of a limit: a permanently open horizon; a world more firmly grounded in our imagination and aspirations than in reality — the world but not yet. The frontier is promise, hope, and the opportunity of forward-moving space, which are alluring enticements for the pioneer and the adventurer. A frontier hence suggests a zone of transition whereas a limit marks clear delimitations decreeing the end of something and the beginning of something else. Frontiers’ outer orientation “toward the outlying areas that are both a source of danger and a coveted prize” (Kristof 1959, 271) may be a remedy against the claustrophobia of the boundary: the “desire to distance oneself from the other in order to uphold the (fantasy of the) self during feelings of fear and anxiety” (van Houtum 2005, 677). The frontier stirs vibrating feelings that pulsate to the beat of foreign influences reverberating across space in waves of cultural shudders (Kristof 1959, 271; see also Ferguson and Raffestin 1986). Frontiers give rise to raptures of improvisation, spontaneity, and resourcefulness. In opposition to the promised immobility of the boundary, the frontier threatens with imminent change. While the boundary’s aim is to erect a self-fulfilled prophecy of clearly marked difference and incompatibility, the frontier’s confusion prevents the formation of the very categories that make such division clear-cut or even thinkable. Seen in this way, the frontier may be a conceptual antidote against pernicious expressions of ossified politico-territorial affiliations that find their epitome in the nation-state, as well...
as in the clearly defined identities it promotes and the neatly severed allegiances these identities inspire.

Although it is as geopolitically malleable as the boundary, the frontier is arguably a better representation of incessant flows and thus a more accurate conceptualization of the continuous transformations that are the concern of human geography. Despite the exact nation-state boundaries that make up the basic grid of our modern maps, by zooming from the dishonestly large scale of maps into the smaller scales of spatial interaction, it is hard not to feed the suspicion that cartographical borders would better illustrate the morphology of lived borders with the rough brushstrokes of a frontier than with the terribly executed portraits of linear boundaries (Febvre 1947, 204). Thus, although “For convenience’ sake, we adopt the abstraction of a boundary line … the reality behind this abstraction is the important thing in anthropo-geography” (Semple 1911, 205).

Their partnership with openness is thus a liberating aspect of frontiers: they endow eyes and feet with the feeling that they can wander aimlessly for days or months without finding a drastic change in the spatial-cultural landscape. Arguably, its imprecision and relentless space of possibility make the frontier’s morphology more exciting than the disciplining customs’ booths, passport controls, and waiting lines associated with the highways and airports of boundaries.

Frontiers are also present in the mesmerizing space-altering consequences of the body’s political implications. Markers of socioeconomic status such as skin color and phenotype; accents and language; religiosity and its behavioral manifestations; fashion, diet, manners, material possessions are sociological borders with spatial contexts and consequences. Their political interpretation may turn them into expected, manageable, or even desirable elements of socialization – for example, multiculturalism – or into obstacles for people’s spatial and social movement – for example, xenophobia or racism – and so transform a frontier’s embracement of inevitable variation into the boundary’s objection of difference (van Houtum 2010a). The political implications of thinking more in terms of boundaries than of frontiers are thus far-reaching, for frontiers animate the sort of imagination that boundaries may smother.

Yet, the free-spirited and bohemian interpretation of the frontier should not seduce us into ignoring the concept’s pitfalls. As with the terms “borders” and “boundaries,” which feature a Janus face (van Houtum 2010a), showing excluding closure on one side and resourceful opening on the other, the term “frontier” clearly has another side too. The frontier has been used to justify brutal expansionism, predatory colonization, and exploitative imperialism. The frontier’s inherent vagueness has dark drawbacks. The unsettledness and lack of rigor to establish the limits of space, culture, identity, and ultimately political space and emotional allegiances may give free rein to the worst tendencies, namely the colonial explorations and oppression brought by the experiences of colonization, African enslavement, and the world wars of the twentieth century.

Perhaps the theory that best illustrates the emancipatory and oppressive tension contained in the frontier is Jackson Turner’s highly influential work. In his collection of essays, The Frontier in American history (Turner 1921/1893), he repeatedly referred to the western American frontier as “an area of free land.” Turner’s could be either an oppressive or an emancipatory idea depending on whether you were an American pioneer in search of property, fortune, and religious freedom or the unlucky Native American, the demise of whose lands, community, and culture was necessary for the constitution of the
pioneer’s apparently “free” land. The tension between liberation and oppression contained in the concept of the frontier is related to another tension about its population density. Unlike Turner’s empty frontier, authors like Kristof considered liveliness a *sine qua non* characteristic of the frontier, which he thought of as a place swarming with people and which would be “inconceivable without frontiersmen” for “an ‘empty frontier’ would be merely a desert” (Kristof 1959, 272). The debates about whether the frontier is liberating or oppressive, empty or populous, show that, like any other concept in geography, the historical interpretations, morality, and political implications of the frontier are contested by power.

**Imperial frontiers**

As already hinted at, the term “frontier” has been often associated with empires seeking to legitimize their expansionism or universal ambitions (Kristof 1959, 271). In the frontier thesis of Jackson Turner, for instance, the western frontier of North America provided the space for a rugged individualism to prosper, and thus the basis of democracy and the American political ethos. The frontier was a metaphor for a steady movement away from the influence of Europe and thus the detachment necessary to justify the American exceptionalism Turner saw in America and its development.

A more critical gaze at the frontier thesis would, however, render a different analysis. The frontier in Turner’s sense provided the distinction between civilized and not civilized, inhabited or “empty,” wild land. The geographical imagination evoked by the idea of “free land” behind Turner’s “frontier thesis” glorified the creation of the American West by providing a morally digestible geopolitical narrative for what more impartially could be told as the forceful colonization of Native American territory.

Because of its neglect of the frontier’s meaning for Native Americans, Turner’s understanding of the moving and pioneering frontier across the North American West as the ethos of American democracy has acquired a disreputable rust. This, however, has not prevented the imperial logic underlying Turner’s frontier thesis from becoming widely adopted by political projects with expansionistic ambitions even up to this day. The geopolitical rationales that the United States, Israel, Russia, and even the European Union, for example, present as vindication for the seizure and control of their respective spheres of influence typically characterize their ambitioned territories as lands that lie “in front” and whose emptiness in physical or ideological terms requires – or at least justifies – the kind of management that would be unacceptable in populated lands – for example, drone strikes, armed invasions, fences. Awareness about the frontier’s colonizing pedigree is crucial for its historical understanding and political analysis. Frontiers have been associated with freedom as much as they have been associated with colonizing notions of people without history, without culture, and consequently with no right to space. Holding one or another passport can either increase or decrease the number of frontiers in people’s minds. The carrier of a privileged passport whose country is seen as part of a familiar world can travel unhindered and easily experience the sensation of a seamless world of frontiers as open spaces of possibility, whereas someone who, as a result of a misfortune dealt by the lottery of birth and cannot travel unhindered, may more likely experience a world of prejudice and obstacles in whose boundaries he or she is trapped (van Houtum 2010b). This dark side of imperial frontiers divides the world into geopolitical allies, enemies, and
buffer zones and has helped justify unjust wars and war crimes, ethnic cleansing, genocides, and the systematic oppression of peoples and cultures whose second-class humanity empires have deemed unworthy of owning the very lands they inhabit and even the very lives they embody.

Frontiers of imagination

Apart from its imperialistic notion, in a geopolitical sense the frontier is also a geographical imagination. Frontiers are as material as they are imaginary. Frontiers can be recognized and studied not only on the basis of their location but, perhaps more importantly, on the basis of their perception. Space is more than a physical location; it is also a political and an ideological position. There is a whole travel, touristic, and migratory industry for which these imaginary worlds matter. Also geopolitically, frontiers of imagination have far-reaching, life-altering consequences for the self and outer perception of entire nations. The Americas and Russia, for example, have been European frontiers as much as Europe has been theirs in each other’s cultural imaginary. Ukraine has been a frontier for both Europe and Russia, a vague transition zone between their mutual frontiers. The United States has been a frontier of economic opportunity for poor Mexicans searching for better conditions that their own country fails to offer them. Africa was the frontier for the expansion of the European mission civilisatrice during the nineteenth and twentieth centuries as much as Europe was a frontier of conquest for the medieval Arab caliphates that colonized its south. Scandinavia was a frontier of the unknown for the Mediterranean civilizations of antiquity as much as the Mediterranean was a frontier of plunder and trade for Nordic raiders during the Middle Ages – when Scandinavia had not even been detected or charted on maps.

The frontier is related to geographical exploration and a sense, an acknowledgment, of ignorance and wonder about what lies beyond the ecumene, that is, the “known world.” Since frontiers are characterized by a “certain width,” the question then is how much width these zones of transition can bear before the places they separate are imagined to be so far apart as to be noncontiguous. This idea of frontiers as moving zones of influence can and has been most dominantly applied in physical-geographical terms to denote spatial contiguity, in the sense of natural frontiers, but even more so in political geography to depict ideological, geopolitical, and culturally moving zones of power.

Yet, frontiers can sometimes be as wide as the Atlantic. The American continent was the first European periphery – in the sense that it was the first significant other from which the idea of Europe as a cultural and political unity distinguished itself when it first emerged in the sixteenth century (Wintle 1999) – and was considered as “difference within sameness” (Mignolo 2000, 58). The anthropocentric focus of geography and cartography has played a crucial role in the definition of the frontier. The frontier, being what lies beyond, only makes sense once a center has been defined. The frontier is thus culturally contextual and as such can be subordinated to particular kinds of knowledge, dependent on civilization and a manifestation of ethnocentrism.

Perhaps some of the most fascinating frontiers are those of a dislocated nature whose lack of geographical contiguity makes them among the most complex. They are best understood as what Michel Foucault called heterotopias, that is, a sort of “effectively enacted” utopia (Foucault 1986, 24): places within places whose atmospheres carry our senses into faraway locations.
They are factories of disconnected experiences whose atmosphere bears little or no relation at all to the contexts in which they are inserted. They snatch our emotions the moment we go past their gates into an ambience different from that we left behind.

Colonies, schools, hospitals, cafes, and brothels are examples of such frontiers. Certain means of transportation, such as trains and particularly boats, as can be seen in the refugee crisis of the 2010s, are among the most epitomical heterotopic frontiers:

the boat is a floating piece of space, a place without a place, that exists by itself, that is closed in on itself and at the same time is given over to the infinity of the sea and that, from port to port, from tack to tack, from brothel to brothel, it goes as far as the colonies in search of the most precious treasures they conceal in their gardens ... the boat has not only been for our civilization, from the sixteenth century until the present, the great instrument of economic development ... but has been simultaneously the greatest reserve of the imagination. The ship is the heterotopia par excellence. In civilizations without boats, dreams dry up, espionage takes the place of adventure, and the police takes the place of pirates. (Foucault 1986, 27)

The boat as a heterotopia is a frontier that, even if rarely conceptualized as such, has persistently awakened the fascination of geographers: “After the discovery of fire the next most important step in the progress of the human race was the invention of the boat. No other has had so far-reaching results” (Semple 1911, 332–333).

Since the boundary resulted from advancements in the techniques for territorial demarcation, the frontier is intimately related to the history of technology. The frontier is a historical concept whose disappearance from the map follows cartographical development, which is a testament of frontiers that have been and are no more – at least on maps and in geopolitical discourse. Map-making is the technique that has tried to put the taming leash of boundaries around frontiers. Medieval Muslim cartography is proof that frontiers, not boundaries, were once the borders represented on maps. Muslim cartography from the ninth to the fourteenth centuries shows boundaries between distinct political projects as “zones of transition” and of “uncertain sovereignty” rather than “sharply defined boundary lines” (Brauer 1995, 5–6).

The frontier belongs to a time whose technology did not allow for precise territorial demarcation, or perhaps to cultures whose environments, such as mighty indistinctive deserts, made the very notion of clearly defined boundaries pointless. Beginning in the fourteenth century, improvements in navigation and world travel by the Muslims, the Chinese, and, most influentially, the Europeans expanded the physical frontiers of each of these civilization’s known worlds and shook the very foundations of mental frontiers around the world. Perceptions of identity and
FRONTIERS

politics, race and religion, and even of humanity itself were altered by the revelation of uncharted lands and peoples.

It would be a mistake, however, to consider the frontier as a thing of the past and a relic of politico-territorial arrangements that did not have the technology to clearly demarcate the legal-territorial boundaries of their power. Not only is the European Union a political project that has found a way to maintain the national boundaries of its member states while opening frontiers between them, but its most powerful foreign policy tool has been the frontier-based geopolitical promise of enlargement. This propensity to expand has been the core of the European Union’s diplomatic and geopolitical strength; and, in itself as well as because of its destabilizing consequences in preventing the coagulation of an EU-wide identity, it remains a robust dam against the recurrent waves of nationalism.

In spite of geographical exploration and the amazing sophistication of instruments of navigation, frontiers have not disappeared. Many of the features and perceptions associated with frontiers remain. For tourists, the frontiers of either new (e.g., a road trip to an unknown destination) or mass-produced happenings (e.g., having one’s photo taken by the Eiffel Tower) are the coveted experiences of their travels; however, the ubiquitous and highly detailed worldwide cartography provided by global positioning systems (GPS), mobile phones, and the Internet may have anesthetized the sense of wonder and appeased the hunger for untrodden paths by providing the misleading impression that maps can capture the world and that there is nothing left to discover.

Since antiquity, concepts like terra nullius, terra incognita, and hic sunt dracones have denoted emptiness, a zone of transition between settled and unsettled, cultivated and uncultivated, civilized and uncivilized. Historically, the frontier has conjured the unknown. When the world was limited to the realm of the ecumene (the Greco-Roman known world), the military imaginary perceived the front as the unexplored danger, excitement, and possibility. The frontier is perhaps the most exciting of borders because it is always expectant. Frontiers still evoke a sense of both danger and adventure, glory and perdition.

Fortunately, the uncertainty of the frontier is still attainable for those who crave it. It is hard not to imagine the sense of wonder, spaciousness, controlled uneasiness, and exciting desperation when traveling to less familiar or unfamiliar places. It would be a mistake to believe that the full mapping of the world has brought about the end of geographical exploration (as Mackinder assumed in 1904). Frontiers as large, wide, empty spaces provoking fear, anxiety, enthusiasm, and whatnot have not disappeared. The possibility to imagine frontiers has been stifled with the advent of maps that create the misperception of a fully settled, fully bordered, fully inhabited, and fully controlled world. Yet, while their morphology has multiplied, frontiers still exist.

Frontiers of integration

Precisely because the term “frontier” is reserved for a not yet, a fearful yet tempting there, some authors see frontiers in terms of spatial integration. Much emphasis has been placed on borders of separation, and less (but growing) on borders of integration. Although the recognition of underlying domination structures within discourses has an emancipatory power, the perception of affinity has an indisputable emancipatory power. Much weight has been laid on coercion while bonds have been overseen. It is important to remember that frontiers are
integrating elements (Kristof 1959, 273). We recognize borders not only when we are confronted with difference and exclusion, but also when we come across unforeseen compatibility and inclusion. Whenever we unexpectedly find people with compatible or complementary beliefs, mores, phenotypes, architecture, food, and relationships to ours, we find frontiers of familiarity. When we find compatibility hidden behind an apparently different facade, when we recognize our endophenotype in someone in whom we did not expect to find ourselves, we feel suddenly rebordered into an abrupt familiarity. These are frontiers of inclusion. They are frontiers hidden in plain sight.

Seas are perhaps some of the most interesting among such eclipsed frontiers. In ancient cartography, the massive number of interactions that occurred between continents and civilizations was artistically depicted by traces of routes (such as in portolan charts), as well as by galleons and other kinds of ships, visually suggesting the migration, connection, and trade routes between merchant cities and between metropolises and their colonies. Today's satellite maps present seas as a mere background, thus dispossessing them of their historical and actual importance.

In the same vein, there are frontiers of transmission and translation, that is, contextually divergent practices and perceptions that nonetheless follow a similar spatial logic or entail an analogous sociological meaning. The illegal border crossing of migrants across both the Mediterranean and the Mexican–American border are a good example. The economic and living-standard disparities, as well as the imaginations of empowerment and emancipation that their destinations offer the migrants, speak of a shared geographical imaginary despite the migrants’ disparate heritages and locations. The treatment African and Mexican migrants receive, the dramas and suffering they experience, the prejudices of which they are the target, and the policy debates their movements arouse may be similar and subject to translation. Socioeconomic disadvantages among the black communities of America, as well as their plights as a minority and ways of coping with them, could be translated to the Turkish German communities of Berlin – a certain kind of protest music already does it. A translation implies an abstraction to identify commonalities. Yet, the uniqueness and diversity of border dramas makes any frontier translation and its validity inevitably controversial.

**Conclusion**

Precisely because of its conceptual openness as well as its conceptual relation to exploration, the frontier has been used dominantly as an oppressive term. Increasingly, however, the term’s potential for constructing a more just interaction among a humanity that has become inexorably and irreversibly globalized has exposed the other side of the frontier’s Janus-faced nature (van Houtum 2010a). As naturally curious explorers of the world and its relentlessly changing spatial and cultural sceneries, geographers have a hard time resisting this double-sided, discovery-arousing charm of the frontier. It is hard not to be conceptually allured by the range of possibilities evoked by the untamable attractiveness of the frontier’s drama-laden history and its constantly mutating meanings. This attraction should be a motive for rejoicing among geographers, for a world of enthralling fields of joyful academic discovery lie in front of the further conceptualization, discussion, and exploration of the frontier.

Fuzzy classification and reasoning

Suzana Dragicevic
Simon Fraser University, Canada

Geographic entities from the real world are commonly represented as vector or raster geospatial data models in computer databases. In the vector data model, reality is represented by the geometric primitives of points, lines, and polygons. In this case, feature boundary and identification are well defined. In the raster data model, reality is represented by geometric area primitives such as squares or hexagons. In this case, feature boundary and identification are not always well defined. Moreover, while it is possible to transform vector data into raster data and vice versa, there is a penalty incurred in precision and accuracy of locations and attributes.

This representation of geographic entities on maps was traditionally based on Boolean logic and crisp sets that use binary terms to classify an element to either one or other set or class (Hailperin 1986). This logic has been transposed to geographic information systems (GIS) and geospatial databases that are suited to use Boolean logic and bivalent/crisp representation of object boundaries in digital GIS data layers. However, many geographic phenomena are difficult to represent in a crisp manner. For example, the boundary between forested areas and grassland, or between water bodies such as coastline, lakes, rivers, and shores which change gradually (Burrough and Frank 1996); in addition, these boundaries change over time. When classifying soils or forest types, the sharp boundary representation does not capture the real-world situation (McBratney and de Gruijter 1992; Brown 1998). Moreover, when remote sensing images are used to extract objects, several features on the Earth’s surface are often captured within a single pixel or raster cell, making it difficult to assign a single class corresponding to only one object (Wang 1990). The problem of bivalent representation has been addressed with the theory of fuzzy sets and reasoning developed by Zadeh (1965). Consequently, fuzzy reasoning has been introduced into geography, GIS theory, and spatial databases (Robinson 1988) to replace the traditional Boolean logic and area-class maps representations (Mark and Csillag 1989), and to represent temporal geographic events that change their physical characteristics or attribute descriptions.

Fuzzy set theory is a general specification of classical set theory. It is based on fuzzy membership functions and the gradual values of membership of an element to one or several sets or classes. The mathematical description of a fuzzy set \( A \) is given by:

\[
A = \{ (x, \mu_A(x)) \mid x \in A, \mu_A(x) \in [0, 1] \}
\]

The quantity \( \mu_A(x) \) is called the membership function and it specifies the degree to which an element \( x \) belongs to the fuzzy set \( A \). The elements have continuous membership values between 0 and 1 such that the value 0 means not belonging to a particular class or a set and 1 represents completely belonging to a class or set. The way an element is classified is based on the characteristic of the fuzzy membership function. Fuzzy membership functions can have various forms, such as linear, triangular,
FUZZY CLASSIFICATION AND REASONING

Figure 1 Example of a triangular fuzzy membership function.

Fuzzy set theory later led to possibility theory, which extends the theory of probability (Zadeh 1978), giving the capability to address the uncertainties raised by the problems of crisp classifications and Boolean reasoning. Fuzzy reasoning is based on fuzzy sets theory and enhanced by artificial intelligence and various information processing areas, such as logic, graph theory, topology, and optimization (Pappis and Siettos 2005). Fuzzy sets and their use in GIS have been addressed in detail by Robinson (2003).

Fuzzy set theory and reasoning are used for a variety of spatial applications that include the definition of a class or a cell state for positional or attribute uncertainty. Fuzzy representation of geographical boundaries and geographic objects are discussed in Burrough and Frank 1996; Wang and Hall 1996; Cheng, Molenaar, and Lin 2001. Examples of the spatial application of fuzzy logic have been widespread and include areas such as: forestry (Lowell 1994), soil science (McBratney and Odeh 1997; Burrough 1989), climate classification (McBratney and Moore 1985), land evaluation and suitability (Sui 1992; Jiang and Eastman 2000; Prato 2009), remote sensing (Wang 1990; Fisher and Pathirana 1994; Foody 1996), landscape ecology (Salski and Kandzia 1993; Marsili-Libelli 1989; Fisher et al. 2006; Foody 1986), landslides (Muthu et al. 2008), geology (An, Moon, and Renz 1991; Luo and Dimitrakopoulos 2003; MacMillian et al. 2000), and spatial interpolation (Bogardi and Kelly 1990; Dragicevic 2005). In addition, handling the temporal component in GIS databases using fuzzy sets has been reported by Dragicevic and Marceau (2000a). These resulted in the use of fuzzy reasoning for modeling dynamic spatiotemporal processes (Dragicevic and Marceau 2000b; Dragicevic 2004a) and the development of fuzzy cellular automata approaches for representing land-use change and urban growth (Wu 1998; Liu and Phinn 2003; Dragicevic 2004b; Al-Ahmadi et al. 2009), propagation of forest fires (Mraz, Zimic, and Virant 1999), forest insect infestation (Bone, Dragicevic, and Roberts 2006) or invasive species (Dragicevic 2010). Fuzzy reasoning was applied to agent-based modeling to mimic the decision strategies that agents, in this case squirrels, implement in order to move in the landscape as part of their food searching process (Graniero and Robinson 2006). Fuzzy kappa statistics and measures have been developed to explain and compare map patterns arising from complex spatiotemporal processes (Power, Simms, and White 2001; Hagen 2003; White 2006; Hagen-Zanker 2009).

Fuzzy classification methods

The goal of classification is to decrease the dimensional complexity of a dataset by grouping statistically similar values into a smaller number of classes or categories. In the commonly used crisp classification method there is a one-to-one correspondence between the measured value and the class into which it is assigned. Class
membership values can be either “1” for complete belonging to a class or “0” for not belonging.

In the case of fuzzy classification, a measured value can have membership in various classes and with different degrees. Fuzzy classification groups values into a fuzzy set where the membership function is defined by the truth value of a fuzzy membership function. In crisp classification, a class is a set of values with specific properties and every measured value that satisfies those properties is a member of the class. The classification algorithm or rule then evaluates the measured values and determines which class they belong to. However, for fuzzy classification there are some modifications to this generality. A detailed explanation of fuzzy classification methods has been presented by Robinson (2008). Ultimately, the fuzzy membership function defines how an element belongs to one or several sets and thus gets classified to a particular class. The key aspect of fuzzy classification is the way in which one or several membership functions are specified to describe the problem, and so can be subdivided into specification approaches that use prior knowledge or those that are data driven.

The fuzzy classification with prior knowledge relies on the knowledge of domain experts to construct fuzzy membership functions that determine the membership values. Aggregation (Burrough and McDonnell 1998) or rule-based methods (Cannon et al. 1986) allow fuzzy membership functions to be combined in specific ways so that an output map can be created with the fuzzy membership values that describe a particular problem. Figure 2 presents an example depicting the stages of generating an urban land suitability map for potential new urban residential development. The analysis is based on three fuzzy membership functions representing the criteria of elevation, proximity to schools, and proximity to roads with their corresponding fuzzy maps. The first fuzzy function and derived map describe the suitability of the land based on the elevation factor. From expert opinion (such as urban planners, urban developers, urban policymakers), the elevations from 0 to 50 m are considered the most suitable for urban development, and thus have the membership value of 1 (purple on the map). Then the elevation value decreases linearly until it reaches 1000 m (red to dark blue on the map). From 1000 m, the land is considered to be unsuitable for any further urban development thus the membership function is 0 (black on the map). Similarly, the second and third functions describe the best distances to schools (500–1500 m) and to roads (100–500 m) where the fuzzy membership function will indicate the value of 1 as the most suitable. The overall fuzzy suitability map (the top right map on Figure 2) for urban land use is generated by combining the individual map layers using the GIS overlay operator. This overall map provides the combined grades of membership function indicating the level of suitability for new urban development at any locations in the Metro Vancouver area based on the three suitability criteria (i.e., fuzzy functions of elevation, proximity to schools, and proximity to roads). The most suitable and least suitable locations for new urban development are presented as purple and black, respectively, on the map.

When expert opinion and knowledge are not available, then data-driven methods can be used (Luo and Dimitrakopoulos 2003). Various techniques can be used, such as fuzzy k-mean clustering methods (McBratney and de Gruijter 1992; Wang 1990; Cannon et al. 1986) or fuzzy neural networks inference systems to guide fuzzy classification (Foody and Boyd 1999). These methods depend on available datasets to derive the rules prior to the classification procedure.
Conclusion

There are many advantages of using fuzzy sets and reasoning in spatial applications and their widespread use in the GIScience community is strong confirmation of their relevance and usefulness. Exact classification methods lose information and increase errors while fuzzy approaches can address the complexity of the typical geographical and environmental data that change gradually over space and time. However, the main disadvantages of fuzzy approaches are the reliance on the choices of the fuzzy membership functions, mainly by expert opinion, as well as the choice of the parameters for the clustering or other data-driven approaches used for fuzzy classification. In addition, the choice of the de-fuzzification technique to classify the output fuzzy function into meaningful categories can be somewhat subjective. Nevertheless, fuzzy sets and reasoning are valuable analytical tools for GIS and geographical analysis.

FUZZY CLASSIFICATION AND REASONING

Gated communities

David Wilson
University of Illinois at Urbana–Champaign, USA

Current gated communities across America, Europe, and beyond are isolated residential enclaves designed to be exclusive, exclusionary, and physically detached from the immediate city or community. To achieve this status, gated communities typically contain controlled entrances, central open courts or streets to enable tenants to perform a maximum amount of traffic surveillance, and class-based meanings embedded in architecture to accentuate who should and who should not be at these microsites. They are also often marked by closed perimeters of walls, fences, and barricades. These communities can vary in size from one or two buildings to coordinated blocks of similar housing and internal retail and recreational facilities. For smaller communities, carefully monitored parks and common areas are common. For larger communities, there are often ample facilities and social activities for residents to stay within the community for most daily activities. Such common interest developments are proliferating across the globe today, fueled by the increased desire of the affluent to separate themselves from other segments of the population.

Economic segregation, of course, is not new. A multiplicity of measures, from zoning to housing covenants to racial steering, has existed for decades across the world to ensure class exclusivity. But gated communities go further, in particular privatizing public space and deepening patterns of social surveillance, in taking segregation to a greater level.

This balkanizing of people into compartmentalized spaces has enormous policy consequences. With people isolating themselves from active social contact with others, understanding of others and recognition of city and community diversity break down. The traditional notions of social contact and class intermixing that have been at least a professed ideal in many cities and communities disappear. As Blakely and Snyder (1997) ask, what is the measure of nationhood when the divisions between neighborhoods require armed patrols and electric fencing to keep out fellow citizens? In their view, when social space is dramatically splintered and the community of responsibility stops at gated community entrances, society gives up too much, and we should not casually disregard this new development. In short, can any community, city, region, or nation fulfill its social contract in the absence of social contact?

Gender and development

Ann M. Oberhauser
Iowa State University, USA

Gender identities and women’s positions in society represent critical dimensions of development theory and practice. In recent decades, international organizations, policymakers, scholars, and activists have increasingly recognized how inequality in the development process contributes to issues such as low literacy rates among women, gender-based violence, the exploitation of women in low-wage jobs, and underrepresentation of women in leadership positions. These conditions affect the progress not only of individuals and communities but of entire regions of the world. Critical perspectives in the gender and development arena, however, often question whether or not the resources and energy that development institutions and policy have invested to advance women and achieve gender equality have made significant impacts on the overall development of countries, especially those from the Global South.

This discussion outlines six themes that highlight major theories and approaches to gender and development, as well as practical and applied aspects of this area of study. The first theme examines how women’s and gender issues in the development framework gained global attention through efforts such as the establishment of the United Nations Commission on Women in 1946 and the UN Decade for Women. The field shifted from an approach that essentialized the category of “woman” to frameworks that examine gender and its intersections with other social categories such as race and ethnicity, class, caste, age, and sexuality (Visvanathan et al. 2011). This shift laid the foundation for a movement that is grounded in voices and perspectives from developing countries and that challenges patriarchal and Western biases in development theory and practice. Furthermore, recent work in postcolonial and transnational feminism critiques the hegemonic discourses and inequities that have been historically constructed in both colonial and capitalist systems.

Economic globalization is the focus of the second theme on women and gender in the development process. Women and men are impacted differently by the global economy, and thus globalization has gendered implications for livelihoods and economic strategies. The third theme outlines local organizing and empowerment as the root of grassroots and community-based initiatives in development work. The discussion includes analyses of the institutions, alliances, and livelihood strategies that constitute women’s efforts and often embody their gendered roles. The fourth theme highlighted later in the entry examines gendered aspects of national and global health issues that impede development and impact families and communities. Gender plays an important role in the overall health of a society, partly due to women’s responsibilities in the areas of caretaking, family nutrition, and reproduction. Of note in this discussion is growing attention to sanitation, and especially access to toilets and clean water in developing regions.

The dynamic and gendered relations between nature, the environment, and development are the focus of the fifth theme. Nature and the environment are often situated at the core of the development process, and therefore gendered access to and control over natural resources and
the environment contribute to inequality in development. The discussion addresses sustainability, feminist political ecology, and climate change in the context of gender and development. The conclusion addresses future directions in the field of gender and development that include information technology, global security, and sexuality.

Conceptual approaches to gender and development

Changing perspectives on women, gender, and development have created a dynamic and somewhat contested field in geography and related disciplines. The shift from a focus on women in the development process to gender and other social dynamics is evident in the conceptual paradigms as well as the institutions within which the field of development is based. Initial efforts to address women and inequality in the 1970s adopted a welfare approach with an explicit focus on women in their reproductive roles as wives and mothers. Specifically, women in development (WID) draws from the modernization framework which was modeled after Global North capitalist theories of development. Ester Boserup’s seminal work revealed that not all people benefited equally from development efforts which often had negative impacts on women. This period also saw global efforts to mobilize and draw attention to the status of women in developing regions through initiatives such as the UN Decades for Women, which began in 1975 with the Nairobi Conference.

Subsequent approaches to development critiqued both the overarching focus on women and the Western bias in theorizing women and gendered aspects of this field. The women and development (WAD) framework was one such approach and drew from Marxist critiques of capitalism to examine multiple aspects of women’s productive and reproductive labor in the context of international capitalism and unequal class relations (Kabeer 1994). This expanded view of women’s roles in society coincided with an emphasis on gender relations at multiple scales of the household, community, and workplace. Furthermore, gendered approaches to development allowed a much greater awareness of how different women experience gender. These approaches highlight women’s active engagement in change that is meant to disrupt power relations between men and women and to enhance women’s legal rights in areas such as inheritance and land reform. Moreover, Moser’s (1993) work emphasizes gender planning and policy by articulating two aspects of empowerment in the development process. First, strategic needs such as legal rights, equal wages, and domestic violence relating to women’s subordinate position in society are a means of addressing gender inequality. Second, practical gender needs relate to immediate necessities such as water, health care, and employment. Further efforts to situate development in regions most affected by the development process arose with initiatives such as the Development Alternatives with Women for a New Era (DAWN) in the mid-1980s. This organization is a feminist research network focused on widespread education and consciousness-raising to empower women in the Global South (Sen and Grown 1987).

The focus on women’s experiences in developing regions is also illustrated by the women, environment, and development (WED) approach, which addresses unequal access to and use of the environment. In particular, ecofeminism draws parallels between men’s control over nature and over women (Mies and Shiva 1994). These views of environmental and patriarchal exploitation are grounded in critiques of Western science and masculinist models of industrialization. In contrast to the ideologically based ecofeminist
approach, Agarwal (1992) developed feminist environmentalism as a way to emphasize more material approaches to the link between gender and the environment. This perspective provided the basis for critical activism and community efforts aimed at sustainable development in fields such as forestry and agriculture.

More recent theoretical approaches in this field include ongoing challenges to the Western bias in development discourse by women and feminists from developing regions. For example, postcolonial feminists critique Western models of development, patriarchy, and feminism that ignore the voices of Global South women or essentialize women as a homogeneous category. In *Third World Women and the Politics of Feminism*, Mohanty, Russo, and Torres (1991) emphasize the role of colonialism and hegemonic discourses that discriminate against women and marginalized voices from developing countries. They cite Western feminist representations of Global South women as universalizing and largely derogatory. Overall, theories and approaches in the field of gender and development have dramatically shifted since the mid-twentieth century from a focus on the status of women in traditional reproductive roles to a broader analysis of gender and other social identities, inequality, and power in diverse geographical contexts.

**Gender and economic globalization**

The approaches to gender and development examined so far are grounded in several themes that have shaped the advancement of this field. The first theme, economic globalization, underlies many aspects of gender and development theory and practice. The erosion of social services under neoliberal capitalism, the concentration of women in low-wage manufacturing, and gender bias in agricultural reform are some of the processes that illustrate the connection between globalization and gender in contemporary society. According to Beneria (2003, 77), gender and globalization are “shaped by the interaction between these forces and the different ways through which gender constructions have been reconstituted during the past three decades.” In particular, neoliberal globalization translates to the institution of laissez-faire economic strategies that promote privatization, free market forces, and reduced government roles in many areas of the world. In numerous cases, these strategies are the results of structural adjustment programs implemented by international financial and development organizations such as the World Bank and the International Monetary Fund (Beneria 2003). The co-constitution of structural adjustment and gender is evident as women experience higher rates of poverty than men, unequal access to well-paid and secure employment, and increased vulnerability in times of economic cutback. Given the gendered divisions of labor in the reproductive arena, women are often at a disadvantage as governments decrease support for social services such as education, health care, and child care (Momsen 2010).

Economic globalization also expands employment opportunities in many developing countries, as capital invests in areas where costs of production are considerably lower than in the Global North. Women form a disproportionate share of the workforce in low-paid and insecure jobs because of gendered practices that undervalue and exploit women’s labor (Runyan and Peterson 2014). While there are negative aspects of women’s employment in what Elson and Pearson (1981) refer to as the “global assembly line,” many believe that these jobs benefit women by expanding their income generation and independence. Kabeer (1994), for example, argues that women have increased autonomy and bargaining power as a result of
their engagement in waged labor. Work in the informal sector is also impacted by the rise of globalization in both industry and the service sector, which employ women in highly marginal and exploitative conditions (Beneria 2003).
