Rapoport’s rule. Rapoport’s rule was speculated to apply to both latitude and altitude gradients, based on the hypothesis that the variability of climate (temperature or precipitation) increases along with elevation or latitude, and therefore species adapted to the habitat at higher elevation or latitude tend to have a larger niche width as well as a broader geographic range.

Topography, geomorphological processes, and feedback. Topographic heterogeneity in a mountain context typically reflects the content of the niche hypervolume concept, that is, a niche space with multiple dimensions and scales, including the temporal dimension as regulated by climate changes and the disturbance of geomorphological processes, as systematically documented in the alpine treeline. Mountain topography provides a diversity of habitats in a hierarchical framework to harbor the components of the mountain species pool. By niche differentiation in this context, the probability
of extinction driven by competitive exclusion is reduced, and the mountain acts as a museum of species diversity.

**Area.** Area is one of the two factors that affect species richness in the equilibrium theory of island biogeography; one interpretation is that species richness increases along with the accumulation of energy over larger areas. An unresolved issue is whether the larger surface area in mountains, relative to the planar projected area, contributes independently to the species richness.

**Mid-domain effect.** As a mountain has boundaries on both upper and lower ends of the altitudinal gradient, although not as a definitive at the lower end as for an oceanic island, the altitudinal range of species is geometrically constrained by the elevational boundaries according to the concept of mid-domain effect (Colwell and Lees 2000): random distributions of ranges will result in more overlap in the middle. The mid-domain effect produces a hump-shaped pattern of species richness along the altitudinal gradient. However, this hypothesis has been controversial for its assumptions, especially regarding the different range sizes of species.

**Historical mechanisms**

**Spatial isolation and disjunct distributions and speciation.** The debate between two biogeographical paradigms of disjunct species distribution and speciation – the vicariance model and the dispersal model – have lasted for more than a century, although both are based on spatial isolation, a basic property of mountain landscape and mountain ranges. Spatial isolation has potential impact on the three processes of migration, speciation, and extinction, depending on the interaction with other natural versus anthropogenic processes.

**Climate change and mountain refugia.** The Quaternary glacial reshaped the contemporary pattern of global vegetation and biodiversity, especially in the northern hemisphere. Refugia as a biogeographical concept refers to the locally favorable habitat condition for species to survive at a local scale in spite of hostile environmental change, especially climate change, at macro-scale. The role of glacial refugia is widely recognized in the survival of many high and mid-latitude species through the Quaternary glacial maximum in remnant populations in the northern mountains, instead of being completely eliminated or driven to the south, and migrating back after the glacial. The recently generalized refuge hypothesis includes micro-refugia of much smaller scale but more prevalent distribution. Although the glacial/interglacial cycling push the back-and-forth movement of species distribution, the survival in refugia or micro-refugia and recolonization is a rule rather than exception (Schmitt and Varga 2012). Glacial refugia in the northern mountains and interglacial refugia in the south mountains highlight the critical role of mountains in biodiversity conservation through the large climate changes of the Earth’s history.

**Mountains as the cradle of biodiversity.** Fossil evidence, genetic experiments, and phylogeographic studies repeatedly suggest that mountains act not only as a museum of biodiversity, by harboring species of different niches and reducing the extinction risk from competitive exclusion, but also play a critical role in the speciation process, in terms of both allopatric and sympatric speciation.

Through both spatial isolation and environmental differentiation, mountains act as a barrier to organism dispersal and gene flow between the populations of the same species. The following breeding isolation would eventually drive the separated populations into diverging evolutionary pathways. At large temporal scale, the fast uplift of mountain ranges was found to correspond with the increase of speciation rate in
time in the Andes and the Himalaya, supporting the idea of the mountain orogenesis process as a pump of regional biodiversity (Badgley 2010).

From island biogeography to mountain biogeography

As the first theoretical model for biogeography, the equilibrium theory of island biogeography suggested that species richness is the outcome of equilibrium between the immigration and extinction processes that are fundamentally determined by the area of the island and the distance between the islands or island to continent (MacArthur and Wilson 1967). The equilibrium theory has since been widely applied to the insular contexts in addition to islands, for example, mountains, caves, and even urban systems. Mountains, as “sky islands,” are an important locus for examining the theory.

The inadequacy of the equilibrium theory has been revealed by mounting tests, and the model was criticized for omitting the role of ecological factors, such as environmental heterogeneity, biotic interactions, as well as species traits in affecting insular biota. However, an early insight of island biogeography has also been reemphasized, namely the species specific island biogeography, which by integrating the evolutionary history of a particular lineage constructs a phylogeography (Lomolino, Brown, and Sax 2010). This approach aims at interpreting the biogeography of the lineage in terms of evolutionary adaptation to the critical environment variations, especially glaciations and mountain orogenesis.

Although mountains as a model are more representative to the isolated or fragmented domains generally applicable to all kinds of insular organisms, a theoretical framework for explicit mountain biogeography has yet to be develop. By absorbing the essence of island biogeography, and addressing the difference in isolation between mountains and real islands, as well as its impacts on the immigration, speciation, and extinction processes, mountain-based studies have a great potential to provide critical insights into the development of biogeography.

Climate change, human activity, and biodiversity conservation in mountains

The concentration of narrow-ranged species in the mountains entail mountains the priority of biodiversity conservation. This role is especially true in the face of the challenges brought about by global climate warming since the second half of the twentieth century, primarily as a result of increasing greenhouse gas emission primarily caused by fossil fuel consumption and land use change.

Observed species range shift responding to climate change is usually 1000 times greater in horizontal distance than in elevational distance (Chen et al. 2011), suggesting mountains as a safer environment for organisms to match the pace of climate change, especially for the taxa with weak dispersal capacity. However, as mountain species generally have narrower ranges owing to the steep environmental gradient, these species might be more vulnerable to the extinction drivers other than climate change, because their restricted and fragmented habitats are more susceptible to the risk from natural disturbance or disease. In addition, species distributed in the isolated mountains face an absolute boundary at the tops, and the upward shift driven by climate warming would eventually be stymied, leading to the risk of local extinction. Increasing records of upward shifts of mountain species imply the reality of the risk. On the other hand,
human activities at global scale have extensively altered the lowland landscape, turning mountains into sky islands separated by the land types difficult or even hostile to the migration of the organisms. By interacting with natural factors and processes at multiple scales, human activity as a pronounced component needs to be integrated into the framework of mountain biogeography, which poses a novel challenge for the development of the discipline.

Mountain climatology

Bryan G. Mark
Ohio State University, USA

Mountain climatology is the study of weather processes and patterns resulting when a section of land is elevated with respect to the surrounding terrain. Mountains are renowned for being sites of unique and often dramatically variable weather, with characteristic winds, clouds, and colder temperatures (Figure 1). In more general terms, they are physiographic features that dynamically couple the atmosphere, biosphere, lithosphere, and hydrosphere. Moreover, mountains are resource-rich, high-energy ecosystems with cultural and biological diversity that are valuable to society (see Ecosystem services) and highly sensitive to changes in climate. Mountain climatology is a particularly apt context for integrating human and physical geography (see Interdisciplinarity and geography).

Because mountains are challenging locations in which to conduct observations, mountain climatology comprises a small and specialized branch of geography with a single comprehensive text, now in a third edition (Barry 2008). There is a long history to mountain climatology, as scientists have been drawn to explore these elevated environments and use them to gain access to observe the upper levels of the atmosphere. The insights of mountain climatology have direct bearing on many other areas of study ranging from water resources and hydrological management, forestry, ecology, and biogeography to human cultural studies.

Mountains are sensitive landscapes, and thus take on a particular interest for studying local responses to changes in global climate (see Global climate change). Going forward, certain dimensions of mountain climatology take on particular relevance in the context of human-induced climate change. These include archiving the nature of past climate variability, monitoring ongoing climate variation at high elevations, observing the rates and nature of ecological shifts in a warmer troposphere, and considering the nature of adaptation and resilience to climate change by diverse populations (see Climate adaptation/mitigation and Climate change adaptation and social transformation).

Defining mountain climates

Consideration of the climatology of mountains requires definition of mountain environments. What gets defined as a mountain is highly variable and even culturally specific, involving not only absolute elevation ranges above sea level, but also relative relief, steepness, and distinctive characteristics such as snowline, treeline (see Treeline ecotones), zone of permafrost (see Permafrost: definition and extent), and limits of glaciation. According to a typology to assess relative water yield, about 20–25% of Earth’s terrestrial surface is considered mountainous, and these regions contain a similar proportion of human population (26%), although they yield slightly more (32%) of the surface runoff (Meybeck, Green, and Vorosmarty 2001). Mountainous environments exist at different scales, ranging from isolated single volcanoes to extensive ranges of
summits and vast plateaus (e.g., Tibetan Plateau, Andean Altiplano). Their relief and altitude make mountains extreme environments, often evoking particular cultural reverence and awe. They also derive significance from containing high degrees of Biodiversity and endemism, and concentrations of natural resources. In particular, the climate and landscape characteristics of mountains make them effective “water towers” of humanity, given that enhanced Precipitation and favorable elevated landforms allow water, Snow, and ice to accumulate and flow from mountain highlands (Viviroli et al. 2007). Finally, mountains are regions of long fascination and opportunity for people, so that mountain climates have direct and cultural significance to society. Many studies have looked at the long-term significance of specific mountain climatologies, and form a genre of long-term observation and insight that mixes measurements with folklore.

Mountains are climatologically diverse settings since atmospheric density and temperature decline vertically through the troposphere. The range of climate variability is excessive, so that most general climate classification systems (e.g., Köppen) opt to simply group all highland zones as a separate category. Likewise, mountains transect many ecosystems and biotic zones vertically, and are often covered by snow and ice. Mountains also form boundaries for prevailing winds. This interrupts airflow, and forces parcels to be displaced vertically, cooling and precipitating. Hence, precipitation is often more intense on windward sides of mountains.
Conversely, the descending air warms adiabatically and dries, leading to “rainshadows,” zones of dry and often windy conditions downwind of mountains. Given this complexity of scale and processes, descriptions of mountain climate are delimited by twinned considerations of purpose and feasibility. Typical interest areas are on winds and precipitation formation, and often involve particular needs for monitoring conditions of hazards in the steep terrain of mountains, such as snow avalanches (see Snow and ice avalanches), runoff/flooding, and landslides (see Geomorphic hazards, Natural hazards and disasters, Glacier lake outburst floods, and Avalanche meteorology). Other implications in mountains for cold air pooling and boundary layer dynamics include atmospheric pollution.

For the geographer, mountain climatology holds a particular fascination and challenge given extreme heterogeneity of scale. Just as defining mountain areas is difficult given their myriad forms, their relative prominence (elevation above surrounding terrain) is responsible for an equally broad range of meteorological phenomena occurring over different scales of space and time. The fundamental regional controls of climate such as latitude and continentality (distance from oceans) that constrain radiation input, temperature, and humidity get further complicated in mountain regions by altitude and topography. These factors change the thermodynamics of the atmosphere by altering air density, pressure fields, winds, and exposure to radiation and moisture. Furthermore, atmospheric energy and momentum interact with the mountain landscape over scales ranging from the micro (e.g., individual rocks, plants, snow patches) through the local (e.g., slopes, valleys, ridges) to the regional (e.g., ranges, plateaus). All of these scales are themselves separate areas of climatic research with implications and relevance for many other realms of inquiry. How surface energy fluxes vary at the microscale impacts ecology, and leads to multiple niches along vertical expanses of mountain slopes. Diurnal heating patterns lead to thermal pressure gradients inducing valley winds, while cold air aloft sums sinks in katabatic flows. The orography of mountains can intensify precipitation along slopes, nourishing diverse tree species that form characteristic biotic ecotones with elevation.

Synoptically, mountains interrupt regional air flow, and cause gravity wave trains that induce subsequent storm generation in what is called lee-side cyclogenesis. Mountains thus play an important role in forcing or enhancing mid-latitude cyclones, and can induce orographic enhancement of precipitation. And on continental to global scales, seasonal variations in climate over mountain ranges and elevated plateaus induce large-scale monsoons. Interconnecting the dynamics of the atmosphere with landscape surfaces among all these scales challenges researchers to collaborate across disciplines and use multiple technologies to gather observations. Future advances will be made as this integration increases, and is able to be better simulated with models.

Measuring mountain climates

Progress in understanding mountain climate is hindered both theoretically and practically given the complexity of processes occurring on many scales. There is a general paucity of observations as many of the world’s mountain ranges lack long-term measurements. Logistical challenges to maintain and standardize data acquisition in different high-elevation locations make it difficult to conduct subsequent analyses or intercomparisons. Important initiatives by organizations such as the Mountain Research Initiative (MRI) are attempting to catalyze better collaborations internationally, motivated by a realization that
Mountains are key locations not only to preserve and herald the changes facing Earth, but also to test the hypothesis that temperatures at higher altitudes are changing faster than in lower places. Satellite telemetry and the use of low-cost embedded sensor networks are emerging in this context, and giving new data and insights, as are higher-resolution air- and spaceborne sensors.

The mountain range with most well-measured climate characteristics is the European Alps, where stations with reproducibly reliable instrumentation have been maintained for the longest duration; many summit stations have been in continuous operation for over a century. It was in these ranges that certain experiments were carried out as early as the seventeenth century to demonstrate fundamental principles of atmospheric pressure. Large science experiments have also been organized in the Alps, such as the meteorological research program ALPEX (Alpine Experiment) and the Global Atmospheric Research Programme (GARP) of the World Meteorological Organization. Many fewer continuous observations are available to the geographic community from the Andes, Himalayas, and more remote ranges. If observations have been obtained, data access has often been difficult, and there have been other issues of checking quality and standardization.

Specific climate variables have relevance for different questions, and researchers face different challenges in maintaining standardized measurement protocols for the highly varied conditions found in mountains. High-elevation locations are of particular interest for understanding the nature of climate changes from the past to the future. Temperature is arguably the most influential variable in mountain climate processes, and is also most straightforward to track for different research questions as it varies most persistently with terrain. Sufficiently dense arrays of measurements can allow components of regional and local physiography to be statistically decomposed to test their relative influence over time series of temperature. Precipitation, wind, radiation, and humidity are more prone to variability over complex topography and also present challenges for conducting standardized measurements to be integrated in models. Testing hypotheses about variability in these quanta on mountains is problematic because of difficulty not only in measurement technology, but also in selection of locations to place instruments; justifying any single place as “representative” is nearly impossible given the complex surface variations in mountains. Some advances have been made in embedding microsensors within the landscape, allowing for higher measurement density. Integration of satellite and aerial observations with ground measurements remains an effective way to address the landscape heterogeneity across scales, and major integrated field campaigns such as the Mesoscale Alpine Programme (MAP) in Europe and the Terrain-Induced Rotor Experiment (T-REX) in the Sierra Nevada have simultaneously deployed many ground and aircraft measurements to yield valuable new data and model simulations to understand dynamics. Mountains in all climatic zones have an impact on modifying precipitation, even if the effects vary. But recent theoretical work has postulated a linear theory of orographic precipitation that provides a simplified conceptual model of how stable atmospheric flow interacts with topography to yield precipitation. This predicts close correlation of topography with precipitation patterns, as manifest in observations from the Himalayas.

In the context of improving understanding of short-term phenomena in complex mountain environments, a host of observational techniques, data assimilation, and modeling all have been developed. Improving the understanding of multiscale meteorological processes in near real-time requires better models, data,
and analyses, motivating collaboration between academic and industry practitioners. Such has been the focus of a particular community effort: the Mountain Meteorology Committee of the American Meteorological Society sponsored a recent Mountain Weather Workshop to help “bridge the gap” between researchers and operational forecasters, which has motivated collaboration in the form of symposia (Chow, De Wekker, and Snyder 2013).

Mountains and climate change

Mountains are also highly sensitive to climate change. The need to sample climate variables directly and detect changes to the Earth system motivates a focus on mountains. This is particularly true as many observational and modeling studies have hypothesized that ongoing and future climate changes will impact high elevations preferentially. Glaciers and permafrost are found at the upper reaches; as temperature increases, these frozen bodies of water are prone to melt. Likewise the long-term and widespread loss of ice on mountains has been heralded as the “canary in the coal mine” of climate change. These changes have important implications for society. For instance, the loss of mountain Snow cover in the western United States has been a crucial issue for water supply, with associated social geographic issues related to the allocation and sustainability of resources for urban development and agriculture (see Snow cover changes).

Since topography and verticality are defining characteristic of mountains, the study of mountain climatology invokes a study of diverse ecology, variability, and gradients (see Hillslopes). Moreover, the existence of vertically defined ecologic zones with characteristic flora and fauna is constrained by climatic limits. Networks have been established (e.g., GLORIA – Global Observation Research Initiative in Alpine Environments) to record global mountain plant species assemblages using a consistent protocol, and revisited to document changes on mountains, and comparing these changes in different regions globally.

Mountain climatology has a broader heritage and legacy that comprises the study of past (paleo) climate (see Paleoclimatology) using proxies preserved in the mountain environment. Geoscientists have long been attracted to mountain environments for learning of Earth’s history; the environmental conditions preserved in the geologic record provide a means to infer past climatic conditions that appear to change radically over time. After the understanding of glacial ice ages (see Glaciations and Quaternary glaciations) was established in the early nineteenth century by reexamining geological evidence, many speculative ideas, often wildly divergent, emerged to explain the changing character of Earth’s climate over time. T.C. Chamberlain gave an address in Toronto to the British Association for the Advancement of Science in which he attempted to synthesize multiple working hypotheses on climate changes. He captures the trepidation of this early endeavor, which lacked data and theory, but makes an emphatic case for combining geology and climate studies that has subsequently borne fruit in the field of paleoclimatology: “While the atmosphere is the most active of all geological agencies, it has received the least careful study from geologists....The atmospheric element in geological history bids fair to long remain obscured by elusive factors and uncertain interpretations. None the less it is an element of supreme importance and should be persistently attacked until it yields up its truths. ... All our attempts at the solution of climatic problems proceed on some conscious or unconscious assumption concerning the extent and nature of the atmosphere at the stage involved” (Chamberlin 1897).
While the climate change theories reviewed were speculative at the time, research in many mountain ranges over the ensuing century has revealed the prescience of Chamberlin’s charge. Many important archives of past climates, from ice cores to lake sediments to ancient tree rings, and the paleoclimate records extracted, have given important context for understanding mountain climate variability over time. Assimilations of paleoclimate proxy databases have become important validation for global climate models. Furthermore, given the strong local topographic mediation of regional climate, more attention has been placed on achieving broader, more spatially distributed sample sets of multiple proxies. For example, using snowlines reconstructed from glacier geomorphologic data (i.e., moraines) to constrain regional to global climate change requires careful scrutiny of intraregional variability (Mark et al. 2005). Also, intercomparison of ice cores recovered from multiple mountain locations outside of the polar ice caps has broadened insights into interhemispheric responses to global climate dynamics.

While mountains are often considered static in relation to the dynamics of the atmosphere, growing interest in Earth systems research (see Earth system science) has shown that there is actually a full coupling that goes in the opposite direction. Geologic processes initiated in the atmosphere and characterized by climate actually impact the lithosphere and ultimately govern weathering and uplift of the mountains. The realm of landscape evolution is a growing focus area that brings together tectonics, geomorphology, and climatology (see Tectonic geomorphology and Quantitative geomorphology). Climate links surface uplift and erosion rates through several mechanisms, including orographic forcing of precipitation, onset of alpine glaciation, and other moderations of erosion efficiency (Willett et al. 2006). In this context, climate models, and even weather forecasting models, are being coupled with landscape evolution models to investigate the influence of mountain climate on erosional processes, landscape evolution, and the entire orogenic dynamics. Furthermore, weathering processes (see Weathering processes and landforms) in mountains and high-standing islands have implications that feed back to global climate by altering biogeochemical cycles such as that of carbon (Lyons et al. 2002).

**Research outlook**

With a summary look to the future, key questions continue to drive research in mountain climatology (see Figure 2): How do mountains impact the atmosphere in their vicinity? How
can mountain environmental changes record and reveal the nature of global climate changes? How do mountain societies adapt to climate change? In a general sense, mountains are obstructions to atmospheric flow, and thus play an important role in impacting synoptic weather regionally (even globally) given dynamic and thermodynamic processes they instigate. Mountains also present themselves as sampling platforms to sample the upper atmosphere over time, not only to test hypotheses about ongoing future warming, but also to better document past climate variability. And more recently, mountain climates have become relevant to understanding the interplay of all Earth systems, including global biogeochemistry and lithospheric crustal tectonic dynamics. Finally, understanding the nature and impact of human-induced climate change has motivated teams incorporating climatologists with other biophysical and social scientists to research mountain environments.

Mountain geomorphology

Olav Slaymaker
University of British Columbia, Canada

Mountains occupy nearly one quarter of the land surface of the Earth and support 10% of its population directly. A further 40% of the Earth’s human population is dependent on mountain environments in terms of resource extraction and exposure to natural hazards originating in the mountains. Because most of the world’s major rivers rise in mountain regions, changes in mountain runoff affect a large proportion of the global population. Mountains are also sensitive indicators of climate change through the shrinking of glaciers and the upward migration or extinction of plants and animals. Mountains are core areas of global biodiversity and the origin of many of the world’s food crops. In many regions this global heritage is significantly endangered by changes in land use driven by a range of economic and political pressures. Because both natural and socioeconomic change is inevitable, fundamental understanding of mountain systems deserves high priority in sustainability strategies worldwide.

Distinctive features of mountain geomorphology

Mountain geomorphology is a “regional component within geomorphology” (Barsch and Caine 1984). The region in question is the world’s mountains defined by two conditions: (i) high absolute elevation above sea level and (ii) high gradient or local elevation range. Troll (1973) who was the creator of modern mountain geomorphology made a distinction between high mountains (“hochgebirge”), which rise above local timberline, and mountains (“gebirge”) which encompass more than one vegetation belt but remain below timberline. Troll’s distinction was important for at least two reasons: (i) his focus on biomes allowed global comparisons that were more difficult to make on the basis of absolute elevation above sea level and (ii) biomes integrate many of the effects of hydroclimate (Körner and Ohsawa 2005). The use of elevation versus biome zones in mountain geomorphology continues to be actively debated because there is no international standard definition.

Fairbridge (1968) provided a comprehensive classical description of mountains in terms of scale and continuity: (i) a mountain is a singular, isolated feature; (ii) a mountain range is a linear topographic feature of high relief usually in the form of a ridge; (iii) a mountain chain is also a linear topographic feature of high relief but usually reserved for features that persist for thousands of kilometers; (iv) a mountain mass, massif, block or group is reserved for irregular groupings of ranges with no simple linear trend; and (v) a mountain system or cordillera describes the largest continent spanning mountain features.

Fairbridge also provided a standard genetic classification of mountain types. Two broad categories of genesis were considered: (i) structural, tectonic, or constructional mountains and (ii) denudational or destructive mountains. Although these categories are useful for local scale description it is important to recognize that they were developed before the science of plate tectonics was fully understood.
Hewitt (1972) and Barsch and Caine (1984) provided creative discussions of the field of mountain geomorphology. Hewitt (1972) suggested that the high energy condition and the denudation history reflected in mountain forms express the distinctiveness of mountain geomorphology. Barsch and Caine (1984) built on Hewitt’s discussion by subdividing the high energy condition into (i) process dynamics and (ii) morphoclimatic models and subdividing the denudation history into (i) morphometry and structure and (ii) relief generation and history.

For the purpose of the following discussion, four broad categories of mountain geomorphology are proposed: historical, functional, regional, and applied.

### Historical mountain geomorphology

Historical mountain geomorphology concerns the evolution of mountains and mountain systems over both long and intermediate time scales. Since the plate tectonics revolution of the 1960s a strong relation between plate tectonics and mountains has been recognized. Most, but by no means all, large mountain systems or cordilleras are associated with plate boundaries, whether convergent, divergent, or transform. Large horizontal and vertical displacements are associated with plate interactions. Nearly all the literature on mountain building over the last 50 years has concentrated on active plate margins where collision and subduction can explain both mountains and the structures within them. There are four convergent plate settings in which some of the most rapidly evolving mountain systems of the world are located. They are (i) oceanic to oceanic plate convergence (e.g., Japanese Alps and the Aleutian Arc); (ii) oceanic to continental plate convergence (e.g., South Island, New Zealand, and Coast Ranges of the Pacific Northwest); (iii) continental to continental plate convergence (e.g., Himalayas); and (iv) displaced terranes along accreted margins (e.g., British Columbia). Divergent plate settings include (i) sites of ocean spreading (e.g., Iceland and the Galapagos Islands) and (ii) intra-continental rifts (e.g., the Gulf of Aqaba and the Scottish Highlands). Transform plate settings are: (i) ridge past ridge (Coast Ranges, California); (ii) trench past trench (Anatolia, Turkey); and (iii) ridge past trench (Pakistan-Afghanistan).

Mountains are also found in plate interior settings, such as (i) hot spots (Hawaii and Yellowstone National Park); (ii) continental flood basalts (Deccan, India, and Columbia Plateau, Pacific Northwest); (iii) shields (Hoggar Mountains, Algeria); (iv) intra-cratonic uplift sites (the San Rafael Swell, Utah); (v) post-tectonic magmatic intrusion sites (Air Mountains, Nigeria); and (vi) evaporite diapirs (Zagros Mountains, Iran).

Ollier and Pain (2000) disagree with the prevailing plate tectonic viewpoint by emphasizing that there are also mountains on passive plate margins and noting that mountains are made by uplift of continental areas. If the uplifted area is deeply dissected it will be a typical mountain chain with isolated peaks. Some mountains are at the edges of the plates delineated in plate tectonic theory, but many are not. The disagreement also arises in part from the different methodologies adopted by those who emphasize the close relation between mountains and plate tectonics, who are heavily invested in fission track analysis (e.g., Summerfield 2000), and the Ollier school, which emphasizes landforms, stratigraphic, and physical geologic data.

Relief development in mountains revolves around the interpretation of accordant summit levels and regionally consistent valley benches. Summit accordances and planation surfaces are present in most mountain systems. The European
Alps were early identified as having a “gipfelflur” (summit accordance) which was explained as a remnant of a pre-existing Pliocene erosion surface. Alpine crests and summit accordances in general have been explained as the product of equally spaced gully/river dissection which would lead to an accordance of summit heights between them. Uniform lithology over a broad area would certainly favor such a process, but this is not found, for example, in the European Alps. Timberline and alp slope accordances are explained as having been formed during warmer, interglacial periods under higher timberline. Rock benches along the sides of major valleys are variously explained as Tertiary, Pleistocene glacial, and interglacial effects.

Functional mountain geomorphology

Functional mountain geomorphology concerns itself with the various ways in which mountain geomorphic systems respond to disturbances, both natural and human. A valuable conceptual framework is provided by the sediment budget. The rate and nature of movement of sediments from sources to sinks and the associated rates of denudation of the mountain landscape can be estimated by determining all components of a sediment budget. It is common practice to examine the following four subsystems of the mountain environment and to aggregate the subsystem responses into a total basin response:

1 The mountain cryosphere includes snow, seasonally frozen ground, mountain permafrost, lake and river ice, and glaciers. Each of the elements of the cryosphere has a different response time to a disturbance. Snow responds on a daily time scale, lake and river ice on an annual time scale, permafrost and glaciers respond on annual to century time scales. Associated ecosystem responses are measured in decades to centuries and sediment systems may take decades to millennia to respond. With respect to sediment fluxes, in glacierized mountains, with their own active glaciers, the highest fluxes are found in the proglacial environment; in formerly glaciated mountains, where glaciers are no longer present, the highest sediment fluxes tend to occur at intermediate elevations due to patterns of sediment storage and availability; and in never glaciated mountains rates of denudation decline from high to low elevation.

2 The coarse grained debris system involves the transfer of debris between cliffs, through chutes to talus and associated colluvial deposits. Rockfalls, landslides, avalanches, and debris flows are the processes that drive the coarse grained debris system. This system is strongly influenced by the cryosphere and either supplies coarse sediment inputs into the fine grained sediment system or may be a closed system that remains uncoupled with its neighboring systems over long periods of time (Barsch and Caine 1984). Where the hydroclimate provides sufficient runoff, gravel-bed rivers are formed and they are commonly coupled with adjacent systems. Where the coarse grained debris system is uncoupled there may nevertheless be high local rates of denudation, as demonstrated in even the earliest sediment budget studies from the Swiss Alps.

3 The fine grained sediment system is well coupled with adjacent systems at progressively lower elevations of the sediment cascade. The upper size limit of fine grained sediments is commonly placed at 1 mm diameter. Weathering, surface erosion, and fluvial processes, which move sediment within basins, and aeolian processes,
importing sediments from external sources, drive the fine grained sediment system. Fluvial processes transport fine sediment in suspension, in solution, and in bed load into adjacent systems with variable lag times.

The geochemical system. The drivers of the geochemical system are solutional weathering, nivation, hydrogeological, and fluvial processes. The contact time between water and material sources and thus the residence time of water within the basin, temperature changes, vegetation cover, and the thickness of unconsolidated sediments dictate the importance of the geochemical system. As the sediment cascade enters more vegetation-dominated zones and soils are also more maturely developed at lower elevations, the breakdown of minerals into solutes and nutrients becomes more rapid and complex. Human disturbance of the land ensures the importance of pollutants in the geochemical system.

Regional mountain geomorphology

Relief type

Based on a consideration of form alone, Barsch and Caine (1984) suggested that there are four distinctive relief types in high mountain systems: (i) the Alp type, associated with an overriding influence of glaciation and glacial erosion; (ii) the Rocky Mountain type, with a less pervasive effect of glacial erosion, including low relief on flat summits and rounded interfluves; (iii) a polar type, which gives evidence of intense glacial erosion but frequently with local relief of less than 1000 m (e.g., Lofoten Islands, Norway); and (iv) a desert type, which is a high mountain according to elevational criteria but does not reach timberline and was only lightly glaciated during the Pleistocene (e.g., Tibesti Mountains, Chad).

Hydroclimate

Biomes integrate the effects of hydroclimate (Körner and Ohsawa 2005) and in many mountain regions, where hydrometric and meteorological data are scarce, biomes are the only reliable basis for global comparisons. Typically, ten mountain biomes are recognized as follows: polar nival, dry alpine, humid temperate alpine, humid tropical alpine, dry temperate montane, humid temperate montane, humid tropical montane, humid temperate hilly, dry tropical hilly, and humid tropical hilly. Of these, the humid temperate and humid tropical montane biomes occupy the greatest area (7 and 6 million km² respectively) followed closely by the polar nival biome (5.5 million km²). Although it is widely recognized that alpine biomes experience some of the most active geomorphic processes, they occupy collectively only 2.5 million km² (<8% of the terrestrial surface) and many of them are decoupled from the montane biomes at lower elevations (as previously noted by Barsch and Caine 1984).

Human activity

Slaymaker and Embleton-Hamann (2009) concluded that human influences on mountain systems have now become so pervasive that global comparisons of mountain geomorphology must incorporate a measure of human impact. They argued that human activity has two broad impacts on mountains: (i) inducing stability by sensitive environmental engineering and (ii) reduction of stability by serious soil and vegetation disturbance. Four distinct mountain geomorphologies are defined by them as follows: (i) polar mountains, such as Svalbard, which are relatively undisturbed by human activity, and which respond primarily to warming of the cryosphere; (ii) low population temperate mountains (such as Canada and
Tadjikistan) which are controlled by steep relief and harsh hydroclimate; (iii) high population temperate mountains (such as Austria and Japan) are strongly influenced by human impact (both positive and negative); and (iv) tropical mountains (such as Papua New Guinea and Ethiopia) are also heavily destabilized by human activity. Huddleston and Ataman (2003) noted that the humid tropical montane and humid temperate hilly biomes are by far the most populous, with >60% of all mountain peoples.

Applied mountain geomorphology

A geomorphic hazard results from any landform or landscape change that adversely affects the stability of a site or drainage basin and that intersects the human use system with adverse socioeconomic impacts (Slaymaker 2010). If there are no people affected there is no hazard and if the landform or landscape is unchanged there is no geomorphological hazard. Mountain geosystems are not exceptionally fragile but they do show a greater range of vulnerability to disturbance than many landscapes and their recovery rate after disturbance is often slow. The combination of extreme geophysical events, apparently increasing in magnitude and frequency during the present climate change scenario, with exceptional population growth and varied land use modifications underlines the urgency of greater understanding of applied geomorphology. Geomorphic hazards are intensifying and societal risks multiply accordingly.

During the past four decades, the world’s population has doubled but the population of mountain regions has more than tripled so that stresses on the physical and biological systems in mountains have intensified manifold. Human activity, in the form of population density and land use, is a direct driver of geomorphic processes in mountains. But geomorphic processes also influence population density and land use. This is what is known as a reflexive relation. It is not, however, the sheer numbers of people but aspects of population composition and distribution, especially the level of urbanization and household size which exercise the greatest demands on the land. High population densities in developing world conurbations, for example, may lead to better management, such as has been documented in Kenya (Tiffen, Mortimore, and Gichuki 1994).

Perhaps the deliberate change in vegetation cover by society is the most important driver of change. Nearly one third of Earth’s land surface is currently being used for growing crops or grazing cattle. Grazing and forestry are the dominant mountain land uses. Huddleston and Ataman (2003) noted that all mountain zones below 4500 masl have exceeded the population that is thought to be sustainable. Deforestation in particular provides timber for fuel and as construction material and, in order to clear ground for agriculture, sets in motion a series of geomorphic processes. Surface erosion of slopes, landslides, and debris flows lead inexorably to environmental degradation. Forest roads, highways, railways, electricity power, and communications networks alter water and sediment pathways. Excessive soil erosion, soil degradation, increase in the frequency of mass movement events and increased flood hazard are the results. But it should also be pointed out that many studies have shown how good management of land can also improve land stability. In either case (whether natural hazards have increased or decreased), the role of society is paramount.

Road and dam construction are also two of the most profound human influences on mountain geomorphic processes. Road building in Nepal has produced about 9000 m$^3$ km$^{-1}$ a$^{-1}$ of...
landslide material and it is estimated that every kilometer of road constructed will trigger circa 1000 tons of land loss from road failures. Many of the world’s large dams are located in mountain regions and there are massive changes in both discharge and sediment transport imposed by large dams.

There is also a need to understand, predict, mitigate, and adapt to the effects of mountain geomorphic processes. Unfortunately there has been inadequate representation of the interactive coupling between relief, land use, and hydroclimate. Based on magnitude, timing, persistence, reversibility, potential for adaptation, distributional aspects of impacts, and likelihood and importance of the impacts, some of these vulnerabilities have been identified as “key.” It is at the point of exceedance of thresholds, where non-linear processes cause a system to shift from one state to another that expresses the key vulnerability. The changing magnitude and/or frequency of geomorphic hazards are the geomorphologist’s favored measures of key vulnerabilities. Slaymaker (2010) has discussed mountain geomorphic hazards as a function of resilience, connectivity, and vulnerability and showed the importance of spatial scale.

Mountains cover approximately 24% of Earth’s land surface, but generate a much higher percentage of global runoff. Estimates of the proportion of mountain runoff to global total runoff vary from 32% (Maybeck, Green, and Vorosmarty 2001) to 40–60% (Bandyopadhyay et al. 1997). The term “water towers” has been used to describe the hydrologic role of mountains as wet islands within dry climate zones (Viviroli et al. 2007). In Wyoming, for example, only 15% of the state area experiences a water surplus – all of which occurs in mountains – and runoff from the mountainous highlands supplies water to the remaining 85% of the state that is situated in water-deficit lowlands (Figure 1) (Ostresh, Marston, and Hudson 1990). As another example, the European Alps cover only 23% of the Rhine River basin, but provide half of the total runoff over the year, ranging from 30% in winter to 70% in summer.

Wohl (2010) pointed out that mountains are situated in a wide range of climate regions, with profound differences in the flow regime as a result. Mountains in warm-arid climates (e.g., Basin and Range Province of the United States, Middle East, western South America, Africa, Australia) experience ephemeral flows with occasional flash floods. Cold-arid mountains (e.g., parts of Antarctica) experience ephemeral flows during the melt season. Semiarid mountains (e.g., Colorado Front Range of the United States, Pyrenees of Europe) can experience ephemeral flow from rainfall or perennial flows where snowmelt augments flows. Mountains in warm-humid climates (e.g., Appalachian Mountains of eastern United States, mountains of Japan) can generate perennial flows, occasionally with very high discharges caused by tropical storms. Mountains in cold-humid climates (e.g., western side of Canadian Rocky Mountains, European Alps, Chilean Andes) also support perennial flows, dominated by either rainfall or snowmelt. Mountains of the seasonal tropics (e.g., Northern Great Dividing Range of Australia, Caribbean region) experience strong seasonal shifts in discharge, in some cases highlighted by monsoon season flooding. Mountains in the humid tropics (e.g., New Guinea, headwaters of the Amazon in South America) tend to be perennial, with lower seasonal variation than in other types of mountain rivers. Finally, high-elevation mountain massifs are dominated by snowmelt and glacier-melt, although the Himalayas are also dominated by monsoon rains. Flow regimes in mountains could shift with climate change.
Figure 1  Water balance (net precipitation minus evapotranspiration) for the State of Wyoming, USA. Ostresh, Marston, and Hudson 1990, 25. Reproduced from Wyoming Water Development Commission.

Net precipitation (that which reaches the ground surface) is thus calculated as gross precipitation (measured above/outside of vegetation) minus the interception loss (absorption + evaporation). Interception storage is greater for low-intensity rainstorms with no wind. Thus, interception storage will be greater for trees in the forest than for isolated trees or trees along the forest margin. Interception storage is greater than snowfall, when measured in water equivalent, because rain generally adheres to vegetation surfaces better than snow. Total interception for deciduous forests may average 13%, contrasted with 22–28% for coniferous forests, and 10–20% for grasses. For crops, interception may be as low as 3% for corn and oats, increasing to 9% for soybeans, and 22% for alfalfa. The percentage interception loss varies inversely with storm size, and is greater for conifers than for deciduous trees. The interception loss is highest in regions where evaporation is highest.

Vegetation affects mountain hydrology in several key ways (Marston 2010).

1  It modifies soil moisture, through interception loss and transpiration. 
2 Organic matter in the soil increases water storage, infiltration, and percolation, thereby promoting vegetation growth and inhibiting erosion.

3 Roots bind the soil against piping, land surface erosion, and shallow mass movement.

4 Aboveground biomass creates microtopography on the land surface that affects overland flow. Roughness in the profile direction (upslope-downslope) slows overland flow; roughness along the contour concentrates sheetflow into rillflow, rills into gullies.

5 Aboveground biomass creates hydraulic roughness against overland flow.

In theory, one should be able to increase water yield by eliminating or decreasing losses by interception and evapotranspiration. Therefore, the conversion of coniferous forest to a broadleaf forest should increase water yield. Conversion from shrubs or trees to a grass cover (as undertaken with chaining of pinyon-juniper woodlands) should result in little or no change. Because the percentage interception loss decreases as storm size increases, it is important to note that decreasing interception loss is unlikely to have a significant effect on floods produced by major rainstorms in mountains.
When rainfall or snowmelt reaches the ground surface, some or all of it will enter the soil in response to gravity. Infiltration rates are commonly very high in forested mountain soils because of the coarse soil texture and high organic matter content. In contrast, soils are thin or absent in desert mountains, which keeps infiltration rates low. Water in the soil is held against the pull of gravity by capillary forces, which are especially strong in fine textured soils. When soil pores are filled to capacity, the soil is saturated. Further additions of water will cause the water to exert pore pressure and force soil grains apart from each other, destroying cohesion and creating deleterious effects on slope stability. The maximum amount of soil moisture after gravitational water has drained is known as the field capacity. Vertical percolation will carry water through the soil water zone, which extends through the zone of plant roots, to the intermediate (unsaturated) zone and eventually to groundwater (the zone of saturation return flow). Subsurface water also moves laterally by throughflow in the soil water zone, interflow in the unsaturated zone below plant roots, and by groundwater flow. Some subsurface water will reach streams as effluent seepage, contributing to the base flow of the mountain stream. Mountain streams also lose water to subsurface zones via influent seepage. Finally, water moves laterally beneath streams as intergravel flow. Available soil moisture is strongly controlled by topographic position in mountains (Figure 3).

Water is evaporated to the atmosphere from mountain lakes, streams, soils, and from intercepted water. Rates of evaporation are controlled by energy transfer, which increases with elevation in mountains. Vegetation pulls water from the soils and transpires it to the atmosphere through the pores in leaves. Transpiration rates also depend on energy transfer processes, but are controlled by many factors other than evaporation, including the phenology (stage of plant growth) and amount and type of pores.

Source: Modified from Wohl (2010, Table 6.1).
Runoff in mountains is generated by Hortonian overland flow, saturation return flow, permafrost melt, and effluent seepage. During Hortonian overland flow, rainfall or snowmelt exceeds the infiltration capacity of the ground surface for a period of time. It is not necessary for the soils to be saturated, but rather that the rate of water reaching the soils’ surface exceed the infiltration capacity. Next, depression storage must be exhausted – the surface water storage created by microtopography. Depression storage may be close to zero atop a paved parking lot, but can reach 25 mm in a tilled soil or even more in forested mountain soils. Finally, in the presence of a slope, Hortonian overland flow begins – this is very rare on forested mountain slopes. Saturation return flow occurs where subsurface flow (in the soil moisture zone, as vadose water, or groundwater) is conducted to the surface. Permafrost can be important in high mountain areas, especially in supplying local springs.

Human effects on mountain hydrology

Human activities can affect mountain hydrologic processes indirectly or directly (Table 1).

Indirect effects of humans on mountain hydrology

Timber harvest usually results in compaction along road and skid trails, which reduces infiltration and increases overland flow. Studies on the effects of clear-cut logging on mountain hydrology in rain-dominated flow regimes along the Pacific Rim generally agree that peak flows increase and low flows decrease. In snowmelt-dominated regimes, narrow clear-cuts enhance snow trapping and help shade snow so the melt is delayed. In such cases, low flows can be augmented without increasing peak flows. However, even in snowmelt-dominated flow regimes, clear-cut logging over a threshold value – 20% of the watershed in the Rocky Mountains in any one year – can increase peak flows to the point that irreversible stream channel changes occur. Studies in the Himalaya have shown that forest cover does not affect monsoon-period flooding, as the effects of land cover on local runoff are less significant compared to the combined effects of steep slopes, thin soils, and long-duration rain events (Marston 2008). Effects of vegetation change on mountain hydrology are most pronounced in mountain headwater regions, but gradually disappear further downstream from the area of impact.

Roads must be constructed as part of the timber harvest plans, with cut-and-fill required on mid-slope roads. Four primary hydrological effects of roads include the interception of rainfall, concentration of flows, rerouting of water pathways unnaturally onto hillslopes, and interception of local water tables at hillslope cuts. Forest roads increase the magnitude and frequency of peak flows by transporting runoff directly into streams at crossings, thereby reducing travel time and distance. Roads are nearly impervious compared to soil, which makes them efficient transporters of flow by limiting infiltration. Effects of roads on local hydrology will be more significant downstream from crossings or regions with high road densities. The hydrologic impact of mid-slope roads is to intercept subsurface flow while also capturing direct precipitation. The excess runoff must be directed via berms, roadside ditches, and culverts to mountain channels that may or may not have the capacity to conduct the increased flow.

Ranching and farming on mountain slopes can alter the hydrology. Heavy grazing on upland soils can compact the soil, reduce infiltration, reduce vegetation cover, and increase
Hortonian overland flow (Wohl 2010). One of the remarkable ways in which humans affect mountain hydrology is through agricultural terracing (Figure 4). Terraces are built to retain soils and water to support crop growth, while simultaneously conducting excess rainfall downslope. In ancient mountain civilizations, terraces have been in place for centuries if not millennia. For khet terraces constructed with a berm (or bund) on the outer edge to retain water, surplus runoff moves downslope from one ramped terrace to the next, and this occurs over hundreds and sometimes thousands of meters of local relief without triggering irreparable erosion. At higher elevations, rain-fed bari terraces built without a berm and sloping outward experience rates of erosion two orders of magnitude higher than khet terraces (Marston 2008).

The conversion of natural vegetation to impermeable urban land cover affects routing of water in mountains. Infiltration is reduced and Hortonian overland flow is increased, with enhanced local sheet flooding as a result. Hard rock (lode) mining can increase streamflow in mountain areas if discharge from active or abandoned mines is not controlled. The impacts of lode mining on water...
quality and sediment load are of greater concern than are the impacts on hydrology.

It is difficult to translate predicted climate change into mountain hydrology impacts, and those changes will vary between mountains located in contrasting eco-regions. Generally speaking, with warming temperatures, the elevation at which snow changes to rain is expected to increase. Glaciers with a lower elevation accumulation zone can be expected to shrink in extent and decrease in thickness. Glaciers with a higher elevation accumulation area can be expected to experience a net gain in mass. The timing of precipitation (e.g., monsoon rains) may also change. Permafrost on lower elevation mountain slopes can be expected to decrease in extent and melt at shallow soil depths.

Removal of vegetation by fire decreases interception loss and soil moisture by affecting infiltration rates and decreasing evapotranspiration. Intense fires, whether deliberately set after clear-cut logging or as wildfires, can create hygrophobic (water repellant) soils, which can enhance runoff. Intense drought is also known to create hygrophobic soils. Whether or not this results in significant alterations to streamflow depends on the path of surface runoff on the local hillslope scale, the proximity of burned hillslopes to water courses, and the cumulative area burned. Forest litter, downed trees, micro-depressions, and unburned segments can help retain runoff and encourage infiltration. Flash floods and associated mudflows are common in the steep San Gabriel Mountains in southern California; however, accelerated runoff was not a widespread problem on the broad Yellowstone Plateau after the extensive 1988 fires. Moreover, the effects of fires on accelerated runoff will diminish after a few years once vegetation recovers. One of the ways that climate change will manifest itself will be to alter fire regimes in mountains of the world, with accordant effects on hydrology.

Direct effects of humans on mountain hydrology

Beaver populations once flourished along streams of North America and Europe, but are presently experiencing reduced numbers (Wohl 2010). Beaver dams are constructed of wood and sediment to a height commonly between 1 and 2 m. The hydrologic effects are to promote more uniform streamflow and raise the water table, which often enhances riparian vegetation. Beaver populations were greatly reduced over past centuries by fur trappers, resulting in channel incision and an associated drop in adjacent water tables. Attempts have been made to reintroduce beaver for stream and riparian restoration, with mixed success. The beaver populations need to have access to sufficient wood to maintain their dams. If the dams breach during peak flows, channel incision occurs downstream.

Mountains are often preferred locations for dam construction because significant relief exists to generate a hydraulic head in combination with constricted valley sides comprised of competent bedrock to anchor the structure. The countries of the Alps have developed 76% of their hydropower potential, but Nepal has developed less than 1% of its potential (Romerio 2008). Dams alter mountain hydrology in the process of providing hydropower, flood protection, and reservoir recreation. Water is lost through evaporation and seepage. Storage capacity is lost with time since initial construction due to sedimentation. Downstream from a dam, peak discharges are reduced, the range of daily discharges is decreased, and the number of reversals in discharge is increased. Further alterations occur to the timing of low flows and peak flows, and to ramping rates. Additional effects to water
quality and riparian and aquatic ecology are widely reported.

Mountain streams are targeted for off-channel diversion of water, sometimes for local uses (e.g., mining, irrigation) and sometimes for transfer to large urban centers. A diversion structure begins with a headgate that allows water to be transferred from a stream channel into a ditch. Barriers are usually placed across stream channels directly downstream from the diversion structures to pool water and reduce stream power, making it easier for flow to enter into the ditch through the headgate structure. In some cases, barriers are built completely spanning the width of the channel to divert 100% of streamflow into the ditch. Water conveyance ditches then follow hillslope contours, transporting water from one watershed to another by transcending drainage divides. Water can be moved across multiple drainages, eventually flowing onto a private farm or ranchland for use as irrigation. Normally, some reduced amount of flow is able to continue down the natural channel past the diversion structure. Effects of diversion ditches on runoff patterns are fundamentally different compared to those associated with dams. A dam will reduce peak flow for flood control and increase low flow. Peak flows commonly pass by diversion ditches uncontrolled. Hydrological impacts of diversion ditches on streams downstream from the diversion include altered flow regimes, depleted stream flows, reduced channel capacity, and lowered local water tables. Total annual water yield and average annual discharge are shown to decrease downstream from diversion structures. Similarly, flow variability increases during low-flow years downstream from a diversion.

Movies and films help us to understand our place in the world and it is the extent to which they produce spatial meanings that interest geographers. Early studies focused on place-based meanings with an emphasis on how accurately places were depicted. The interrelations between movies and films on the one hand, and the politics of social and cultural representations on the other, became increasingly important to the discipline from the early 1990s onwards. At the time, a number of central works were emphasizing the importance of visual culture (Harvey 1989; Bruno 1993) and within the decade a critical visual geographic engagement with films and movies was codified methodologically (Rose 2001) and substantively (Aitken and Zonn 1994). Perhaps most critically, the last two decades has witnessed a flowering of spatial theories that elaborate new ways of knowing our cinematic world.

From a less critical stance, the discipline’s engagement with film may be traced back to when the Geographical magazine published a series of articles in the 1950s in collaboration with Dr Robert Manvell, then director of the British Film Academy. The series emphasized the national character and factual basis of filmmaking, focusing on the realism of the medium as its most significant contribution to geography. Most of the papers focused on documentary filmmaking, although some broached the issue of vérité or realism in narrative and fictional films (Manvell 1953). These articles outlined the ways film dealt effectively with the culture, customs, and behaviors of the everyday lives of people in the country portrayed. The pervasiveness of French cinéma-vérité and Russian Kino-Pravda had held sway in continental Europe since the Lumière brothers famously projected their first images in the late nineteenth century. British filmmaker John Grierson coined the term “documentary” in the late 1920s from the French adjective documentaire, used at the time to describe the accuracy of travel films. In the 1940s, a much older and perhaps less wiser (but perhaps presaging the influence of Hollywood and Bollywood) Louis Lumière took the idea of accuracy further by suggesting that the space of film is the space of reality, and film’s ambition is to “reproduce life.”

Aitken and Zonn (1994) coedited the first book on film geographies that attempted to bring together the work of film studies theorists like Christian Metz, Stephen Heath, Jean-Louis Baudry, and Thierry Kunstel with emerging critical theories of space and place. At around the same time, Wolfgang Natter and J.P. Jones (1993) published an acerbic critique of the “reality effect” of documentary filmmaking that highlighted performed narrative conventions as the outcome of social, cultural, and political mediations. Behind this work, and pushing a media savvy troop of young academics to aspire to new giddy heights, were the spatial and social theories of David Harvey, Doreen Massey, Michael Dear, and Ed Soja, who in turn drew on Walter Benjamin, Henri Lefebvre, Guy Debord, and other Marxist-leaning theorists. Caught in the rational
objectivity of the quantitative revolution where the most coherent spatial theories – like Waldo Tobler’s pronouncement that things close to other things have the most influence on those things – seemed banal and self-evident, these young academics were inspired by a set of social and spatial theories about the complex ways media and culture link insidiously with a capitalist-industrial-military complex.

Inspiration came from writers such as Frederic Jameson and Jean Baudrillard who spoke to how seeming interior psychic conditions and larger social structures intertwined with cultural products, and in particular the spatial arts of architecture, urbanism, and film. In addition, feminist writers such as Anne Friedberg and Guilliana Bruno (1993) countered through film and the spaces of movie theaters male dominated urban and architectural strictures, offering shrewd insights into what makes cities magical, fun, and empowering for women, despite their vulgarity, rabble, vice, and dangerously empty corporate plazas. Bruno (1993, 51) argues that cinema is a transgressive space because it allows women to experience the “erotics of darkness and (urban) wandering denied to the female subject.” Bruno and Friedberg in tandem relate society’s panoptic and objectifying gaze to movie-oriented experiences, arguing with Laura Mulvey that the audience looks with the male character and the female character is “looked at.” In her account of cinema’s role in culture, Friedberg positions the virtual gaze as a mode of looking that is based upon mobility rather than confinement and, by so doing, she opens an arena of speculation over the relations between visual spectacles and fluid subjectivities. As Mike Crang (1997) notes, the attenuation of other senses within the darkened interiors of theaters is an especial configuration and practice of viewing, which sets up the possibility of the illusory eye following the camera.

Geographers mobilized these ideas in new critical spatial theories. In his acclaimed The Condition of Postmodernity, Harvey (1989) uses Blade Runner (1982, directed by Ridley Scott), among other films, to argue for the ways movies elaborate what was referred to at the time as our postmodern condition and, in particular, the conflicts that contemporary capitalism wrought on time scales and spatial resolutions. Unwilling to cede too much power to film, Harvey sees Blade Runner as a parable in which postmodern conflicts are set in a context of flexible accumulation and time-space compression. Harvey is not willing to move beyond using film as a mimetic device that reflects changing societal structures, whereas other geographers wanted to understand also the ways that film changed society. Ed Soja and Michael Dear, for example, are sacrosanct about the spatial powers of film. Soja is particularly influenced by Fredric Jameson, who in The Geopolitical Aesthetic (1992) not only uses films as parables for conditions of postmodernity but argues convincingly about larger global/capitalist conspiracies that are mediated by the subtle and enduring influences of images and moving pictures. Jameson’s concern is not only to unpack cinematic representation in order to discern adequate allegories for our social and political existence, but to understand how it influences our political unconscious. The films that he analyzes are narrative figurations and examples of the way contemporary narrative “conflates ontology with geography and endlessly processes images of the unmappable system” (Jameson 1992, 4). Soja (1996) brings Jameson together with his mentor, Henri Lefebvre, to help elaborate the context of “real-and-imagined” places. Like Soja, Dear is also an advocate of postmodern theory and the postmodern city, but his focus on movies and films is much more direct. In The Postmodern Urban Condition (2000) he reworks urban theory through movies, architecture, and filmspace.
Also influenced by Jameson and Lefebvre, but trying to move beyond the work of Soja, Dear insinuates not only how spaces are produced through representations but also how it may be possible to create an urban and policy agenda for the twenty-first century that simultaneously incorporates film, local art, and global politics.

Through the 1990s, interest among geographers in understanding movies and film simultaneously as unstable constructions and quirky constructors of society rose significantly with a multitude of articles published in a wide array of journals. Unfortunately, with the rush to publish in mainstream journals many of these papers lacked geographic insight and came across as interesting but somewhat superficial place-based film reviews. To counter this trend, *Engaging Film*, edited by Cresswell and Dixon (2003), provided a set of thoughtful manuscripts that were theoretically grounded in issues of space, place, and spatiality. By so doing, the book mapped out a future for film studies in geography that reflected critical concerns of the discipline. Going beyond Friedberg’s understanding of mobility, for example, Creswell and Dixon argue that it can be thought of in a broader sense as a certain attitude, at times openly radical and at times quietly critical, toward fixed notions of people and cities as they may appear in film, art, and architecture. That is, an emphasis on mobility suggests a certain skepticism in regard to stability, rootedness, surety, and order, and yet it is not entirely about disorder either.

A large swathe of geographic endeavor these last two decades has focused on cinema and the order/disorder of the city. David Clarke’s (1997) focus on *The Cinematic City* as a “contained” spatial sphere of practice was a change away from earlier obsessions of some critical geographers, planners, architects, and cultural theorists with spatial metaphors that tended to hide and depoliticize the material conditions of lived experience. This wide-ranging book tackles issues of self, otherness, homelessness, community, race, and family through discussions of over a hundred movies. Elisabeth Mahoney’s essay, for example, begins boldly with a critique of Soja and Harvey’s postmodern geographies, and then follows with a fascinating discussion of Elizabeth Grosz’s (1995) conceptualization of the chora (a prosocial feminine and maternal space, p. 172). This theoretical “hook” is elaborated through empirical analysis of *Falling Down* (1992, directed by J. Schumacher), *Night on Earth* (1992, directed by J. Jarmusch), and *Just Another Girl* (1992, directed by D. Harris). Clarke’s continued interest in cinematic spaces narrows from cities to motel spaces in a 2009 volume coedited with Valerie Pfannhauser and Marcus Doel, and the important point about this emphasis is his enduring focus on movement and using the motel as an analytic device for understanding stopping (Clarke, Pfannhauser, and Doel 2009).

The idea of the cinematic city and narrower motel spaces joins a movement outward to consider cinema and national and international geopolitical issues (Power and Crampton 2007). It is reasonable to argue that this focus goes back to the beginnings of geography’s critical engagement with the elaborated on First, Second, and Third (World) Cinema, but today the focus is more on borders, boundaries, and territories in cinematic narratives, with concern for exploring interconnections between cinema and geopolitics (Power and Crampton 2007, 4). In one essay in this volume, the coming to film from a poststructural inspired critical geopolitics, for example, uses *Behind Enemy Lines* (2001, directed by John Moore) to elaborate gendered politics and what is called a pornographic gaze on weaponry in terms of larger structures of feeling around American militarism.

The turn to poststructuralism is important. Movies are about movement and, as such, they...
MOVIES AND FILMS, ANALYSIS OF

are fundamentally different from other forms of representation. Movement requires a different way of understanding your subject and a more flexible academic practice. Henri Bergson argued that it is only possible to understand movement intuitively because any kind of analysis that stops a frame loses the context of the frame. Standard, more structured, textual, and visual analyses do not apply to the mobilities, identities, and politics that are part of film and so many geographers are turning to poststructural methods and practices. Contemporary geographers writing about film note that the study of films and movies loses its transformative edge if it is reduced to language games and analysis of static visual symbolism. Bergson was one of the first to look carefully at what Grosz (2011, 1) calls “imperceptible movements, modes of becoming, forms of change, and evolutionary transformations.” Movement is about difference and transformation. It is the process of movement that makes and unmakes objects, including people and institutions. This is why the study of films and movies is crucial for understanding our geographic world and changing it for the better.

Multi-aperture telecentric lens

Bo Wu
Lei Ye
The Hong Kong Polytechnic University, China

A multi-aperture telecentric lens is a single telecentric lens with multiple aperture stops that enable it to capture multidirectional parallel light rays. Unlike conventional optical systems in photogrammetry or computer vision, which use a pair of stereo cameras for three-dimensional (3-D) reconstruction, a multi-aperture telecentric lens uses image(s) obtained from the light rays separated by different aperture stops for 3-D reconstruction. A multi-aperture telecentric lens is ideal for use in a variety of machine vision applications, such as noncontact measurement and inspection systems, 3-D reconstruction of close-range targets, and intelligent vision systems in robotic equipment.

The telecentric lens is discussed here firstly. Detailed configurations of the multi-aperture telecentric lens are then discussed. Key aspects of using a multi-aperture telecentric lens for 3-D reconstruction – including its geometric model and an evaluation of the potential accuracy – are then presented.

Telecentric lens

A telecentric lens is a compound lens used in an imaging system to make objects appear to be the same size independent of their location in space. Most imaging systems with conventional lenses exhibit varying magnification for objects at different distances from the lens. This causes several problems for machine vision and other applications. (i) Objects closer to the lens appear to be larger than those farther from the lens; for example, in an image of a cylindrical pipe the top and bottom crown edges appear to be concentric even though the two circles are perfectly identical. (ii) Object shapes vary with their distance from the center of the field of view (FOV); for example, circles near the center of the FOV appear to be egg-shaped when moved toward the periphery. (iii) Some features or objects may be hidden by objects closer to the lens. In contrast, a telecentric lens removes these perspective or parallax errors to produce an orthographic projection that provides the same magnification at all distances. Pioneered by Moore (1973), telecentric lenses have been pursued by researchers in various settings (Watanabe and Nayar 1996; Bai and Sadoulet 2007). In particular, telecentric lenses are commonly used in machine vision applications, where software analysis is simplified and more accurate due to the reduction of parallax. Imaging systems with telecentric lenses have made it possible to reach dimensional measurement accuracies that can be better than those generated by contact and laser-based methods (Djidel et al. 2006).

There are three types of telecentric lens. The first is an object-space telecentric lens, in which the aperture stop is placed at the front focal plane of the lens, resulting in an entrance pupil location at infinity. A shift in the object plane does not affect image magnification. Such lenses are used in machine vision systems because image magnification is independent of the objects'
distance or position in the field of view. The second is an image-space telecentric lens, in which the aperture stop is placed at the rear focal plane of the lens, resulting in an exit pupil location at infinity. A shift in the image plane does not affect image magnification. Such lenses are used in image sensors that do not tolerate a wide range of angles of incidence. The third is a double telecentric lens, in which the aperture stop is placed at the common focal plane, resulting in both the entrance and exit pupils being located at infinity. Shifting either the image or object planes does not affect magnification given that double-telecentric systems are afocal. Double telecentric lenses have magnification that is more precisely constant than those that are only object-space telecentric because the intersection position of the principal ray on the detector does not change, which allows for the precise measurement of objects regardless of their positions. Figure 1 illustrates an idealized double telecentric lens with two thin positive-powered elements, with the aperture stop placed at the common focal plane of the front and rear elements such that it only passes the light rays that are parallel to the optical axis.

In summary, telecentric lenses have the following advantages over conventional lenses: (i) constant magnification independent of shift in object and/or image planes; (ii) low distortion, normally in the range of 0.1% for high-quality telecentric lenses; (iii) reduction or elimination of perspective error; (iv) increased image resolution; and (v) uniform image plane illumination. However, they also have several disadvantages. First, more optical elements are used than in conventional lens systems due to the complex design. Second, large aperture optical elements in the region of telecentricity are required to provide a nonvignetted FOV. The large aperture and more optical elements lead to increases in the cost and weight of the imaging system. Third, traditional telecentric lenses use fixed focal lengths, which result in fixed FOVs. An investigation of varying FOVs requires the use of several fixed magnification lenses. Zinter
and Sanson (2001) presented an endeavor to develop a telecentric zoom lens for this type of task. Finally, it is not possible to obtain depth information from the telecentric images due to the orthographic projection of the telecentric lens. Despite the disadvantages inherent in the telecentric lens design due to its increased complexity, the numerous benefits make telecentric lenses a popular choice in a variety of applications. The last drawback evokes the development of a multi-aperture telecentric lens.

Multi-aperture telecentric lens

In applications such as machine vision, the 2-D information and the 3-D depth information from the scene must be extracted simultaneously. Stereo vision using multiple cameras is the conventional approach to infer depth information based on parallax from multiple perspectives, which has a long history in the fields of photogrammetry and computer vision. In recent years, a variety of techniques, such as motion parallax and depth-from-focus, have been implemented in 3-D imaging systems. However, these systems are relatively expensive and require complex camera calibration and geometric processing. As mentioned, the telecentric lens has the desirable property of orthographic projection, which makes it easier to measure or compare an object’s physical length independently from its depth in relation to the camera. However, it is not possible to obtain depth information from the image, as there is no foreshortening effect in telecentric images. The multiple aperture technique has been used in imaging systems to provide 3-D information. For example, Fife, Gamal, and Wong (2006) presented an image sensor comprising an array of apertures each with its own local integrated optics and pixel array. A lens focused the image above the sensor, creating overlapping fields of view between apertures. Image disparities from multiple perspectives in the focal plane facilitated the derivation of 3-D information. To take advantage of the orthographic projection of the telecentric lens and the image disparities from multiple, multi-aperture telecentric lenses have been investigated for use in 3-D reconstruction in recent years (Kim and Kanade 2011).

A multi-aperture telecentric lens has multiple aperture stops rather than one, as in a conventional telecentric lens. Figure 2 illustrates an idealized multi-aperture telecentric lens. There are two aperture stops $O$ and $O'$ on the focal plane, of which $O$ is located at the focal point of the lens and the other $O'$ is at a distance from the focal point. The aperture stop $O$ selectively passes light rays that are parallel to the optical axis because $O$ is located at the focal point of the lens and only passes the rays. The aperture stop $O'$ selectively passes light rays that are parallel to each other but not parallel to the optical axis. Assuming $O'$ is an infinitely small aperture stop, the light rays selected by $O'$ are parallel to the vector from the lens center to $O'$ (blue dashed line in Figure 2).

In a conventional stereo vision system, as illustrated in Figure 3, two cameras are used to form stereo images and the depth information of any object in the scene can be derived from the disparity of the same object imaged on the stereo images. From Figure 3, for an object point $P$, its disparity is:

$$d = x_1 + x_2 = \frac{f}{Z} \cdot B$$

where $f$ is the focal length of the camera, $B$ is the baseline between the stereo cameras, and $Z$ is the depth of point $P$. In equation 1, both $B$ and $f$ are fixed, and thus the disparity $d$ is linearly proportional to the inverse of the depth.

In a simplified multi-aperture telecentric lens system ($1 \times$ magnification), as illustrated in Figure 4, the distance between the two aperture stops is not constant but rather varies according to the object’s depth. This variation allows for the extraction of depth information from a single telecentric image.
MULTI-APERTURE TELECENTRIC LENS

stops is $B$, which can be considered the baseline between the two aperture stops. The focal length of the lens is $f$. The image plane is located at a distance $f$ from the focal plane. A spatial auxiliary coordinate system is used with its origin at the center of the image plane. Its $z$-axis aligns with the optic axis and points to the front of the lens while its $y$-axis points up. Its $x$-axis is perpendicular to the plane determined by its $z$- and $y$-axes. For an object point $P$ located at $(0, Y, Z)$, the light rays selected by the aperture stops $O$ and $O'$ pass through the points $p_1$ and $p_2$ at the image plane. The distance between $p_1$ and $p_2$ is the disparity of the same point $P$ imaged on the image plane through the two aperture stops. The coordinates of $p_1$ and $p_2$ on the image plane can be determined as:

\[(0, -Y) \text{ and } (0, -Y - \left(4 - \frac{Z}{f}\right)B)\]

respectively. Therefore, the disparity is:

\[d = \left(4 - \frac{Z}{f}\right)B \quad (2)\]

In equation 2, both the baseline length, $B$, and focal length, $f$, are fixed; thus the disparity, $d$, is linearly proportional to the depth, $Z$, of the object point. When $Z = 4f$, the disparity, $d$, becomes zero. It should be noted that $d$ can also be negative.

A multi-aperture telecentric lens system has the following major advantages over a conventional stereo vision system, as follows:

1. The disparity given by the multi-aperture telecentric system is linearly proportional to the depth, which is a critical difference from the conventional stereo vision system in which the disparity is proportional to the inverse depth, as already mentioned. This property results in a more accurate and stable determination of depth information.
The absolute location of an object point other than the depth can be easily determined based on the image captured by the aperture stop at the focal point, which maintains the advantages of a conventional telecentric lens.

When an object point goes farther, the angle between light rays in the conventional stereo vision system becomes narrower, as can be inferred from Figure 3. This results in less disparity in the image space, that is, less accuracy in depth determination. In the multi-aperture telecentric system, the angle between the rays remains constant because the disparity is linearly proportional to the depth, that is, the accuracy of depth determination remains at the same level.

Figure 3  A conventional stereo vision system.
Figure 4  A simplified multi-aperture telecentric lens system (1× magnification).

Unlike the conventional stereo vision system, the multi-aperture telecentric system does not require any photometric calibration or intensity adjustment between cameras because it is a single-lens imaging sensor.

3-D Reconstruction and accuracy potential using a multi-aperture telecentric system

The geometric model for 3-D reconstruction might differ among multi-aperture telecentric system types. Taking the simplified multi-aperture telecentric lens system illustrated in Figure 4, for example, the geometric model can be derived as:

\[
\begin{align*}
X &= -\frac{u_1 + u_2}{2} \\
Y &= v_1 \\
Z &= \left(4 - \frac{d}{B}\right)f
\end{align*}
\]  

(3)

where \((X, Y, Z)\) are the 3-D coordinates of the object point \(P\), \((u_1, v_1)\) and \((u_2, v_2)\) are the image coordinates on the images acquired from the aperture stops \(O\) and \(O'\), respectively, and \(d = v_1 - v_2\). From equation 3, it can be seen that the geometric model of the simplified multi-aperture telecentric lens system for 3-D
reconstruction is much simpler than other machine vision systems.

Camera calibration is an important step in 3-D reconstruction using conventional stereo vision systems, but with the multi-aperture telecentric lens system, because the telecentric lens offers orthographic projection and the projection center is at infinity, the lens distortions for telecentric lens systems are very small (normally in the range of 0.1%). Therefore, only the offset of the principal point needs to be considered in the calibration. This can be achieved by following the general methodology of calibrating the principal point in photogrammetry or computer vision by adding additional terms to the right-hand side of equation 3. The accurate principal point can be determined through several control points measured in object and image space. In a high-quality multi-aperture telecentric lens system, the calibration procedure might be ignored, as the influences of lens distortion and the offset of the principal point on the measurement accuracy are negligible.

Image matching is another important issue in 3-D reconstruction. In the multi-aperture telecentric system, image matching involves identifying the image coordinates on the images acquired from the two aperture stops, which belong to the same object point. The illustration of the multi-aperture telecentric lens in Figure 4 reveals that for an object point, the light ray should pass through two aperture stops and build a pencil of the planes containing the baseline. Because the image plane cuts the pencil of the planes, all of the correspondences should be on a line – the epipolar line. For an image plane parallel to the focal plane, all of the epipolar lines are parallel to the baseline and parallel to each other. Therefore, image matching is much easier than it is in conventional stereo vision systems, as it only needs to search for image correspondences along the epipolar lines, which are parallel to the baseline. Automatic and reliable image matching can be expected for the multi-aperture telecentric system.

To evaluate the potential measurement accuracy of the multi-aperture telecentric system, the simplified multi-aperture telecentric lens system illustrated in Figure 4 is used for analysis. Through an error-propagation derivation based on equation 3, the measurement errors can be calculated as:

\[
\begin{align*}
\sigma_X^2 &= \frac{1}{4} \sigma_{u_1}^2 + \frac{1}{4} \sigma_{u_2}^2 \\
\sigma_Y^2 &= \sigma_{v_1}^2 \\
\sigma_Z^2 &= \frac{(4f - Z)^2}{B^2} \sigma_B^2 + \frac{f^2}{B^2} \sigma_d^2
\end{align*}
\]

where \(\sigma_X\), \(\sigma_Y\), and \(\sigma_Z\) are the standard errors of measurement in the \(X\), \(Y\), and \(Z\) directions, respectively; \(\sigma_B\) is the standard error of the baseline length; \(\sigma_d\) is the disparity measurement error; \(\sigma_{u_1}\), \(\sigma_{u_2}\), and \(\sigma_{v_1}\) are the measurement errors of the image coordinates. \(\sigma_d\) can be determined by the accuracy of image matching. According to a theoretical analysis, pixel-level image matching (correlation) can reach an accuracy of about one-third of a pixel. Given the homogeneity of the imaging sensor:

\[
\sigma_{u_1} = \sigma_{u_2} = \sigma_{v_1} = \sqrt{1/2 \sigma_d}
\]

As equation 4 shows, the measurement errors in the \(X\) and \(Y\) directions are fixed because the CCD sensor is fixed, whereas the measurement error in the \(Z\) direction (depth) is related to the baseline length, depth, focal length, and disparity. To investigate the measurement error in the \(Z\) direction, a theoretical analysis is conducted based on the third equation in equation 4, referring to the parameters of a commercially available telecentric lens as listed in Table 1.

Because the best working distance is 500 mm, distances ranging from 300 mm to 1000 mm
are investigated. The baseline length error is assumed to be 10 μm. The measurement errors in the Z direction are calculated for each working distance under different baseline lengths from 10 mm to 60 mm. The results are shown in Figure 5.

Figure 5 shows that as the baseline length increases, the measurement error in the Z direction decreases, and the farther the working distance is, the larger the decline. When the baseline length is about 30 mm (about 14% of the focal length), a measurement accuracy in the Z direction of 0.1% (measurement error divided by distance) can be expected around the best working distance.

It should be noted that only a theoretical analysis has been performed here. The real performance of the multi-aperture telecentric system in 3-D reconstruction requires further investigation based on experiments using a real multi-aperture telecentric system.

There are several promising future research topics related to multi-aperture telecentric systems. For example, it remains difficult to obtain two separate images from the two aperture stops while maintaining relatively simple optical geometry. Previous studies have used complicated lens elements to separate images from multiple aperture stops (Yahav and Iddan 2000). A more productive approach would be
to design the apertures to be controllable and the two apertures to open successively to acquire two images separately. However, the actual implementation of this mechanism depends on future research. In addition, real applications in machine vision may require telecentric lens systems with better magnification capabilities (e.g., 10× or 20×). The geometric model for multi-aperture telecentric systems with magnification capabilities will be more complicated, as it will involve more optical elements, which requires future research.

Multicriteria decision-making

Piotr Jankowski  
San Diego State University, USA

Multicriteria decision-making (MCDM) denotes a structured approach to solving decision problems involving decision alternatives. The fundamental idea underlying MCDM can be described as follows: find feasible options (alternatives) for solving a decision problem, evaluate the overall merit of each feasible option by measuring its performance on multiple criteria (objectives), and compare the relative merits of evaluated options to choose the best performer. MCDM has been an academic field with practical applications in many domains, including finance, marketing, business processes, engineering, medicine, environmental management, and planning. In geographical sciences, MCDM methods have been developed to account for explicit spatial footprints of decision alternatives. Much of the development happened through integrating MCDM with geographic information systems (GIS) and putting MCDM methods at the core of spatial decision-support systems (SDSS). Applications of MCDM in decision problems involving explicit representation of geographical space include land-use allocation, site selection, environmental planning, urban and regional planning, ecological management, transportation, waste management, water management, agriculture and forest management, natural hazard management, and real estate and housing.

Roots of MCDM

Early papers on MCDM methods started appearing in the late 1960s and early 1970s, and the first MCDM conference was organized in 1975. However, the roots of MCDM can be traced to the nineteenth century and even earlier. According to Kõksalan, Wallenius, and Zionts (2011), Benjamin Franklin (1706–1790), the American statesman, scientist, and inventor, was a pioneer of a simple multicriteria approach to decision-making. In making important decisions, he used a two-column table to evaluate a decision by writing arguments for the decision in one column and arguments against in the other. He then employed an informal weighting system by identifying for and against arguments of equal importance and crossing them out. The column that had more uncrossed arguments remaining identified the decision to make.

Theoretical concepts that later contributed to the development of MCDM come from mathematics, economics, behavioral decision theory, and mathematical programming. Mathematical underpinnings of MCDM came from calculus methods of identifying function optima, known contemporarily as mathematical optimization, contributed by Pierre de Fermat (1601–1665), Isaac Newton (1642–1727), Joseph-Louis Lagrange (1736–1813), and Carl Friedrich Gauss (1777–1855). Other mathematical concepts, fundamental for MCDM, came from set theory created by Georg Cantor (1845–1918). In the field of neoclassical economics, Francis Edgeworth (1845–1926) introduced the concept of the indifference curve and set the foundations of utility theory, developed after World War II.
by Howard Raiffa (b. 1924), Ralph Keeney (b. 1944), and Peter Fishburn (b. 1936). An indifference curve can be depicted by a graph representing choices between two different categories (e.g., two different resources). The defining property of the indifference curve is that any point that belongs to it represents equal utility (satisfaction) that can be derived from the two corresponding resource levels found on $x$- and $y$-axes. Just as one can graph a utility (tradeoff) level between two resources by finding a proper form of indifference curve, one can also find a utility function for a given resource. The problem then becomes how to aggregate various utility functions into one synthetic, index-like measure. The question arises as to why this is a problem from a decision-making standpoint. Imagine selecting real estate based on a number of measurable criteria (price, square footage, number of bedrooms, distance to work, etc.). Each of the criteria could be represented by a separate utility function representing a specific level of utility for a specific value of a criterion in question. Providing a measure of the overall utility for each piece of real estate (e.g., a house), in order to facilitate their comparison, requires aggregating various individual utilities. The French-Italian economist Vilfredo Pareto (1848–1923) studied the problem of aggregating criteria into a single overall measure. The concept of efficient allocation of resources, also known as Pareto efficiency, is due to him. Accordingly, a Pareto-efficient choice is achieved if no other choice exists that performs better than the choice under consideration on most of the criteria without scoring worse on at least one criterion. The concept of Pareto efficiency has become influential in economics and decision theory. Along with the Pareto efficiency frontier representing a set of Pareto-efficient choices, it has also been one of the key concepts in MCDM.

Much of the theoretical work on decision-making that influenced MCDM came from behavioral economics. Working at the intersection of psychology and economics, Ward Edwards (1927–2005) published in 1961 an influential paper (Edwards 1961) probing into psychological mechanisms of decision-making and establishing the field of behavioral decision theory. Herbert Simon (1916–2001) postulated that people in their decision-making practices by and large did not adhere to a theoretical model of “rational man,” which was one of the cornerstones of neoclassical economics. Instead, Simon argued that people followed a satisficing behavior driving them to achieve subjective aspiration levels, which did not equal optimal levels. He termed such a decision-making behavior “bounded rationality.” The concept of aspiration levels was adopted by a number of MCDM methods developed during the 1970s, 1980s, and 1990s. Simon is also credited with popularizing a three-stage model of rational decision-making (Simon 1976), in which a decision-making task is subdivided into three stages: (i) intelligence – search for feasible alternatives, (ii) design – involving the determination of consequences/impacts of feasible alternatives, and (iii) choice of a particular alternative guided by a decision rule. Simon’s model of rational decision-making has been influential in decision-support systems (DSS) and SDSS including MCDM methods.

The search for feasible decision alternatives and determination of their characteristics can be facilitated by formulating and solving a constrained optimization problem or a mathematical program. Solving a mathematical program with many decision variables can be a difficult task, even if the program is composed of linear inequalities (i.e., a linear program). In 1947, George Dantzig (1914–2005) proposed the simplex algorithm providing an efficient procedure for solving linear
programs. This was a breakthrough leveraged by developments of mainframe computers and programming languages, which enabled solving large linear problems composed of hundreds, even thousands, of decision variables. Danzig’s discovery was preceded by a similar method of solving linear programs proposed in 1939 by Leonid Kantorovich (1912–1986) and applied to central planning in the Soviet Union. Unfortunately, Kantorovich’s work remained largely unknown to the Western world until the 1970s. The simplex method popularized linear programming and spurred many of its applications in the 1950s and 1960s in resource management, business and military logistics, and production management. Practical applications were accompanied by theoretical developments of linear programming extensions including nonlinear programming, goal programming, and multiple objective linear programming. In 1967, Arthur Geoffrion published an article in *Operation Research*, in which he showed how Pareto-efficient solutions can be generated for optimization problems with two objective functions. The period of the next 40 or more years witnessed the emergence of the MCDM field marked by developments in theory, methods, and applications, which proliferated into new domains including location analysis, land-use planning, and applications of GIS.

**MCDM concepts**

Fundamental concepts in MCDM relate to its structural components, including *objective, attribute, criterion, constraint, preference, decision variable, dominance, decision alternative, and decision rule*. Among the fundamental concepts are also two different ways of addressing MCDM, as either a problem of choice from a set of pre-existing decision alternatives, or a problem of a search for feasible decision alternatives. The former is referred to as the *multiple attribute decision-making* (MADM) approach, while the latter is called the *multiple objective decision-making* (MODM) approach.

*Objective* refers to a desired level of property or quantifiable result of some action that follows a decision. Examples include minimum cost, maximum profit, or some broader notion of desired outcome that can be quantified (e.g., increasing a suitable habitat). *Attribute* is a measurable characteristic of an entity and/or action comprising a decision alternative. The MCDM approach adopts the notion of more than one objective that is relevant for analyzing a decision problem. It follows that multiple attributes are employed to characterize each decision alternative and that the same set of attributes is used for all decision alternatives under consideration. A good example of such a set of attributes is a list of fields (attributes) in a GIS layer. Each spatial entity present in the layer, which could also be conceptualized as a spatial decision alternative, is characterized by a common set of fields in a layer attribute table.

A *criterion* is an attribute that has been qualified by a desired direction of improvement (e.g., maximization or minimization of attribute value). Hence, criteria in MCDM are the basis for measuring, either explicitly or implicitly, the performance of decision alternatives. The explicit measurement happens when decision alternatives and their outcomes are known. In such a case the performance of decision alternatives is represented by criteria values, which can be computed using various analytic methods. Feasible decision alternatives and their outcomes need to be identified in the first place. Under such a requirement, criteria and their predefined directions of improvement can be used to gauge progress in the search for feasible decision alternatives. To facilitate the search, criteria are used as quantifiable objectives, which can either be minimized or maximized.
Criteria can also be constrained by imposing a standard: a minimum value required, a maximum value allowed, or a range of admissible values. Constraints serve the purpose of ensuring decision alternative performance levels or representing the availability of resources required by decision alternatives. Thresholds and cutoffs are common forms of constraints requiring certain minimum criterion values to be achieved (thresholds) or certain maximum criterion values not to be exceeded (cutoffs).

Preference is an expression of criterion importance relative to other criteria under consideration. Criteria preferences are commonly represented by weights, with the property that the sum of weights equals 100% of preferences (typically the weight values range between 0 and 1 and the sum of weights equals 1). A criterion weight is in effect a scaling constant indicating a relative importance of a given criterion vis-à-vis other criteria. Another common way of representing criteria preferences is by means of tradeoffs. A tradeoff is a statement of indifference (equivalence) between \( x \) units of criterion \( c_1 \) and \( y \) units of criterion \( c_2 \).

The decision variable is a measurable quantity that has a value for every decision option. The simplest of all is a binary integer decision variable (1–0) often associated with a go–no-go (yes, no) type of decision. This type of decision variable can represent location decision alternatives, where not the site itself, but the question of whether or not to locate an activity at a given site, gives rise to location decision alternatives. Decision variables can also take on integer and real values.

The dominance principle, due to the already mentioned Vilfredo Pareto (hence called Pareto-dominance), states that a decision alternative is nondominated if there is no other feasible alternative that surpasses this alternative on any of the criteria without reducing performance on another criterion. Nondominated alternatives are naturally preferred over dominated alternatives and finding them has been the focus of many MCDM methods.

Decision alternatives (decision options) give purpose to MCDM regardless of whether there are only two alternatives representing a so-called go–no-go decision situation, or whether there are more than two feasible alternatives. In spatial decision problems, each decision alternative consists at the minimum of action specification (what to do) and location (where to do it).

A decision rule is an analytic procedure for processing performance data about decision alternatives in order to find a solution to a decision problem. Three generic approaches to solving a decision problem with MCDM are as follows.

- Selection: given a set \( A \) of alternatives, the selection task operation involves finding a subset \( A' \) of \( A \) composed of as small as possible a number of alternatives, judged by decision-makers as the most satisfying.
- Sorting: the sorting operation (also called classification) consists of assigning each alternative from \( A \) to one of the predefined categories. The assignment should be based on the intrinsic measure of a criterion for an alternative and not on its comparison with other alternatives from \( A \). However, in practice the assignment is often based on relative differences of alternatives along a criterion.
- Ranking: the ranking operation involves establishing a preference pre-order on the set of alternatives \( A \). The pre-order represents a priority list of the alternatives.

The MADM approach to MCDM requires that the selection, sorting, or ordering of decision alternatives be made on the basis of their criteria performance. MADM problems are
assumed to have an a priori known number of decision alternatives. Problems solved with the MADM approach are also called discrete because the number of evaluated decision alternatives is known and hence it can be enumerated. In the spatial decision domain, feasible decision alternatives are commonly identified with GIS suitability analysis leading to identification of suitable locations. Depending on the scale and spatial data representation model used, the number of suitable (feasible) decision alternatives can range from few to many with many corresponding to a situation, where each spatial unit (e.g., a raster layer cell) represents a feasible location decision alternative.

In the MODM approach, contrary to MADM, the decision alternatives are not known a priori. MODM uses a mathematical framework to search for a set of feasible decision alternatives. The search is carried out by an algorithm that evaluates different candidates for decision alternatives, composed of decision variable values, which are bound by constraints. The decision rule that guides the search is to optimize the objectives. Each alternative, once identified, is judged by how closely it satisfies an objective or multiple objectives. Since the decision variables can take on real number values, problems tackled with the MODM approach are also called continuous. The MODM approach can potentially result in a large number of feasible solutions (decision alternatives); hence, MODM methods focus on finding non-dominated solutions comprising a subset of feasible solutions. A comparison of both approaches contrasting their salient characteristics is given in Table 1.

**MCDM methods**

Many MCDM methods have been proposed over the last 40 years or more for solving either MADM or MODM problems. MADM methods, also referred to as scoring or multiple criteria evaluation methods, use simpler algorithmic procedures than MODM relying on optimization and heuristic algorithms. It is beyond the scope of this encyclopedic overview to provide a full account of various MADM and MODM methods. Hence, only the methods that have been widely used in spatial MCDM are briefly reviewed.

**MADM methods**

Two approaches to MADM, one based on multiple attribute utility theory (MAUT) and the other on outranking relation, led to the development of a number of MADM methods. The MAUT-based methods use the notion of utility/value function, which theoretically can be established for any decision criterion. If a criterion value attained for a given decision alternative is substituted for the function's argument, the function's value returned for the argument represents a standardized number ranging between 0 and 1 (or 0% and 100% representing the utility/value scale). The MAUT-based methods use various techniques of determining the shape/form of utility/value functions and aggregating the functions' values for multiple criteria in order to arrive at one number representing the overall utility/value of a given decision alternative. A simple and commonly used form of multiple attribute value function is the additive function given in equation 1, where:

\[ V_i = \sum_{j=1}^{m} w_j x_j \]

\[ 0 \leq w_j \leq 1 \text{ and } \sum_{j=1}^{m} w_j = 1 \]

\[ V_i \] represents the overall value of the \( i \)-th decision alternative

\( w_j \) is the weight representing the relative importance of the \( j \)-th criterion, such that \( 0 \leq w_j \leq 1 \) and \( \sum_{j=1}^{m} w_j = 1 \)

</tbody>
</table>

\[ v_j \] is the value function for the \( j \)-th criterion

\[ x_{ij} \] is the \( j \)-th criterion value for the \( i \)-th decision alternative.

The additive function form given in (1) can be simplified when the value function \( v_j(x_{ij}) \) is the same for all \( N \) criteria. This case is presented in the equations 2–4, where \( \min_j(x_{ij}) \) and \( \max_j(x_{ij}) \) are the minimum and maximum criterion values for the \( j \)-th criterion, respectively.

\[
V_i = \sum_{j=1}^n w_j v(x_{ij})
\] (1)

\[
V_i = \sum_{j=1}^n w_j v(x_{ij})
\] (2)

\[
v(x_{ij}) = \frac{x_{ij} - \min_j(x_{ij})}{\max_j - \min_j}, \text{ for the } j \text{-th criterion to be maximized}
\] (3)

\[
v(x_{ij}) = \frac{\max_j(x_{ij}) - x_{ij}}{\max_j - \min_j}, \text{ for the } j \text{-th criterion to be minimized}
\] (4)

MADM functions that combine criteria weights with criteria values, in a similar way to the function given in (1), are called aggregation functions. The additive value function in (1) results in ordering decision alternatives from the highest to the lowest performer. The resulting order is called a weak order since it follows a complete and transitive binary relation, which allows for an inference of the kind: if \( A > B \) and \( B > C \), then \( A > C \) (where \( A, B, C \) denote the decision alternatives). Ordering the decision alternatives requires that the criteria weights represent tradeoffs. In practical terms, this means that, for example, given two weights \( w_1 = 0.5 \) and \( w_2 = 0.25 \), the tradeoff between criterion 1 and criterion 2 equals \( 0.5/0.25 = 2 \), or in other words, the decision-maker is willing to trade off two units of criterion 2 for one unit of criterion 1. This type of information may not always be available, and if it is then its reliability is not always assured.

Equations 3 and 4 define a nonlinear value function that standardizes the criteria values to fall in the range from 0 to 1, with 0 representing the lowest and 1 representing the highest worth of a criterion value. Equations 2–4 provide the basis for weighted linear combination (WLC), which is one of the simplest MADM methods. In the spatial realm, WLC has been the most popular MADM method. According to an extensive
literature review by Malczewski (2006), of all articles describing research on integrating GIS with MCDM published between 1990 and 2004, 143 (39.3%) included WLC as the leading MCDM method.

Other prominent MADM methods that loosely follow the multiple attribute utility/value function approach include the analytical hierarchy process (AHP) – developed by Thomas Saaty (1980); ideal point methods, an example of which is the technique for order of preference by similarity to ideal solution (TOPSIS) – developed by Hwang and Yoon (1981); and ordered weighted averaging (OWA) operators – proposed by Yager (1988).

AHP has been arguably the most widely used MADM method, with applications in business, politics, engineering, and environmental management including spatial analysis with GIS. The method is based on structuring (decomposing) a decision problem into a multilevel hierarchy, and on pairwise comparisons of elements within the hierarchy. A typical hierarchy in a decision problem might include the decision goal, criteria, and alternatives. Criteria might be decomposed into two levels: higher-level criteria representing general categories (e.g., environmental, economic, and social) and lower-level criteria specifying each of the higher-level criteria. With the hierarchy established, the elements within each hierarchy level are compared to one another in a pairwise manner to measure the relative importance of their contribution to a higher-level element. For example, in a pairwise comparison of two lower-level environmental criteria, the importance of one criterion vis-à-vis a higher-level environmental criterion is judged against the importance of the other criterion. The judgments are expressed numerically using the 1–9 ratio scale, where 1 denotes equal importance and 9 represents the extreme importance of one element over the other element. The results of the pairwise comparisons obtained at each level of the hierarchy are then arranged in a pairwise, square comparison matrix and aggregated by computing its eigenvector. The elements of the eigenvector are weights \( w_j \), such that

\[
\sum_{j=1}^{m} w_j = 1
\]

expressing the importance of the \( j \)-th element relative to other elements at the same level of hierarchy. The procedure leads to rank-ordering of decision alternatives on the basis of a final score computed as a simple weighted sum for each decision alternative. In the weighted sum formula used by AHP, criteria weights are multiplied consecutively by a decision alternative weight and the products are summarized. The resulting sum is a ratio-scale score representing the worth of an alternative relative to other alternatives.

Various MADM methods have been developed around the concept of distance separating a decision alternative from an a priori reference point. A multidimensional reference point, or rather a vector of values corresponding to decision criteria under consideration, can be conceptualized as an aspiration level for each criterion, beyond which the utility/value of the criterion increases only marginally or remains unchanged. Another conceptualization of the reference point is used in the TOPSIS method where two opposing vectors of criterion values are established. One of them – called the ideal – is composed of the most favorable values for the criteria under consideration. This includes the maximum values for the criteria to be maximized and the minimum values for the criteria to be minimized. The other – called the nadir – is composed of the least favorable values, including the minimum values for the criteria to be maximized and the maximum values for the criteria to be minimized.
A distance between a given criterion value and the corresponding ideal and nadir values is computed for each criterion and the overall normalized separation metrics from ideal and nadir are computed for each decision alternative. The alternatives are ordered based on the proximity to ideal and the separation from nadir.

The OWA operators-based method computes for each decision alternative an aggregate of criteria weights and criteria values using two sets of weights: the criterion weights representing relative preferences attached to decision criteria and the order weights corresponding to a selected OWA operator. Common OWA operators include MEAN (order weight values are the same and they equal the ratio of 1/number of criteria), MIN (corresponding to Boolean AND), and MAX (corresponding to Boolean OR). In the case of the MEAN operator, the result of OWA-based calculation becomes identical to the result of WLC. The MIN and MAX operators represent two extreme cases, with MIN corresponding to a “pessimistic” decision choice behavior or the worst-case scenario, and MAX corresponding to an “optimistic” behavior or the best-case scenario. Other OWA operators residing between MIN and MAX can be selected to represent choice attitudes ranging between pessimistic and optimistic.

Methods based on outranking relation are associated with the European School of MCDM and with Bernard Roy (1996), his collaborators, and students. The outranking relation is a binary relation \( S \) on the set \( X \) of alternatives such that \( xSx \) (read: alternative \( x \) outranks alternative \( y \)) if there is sufficient information to reason that \( x \) is at least as good as \( y \), and \((x, y) \in X\). In most of the methods the outranking relation is established through a series of pairwise comparisons of the decision alternatives by employing the concordance – discordance principle. The principle states that \( xSy \) if (i) a majority of the criteria supports this assertion, thus fulfilling the concordance condition, and (ii) the remainder of the criteria representing the discordance condition do not outweigh in their aggregate the concordance majority. The crucial difference between the outranking relation approach and the value function approach is that the former uses ordinal comparisons and does not require quantitative tradeoffs between criteria. In practical terms this means that the outranking approach does not require a precise quantification of the decision-maker preferences in regard to the criteria. There are many situations where eliciting preferences from the decision-maker is difficult at best (e.g., when the decision-maker is not an individual but a diverse organization) and the preferences are only partially defined. In such situations, a less rigorous representation of preferences than the tradeoff weights, such as the one based on the concordance – discordance principle, has its advantages.

The oldest, simplest, and perhaps the best known outranking method is ELECTRE I (ELimination Et Choix Traduisant la REalité I (Elimination and Choice Expressing Reality I)). The method can be used effectively to sort the decision alternatives into those that are inferior and those that warrant further scrutiny (acceptable choices). The sorting is done by calculating measures of concordance and discordance for each pair of decision alternatives under consideration, and selecting a concordance cutoff and a discordance threshold. As long as the minimum level of support (concordance cutoff) is achieved while not exceeding the threshold for the opposite point of view, the concordance in favor of an alternative \( x \) outranking an alternative \( y \) outweighs the discordance. The successors to ELECTRE I include ELECTRE II, III, IV, and ELECTRE TRI.
PROMETHEE (Preference Ranking Organization METHod for Enrichment of Evaluations) methods comprise another well-known family of outranking MADM methods.

MODM methods

Multiple objective decision problems are typically structured by defining more than one objective function and constraining a solution space. A generic linear MODM problem has the following form:

\[
\begin{align*}
\text{Optimize} & \rightarrow f_1(X), \ldots, f_j(X) \\
A \times X & \leq B \\
X & \geq 0
\end{align*}
\]

(5)

where:

\[X = x_1, x_2, \ldots, x_j, \ldots, x_m\]
\[A = a_{ij}, i = 1, \ldots, n, j = 1, \ldots, m\]
\[B = b_1, b_2, \ldots, b_i, \ldots, b_n\]

\(X\) represents the vector of decision variables \(x_j\)
\(A\) represents the matrix of inputs \(a_{ij}\) required per unit of decision variable \(x_j\)
\(B\) represents the vector of available inputs \(b_i\).

MODM problems are typically solved with optimization techniques. A common solution strategy involves transforming a problem with multiple objective functions into a single objective function by weighting and summing each objective based on decision-maker preferences. For example, given two objective functions to be optimized separately, \(\text{Min} \rightarrow f_1(X)\) and \(\text{Max} \rightarrow f_2(X)\), and the decision-maker’s preferences for the two objectives expressed by the weights \(w_1\) and \(w_2\), where \(w_1 + w_2 = 1\), one can formulate the following single objective optimization problem: \(\text{Min} \rightarrow w_1 f_1(X) - w_2 f_2(X)\).

Optimization algorithms developed as extensions of linear programming are not very practical for solving large spatial MODM problems as these algorithms may be computationally expensive and do not guarantee finding optimal problem solutions. Various heuristic methods, including evolutionary multi-objective algorithms (EMO) and their subset, called genetic algorithms (GA), were proposed as alternatives to optimization algorithms for solving large MODM problems. Evolutionary algorithms are heuristics inspired by Darwinian ideas of evolution suggesting that fit members will emerge in a population through natural selection. A genetic algorithm begins with an initial random population of individuals, or potential solutions. In an optimization problem the fitness of individuals is evaluated based on their objective functions and constraints. Decision variables of the optimization problem are represented by chromosomes in the GA, which are often a string of bits or an array of values, where each value may be called a gene. For example, in a spatial decision problem a chromosome might be represented by a binary array of 1s representing locations that are initially selected and 0s representing nonselected locations. Typically, individual solutions with high fitness are chosen for reproduction, which consists of a series of operations. The most common genetic operators are selection, crossover, and mutation. Selection operations choose individual solutions, and then with a specified probability a crossover operation swaps a portion of chromosome genes between pairs of solutions to create new children solutions. A mutation operation may then be applied and considered as a random perturbation that will occur with some specified probability. Mutation operators often randomly alter one or more gene values, or initialize a new solution from scratch and add it to the population.
MULTICRITERIA DECISION-MAKING

MCDM in geography

The initial thrust of work on bringing MCDM into the realm of the spatial domain focused on the adaptation of methods proposed outside geography to spatially explicit representations of space (raster/field and vector/object). The crucial distinction between the two predominant models of planar space is that in the raster/field model, each fundamental element of model representation (i.e., a raster cell) is a potential location of a decision alternative, whereas in the vector/object model, each discrete object on the map (i.e., point, line, or polygon) is a potential location. Much of the initial work went into integrating MCDM methods with GIS software. Various integration forms were proposed, ranging from a simple file exchange between MCDM tools and GIS, through loose coupling, automating the exchange of data between MCDM and GIS modules, to full integration, embedding an MCDM module into a GIS. An example of the latter is the IDRISI GIS software containing a fully integrated MCDM module with multicriteria decision analysis functions.

Spatial implementations of MCDM included both MADM and MODM, with the majority of methods belonging to the MADM category. Owing to the early applications of MCDM in planning, relative simplicity of solution algorithms and mathematical representation, and obvious applicability to land suitability analysis, the ratio of publications reporting on the use of MADM methods in comparison to publications on MODM has been more than 2:1 (Malczewski 2006). The most popular MADM methods for solving spatial decision problems included WLC, ideal/reference point methods (TOPSIS and MOLA – an iterative procedure for multi-objective land allocation developed and implemented in IDRISI GIS software), AHP, and outranking methods ELECTRE and PROMETHEE. The MODM methods applied to spatial decision problems included multiple objective optimization, heuristic (evolutionary/genetic) algorithms, and reference point methods.

The range of MCDM applications in the spatial domain has been impressive. The major application domains include environmental management, transportation, urban and regional planning, water resources, agriculture, forestry, natural hazards, recreation and tourism, and real estate. The most common decision problem tackled with the MCDM approach has been land suitability analysis, followed by evaluation of decision alternatives, site selection, resource allocation, route selection, impact assessment, and location allocation.

Recent advances at the intersection of MCDM and geography have been centered on developing spatially explicit MCDM methods. In the area of MODM, spatial optimization methods have been proposed that take advantage of various representation models and address spatially explicit objectives such as contiguity, compactness, and area shape (Tong and Murray 2012). Using the principle of range sensitivity, according to which criteria weights may depend on a spatially variable range of criteria values, Malczewski (2011) proposed a local version of the WLC method including local and global
MULTICRITERIA DECISION-MAKING

criteria weights. Prior to this development, a conventional or global version of WLC assumed spatial homogeneity of criteria weights, meaning that the importance of a decision criterion is stationary throughout the study area. The local version of WLC adopts instead the idea of a heterogeneous criterion surface, in which the criterion weight (criterion preference) may vary depending on the range of criterion values within a local neighborhood.

Criteria weights are the obvious source of uncertainty in MADM models due to unstable human preferences and the difficulty of articulating preferences in regard to decision criteria. Accounting for this inherent bias in criteria weights has been traditionally a task of sensitivity analysis in MADM methods. The most common and also straightforward form of sensitivity analysis has been a so-called one-at-a-time (OAT) approach, in which a selected criterion weight is changed by a certain value/percentage up and down, while the other weights are kept unchanged, and the effect of change on the model solution (e.g., rank-order of decision alternatives) is observed. The OAT approach, however, does have its limitations, including a potentially arbitrary change of weight values and the inability to account for interaction effects among the weights (i.e., multiple weights changing simultaneously). To address these shortcomings in the sensitivity analysis of criteria weights in MADM models, Ligmann-Zielinska and Jankowski (2014) proposed an integrated and spatially explicit approach to uncertainty and sensitivity analysis. The approach and its methods allow generating an uncertainty map of an MADM model solution (e.g., an uncertainty map of land suitability ranking) and a number of sensitivity maps, which may reveal areas where the specific criteria weights influence the uncertainty of the model solution.

Future directions

It is reasonable to expect that further development of spatially explicit MCDM methods will continue by incorporating spatial representation and abstraction in decision problem modeling with multiple criteria. In addition, three research areas offer opportunities for future advances at the intersection of MCDM and geography: (i) flexible MCDM toolkits, (ii) behavioral considerations, and (iii) MCDM for big data.

Developing flexible toolkits has been a long-term objective of research on DSS and SDSS, which until now has eluded any satisfactory progress. The main motivation has been the high cost and considerable effort required to build realistic models of real-world decision situations, in light of which one often resorts to simplifications in problem representation and fitting a problem into the MCDM method, rather than the other way around. Advances in the Semantic Web, domain-specific model ontologies, and linked data might offer conceptual and methodological support for developing flexible MCDM toolkits, which might enable quick and inexpensive tailoring of MCDM models to fit a decision problem at hand.

Behavioral considerations of decision-making have been given attention since the 1950s in psychology, economics, and decision science. The Nobel Prize in economics awarded in 2002 to Daniel Kahneman amplified the importance of research on the behavioral foundations of decision-making. In the field of behavioral geography, some research has focused on the question of how cognitive processes, including environmental perception and cognition, wayfinding, and the development of attitudes about space and place, explain human decisions and behavior related to choice-making. Yet, despite the recognition of this topic, behavioral issues have received little attention from MCDM
MULTICRITERIA DECISION-MAKING

Researchers in geography and GIScience. Not much is known about how the attitudes about space and place influence possible biases in the selection of decision criteria and the elicitation of their preferences expressed by weights. Similarly, little is known about what role perception and cognition shaped by spatial organization play in the dynamics of group decision-making processes. These and other related questions offer ripe opportunities for infusing behavioral considerations in developing spatially explicit MCDM methods.

Big data present both a challenge and an opportunity for MCDM. In the geographic domain, large multi-attribute datasets are made larger by incorporating spatial and temporal dimensions. Optimizations—techniques developed in MODM often fail when applied to large spatial or spatiotemporal decision problems as exact optimal solutions cannot be found. Evolutionary multi-objective optimization methods have been shown to be effective at approximating exact solutions and there has been an increased interest in the use of EMO to solve large, computationally challenging spatial problems. As EMO methods typically generate a large number of discrete solutions approximating a continuous set of nondominated solutions, there is a need to aid the decision-maker in efficiently evaluating tradeoffs between different discrete nondominated solutions. This calls for development of new techniques facilitating visual exploration and assessment of tradeoffs between alternative solutions. Opportunities for research in this area can be found at the intersection of visual analytics, MCDM, and GIS (Andrienko et al. 2007).

Multiculturalism

Katharyne Mitchell
University of Washington, USA

Multiculturalism is often used as an umbrella term to capture a wide range of ideas and policies associated with human difference – particularly cultural and religious diversity. The concept has a number of associated referents: to the lived realities associated with plural societies; as a set of perspectives and debates in political philosophy about the best management of group difference; and as a form of state-sanctioned politics of incorporation and accommodation. In all three of its formulations it has defenders and detractors spanning the political spectrum.

As a reality of everyday life, multiculturalism reflects the mixing and unmixing of populations throughout history. Few areas on the planet remain untouched by the movements of people, who bring diverse ways of thinking and being into new contexts. Plurality is thus a common feature of most societies and multiculturalization can be seen, in this light, as a de facto process that has occurred and will continue to occur regardless of the ideologies and policies of theorists, states, and citizens.

Nevertheless, multiculturalism is also a feature of everyday life that most individuals associate primarily with late modernity and the movements and flows of contemporary globalization. The intensive labor migration networks from North Africa and the Middle East to western Europe following World War II are often considered to be the primary galvanizing force of this period of accelerated mixing. Likewise, migration networks from less developed to more developed regions in North America and Asia are also part of the contemporary imaginary associated with the rise of a vigorously multicultural period. Multiculturalism is also connected to the rights claims of disadvantaged groups, who effectively expressed their demands in a series of identity-based social movements beginning primarily in the 1960s.

Thus, although in its broadest usage the term could be applicable to most urban centers, ports, and long-distance trade routes across the globe and throughout human history, it is most frequently defined in relation to the concentrated migration and associated cultural intermixing of the postwar era. It is also associated with the social movements, minority nations, and indigenous and other group-based claims of the civil rights era. Some variation of the term, consequently, remains closely identified with the state policies and politics of Canada, Australia, the United Kingdom, the United States, Singapore, Malaysia, and many countries of western Europe as they negotiated – and continue to negotiate – the social transformations of this period.

Multiculturalism as political philosophy

With respect to the effective management of group difference, multiculturalism has many proponents in political philosophy. These include a number of different positions and justifications, but all share the foundational proposition that disadvantaged groups who have been marginalized by the dominant culture have the right to be recognized and respected by the state; moreover, the patterns of representation and recognition
Multiculturalism

that have produced economic and political disadvantages for minority groups should be remedied.

Beyond this desire for recognition and remediation there are nearly as many different philosophical viewpoints and propositions as there are different interpretations of the meaning of multiculturalism. As a starting point the term is understood to refer to identity and to cultural difference and hence it is associated with forms of politics such as “the politics of recognition,” and “identity politics.” But culture itself is an infamously slippery term, variously encompassing religion, language, aesthetics, food, music, way of life, and/or the whole range of learned human behavior. In association with the word multiculturalism it is also often connected to race and nation. Thus when brought into the realm of political philosophy and the question of how best to negotiate diversity, there are many differences of judgment and outlook.

The varied positions in this body of thought can be best summarized in three major categories: liberal egalitarianism, communitarianism, and postcolonialism. In liberal egalitarianism, culture is perceived as important for the life chances of individuals; it brings feelings of positive self-worth and self-respect, but only if the culture identified with is given positive recognition by other entities, such as the state. Culture is also important for individuals because it can provide a kind of scaffolding that enables choices to be made and learning to occur within certain parameters of meaning; it thus brings a sense of autonomy and self-reliance necessary for negotiating one’s path through life.

Theorists such as Kymlicka (1995) argue that given the instrumental importance of culture for an individual’s life chances, all cultures must be protected. Without special protections afforded by majority cultures (and their representative bodies such as the state), individuals associated with minority group cultures will be irreparably harmed. Thus it is up to the state to provide the accommodations necessary for equal valorization of minority cultures, and citizens must help to bear the costs of this accommodation.

Kymlicka’s philosophy of liberal egalitarianism reflects the author’s professional experiences and particular interest in Canada, which has a significant First Nations (indigenous) population, two colonial powers, and extensive immigration. Along with other liberal multiculturalists, Kymlicka’s normative argument justifies a hierarchy of differential rights and expectations of accommodation to groups based on a perception of coercive or noncoercive incorporation into the state. From this perspective, Canadian immigrants, seen as voluntarily joining the majority culture, would expect less in the form of group-differentiated rights than First Nations groups, who were incorporated against their will.

Another justification for multiculturalism comes from the communitarian position. This political philosophy embraces the value of social goods and communal life over the liberal emphasis on individual rights and liberties. Because it recognizes all cultures as collective projects with equal social value, multiculturalism is upheld as a positive normative ideal for the nation-state.

Operating in a different register, a third set of arguments justifying multicultural politics and policy brings in the question of history and power. These claims can be broadly situated under the rubric of postcolonialism. Drawing on a much wider body of social theory, and critical of the “neutral” stance of liberal arguments, postcolonial claims in support of multiculturalism point to the long-term negative impacts of colonialism. In this view, dispossession and dislocation caused by the colonial encounter led to the fragmentation or loss of cultural
artifacts and practices for aboriginal peoples worldwide; additionally, colonialism spurred the forced migration of millions of often unskilled workers and peasants, who lost their land and livelihoods at home, and who had little recourse but to move and sell their labor in the colonial metropole.

According to the postcolonial position, this history of violence and subjugation both delegitimizes the state’s authority over the indigenous, and also upholds their demands for redress; likewise, it positions immigrants and immigrant cultures in Western nations as minority cultures deserving of validation and accommodation. As the well-known phrase “we are here because you were there” indicates, the relationship between colonialism and migration is profound, and demarcations of coerced versus uncoerced incorporation into the state are frequently problematic. Thus liberal egalitarian arguments about the hierarchies of multicultural rights claims, in which immigrants are accorded relatively low status because of the “voluntary” nature of their state incorporation, are eschewed in most postcolonial critiques. Rather, overarching protections for diverse groups that have experienced structural violence and seek redress are propounded, along with insistence on examining the limitations of liberal thought and practices more generally.

State-sponsored multiculturalism and backlash

Multiculturalism has a range of meanings in different historical and geographical contexts. Depending on the philosophies and the practices of different states, it can refer primarily to a particular mode of immigrant incorporation and/or to the rights of minority groups to state recognition and protection. Multiculturalism is one feature of a broader trend in liberal social thought emerging in the mid-1960s in which cultural difference was acknowledged and valued and the national imperative for “outsiders” to assimilate to a national ideal was greatly reduced. This “differentialist” turn, as some scholars have labeled it, resonated with broader epistemological critiques of foundationalism and universalism.

Perhaps the most important impact of multicultural ideas at this time took place vis-à-vis perceptions of effective immigrant and minority integration. From a strong assimilationist ideology of immigrant absorption that was prevalent in most nations until the late 1960s, multicultural ideals of the right to difference (and to an institutional recognition of that difference) led to perceptible shifts in both the rhetoric and policy of numerous state institutions associated with minority rights and immigrant acculturation.

Through struggles in political spaces and in institutions like schools, proponents of the right to a public recognition and affirmation of difference won numerous legislative and budgetary victories beginning in the 1970s. These included funding for the teaching of regional and immigrant languages in the United States and Europe, the recognition of minority rights in the charters or constitutions of several nations worldwide, the recognition and affirmation of indigenous cultural groups, and the introduction of educational curricula supportive of multicultural principles.

Canada, in particular, was one of the strongest early adopters of multicultural language, policy, and practices, advocating strongly for bilingualism, and making multiculturalism an official national policy beginning in 1971. Because of its leading position in multicultural debates, numerous geographers such as David Ley and Audrey Kobayashi have investigated the discourse and practices of multiculturalism in Canada through
MULTICULTURALISM
time. Ley (2007) suggested recently that one of the critical scales in which to investigate the successes and failures of multiculturalism is that of the city, where the encounter with difference is highest, and where political fears about segregation and political alienation remain strong. Despite recent pessimism and unease about the ongoing value of multiculturalism, he provides a defense based on the importance of immigrant gateway cities in Canada and elsewhere, arguing that a robust philosophy for engaging difference of this order is critical for defeating racism and supporting culturally plural urban environments such as these (see also Keith 2005).

Multicultural victories at the national scale, such as those in Canada and Australia, were often the result of strong and persistent demands in formal political venues, but they also reflected the micropolitics of the workplace, urban sites, public venues, social media and the arts, and the encounters of everyday life. Geographers have probed these formal and informal spaces with an eye toward elucidating the importance of sociospatial interactions in the encounter with and acceptance of difference. In recent work, Amin (2012) defends a politics of encounter that exceeds human engagement, arguing for the importance of material transactional exchanges that include the nonhuman: for example, objects, physical environments, affect, atmosphere, and other material entities. He believes it is these types of situated practices and exchanges, where many kinds of tangible and intangible things flow together to create the site and all-important framing of the encounter, that enable the achievement of diversity in the contemporary world.

In recent years the acceptance of state-sponsored multicultural programs and practices has declined, and both the discourse and the practices related to minority integration are currently undergoing a process of profound change. Although uneven, the immigration and integration policies of many European nations reflect a general movement away from an official recognition and facilitation of pluralism in the public sphere, alongside a renewed affirmation of the core values of laissez-faire liberalism.

In the United States, Australia, and several European countries, an active state-sponsored effort to achieve diversity has been largely abandoned, and the promotion of assimilation – in the sense of a renewed defense of a sharp separation of public and private realms – is increasingly apparent (Joppke and Morawska 2003). Although these transformations play out differently in different national settings, much of the state-based rhetoric now emphasizes the choice of individual immigrants and minorities to assimilate to the values of liberalism. If they choose not to do so, it is no longer considered the state’s responsibility to protect or accommodate them. Meanwhile, many of the state-provided social services that had formerly aided integration have been removed, subcontracted, or devolved to the community level.

Recent examples of these types of transformations include Denmark and the Netherlands, both of which have experienced stark shifts away from a strong official policy of multiculturalism over the past decade and a half. After many years of promoting the value of immigrant difference and of offering state recognition and providing numerous state safeguards for ethnic pluralism in the public sphere, the discourse and policy on minorities now favors a far more assimilationist tone and set of policies. Similarly, under the French presidential administration of Nicolas Sarkozy from 2007–2012, a sharp stance against publicly manifested difference was also intensified (Vertovec and Wessendorf 2010).

Perhaps the most dramatic and aggressive shifts in state policy have involved the early
twenty-first-century conservative governments of David Cameron in the United Kingdom, and Angela Merkel in Germany. Both of these political leaders gave speeches in the late 2000s indicating a crisis and failure of multiculturalism in their respective nations; Cameron went so far as to advocate the end of “state multiculturalism.” Their rhetoric implied that despite the benevolence of European nations toward postwar immigrants the multicultural experiment had failed and minorities remained a “problem” vis-à-vis national unity and shared values; part of this problem was seen to reside in the state’s effort to accommodate these outsiders by encouraging them to preserve their own cultural values and way of life.

Although a kind of de facto or noninterventionist multiculturalism remains in place in most liberal states, the pressure toward national languages and the acceptance of the core values of laissez-faire liberalism reflects a new discursive frontier that may well be the precursor to ever-harsher assimilative policies and practices. The discourse of multicultural failure and the renewed state policies of assimilation represent a return to a recuperative national project that seeks to relocate universalist notions of civil society firmly within the bounded contours of the nation-state. The economic and political component of this shift is rarely discussed yet critically important.

The current discourse of multiculturalism in crisis is intertwined with ongoing political and economic efforts to shift the responsibility for controlling, facilitating, and paying for immigrant integration from the institutions of state government to the local level. A generalized state rhetoric of multicultural failure and the necessity to rethink the advantages of national assimilation accompanies the devolution of responsibility for ethnic integration to the scale of the community and the individual. This is but one of many new technologies of knowledge/power under neoliberal regimes of governmentality, in which individuals are constituted as atomized, free-thinking, and entrepreneurial subjects who can “choose” to assimilate or not as they wish. Those who choose not to assimilate are represented as individuals unwilling to participate in public or civic life, who can, as a result, be excluded from society without incurring damage to the core ideals of a universalist liberal project.

A second political component of the contemporary backlash involves the jockeying of politicians for a position that allows them to address popular anxieties related to neoliberal globalization and immigration. Using multiculturalism as the scapegoat, Cameron, Merkel, and other political leaders can appear to confront the “problems” of social and economic dislocation and change, while at the same time absorbing and nullifying some of the even shriller claims of the far right. For example, following Cameron’s speech, Marine Le Pen, the leader of the French far right party Front National, congratulated him for his “endorsement” of her party’s anti-immigrant position, indicating their strong overlap on this issue.

Scholars critical of this sharp turn have noted how the state rhetoric of multiculturalism as failing provides an alibi for renewed forms of racism. Culture as “problem” inevitably references those groups and individuals outside of the dominant culture, which is assumed to be a neutral, universalist space. Consequently, the identification of an unassimilable culture – often represented as Muslim immigrants in the context of liberal Western nations – gives license to the practice of racial discrimination in the name of the nation (Lentin and Titley 2011).

The discourse of the unassimilable “other” is part of a larger right-wing critique of multiculturalism that rests on the idea of a “clash of civilizations.” In this view, the primary source of post-Cold War conflict is the inherent and
MULTICULTURALISM

insurmountable differences in people’s cultural and religious identifications. By this reckoning, multiculturalism will always be a failed project because certain kinds of integration are impossible, especially between those holding “liberal” and “illiberal” viewpoints and values.

Critiques from the left are also quite varied. In the current period, many scholars who have been critical of the concept for its theoretical and practical deficiencies have felt compelled to defend it in the face of contemporary conservative attacks and renewed racisms. Nevertheless, one of the primary poststructuralist critiques rests on the problematic notion of culture as hermeneutically sealed, as a contained entity that groups maintain over time despite all of the intervening influences of a contemporary world of constant movement, flow, and interaction. In this view there is no pure or autonomous culture, and to pretend that there is and try to protect it relies on a false view of both culture and individuals’ relationships to it. Moreover, group-based state protection of this kind risks harm to vulnerable members within minority groups. These may include women, sexual minorities, religious dissenters, and so on, who do not necessarily share the opinions or the embodied characteristics of the dominant members of the group, and who may experience internal discrimination from the group’s leaders and representatives.

Another critique challenges the prioritization of identity politics in general; this view holds that the politics of redistribution, with its stronger economic emphasis, is more critical than the politics of recognition and should be supported more vigorously. Relatedly, state-sponsored multiculturalism in its actual practices is often quite superficial – obsessing about aesthetic issues such as food and clothing rather than addressing the deeper issues of economic and political integration into society. Additionally, numerous scholars have observed that multiculturalism as a term and set of practices is often appropriated by capital to further its own interests (Mitchell 1993). Finally, many have argued that the real problem vis-à-vis the question of difference in most Western nations is racism, and that multiculturalism – as a political philosophy and as state-sponsored policy – does not sufficiently address the underlying issues of power and structural violence that allow racism to endure and flourish.

Multilevel governance

Andrew Beer
University of South Australia Business School, Australia

Multilevel governance is a wide-ranging theory about the ways in which governments act in contemporary society which emphasizes both the vertical exercise of authority and the horizontal sharing of power. It is an interpretation of government systems that foregrounds the social and political context within which power and influence are exercised, and which highlights the processes of dialogue, debate, and knowledge-sharing with other tiers of government and nongovernment actors. From its foundation with the initial work of Marks (1992) and the subsequent development of the concept (Marks 1993, 1996; Marks and Hooghe 2000, 2004) there has been increasing use by academics of the concept of multilevel governance to explain the decision-making processes of governments, especially in complex policy environments. Some researchers have suggested that the term has achieved almost universal acceptance within both policy-making and academic circles, and that the rate and pace of take-up of this term is virtually without precedent in the field of European studies (Stephenson 2013). Potluka and Liddle (2014) note that multilevel government remains a contested concept, but has a broad appeal and a shared concern with the increasing intricacy associated with government decision-making.

Multilevel governance recognizes that governments increasingly make binding decisions as a result of processes that include other actors, such as discussions with other nations or the influence of nongovernment agencies. As Piattoni (2010) has acknowledged, the concept emerged out of the attempt to uncover the processes shaping policy development in the European Union (EU), and while the EU represents a unique policy and governance environment, there has been sufficient resonance with other contexts to encourage the adoption of this concept elsewhere. Work in this area commenced with Marks (1992), who concluded that whereas the theory of the time suggested policies emerged from an orderly set of processes dictated by the nation-states of the EU, empirical observation suggested policy formation was more chaotic, and subject to the influence of a far broader range of actors. Researchers noted that policymaking in Brussels – the center of EU administration and deliberations – was not restricted to the staff of the European Commission, the administrative arm of the EU, and the representatives of the participating nations in the European Council and European Parliament. Instead, nongovernment organizations, provincial governments, and industries maintained a presence in Brussels and worked to shape the outcomes of policy deliberations. The idea of multilevel governance – with a constellation of government and nongovernment agents interacting to shape agendas and influence outcomes – was established to better explain how policies emerged and how governments took decisions. It acknowledged the pluralistic nature of decision-making in an environment marked by both complex issues and opaque institutional structures.

Multilevel governance as an observable phenomenon is premised on the idea of governance
MULTILEVEL GOVERNANCE

as a new model of government decision-making evident in many developed economies. Governance, therefore, is the precondition for multilevel governance, and lies at the heart of a substantial body of contemporary scholarship that addresses the role of governments in social and economic policy. It has been especially important in work on the development of urban and regional policy, one of the key policy domains of the EU (EU 2010). Despite its significance, governance can be a difficult concept to define categorically: Jordan, Wurzel, and Zito (2005, 478) observed that “there is no universally accepted definition of governance; there is not even a consensus on which set of phenomena can be properly grouped under the title of governance.” While there is merit to this argument, there is now a substantial body of work that acknowledges a number of common elements that have been accepted as typifying governance regimes and their outcomes. These include the movement away from restricting decision-making to the formal structures of government and instead incorporating a wider range of interests in decision-making (Whitehead 2003). In his working definition, Stephenson (2013) highlighted governance as system of power sharing both within governments and with nongovernment actors, including the private sector. Commonly, governance is associated with the rise of partnership arrangements and the reduced ability of governments to mandate or directly determine outcomes.

Governance takes different forms in different nations, with Blatter (2004) noting that there are significant differences between unitary systems of government (such as those in the United Kingdom, New Zealand, and Finland) and federal systems of government (such as those found in Australia, Canada, Malaysia, Germany, and the United States). Governance in federal systems, it has been argued, is marked both by horizontal links between agents and institutions, and by hierarchical, competitive, and cooperative modes of interaction. Governance, therefore, can lead to complex forms of interaction within federations, with both positive and negative relationships possible.

It has been argued that the adoption of governance is commonly associated with the rise of neoliberal policies and philosophies of government (Geddes 2005), which have effectively disempowered governments and forced them to find new ways of achieving societal aims, often in association with the private sector or community associations.

Explanations based on multilevel governance are differentiated from the broader literature on governance on a number of key dimensions. Perhaps most importantly, multilevel governance postulates that changes in the relationship between government, on the one hand, and society and the economy, on the other, occur as a result of shifts in policy domains, both internal and external to the nation-state. That is, political movements and strategic positioning by subnational governments is as likely to find expression in the international domain as domestically. Marks’s (1993) original conception highlighted the role of subnational governments in shaping decisions, and the fact that multilevel governance could be thought of as “a system of continuous negotiation amongst nested governments at several territorial tiers” (392). One of the arguments presented in support of multilevel governance is that it is more flexible, and therefore more adaptable, than the concentration of power in a single entity.

Hooghe and Marks (2003) suggested that multilevel governance could be divided into two forms. Type I was characterized as being constituted by general-purpose jurisdictions, with nonintersecting memberships, a limited number of levels, and a system-wide architecture
or remit. As they evocatively noted, under Type I governance “every citizen is located in a Russian Doll set of nested jurisdictions, where there is one and only one relevant jurisdiction at any particular scale” (Hooghe and Marks 2003, 236). Type II multilevel governance, by contrast, is characterized by task-specific jurisdictions, intersecting memberships, the absence of a limit on the number of jurisdictional levels, and flexible design. Examples of the latter could include a particular resource problem, such as the management of a catchment or the negotiation of trade treaties. Type I and Type II forms of multilevel governance are both seen to be departures from the centralizing state, but in different ways and with sharply differing outcomes. Inevitably, multilevel governance is seen to carry with it both costs and benefits. On the positive side, it can be flexible about the scale of action – with higher-level agencies responding to nationwide challenges or difficulties, while lower-level institutions respond to questions evident at the local scale. Such flexibility, however, comes at a cost, as there are considerable potential (and realized) coordination costs arising from the need to consult, deliberate, and potentially negotiate before acting.

Marks and Hooghe (2004) conceptualized multilevel governance as differentiated by processes as well as by form. They saw Type I and Type II forms of multilevel governance as being generated through separate, but related, processes: Type I processes were seen to be focused on the negotiation of powers and responsibilities at different levels of government, and Type II processes were an outcome of a concern with the interconnections between agencies and governments at the same level. These horizontal linkages were accepted as important in delivering coordination, building political consensus, and establishing a discourse for a particular course of action. Further work has broadened the original conception of multilevel governance to include a more expansive range of agencies and actors. These more embracing perspectives recognize that nongovernment organizations seeking to advance the rights of Indigenous Australians, for example, are as likely to argue their case in international forums – the United Nations (UN) in New York or at the Organisation for Economic Co-operation and Development (OECD) in Paris – as domestically. Campaigns for greater environmental or labor market protections are often argued in world forums. Multilevel governance is differentiated from comparable work on networks because, while the latter are intrinsically ephemeral, research on multilevel governance acknowledges the enduring nature of many institutions and their arrangements. Some researchers have suggested that economic policymaking – especially in federal systems – should be considered part of a single multilevel governance system (Stephenson 2013). To a degree, this idea is intuitively attractive, as economic policies inevitably involve multiple stakeholders, international negotiation and arrangements, and near-permanent processes of interaction and engagement. While the World Trade Organization (WTO) is an outcome of global engagement with the liberalization of trade, new initiatives in this field come about through the ongoing work of governments in bilateral and multilateral agreements. Industry pressure groups also play a pivotal role in advocating for change.

Multilevel governance as an explanatory framework has been applied to environmental questions, including the development of strategies for mitigating, and adapting to, climate change. Its application to this policy domain could almost be considered inevitable, given that climate change adaptation and mitigation strategies inevitably involve a multitude of participants, including national governments, provincial governments, industry bodies, local governments,
MULTILEVEL GOVERNANCE

community groups, and international forums. Bates et al. (2013) noted that the processes that typify multilevel governance – participation in forums, networking and lobbying across and between tiers of government, and so on – help mobilize businesses and institutions to environmental action. Such activities simultaneously add “trusted knowledge” and reduce the perception of risk. Multilevel governance also plays a more instrumental role in adaptation to climate change, as an effective response can only be achieved if all tiers of government – and many sectors of the economy – take action.

Bulkeley and Betsill (2005, 2013) commented on the importance of interrelations between global, national, and local actors in formulating responses to climate change. They argued these relationships have had substantial impacts at the urban scale, helping to reshape planning discourse and practice. Early academic work and policy development on cities and climate change was dominated by a “new localist” perspective that highlighted community-level action independent of context. To a degree, this outlook was typified by the Agenda 21 slogan, “think global, act local.” The researchers noted that this analytical framework did not adequately explain why some cities and communities took no effective action on climate change, while others led the way. Multilevel governance, by contrast, was seen to offer an effective explanatory framework. Bulkeley and Betsill (2005, 138) concluded from their analysis of urban planning in Newcastle upon Tyne and Cambridgeshire, in the United Kingdom, that in seeking to understand shifts to more sustainable development, “the most significant dynamics exceeded any purely local framing.” Reviewing their own work almost a decade later, Bulkeley and Betsill (2013) concluded that a multilevel governance perspective remained important in understanding the management of climate change in cities, but that increased attention needed to be paid to how these processes resulted in governance innovation across, and within, tiers of government, which in turn can usher in new policy outcomes.

Multilevel governance perspectives are deeply embedded in many accounts of local economic development initiatives and the agencies that support them (Eversole and Martin 2005). Cross-national work has consistently identified governance, and especially multilevel governance, arrangements as a defining feature of the structures established to promote local or regional economic development (Beer, Haughton, and Maude 2003; Halkier, Danson, and Damborg 1998). A number of authors have noted that many provincial, city, and local governments have embraced a multilevel perspective in attempting to promote their economic and other interests on the global stage. Multilevel governance in economic development sees national, local, and community scales of engagement in operation at the same time, and this simultaneous activity is inevitable. Importantly, economic development frameworks that ignore the other actors operating within this environment are likely to be less effective than those that encourage positive engagement vertically and horizontally.

Academic acceptance of multilevel governance has contributed to its adoption amongst policymakers, especially in the EU, where the distribution of significant monies in the form of structural funds to identified territories has encouraged cities and regions to establish a presence in Brussels. It has also lent a distinctive regional flavor to much of the discussion of multilevel governance. Stephenson (2013) noted that the EU itself explicitly acknowledged multilevel governance in its attempt to introduce the open method of coordination (OMC) – a system intended to simultaneously deliver both vertical
MULTILEVEL GOVERNANCE

and horizontal integration. And while OMC was not successful, its very failure has served to strengthen the conceptual and programmatic impact of multilevel governance as an efficient, democratic, and accountable set of political structures.

Other research has noted the usefulness of the concept of multilevel governance in dealing with economic shocks, especially the global financial crisis (GFC) of 2008 and 2009 (Allain-Dupré 2011). This research highlighted the fact that the policies of fiscal austerity that followed the immediate stimulus packages needed to be mindful of the ways in which reductions in national public sector outlays were transferred to state or provincial governments, and potentially undermined their capacity for future growth. This body of work acknowledged that there is a risk that budget cutbacks introduced at the national level have the potential to cascade through the more junior tiers of government. This in turn results in greater than expected reductions in public sector outlays, thereby undermining strategies to raise productivity over a range of time horizons. Subnational governments, it has been argued, play a leading role in the infrastructure investment needed to foster growth, and are best placed to target assistance to the areas of greatest impact. National economic policies that ignore multilevel governance and fail to acknowledge the significance of the more junior tiers of government may find their actions undermined in the short term, resulting in restricted economic growth in the longer term. Fortunately, these authors have identified a range of policies and practices mindful of multilevel governance that can help overcome these challenges. These include co-investment strategies between national and subnational governments, the use of existing institutions that embrace multilevel governance, and the creation of new entities that can overcome the challenges inherent in addressing economic crisis within a multitiered system of government. In 2008, the EU explicitly deployed its cohesion policy as part of its strategy to overcome economic crisis. Its actions included the modification of existing programs, the closure of some program areas, the introduction of a renewed commitment to the growth of regions, accelerating the cash flow associated with new projects, and the development of new methods for identifying the best possible investments in regional productivity.

More generally, the OECD (2009) has recognized seven important gaps in the multilevel governance of public policy, each with implications for the effective management of their economies (Allain-Dupré 2011, 21). These gaps are: an information gap associated with inevitable information asymmetries as subnational governments are not, and cannot be, party to all information available to national governments; an administrative gap resulting from a mismatch between the functional areas associated with an issue – for example, a functional labor market or a catchment – and administrative boundaries; a policy gap arising from the fragmentation of responsibilities across ministries; a capacity gap associated with insufficient technical or other expertise at the local level to meet needs; a funding gap that emerges from unstable or insufficient revenues at the subnational level; an objective gap as competing priorities direct national and subnational governments in contrary directions; and an accountability gap resulting from inadequate transparency. Often it is not clear which tier of government or government agency has brought about adverse outcomes or reduced the opportunities for growth.

Piattoni (2010) argued that multilevel governance has made important contributions to our understanding of government processes and the reshaping of cities and regions in three fundamental ways. First, she argues that it has
MULTILEVEL GOVERNANCE

encouraged researchers to think about the ways political mobilization takes place, both within the boundaries of individual nations and across boundaries. Second, she contends that “policy-making no longer neatly separates policy-makers from policy-takers, nor does it distinguish between public and private actors” (2010, 250). Third, she believes that multilevel governance results in political structures – polity – that look like nation-states but are not. The EU, she notes, is one example of a state-like entity, but it is not the only such institution. The actions and decisions of the UN, the World Bank, the OECD, the WTO (Knodt 2004), the Asia Development Bank, and even the International Olympic Organising Committee (IOOC), to name just a few examples, all contain elements of multilevel governance, including the influence of a host of interested third parties, some of whom are nation-states.

Some of the most important insights to come from the multilevel governance literature relate to the simultaneous interaction between provincial-level governments and nongovernment organizations, on the one hand, and supranational bodies, on the other. Piattoni (2010) suggests that the eagerness of state or provincial-level governments to become involved in matters above the level of the nation has the capacity to simultaneously unsettle the nation-state, while reinforcing the significance of supranational entities as a source of funding, legitimacy on the world stage, and/or political influence. Marks, Hooghe, and Blank (1996) label this process as one of “dilution,” with nation-states surrendering their capacity to influence the representation of domestic interests in international forums. Benz and Eberlein (1999) take a different perspective on the relationship between the nation-state and multilevel governance: they argue that national institutional structures both guide and limit the impact of multilevel governance on individual territories. They also discuss the significant costs associated with multilevel governance, to governments, nongovernment actors who participate in policy debate, industry, and the broader community. Perhaps most importantly, Piattoni (2010) argues that multilevel governance generates, and then maintains, fluid relations between a host of actors – nation-states, subnational governments, private sector representatives, and nongovernmental agencies – that remain in a state of flux.

Policy debates emerge, gather strength, and are then replaced by other discourses as new priorities emerge and new arguments for intervention garner support. Along the way, this process of policy formulation has real-world impacts, as programs of regulation (trade protocols and tariffs), pricing (emissions trading schemes to control the release of fossil carbon), and regional development (EU territorial development programs) are introduced, reshaped, or abolished.

Multilevel governance is not simply an unsettling influence on established policy frameworks and programs. Potluka and Liddle (2014), working in the Czech Republic, highlighted the benefits associated with the delivery of EU programs within a multilevel governance framework. They noted that the interactions that characterize multilevel governance resulted in better-tailored programs, able to achieve at the local scale policy objectives established by distant central authorities. They also generated an environment that was more open to participation in program delivery by a wide array of actors, including community-based organizations. Other researchers working in very different contexts have also identified benefits arising from multilevel governance. Homsy and Warner (2014), for example, used quantitative analysis to examine the take-up of sustainability actions by municipalities across the United States. They found that local governments that operated within a
Multilevel governance framework were much more likely to support sustainability initiatives. State governments across the United States played a clear role in promoting discussion of environmental protection, resulting in a “broad and co-ordinated discussion, which is important because most environmental issues cross local political boundaries” (Homsy and Warner 2014, 19). State governments also served as a reservoir of technical expertise, thereby adding to the stock of local social and political capital embedded within local governments. Active engagement with environmental sustainability was not simply a product of government actions; civil society institutions were also important for creating an environment supportive of environmental protection. Such engagement typifies systems of multilevel governance, and supports the extension of this concept beyond its European origins.

Multilevel governance has been criticized as an explanatory framework by a number of authors. Its popularity as an intellectual device and its widespread adoption by academics and the policy bodies of governments alike has, in some ways, undermined the utility of the concept. Some authors use the term to describe a wide range of circumstances that bear little resemblance to the original conceptualization. This includes labeling formal federal systems of government, such as the United States, Australia, or Malaysia, as systems of multilevel governance without acknowledging the constitutional basis for the division of power, or the fact that powers and responsibilities are formally prescribed, rather than an outcome of ongoing dialogue and debate. Some authors also appear to struggle to differentiate between multilevel governance and other types of associational activity. Potluka and Liddle (2014), for example, treat multilevel government, partnership formation, and network development as interchangeable entities. Such use of these terms would appear to dilute the impact of each.

Some authors have argued that, while multilevel governance provides a useful description of the interaction of agencies, it confuses involvement in the decision-making process with the real power to influence outcomes, and insufficiently analyzes differences in degrees of fiscal and decision-making autonomy, sometimes captured in the distinction between decentralization of administration and decentralization of choice. It does not predict which actors are likely to be important in shaping debates and the outcomes of consultations on an issue, nor does it provide insight into which types of agency are likely to be influential in the short, medium, or long term. Questions remain about the viability of multilevel governance as a concept outside the special circumstances of the EU. The EU allocates billions of euros through its multiyear structural funds and associated programs, and these substantial transfers – directed to regions, not nations – have generated their own political and economic dynamic. Sbragia (2010) notes that, in contrast to the EU, the North American Free Trade Agreement (NAFTA) contains strong measures to ensure a minimalist approach to implementation – effectively a guarantee against institution building. Most scholars acknowledge that multilevel governance as an explanatory framework has limitations, many of which have been exposed by the GFC and its aftermath. To a certain degree, multilevel governance is a concept that has focused inwards on the political dynamics of the EU and one of its redistributive functions. It is also a perspective intuitively attractive to scholars confronted by the reality of pluralist politics that are at odds with their structuralist intellectual traditions. Increasingly, it is accepted that there is a need for the discussion of multilevel governance to adopt a more global perspective, one which extends beyond the political structures and the territory of Europe. Others have suggested that multilevel governance remains a “statist”
concept, awarding considerable priority to the actions of governments – and especially central governments – while failing to pay attention to other drivers of change, including community action, small and medium-sized enterprises, global corporations, and political movements.

Geographical engagements with music and sound more broadly offer significant insights into the many and varied ways in which concepts of place, identity, and community are constituted. As many researchers have pointed out, music and sound should not be conceived as simply a background to place. Rather, they play a crucial role in the social relationships that help comprise a particular spatial context (Smith 2000). This is due to the ways in which certain acoustic properties are attributed particular and ideologically loaded meanings. For example, sound becomes music when placed within an appropriate context, be that the physical space of a concert hall or the marking out of a temporal frame as performance. Furthermore, as Jacques Attali argues in his seminal text, Noise: The Political Economy of Music (1992), the ways in which sound is defined as music or noise is an expression of power, one where the appropriation and control of sound reflects and affirms the sociopolitical structures of a community. Therefore music is not an aesthetic experience alone but a medium through which the social world is made and remade through various social relations.

Early twentieth-century scholars working in a variety of disciplines – including sociologists Georg Simmell and Alexander Ellis, and ethnomusicologists such as Alan Lomax – were interested in music for three main reasons: as an expression of meaning, as a basis for social differentiation through taste, and (perhaps the central reason) as a superorganic form of regional cultural traits or artifacts. Music has been understood to somehow reflect or represent a group of people, with the repertoire of different groups maintaining a highly patterned and stable sound profile that serves to identify the social group from which it originates. Geographers therefore sought to uncover the spatial diffusion patterns of these different social groups through differing musical styles and genres. Yet, a focus on music’s spatial distribution fails to recognize the significance of the social and cultural contexts in which music is produced and afforded meaning, nor does it consider the importance of interactions between local and global forms of music production for both creativity and industry. In addition, the framing of music as a cultural trait has led to a quest for authenticity and authentic practice. Yet authenticity is a highly problematic concept, and concern about authenticity masks the complex processes of music, as well as the ideological framings of tradition that serve to condemn change. Even so, as anthropologists acknowledge, there is some correlation between sound structures and social structures. As with language acquisition, we learn to recognize certain musical patterns or conventions as correct. Such conventions constitute a part of our social world and are the means by which we understand reality.

In their introduction to an edited collection of essays, The Place of Music (1998), geographers Andrew Leyshon, David Matless, and George Revill argue that space and place are not the sites in which music occurs or through which music diffuses but that place is formed and created through music and sound. This observation signals an important paradigm shift in human geographical research more broadly, a
MUSIC

poststructuralist turn that argues that there is no stable, fundamental link between music, identity, and place. Instead the interactions between composer/musician, listener, and the cultural context in which music is performed result in various complex sets of meanings that are constantly formulated and reinscribed. While recent research has moved away from attempting to categorize certain patterns of sounds as definitively representative of specific social groups, the use of music to create identity remains an important geographical interest. For example, some have examined how notions of identity and community are constructed through the deliberate associations attributed to music and lifestyle (Connell and Gibson 2003). Geographers have also examined the role of sound and music in constituting particular spatial entities such as the workplace, the city, the countryside, and everyday life (Bull 2000). Others have focused on the ways in which musical elements, such as song lyrics and language idioms, are strategically used to evoke images of particular places and to create a sense of connection to that place.

Music tourism, specifically festivals and events, demonstrate the intentional use of music to construct notions of identity and community through a focus on place-making and place-marketing practices. Much of the festival literature explores how these events sustain social benefits through the economic opportunities they generate, which arise out of deliberate representative practices that associate certain music with certain places. This area of research encompasses music in terms of an economic commodity, a cultural signifier, an expression of identity, a set of activities within the creative economy, and as a means to instigate political action. However, while a festival program tends to support notions of boundedness to particular places and people, the creation of community identity involves complex processes with potentially divisive outcomes. Some studies suggest that, rather than encouraging the formation of belonging and community, festivals often operate as spaces of exclusion.

Until recent geographic interest in performativity, embodiment, affect, and nonrepresentational theory, music geographies have most often focused on sound as an object, something seen rather than heard or felt. This emphasis on representation has meant an unintentional privileging of visual and textual discourses as research has examined such things as the score or lyrics, as well as associated paraphernalia such as instruments and promotional material, obscuring the ways in which the processes of music influence us and shape our actions in space and time. More recent research has started to shift. More recent research has started to shift this focus. One important way in which music operates is that it taps into our emotional and intuitive selves, opening up a means to examine how the emotions influence social interactions (Smith 2000). For example, Tia DeNora’s (2000) *Music in Everyday Life* examines how music in daily life demonstrates how the affordances of sound – that is, music’s melodic structure, rhythms, tone, and color – are an important means to organize our individual and collective lives both spatially and temporally. In addition, a focus on music as a process has meant closer examination of the characteristics of sound and how we process this information. It is not just the affordances of sound that make us who we are. Rather, where and how we hear and listen are integral to experiential practices of making sense of self in and through place.

Considerable empirical work has explored a phenomenology of sound, opening up new possibilities for what it means to listen. For example, some geographers have addressed the politics of music by drawing on a Foucauldian-type disciplining of listening. Yet, the type of listening
invoked in such studies relies on a simplified classification of the senses that limits auditory geographies to the ear, thus ignoring the significance of the whole body in sonic processes. Sound alters our perception of places and of others because it demonstrates the continuity and discontinuity of our subjectivity; we are immersed in its sounds and can either be drawn into feelings of connection or feel alienated. A multisensory approach that explores music in this way has drawn on the ideas of Deleuze and Guattari or that of nonrepresentational theory. Implicit in these approaches is the capacity of the body to sense sonic elements, such as rhythm, melody, and timbre, and how our affective and emotional responses to these then play a role in the emergence of bodily processes that can regulate the dynamics of social interaction (Duffy and Waitt 2011).

One of the challenges in investigating the experience of music is communication, as such experiences are ephemeral and difficult to express in words, a difficulty also recognized by musicologists. While interviews and participant observation can, to some extent, access how people may feel in response to music, geographers have begun to explore ways to capture nonverbal and noncognitive experiences. Some have begun to develop projects that bring together musical and geographical concerns in practice-based responses that facilitate what Derek McCormack (2008) calls a “co-intensive sensing” of emergent space. A deeper exploration of listening practices has therefore become important in recent geographical work. Such methodological and analytical approaches include rhythm analysis (based on the work of Lefebvre; see Edensor 2010), “participant sensing” (Wood, Duffy, and Smith 2007), sound diaries, phonography, and field recordings (Gallagher and Prior 2013), the extralinguistic elements of communication and the nonverbal components of performance (Kanngieser 2012), acoustic ecology and soundscape studies, and soundwalks.

National and regional integration

John Agnew
University of California, Los Angeles, USA

National and regional integration involves the infrastructural and fiscal integration of polities at, respectively, national state and supranational scales. Progressively since the eighteenth century, but at a more rapid pace in the years since World War II, the world has been divided up into territories to which the term “nation-state” has usually been attached. Whether or not these states are true representatives of single nations or effective as governments remains an empirical question. Nevertheless, a central claim of governments of such states is that they have domestic sovereignty or the combined desire and capacity to authoritatively provide public goods and serve the material and symbolic interests of their populations, irrespective of where they live within the national territory. Spatial disparities in incomes and public good provision, therefore, can provide the basis for the politicizing of local cultural and political differences that are otherwise repressed. Of course, whether or not they are politicized depends on the emergence of political movements to mobilize local populations for either greater autonomy in fiscal policy or outright independence (Agnew 2013).

State formation and national integration

The worldwide rise of the nation-state is one of the most significant topics in social science. Such states have come about in numerous ways: nationalist secession (as in Mexico and Yugoslavia), revolution (as in the United States and Russia), transition from clan and feudal societies (as in Sweden and Thailand), unification movements (as in Germany and Italy), and top-down reform (as in Japan). Rather than global forces, world regional imitation and diffusion among neighboring nationalist elites drawing on the example of already established prototypes (France, the United States, etc.) as existing imperial centers and ancien régimes disintegrate seem to have been the dominant governing processes driving the spread of the nation-state since the early nineteenth century (Duara 2008; Wimmer and Feinstein 2010). The unmaking of empires is a fraught business, with some fault lines emerging relatively painlessly and other divisions, for example Russia’s recent wars in the North Caucasus and the conflicts in the former Yugoslavia, revealing historic fractures not readily healed. The stability and sustainability of specific states over time seems to have depended as much on their location relative to potential expansionist neighbors as on either their internal ethnic homogeneity or the existence of some putative ethnicity-spanning peoplehood (such as “British” or “Chinese”) and on the extent to which they have had external supporters. So-called buffer states, in particular, ones located between larger, pre-existing, and more stable states, are most vulnerable to annexation or partition by neighboring rivals (Fazal 2007).

Be this as it may, both the persistence of some nation-states and the revival of others after periods of demise is invariably the result of nationalist movements that thereafter use the typically contested claims to the precise territories
they occupy to constantly keep the “national question” on the political agenda. Within states, however, such nationalist projects frequently encounter resistance from localities and subnational regions that either favor some looser form of political organization than a centralized state or that see the new state as compromising the historic freedoms they have exercised as city-states, as provinces within decentralized empires, or as polities without much bureaucratic apparatus at all (see, respectively, e.g., Deudney 1995; Tilly and Blockmans 1994; Scott 2009). Consequently, a major challenge for states is often to ensure that state resources and infrastructure are distributed reasonably equitably across the national territory, for fear that the pooling up of advantages in some localities or subnational regions can spur efforts at secession or irredentism on the part of indigenous or neighboring nationalist movements.

“Sovereignty regimes” and the geography of state capacity

Once initially established, the legitimacy of centralized power is thus hardly unquestioned. In distinguishing despotic from infrastructural power, Michael Mann (1984) usefully identifies two different ways in which a state acquires and uses centralized power. These words refer to two different functions that states perform for populations and that jointly underpin their claim to authoritative rule: respectively, the struggle among nationalist elites within and between states, and the provision of public goods by states in the interest of placating various social groups and pursuing and legitimizing despotic power. In Mann’s (1984, 188) words:

Let us clearly distinguish these two types of state power. The first sense denotes power by the state elite itself over civil society. The second denotes the power of the state to penetrate and centrally co-ordinate the activities of civil society through its own infrastructure.

Before the eighteenth century the second type, infrastructural power, was relatively less important than it is today. This is because elites have been forced by political struggles to be more responsive to their populations through providing more public goods. But elite and popular pressures for economic development have also mandated the increased provision of roads, of standardized weights and measures, of elementary education, and so on, which will always be absent or underprovided with a simple reliance on private provision. This boosted the territorial sovereignty of states because economic demand was defined in terms of territorial populations and provision was oriented to satisfying that demand.

Since the mid-1970s, technological change, the increased intensity of all kinds of flows across borders, and the vulnerability of state populations to increased global economic competition threatening public good provision when foreign competitors provide fewer public goods have all conspired to make infrastructural power increasingly valuable for economic competition but also vulnerable to the fiscal crises of states as they struggle to attract global capital, demanding lower effective taxes (Frieden 2006). Increasingly, city-regions and supranational entities (such as the European Union) also challenge the state monopoly over public goods and international organizations, both public and private, and demonstrate the capacity to deliver regulatory, financial, and legal services hitherto usually associated with the bureaucracies of states.

At much the same time, despotic power has come to rely much more on popular legitimacy than it did historically. At one time, and this is at the root of Western territorialized conceptions of sovereignty, the ruler relied on the
claim to stand in apostolic succession to God, as in the divine right of kings. This eventually translated into the idea of the “body politic” as a territorialized people or nation. Rulers needed to establish at least a modicum of popular authority before they could pursue their goals. Such legitimacy as they have, however, is increasingly fragile. As interests and identities cease to conform to territorial norms, rulers must likewise adjust. This can involve pursuing increased influence elsewhere (as in an *imperium*) or ceding authority to other parties in order to manage dissent and resistance. There is no necessary correlation, therefore, between despotic power and central state authority. Elites are increasingly globalized both with respect to pursuing their goals through expanded political influence beyond home shores and in terms of alliances with multinational companies, banks, and other agents in a more networked world.

The degree of real state autonomy from outside influence or control, and the extent to which it is territorial in terms of delivering effective infrastructural and fiscal resources, varies from nation-state to nation-state. Four extreme or ideal type categories, or what may be termed “sovereignty regimes,” can be identified (Agnew 2009; see Table 1). These are relational in character. They refer to the differing combinations of effective central state authority and territorialized provision of public goods in different countries. They are not best thought of as entirely characterizing particular states in all their aspects; no particular state fits exactly into any of the boxes in question. But they do provide a heuristic basis for identifying the relative complexity of state fiscal and infrastructural authority. This is a patchwork of more and less sovereign spaces and flows, not a rigidly territorialized order, with some territorial states and space-spanning organizations more effective than others.

Source: Agnew (2009).

Of the four ideal types, the first one, the *classic*, comes closest to the conventional story about state authority. Both despotic power and infrastructural power are largely territorialized and central state authority remains effective. Contemporary China perhaps best fits this case. The second case, the *imperialist*, represents best the case of hierarchy in world politics but with networked as well as territorialized reach. It is the complete opposite of the classic case. Central state authority is seriously in question, often exercised by outsiders if in collusion with local elites, and infrastructural power is weak or reliant on external support. Most of the states in the Middle East and sub-Saharan Africa fall under this regime.

The other two regimes are more complicated. The first, the *integrative*, is a regime where authority has migrated to both higher and lower tiers of government as a result of a sharing of sovereignty among states, and infrastructural power takes both territorialized and networked forms. Various sorts of unions or confederations of states take this form. The fullest contemporary example would be the European Union from the perspective of its member states. Other economic blocs, such as NAFTA, reproduce some features of this regime but remain much less integrated.

The second of the two more complex sovereignty regimes is the *globalist*. This regime is closely associated today with the globalization of the world brought about since the 1960s under
NATIONAL AND REGIONAL INTEGRATION

US auspices, but which has older roots. In this construction, the world city system, particularly the cities at the top of it, such as New York and London, provide the geographical nodes for the agents who are central to this regime. They exercise power wherever states have ceded authority to external agents (credit-rating agencies, accountancy standards boards, etc.) because of their debt dependence or need for independent regulatory oversight. This regime has a potentially worldwide reach but its effects are particularly strong in those parts of the world most integrated into the world economy and without the limits set on integration by, for example, managed exchange rates and capital controls, by states with greater effective central state authority (such as China). The historic basis of this regime in US global hegemony since World War II means that, at least until recently, US governments were able to use this regime as an alternative to the imperialist one in many parts of the world. But, as authority has slowly seeped out of US governmental hands worldwide, other regulatory and fiscal agencies, including many private as well as public organizations, have picked up the slack.

Contemporary challenges to national integration

Increasingly, to many of their residents as well as to multinational businesses and globalized elites, many nation-states have become either too big or too small with respect to their capacities to both represent emerging elites (despotic power) and effectively exercise infrastructural power – deliver public goods – in a globalizing world. Smallness in area and population were historically disadvantageous for states but are arguably much less so today (e.g., Alesina and Spolaore 2005). Small states were once easy prey for larger states or empires and could not enjoy the economies of scale in the provision of consumer goods and public goods that were potentially available to larger countries. In a world in which insertion into world markets has largely replaced import substitution based on large domestic markets, not only is a large national territory and population no longer necessary, but where serious spatial disparities in incomes and wealth emerge, allied to cultural and political fissures, a large territory itself can become a candidate for fragmentation. Smallness is less problematic in a world of flows than in one of territories. Of course, large states have hardly disappeared, but this owes less to any economic logic than to bureaucratic inertia and continuing nationalist loyalties. The five countries with the highest GDPs per capita in the world today are Qatar, Luxembourg, Singapore, Norway, and Brunei, none of which has a population greater than 6 million. The tax policies favorable to multinational businesses, resource bonanzas, and lax legal regimes that allow for anonymous firm ownership and transfer price invoicing (parking profits in low-tax jurisdictions) have in different respects allowed for this efflorescence of small jurisdictions. Moreover, large countries typically have more culturally diverse populations that increase internal political tensions, particularly if the economic benefits of larger size are not equitably distributed to minorities. Larger dependent populations also mandate that governments cannot adopt the low tax practices of small states even as they try to reduce their overall levels of spending.

Worldwide, and as a result of increased global economic competition involving the footloose corporate actors that has made smallness less problematic, the government-sponsored social rights that came to characterize large, developed industrial countries in the 40 years after World War II are in retreat. Under policies often labeled as constituting “neoliberalism,” governments
have been retreating from direct provision of what had been defined as public goods necessarily provided by them to a range of indirect and privatized approaches that can be seen as representing the decline of a territorialized “society” congruent with the territory of the nation-state. Regional policies geared to attracting investment and jobs in poorer regions have been replaced by “private–public partnerships” and reductions in infrastructure spending relative to richer regions. Yet, this decline in commitment to the nation as a collective enterprise opens up the possibility of a serious legitimation crisis for states both generally and more specifically in relation to the withdrawal of support from localities and subnational regions heavily dependent on state spending, not least because of the hollowing out of industries located in some of those places as a result of globalization (Brenner 2009). At the same time, there are limited possibilities for new employment in emerging or more competitive sectors because the new jobs are limited in number and require skills that the now redundant people do not have. The new jobs are also often located in places such as capital or other large cities with housing and other costs beyond the possible incomes of those displaced from elsewhere.

Even while it is under threat from the fiscal crisis outlined, it is still government spending that holds together the fabric of national integration in the face of increased interregional income inequality. Of course, the degree to which states have engaged in fiscal transfers (such as tax credits for lower earners and social transfers such as unemployment payments and food supplements, etc.) has always varied since such programs began early in the twentieth century, with Scandinavian countries making much higher payments/subsidies to individuals than countries such as the United States and Japan. Nevertheless, equalization transfers have been very much accepted as part of the governance process in both federalist and centralist states. In a federalist state such as the United States, for example, many payments over the years have been indirect, through defense spending and other stimulative measures to encourage employment and income growth in different places than through direct payments to individuals.

To take just one example, in the United Kingdom as of 2007–2008 dependence on public spending as a percentage of regional GDP varied enormously across regions: from 34.1% in southeast England and 37.0% in London to 57.4% in Wales and 62.75% in Northern Ireland. This is in a context in which major gains in incomes over the past 40 years have taken place overwhelmingly in London and the southeast compared to modest gains in Scotland and decline or stagnation in average incomes in most other regions. Such economic differences and the potential political tensions that follow from them are visible across a number of large countries from Italy to Spain and China, to name just three, where economic growth is increasingly concentrated in some localities at the same time as public spending to even out collective welfare across the national territory is in decline (Figure 1). Over the period 1990–2009, however, the United Kingdom and the United States showed the largest increases in regional income inequality compared to most other countries for which data are available; these countries have also restructured their public sectors the most, along with New Zealand and a couple of others, by privatizing the provision of many public goods and outsourcing government functions to private firms.

Regional redistribution itself is under attack in some countries, such as Italy and Germany, where there is a fear that such redistribution is merely a stopgap to maintain incomes in poorer regions while removing needed revenues for infrastructure spending and providing public
Figure 1 GDP per person of poorest and richest regions as a percentage of latest national average (OECD TL3 regions for all except United States (states) and China (provinces)) (CEIC Data; Eurostat; OECD; The Economist).

goods to keep the richer regions competitive in global markets (Figure 2). In the United States similar concerns over local economic competitiveness, allied to cultural differences, have generated the regional polarization between the main political parties, and growing regional divisions over federal government policies in relation to welfare and health-care spending. The long-standing consensus about the need for national policies to underpin national integration that lasted from the 1930s until the 1980s has been undermined.

This has provided a propitious historical context for the revival of autonomist, irredentist, and secessionist movements geared toward fragmenting existing states. This can be because of perceptions of lagging behind other regions within one’s country or redistributive programs that are seen as reducing the relative competitiveness of one’s region in world markets. If in the past new states were mainly the product of major wars, today it is internal challenges that take prime position. From the Uighurs and Tibetans of western China to the Scots and Catalans in Europe, to name just a few, centrifugal forces are challenging the authority of larger centralized states. Existing cultural fractures are undoubtedly important in this process. But recent political-economic triggers also count: “Growing spatial inequalities within states based on the success of some regions in attracting capital in the global market put pressure on national solidarity and give regions an incentive to mobilize in protection of their own interests” (Fitjar 2010, 1).

Regional integration

The possibility of such disintegration is enabled by supranational integration. Smaller states can have their putative independence and immediately join more spatially extensive regional organizations to enjoy the fruits of potential economies of scale. Supranational integration involves neighboring states entering into agreements with one another to lower barriers to trade, capital and human movement, and forming institutions to manage disputes and encourage both the enlargement of the enterprise to include new members and the deepening of its reach into policy areas such as subnational regional development which were hitherto entirely in the hands of the states. This is the integrative sovereignty regime described earlier.

Though regional integration offers a tentative resolution to the economic conundrum of state size, it more often than not also reflects immediately political goals, such as the desire to reduce frictions between states in the interest of common security, and to stimulate the spread of “values” and policies beyond current membership into the wider regions around which they are organized. Indeed, the most institutionalized example of regional integration, the European Union, had at its origins in the 1950s the twin goals of reducing the possibility of the interstate conflicts that had wracked Europe earlier
in the twentieth century and providing the economies of scale necessary to make European industries more competitive globally than they could ever be on a state-by-state basis. Whatever its successes over the years, it faces ongoing challenges from the other sovereignty regimes, not least the globalist regime and its hollowing out of whatever territorial forms, state-based or supranational, governance might take. Most of the other attempts at regional integration, such as NAFTA (involving the United States, Canada, and Mexico), Mercosur (in South America), and ASEAN in Southeast Asia are more like regional multilateral free trade agreements. Perhaps in time so-called subregional economic zones may provide the elements for a more bottom-up type of regional economic integration in regions such as East Asia. But nothing elsewhere has as yet produced anything like the range of policies or institutional depth of the European Union – covering executive, legislative, and judicial initiatives. For example, the European Union has its own parliament which oversees its budget (a relatively modest 1% or so of EU GDP) and a court devoted to human rights, and it has developed its own version of competition law to deal with antitrust and uncompetitive behavior by businesses. In other words, it has supranational institutions and policies at its heart rather than being simply a regional intergovernmental organization like the others.

In the 1960s many commentators saw the European Community, the earlier version of what became the European Union in the late 1980s, largely in terms of functionalist notions of integration. Over time, it was held, economic measures encouraging cooperation would lead to a politicization of actors’ purposes and new
loyalties beyond those of member states would emerge. More recently, however, the idea that one would replace the other has been thrown into question by the actual course of integration. Since the 1980s a multilevel system of governance has emerged, with different levels from supranational, through national state, to subnational regional, playing distinctive and shifting roles in the entire enterprise. This too is now challenged, particularly in light of the crisis that has enveloped one of the most ambitious of the European Union’s initiatives, the euro, since 2010 by a reassertion in some quarters, not least in the United Kingdom, of state sovereignty and a desire to selectively “opt out” of EU policies. Yet, as Keating (2009, 48) says:

The state can no longer be presented, even in an ideal-type theory, as the sole focus and framework for territorial ordering in Europe, but it is not being replaced by similar structures at the sub-state or supranational level. Rather we are returning to a diversified and complex order more typical of Europe’s long-term experience.

Quite what “integration” is to be, then, is open to question, notwithstanding the seemingly self-evident use of the term by proponents of whatever it is (Murray 2009).

Recent thinking about the course of regional integration in Europe tends to involve a number of approaches, not always alert to the historical difficulty, given the twists and turns in its geographical expansion and policy thrusts, of giving the European Union a singular purpose or form. One emphasizes questions of “Europeanization” or the emergence of identities and interests transcending those of the member states (e.g., Clark and Jones 2008). The roots of Europeanization are often seen as going back prior to the formation of the nation-states of Europe – in medieval and early modern epochs, when authority was not neatly territorialized and a common European culture was at work – and thereby providing a mythos for the European Union that does not simply involve starting from scratch. The rescaling of governance then can be seen as having old, if not necessarily primordial, origins. The European Union is taking Europe “back to the future.” In this view, the future of Europe and that of the European Union are not readily disentangled. Yet, as Kuus (2011, 284) shows, “the fetishization of history” is problematic. This is so not least because it tells a “progressive story of European integration” (Gilbert 2008), of the eroding of national sovereignty, and of the emergence, phoenix-like, of a new supranational authority.

Another approach focuses rather more on the character of the European Union as a “polity” in comparison to that provided by other governmental models such as the United States (e.g., Sbragia 2004). Here the mechanics of integrating disparate states, from a minute Malta to a gigantic but federal Germany, receive pride of place. The workings of the EU Council of Ministers can be compared to those of the US Congress. In this construction, the specialization of different US states in specific industries produces a different type of political representation nationally than a Europe in which most regions/countries are much less specialized than the US states and thus lacking in the “defenders” that industries have under the US federal system. Recall that a late senator from Washington State was called “the Senator from Boeing.” These differences have serious consequences for redistributive policies within the United States and the European Union. The United States is a much more territorialized system in that, as a result of the ways in which its economy has evolved, “territorially defined constituencies are central to the dynamics of Congressional policy making” (Sbragia 2004, 211). With the Council of Ministers, the European Union has a much
more flexible (if obviously not directly democratic) institutional capability. For one thing, it is engaged in interstate bargaining and can thus adopt policies that are not uniform and allow adaptations for different member states. Ministers and their civil servants without narrow territorial interests to defend are also much more open to negotiation and compromise than Congressional representatives subject to constituent and lobbyist influence. Finally, national representatives can make trade-offs much more easily, particularly when they come from the diversified economies more typical of the European Union, than US politicians who are beholden to the typically sectoral interests based in their districts. Despite these advantages, however, the growth of an EU menu à la carte, with some countries opting out of this or that policy and the problematic administration of the common monetary policy among those EU countries using the euro, has led to a major credibility problem for the European Union in European public opinion (Mamadouh and van der Wusten 2013).

A final approach tends to engage more with the problems facing the European Union: from the difficulties of expanding to incorporate new members, to the neoliberalization of its policy agenda since the late 1980s (particularly the switch of cohesion policies from more or less supporting declining regions to attracting private investment to them). There is also the challenge of managing a common currency for 17 of the 27 member states in the face of serious fiscal problems among a significant number of them following the recession of 2008–2013, and the lack of common fiscal policies across the Eurozone as a whole, and growing disillusionment with the European Union (and its central institutions) in the face of ballooning unemployment and antipathy to the free movement of other members’ citizens in many member countries. Several problems seem particularly serious from the specific perspective of “integration.” One of the most noted of these is the noncompliance of many member states with EU rules and regulations, including those on democratic governance. The failure to enforce the rules about government public debt and revenue collections in the making of European monetary union is perhaps the most devastatingly important of these. Opting out, when done explicitly, has become a serious problem for creating a common direction for the European Union as a whole, but noncompliance compounds the problem because it implies lip service to the project without bothering to put it into actual practice (Falkner 2013).

Even more urgent, the geographical patterning of the Eurozone crisis has brought to attention the serious fracturing of the European Union between core states, on the one hand, and various types of peripheral state, on the other. This signifies the conjuncture between economic problems and geographical placement (Agnew 2001). As a result, it has become commonplace to hear about the group of so-called PIIGS countries, Portugal, Ireland, Italy, Greece, and Spain (to which could be added Cyprus), which have had serious problems financing their public debts, and countries such as Germany, Finland, and the Netherlands, which are seen as “virtuous” in terms of their public finances. Beyond this, of course, lie the vastly different economic growth problems of states on the edge of the European Union as a whole (such as Romania and Bulgaria) and those awaiting the call to membership (such as Macedonia and Serbia, among others). Added to the growing skepticism about EU membership in some countries (particularly the United Kingdom, France, and the Netherlands), the fractures within the EU project have led some writers to refer to the prospect of “European disintegration” (Vollaard 2014). In a globalizing world in which national integration
NATIONAL AND REGIONAL INTEGRATION

is now inherently doubtful, the difficulties of regional integration in Europe highlight the limited possibilities of this alternative approach without significant change in the ways in which capital circulates worldwide.

Nationalism and geography

Virginie Mamadouh
University of Amsterdam, Netherlands

Nationalism has proved to be one of the most powerful ideologies of the past two centuries and is certainly the most geographical. Political claims based on national identities generally involve strong territorial claims and strategies. “Space, place, territory are absolutely essential to the imagination of nationhood and to nationalist politics” (Brubaker, interviewed in Sturm and Bauch 2010, 186). This might explain the fascination of political geographers with its occurrences and their consequences. Nevertheless, the primary purpose of deploying nationalism is to mobilize people as a group by prioritizing national identity over all other social identities; it is a powerful form of groupism. Key to nationalism is the conceptual confusion of the state as political organization with the land (or territory), or with the people (or nation), under its jurisdiction. In English and many other European languages this confusion is expressed in the indistinct use of “people” and “nation,” “state” and “country,” and “state” and “nation” as if they were pairs of synonyms. Think of the adjective “national” used to qualify features related to a state, the term “international relations” for relations between states, or the name “United Nations” for a formal association between states. Modern territorial states are also routinely identified as nation-states (i.e., nation hyphen state) to stress the close association of the nation as a social body with the state as a political entity.

Nationalism comes in many guises, depending on the representation of the nation it advances, the political agendas it supports, and the societal effects it brings about. Agnew (2013) has warned against the easy dismissal of nationalism in contemporary social sciences, neglecting both its appeal and its emancipatory effects. Too often, it is seen as a dark force and an outdated one. The campaign for the 2014 Scottish referendum for independence showed how nationalism can mobilize large numbers as a progressive force, foregrounding cultural diversity, inclusion, and solidarity. Still, there are plenty of examples where/when nationalist ideologies are used to exclude, disempower, displace, and even murder the other (those who do not belong to the nation).

The importance of geography in nationalist ideologies

Geographical features are important in nationalist ideologies in several ways. A generic nationalist ideology asserts the hegemony of national identity over all other social identities, while specific nationalist ideologies assert the content and claims of a specific national identity. These specific nationalist ideologies, although they share the same generic nationalism, often clash with each other because they make competing and contradictory claims on specific groups and territories. Therefore, on top of opposing alternative ideologies such as socialism, liberalism, anarchism, communism, or Islamism, nationalists often oppose each other, and these claims can easily lead to conflicts and generate vast human suffering. But even when the territorial borders...
between national groups are pacified and largely uncontested, the generic ideology can put individuals in a difficult position when they do not conform, either because they have no national identity or it is not important to them, or because they combine several national identities.

Political geographers are particularly interested in territorial claims. The justification of such claims can be very diverse and may foreground different and largely contradictory arguments. For example, claims to a specific territory and claims about the specific positioning of the border between two territories can rest on historical arguments (“We have always lived here”; “Our ancestors lived there for centuries”), necessity and productivity (“We need more agricultural lands to produce enough food for our population”; “We can develop the land and utilize the available resources better than another group”), geopolitical logic (territorial integrity and the avoidance of enclaves and exclaves; practicalities regarding the defense of the territory against external attacks; buffers to protect a nearby city), a distinct physical geographical shape (islands), or teleological goals (i.e., the promise of a bright future). Historical claims are particularly likely to generate conflicts, especially in densely populated areas. Coexisting groups often claim historical events and past political organizations as heritage in the same way as they claim space, and they base conflicting territorial claims on such appropriation. Reactualizing the political organization from the past that best suits their present political goals, they can attempt to project power onto space, according to the most extended area this particular entity ever controlled.

Nationalist claims to territories are multidimensional. They entail claims to specific lands and the use of the resources in these lands: crops cultivated; labor force living there; ores, salt, or oil extracted from the soil; water running through the area. They also pertain to the territorialized bordering processes that consist of both the specific location of the borderline and the guarding of the border, especially the regulation of the entries into the national territory and the entitlements associated with membership of the national community. The most explicit and formal cases are nationalist ideologies promulgated by the state to regulate citizenship, but stateless nations also sustain strong views about who belongs and who does not, and a myriad of practices regulate these social boundaries.

Nation (and) state

The relation between nation and state is complicated. While nationalism first emerged in existing states to mobilize the population in its territory, that is state nationalism, it soon became a force to mobilize against the state, that is bottom-up nationalism against the existing state(s). Nationalism has notably inspired the articulation of struggles for autonomy and independence in multinational empires in Europe, such as the Habsburg empire, the Ottoman empire, and the Russian empire, and in colonial empires beyond Europe, in the Americas, Asia, and Africa. Bottom-up nationalism against the state is still a powerful force wherever groups see their cultural differences from the majority group of the state as a cause of discrimination against them; such differences are framed as sufficient conditions to warrant claims to autonomy and independence. Sometimes such differences are very consequential in everyday life and are expressed in different languages, religious beliefs, norms and values, and/or lifestyles, but at other times they may be very small and social boundaries between groups may be very fluid. Moreover, spatial identities can be sufficient by themselves: the distance from the capital city of the state, different climatic conditions and physical harshness, and different relations with the outside world may also foster a
feeling of alienation from the center of the state and its rulers that can be the very motivation for aspirations to autonomy. Finally, economic disparities can inspire such mobilization to resist exploitation from the political center, but sometimes it is in richer regions that national identities are mobilized against the state, to opt out of solidarity arrangements with poorer regions.

In general, it should be stressed that the very institutionalization of a territory as a separate territorial entity coevolves with the institutionalization of a group as a separate cultural entity. In other words, the nation and the territory co-constitute one another, even more strongly when state institutions are available to organize both the nation and the territory. Regulations promoted by the state, especially regarding language in public space, political institutions, media, and educational institutions, are strong vehicles for these identity-building processes.

Typologies of nationalisms reflect the key importance of the very nature of territorial claims to classify nationalist ideologies. Whether nationalism refers, in its generic form, to the isomorphy between the territory of the state and that of the nation, there are different ways to try to achieve this ideal state of affairs. State nationalism refers to nationalist ideologies enforced by the state to mobilize the population on its territory and to homogenize it to form a national community. In such discourse territory and nation are so intertwined in nationalist discourses that love for the nation as community and love for the land and its iconic landscapes can hardly be disentangled from one another, and are used next to each other, as in the British recruitment posters shown in Figure 1. Ethnoregionalism and substate nationalism cover a wide array of nationalist ideologies that demand a separate state for a community with a clear territorial shape through secession from an existing state or a multinational or colonial empire.

Many nationalist ideologies are more complicated, even if we consider only geographical aspects. Irredentism refers to groups that do not accept the delimitation of the border lines between two states and support claims to reunify a territory beyond the border to the state, hence the name – not yet recovered. Typically irredentism pertains to areas where people speak the same language in a contiguous area across an international border (originally the Italian speakers in Istria and Dalmatia), a situation, however, that is very common and not always conducive to such claims (think of French-speaking or German-speaking Swiss, Dutch-speaking or French-speaking Belgians, Swedish-speaking Finns, etc.). Irredentism can be either a local force (when the local population campaigns for a change of the borderline), a national one (when the state or a national movement claims a territory “back” from its neighbor), or both. The national variant might even completely negate local self-determination, when the adjacent territories are claimed on the grounds that they were once part of the national homeland and have been unduly annexed by others, while the local population has other linguistic and religious characteristics and publicizes other political affiliations – think of the claims of Serbian nationalists on Kosovo.

Another noteworthy form of nationalism, from a political-geographical point of view, is pan-nationalism: a nationalist ideology that unites populations of different states, generally on the basis of common cultural features, like language and religion: Italian and German nationalism led to the unification of Italy and Germany as modern states in the nineteenth century; pan-Europeanism was unsuccessful during the interbellum; pan-Slavism, pan-Turkism, pan-Arabism, and pan-Africanism were vigorous forces in the twentieth century; and
Figure 1  Two British recruitment posters encouraging men to enlist to fight against other nationalists during the Great War. The posters refer to (a) territory (i.e., the landscape) and (b) the nation (i.e., the women and children) to be protected. Both posters were produced and circulated by the Parliamentary Recruiting Committee in 1915. Image credit: Imperial War Museums (IWM).

pan-Americanism (aka Bolivarianism) still is in certain parts of South America.

Last but not least, diaspora nationalisms (or more neutrally labeled long-distance nationalisms) demonstrate the enduring strength of cultural bounds in exile and how feelings of belonging can be maintained while living far from the original homeland. They have been studied extensively, especially when the discursive, financial, and physical engagement of the diaspora has weighed in hot conflicts, such as the cases of the Irish diaspora in Northern Ireland and the Jewish diaspora in Israel.

It should be stressed that nationalist ideologies may have different relations to territory. Some ideologies may be more interested in the generic characteristics of territory (extent, natural resources, access to the sea) as resources for the state and the nation, and others more concerned with a specific place because it has a specific meaning for the nation and its history. The first type will accept land swaps – the
NATIONALISM AND GEOGRAPHY

The territorially equivalent of ethnic cleansing – to culturally homogenize the state population or to achieve a compact shape for the state territory more easily than the second, which will see a specific place as irreplaceable.

Nationalism and citizenship

The politically framed association between nation and territory matters for relations between nations or between states, but it also defines the individual’s membership of the nation and the (nation-)state. It is customary in this regard to distinguish civic and ethnic nationalism. In civic nationalism, or liberal nationalism, membership is rooted in a political definition of the community and the political will to apply the law, to participate in the civic community, and to advance the common good. Ethnic nationalism, by contrast, stresses blood ties and descent as the essence of membership. In this case it is difficult to become a member if one is born to parents who are not members of the national community. Sometimes an intermediate variant is distinguished, cultural nationalism, when blood ties do not matter but the willingness to endorse a specific cultural identity is expected. In civic and cultural nationalism, membership is generally based on birthplace and there are more generous procedures for naturalization (the conversion to citizenship) and more tolerance for dual citizenship (the combination of the citizenship of different states).

The role of (academic) geographers in nationalist projects.

It is well known that the institutionalization of geography as an academic discipline and as a school topic in the late nineteenth century in European countries has been strongly associated with their nationalist and imperialist projects (Hooson 1994). The making of modern (national) citizens was promoted through the spread of universal (state-sponsored and state-controlled) education; the formalization, homogenization, and imposition of a common national (i.e., state) language; and the circulation of a common body of geographical and historical knowledge that naturalizes the existence of the nation and state. Schoolbooks have proven illuminating sources to study how whole generations were socialized into a specific perception of the nation to which they belonged and its position in the world. Geographers have been instrumental in the production of knowledge and of teaching methods to achieve this task. Theirs could be labeled as the main “banal” contribution of geography to nationalism.

Another banal contribution common to all social sciences and humanities pertains to the nationalization of research objects, and is sometimes called methodological nationalism as it takes for granted nationally defined sets of social relations, that is, national societies. The states are accepted as given, as natural containers of social relations: we speak of Dutch politics, French media, German culture, Italian economy, as so on, as if they were material entities. Just as art historians tie painters to specific countries and therefore contribute to the idea that there is a national painting culture and a national identity essentially distinct from that in neighboring and competing states, geographers contribute to the idea that there are national landscapes and national geographic features essentially distinct from those in other states and contributing to the specific essence and vitality of the nation. Of course, geographers have also been involved in many other state policies that have contributed to the strengthening of the infrastructural power
NATIONALISM AND GEOGRAPHY

of the state, such as regional and urban planning, infrastructural decisions, and economic development policies.

Geographers have also played a role in “hotter” nationalist projects, with interventions in nationalist struggles, as participants in nationalist movements or as advocates of nationalist claims. Geographical knowledge and academic credentials have often been welcome to produce and circulate narratives and maps to support nationalist claims to territory or autonomy, or to defend the nationalist project of an existing state. Rudolf Kjellén (a Swedish law professor who coined the very successful neologism “geopolitics”) argued and campaigned against Norwegian independence from Sweden at the turn of the twentieth century. In the same period, Halford Mackinder, a key figure of British geography, promoted good relations with Russia to counter Germany as challenger of British hegemony. Paul Vidal de la Blanche, the influential founder of French regional geography, wrote a book to demonstrate that Alsace-Lorraine, the French region annexed by the unified Germany in 1871 after the Franco-Prussian war, ought to be returned to the French Republic. These scholars were certainly not exceptions.

Geographers have also been instrumental in the settlement of nationalist conflicts. They were especially influential at the end of World War I, when a new political map of central and southeastern Europe and of the Middle East was negotiated in a series of peace conferences to dismantle the multinational Habsburg and Ottoman empires. Guided by the 14 principles enunciated by the American president Woodrow Wilson, geographers were important advisers to the statesmen applying self-determination to the redrawing of the European political map. They were asked to provide scientific evidence for the determination of the nations (i.e., the nationalities, in the jargon of the time) that were entitled to a state of their own and the delimitation of the borders between the new states. Language and religion were the two main characteristics to determinate “objectively” the existence of separate nations, but there were many disputed cases. Indeed, when is a language a separate language, and when is it a variety of another language? A notorious case is the fate of Macedonians which depended on whether Macedonian was seen as a separate language, as a variety of Serbian, or as a variety of Bulgarian. The Serbian geographer Jovan Cvijić, who had published very different cultural maps of the region over previous decades, advocated, as the adviser of the Serbian delegation, the incorporation of Macedonians into the new Yugoslavian state federating the South Slavs (Wilkinson 1951). The negotiation of the borderlines was even more difficult, because the pattern of settlement in that part of Europe and the Middle East was such that different groups lived in mixed areas and it was virtually impossible to design (ideal-typically) contiguous territories inhabited by a culturally homogeneous population. Self-determination was applied very selectively, depending on the interests of the winners and their alliances.

Isaiah Bowman, the geographer advising the American delegation, published The New World (1922) afterward, in which he identified the contested areas and the territorial conflicts that would eventually emerge from the peace settlement and the new political map of the world. In Germany, the main loser of the war, resentment was widespread against the conditions and penalties imposed, including the loss of its colonies and of territories in Europe, the displacement of German-speaking populations, the demilitarization of the Rhineland, and huge financial reparations. Geographers involved in the establishment of a German school of geopolitics provided this revanchist political agenda with scientific arguments about the Lebensraum the German nation
needed, its precarious position surrounded by hostile neighbors, and the need to reunite German-speaking populations in one state.

To balance this account, it should be also remembered that others among the founding fathers of geography had completely different aspirations. Anarchist geographers such as Élisée Reclus and Peter Kropotkin clearly envisaged a different role for geography and the popularization of geographical knowledge. They saw geography as a tool to overcome cleavages between nationalisms, to promote peace universally, and to empower free world citizens.

The geographical study of nationalism

The geographical study of nationalism is characterized by case studies addressing nationalist projects of states as well as nationalist projects against states, and a wide array of topics, including the representation of the nation; the implementation of state- and nation-building policies in newly established states; the disintegration of multinational states, the emergence and diffusion of nationalist ideologies; the mobilization and organization of nationalist movements and their strategies and tactics, especially the use of violence; patterns of distribution and diffusion of nationalist protests and nationalist organizations; the electoral geography of nationalist parties; the representation of national identities in popular culture and the media; the reproduction of national identities in everyday life; and the dynamics of nationalist struggles. In these later types of study the case is not one nationalism but the clash between two nationalisms.

Much of the research pertains to European cases, the cradle of the generic nationalist ideology and for two centuries the battlefield of numerous hot and murderous conflicts between specific nationalist ideologies. It is typically a field in which the depth of a case study is the best way to achieve conceptual progress. Comparative studies are less common. They distinguish different types of nationalisms, and they try, foremost, to identify factors that fuel conflict and that enable pacification. For example, the Irish political scientist John Coakley (1993) examines the geographical determinants of success using two dimensions: concentration and dominance. The first measures the degree to which the group is concentrated in the claimed area, the second the degree to which the group dominated in the area or whether other groups are more important. Claims for a group with high concentration and high dominance are more likely to be successful. When a group is spread over a much bigger territory, autonomy in one region seems insufficient as it will create different situations for group members according to their place of residence that might lead to the (forced) displacement of those outside who will be resettled in the chosen area. When a group is not dominant in the area, autonomy might be resented and opposed by the rest of the population in the region or might set in motion new autonomist mobilizations at a subregional scale – think of the mobilization of the anglophone minority in Montreal after the status of French was enhanced in Quebec, the Canadian province with a majority of French speakers.

The scheme warrants at least two important remarks in this discussion of the relation between nationalism and geography. First, Coakley puts areas before groups. His examples are labeled after the area, not the group for which autonomy is claimed, and even less the movement or party making these claims, thus contributing to the blurring of the spatial container and the social entity it represents, and even more the political entrepreneurs that speak/act in its name. Second, his examples demonstrate that labeling is already constitutive of the nationalist discourse.
NATIONALISM AND GEOGRAPHY

and of the assessment of the situation, rather than a neutral observation. Whether a group is concentrated and/or dominant depends on how it is defined, named, and delimited with regard to the surrounding groups.

Coakley also provides a typology of state responses to territorial claims. These responses can be repression and the removal of difference, through compulsory assimilation or through ethnic cleansing (either displacement or murder). Europe’s history in the nineteenth and twentieth centuries has been rich with examples. The French state is the most famous example of a state that homogenized its population linguistically by actively suppressing the use of regional languages in public space. Exchanges of population were common after changes of the political map: Greeks and Turks in modern Greece and Turkey (much later, in 1974, between Cyprus and Northern Cyprus); German speakers expelled from Czechoslovakia and Poland; and Finns and Poles displaced from the Soviet Union. The list of extermination policies in the twentieth century is very long: Armenians in Turkey, Jews in territories controlled by Nazi Germany, Poles in Lithuania, Bosniaks/Muslims in the Serbian and Croatian territories of Bosnia–Herzegovina. Outside Europe nationalist ideologies have been deployed to homogenize the state population as well, the largest example being the displacement of population and the killing of Muslims and Hindus at the partition of the British Indian empire and the independence of India and Pakistan in 1947.

Alternatively, the state can respond positively to territorial claims and accommodate demands in a nonterritorial manner, for example by providing services and support for specific cultural institutions across the state territory. The response can take the form of a territorial arrangement: providing not only services and support but also autonomy to claimed areas. Such autonomy can be limited and conditional, with sovereignty remaining with the central state (as in the case of regionalist arrangements), or sovereignty can be shared (federalism) or even transferred to the smaller entities (confederalism or independence). Arrangements can be symmetrical when the tasks and competencies are delegated to all entities across the state territory in an identical manner (Belgium, France) or asymmetrical, giving more privileges to areas with strong mobilization and less to others (United Kingdom, Spain, Italy). New territorial arrangements set the stage for a new round of mobilization (Van der Wusten and Knippenberg 2001), and whether or not devolution or autonomy demobilize substate nationalists or encourage them to claim more autonomy is a matter of debate.

The study of nationalism from a geographical perspective has blossomed over the years, inspired both by the debates in the field of nationalism studies (primordialism vs modernization theories about the nature and continuity of nations and nationalisms) and the theoretical and methodological evolution of human geography. Geographical analyses of nationalisms demonstrate that place matters and that nationalism is not equally important everywhere but appears in different shapes at different times and places. It also underlines the importance of the context for the evolution of nationalist projects and of the interaction between nationalist movements and political institutions.

The role of nationalism in the disintegration of multinational federations, especially in the Soviet Union and in its successor states, including the position of Russian speakers in these new states, has drawn much attention. Nationalism was first seen as resurgent after decades of state communism but more careful examinations of Soviet policies demonstrated the complexities of Soviet policies regarding (titular) national
identities and showed how nationalism had been shaped by these state policies (Kaiser 1994). Nationalism was so important in 1991 not despite decades of state communism but thanks to Soviet policies toward nationalities.

The relation between state nationalism and substate nationalist movements has been explored by Mansvelt Beck (2005) in his study of Basque nationalism in the Spanish and the French part of the Basque Country. He shows how different state- and nation-building trajectories, the Spanish one and the French one, brought about different articulations of national (state) identities with Basque cultural identities and different national (substate) mobilizations of Basque nationalism, south and north of the state border.

Other geographers have stressed the intimate relation between national identities and geopolitical representations (Dijkink 1996; Paasi 1996), and how the representation of national identity and the nationalist (state) project are co-constitutive with the representation of the role of the nation in the world and of its relations with neighboring and other states. Following the cultural turn in geography, much attention has been given to cultural artifacts like national monuments and cultural events like national days and their role in fostering national identities, and to the circulation of nationalist discourses in popular culture and in the media. A particularly important development has been the study of nationalism from a multiscalar perspective. It was also inspired by feminist studies on the importance of the family and the everyday in the reproduction of national identities and of nationalism, and of gender roles in nationalist movements. Generally, the intersection of different identities and ideologies and the configuration of nationalist discourses with other ideologies such as socialism, and of national identities with language, religion, and race, need more engagement.

The local (re)production of nationalism is another theme of growing importance. Geographers have also followed the call of the British social psychologist Michael Billig (1995) to address banal nationalism instead of only looking at the more extraordinary expressions of nationalism, when people are prepared to kill others in the name of their nation and to be killed in the process. Sport appears to be a particularly powerful domain for the mobilization and the expression of such nationalist sentiments. Nationalism in the culturally diverse city is another. Inspired by the recent materialist turn of nonrepresentational geographies, attention is now firmly focused on the way nationalism is practiced and embodied.

The future of nationalism in the transnational world

Nationalism is a modern political ideology centered on national identity and territorial claims. It will eventually lose its appeal, but for now it remains one of the most pervasive ideologies in contemporary (local, national, and global) politics. Recent processes of globalization – including enhanced interactions stretching over large distances and the potential of new media – seem to have reactivated its salience rather than to have brought about its often announced dismissal. This may be because nationalism provides individuals with a strong sense of belonging that is easy to communicate and to ground in institutions and routines, and because the need to belong somewhere is felt all the more acutely when uncertainties and anxieties grow with globalization. At the end of the nineteenth century, nationalism competed with
two other main ideologies, liberalism and socialism; at the beginning of the twenty-first century nationalism and neonationalism compete mainly with neoliberalism and religious universalism.

In times of enduring transnational migration and transnationalism through the maintenance of cultural ties across state borders, migration and the management of the flows of people has become a particularly important issue in nationalist ideologies that often surpass the pre-eminence of drawing borderlines and the management of territorial claims proper. Nationalist and neonationalist discourses in Western countries – which in Europe are also directed against integration in the supranational framework of the European Union – often incorporate time in claims to authenticity and belonging to a certain place, scripting cultural elements associated with recent immigrants as less legitimate because of their recent arrival in the national territory. In turn, newcomers therefore feel excluded and this may encourage an orientation toward other cultural centers, demonstrating that place-making and home-making are at the core of the nationalist imagination of the world. Evidently the length of stay needed for individual residents and their families to qualify as legitimate inhabitants of the national territory along with established groups of residents, to stop being out of place, and to be seen as a host too instead of as a(n unwelcome) guest, is open to contention and a hotly debated issue.

While more traditional nationalist conflicts over territory and borders remain high on the political and research agendas (think of the Israeli–Palestinian case), new salience is given to the clash between inclusive nationalist discourses and national identities embracing multiculturalism and exclusive ones. Such inclusive national identities may also provide new horizons for institutional arrangements in traditional conflicts. In both types of conflicts, old and new nationalisms, geography can contribute to understanding these dynamics better, by providing studies that are sensitive to local differences and by conceptualizing the contingencies of nationalisms as they emerge and develop in time and place-specific sites.

Geographers have studied the state in a number of different ways, focusing especially on the state’s role as a regulator of the economy, provider of social welfare, and arena for political participation. The concept of nation-state draws attention to the state as a community, that is, the state as a focal point for identity, and the nation as a source of legitimacy for the state. These links between the state and nation define the conceptual core of the nation-state and provide a basis for distinctions with regard to state forms that are based on other conceptions of community, state territoriality, and state–community relations, for example, city-states, multination states, empires, and confederations. State–community relations are also the focal point for nationalist ideology, revolving around the principle of political and territorial congruence between a sovereign state and an autonomous national community.

Nations, nationalism, and nation-state formation

The focus on the community dimension of the state makes national identity an obvious analytical starting point for examining nationalism, nation-state formation, and nation-state models of citizenship. There is, however, no consensus on the meaning of the “nation.” Debates about its character, origins, and political roles have revolved around a polarization between primordialist and perennialist approaches, which see nations as essential, bounded, and stable, and modernist and constructivist perspectives, which view nations as constructed, changeable, and historically contingent (Özkirimli 2010).

Primordialism sees the nation as a natural category that is defined by objectively given organizing principles such as blood, race, ethnicity, language, religion, and territory. Such primordial bonds of human association, it is argued, have always and naturally divided populations. They hence precede and provide a given basis for the formation of nation-states. Perennialism does not share this view of nations as natural categories, but nevertheless sees them as long-standing and relatively stable social and historical phenomena. Contemporary nations stem from entrenched ethnosymbolic systems with deep historical roots. Both approaches hold that contemporary nations and their homelands are objectively defined and premodern in origin, and hence predate and shape modern state formations and nationalist politics.

Primordialism and perennialism held a hegemonic position in both popular and academic discourses on nations and nationalism for a long time, but have come under strong scholarly criticism because of their essentialist, static, and universalizing analyses of nations, nation-states, and nationalism. These perspectives are also viewed with skepticism as a result of their association with nationalist ideology. Primordialism provides a conceptual foundation and political legitimacy for the core argument in nationalist ideology that nations do exist and have unique characters, that the values and interests of nations take priority over those of other collectivities, and that the nation must be politically autonomous.
and protected through nation-states. Nationalism as a political movement seeks to achieve these core principles, and primordialism may provide a conceptual basis and political legitimacy for such actions (Herb and Kaplan 2008).

Modernist and constructivist perspectives share a view of nations as social constructions that are interwoven with nationalism. This means that nations are not given and fixed categories, but have come into being in the context of nationalist ideas about natural, bounded, and stable national communities. The principal difference in opinion between modernism and constructivism is with regard to the possibility of causal explanations behind the construction of national communities. Modernism holds that it is possible to identify economic, social, and political causes behind the invention and instrumental use of national identities and traditions. While some scholars emphasize capitalist economic transformations and the associated social division of labor as the drivers behind nationalism and the invention of modern nations, others emphasize the emergence of modern states that made nationalism a particularly appropriate form of politics, not least for the dominant classes in pursuit of hegemony in the face of radical politics by subordinate classes. Modernist scholars thus agree that the modern state and nationalist ideology preceded the invention of nations, rather than nations being an objective basis for nationalism and nation-state formation.

Constructivism rejects the modernist view of nations as invented traditions that can be causally explained with the needs of capitalism, the modern state, or dominant class interests. The focus is instead on understanding nations as discursive constructions – “imagined communities” – built around boundary demarcations of nations and national homelands, and the bonds between people and place (Jackson and Penrose 1993; Paasi 1998). Nations are constructed and institutionalized through narratives about who “we” are, where we belong, and how we are different from the “others,” who belong elsewhere. To examine the meaning of the nation is to examine who are rendered culturally and territorially included or excluded in representations of national communities, how imagined communities are institutionalized, and the manner in which discursively constructed identities constitute a basis for identification and everyday banal nationalism.

Nations and their “homelands” may be seen as given or constructed, but there is broad agreement that national identity and territorial self-determination are intrinsically linked to nation-states. The formation of nation-states has been a long-standing research tradition within and outside human geography. The existing literature revolves around two principal ways of pursuing congruence between national and state boundaries; either from nation building to nation-state, or through state building to nation-state (Penrose and Mole 2008). The state route to nation-state involves modern state formation as a precursor to building a nation of all people living within its territory. The nation is thus conceived as a civic collectivity built around universal citizenship, democracy, and liberalism. The process of creating cultural uniformity thus follows from rather than precedes the formation of the modern state. This focus on state building is in contrast to the nation route to nation-state formation, where self-determination is demanded for a culturally predefined nation. Both trajectories of nation-state formation are nationalist in the sense that they seek to achieve congruence between the boundaries of a modern state that is based on the idea of government for and by the people, and a nation that is construed as a cultural community of equals. Where they part
ways is in the sequencing of nation and state building in the process of nation-state formation.

Geographers have also given extensive attention to nation-state building, that is, the interrelated processes of constructing and politicizing the nation and to building the state and imbuing it with national meaning. Penrose and Mole (2008) observe that nation-state building includes at least some of five main processes: state building centered on creating state institutions for government and representation; establishing state monopoly over the legitimate use of force; building national systems of education and language; developing media institutions and mass communication; and fostering shared systems of meaning. All of these are always and unavoidably spatial and territorial processes, providing rich opportunities for geographic scholarship on the building and transformation of nation-states.

The nation-state and citizenship

While the analytical foci and theoretical perspectives may change, geographers continue to pay critical attention to state–community relations. One notable reorientation is that contemporary studies are increasingly framed by theories and debates about citizenship and nation-state transformation. Citizenship is conventionally taken to mean a formal legal status that is based on membership in a community and that provides a basis for citizen rights and responsibilities. The modern nation-state model of citizenship rests on membership within a nation, but the national community may be constructed in different ways. The previous section pointed to a general distinction between ethnocultural and juridical–political constructions, that is, nations that are built around cultural bonds and a historical homeland, or around people living within a territorial state under common law and legislature. Following from this distinction, citizenship has conventionally been granted on the basis of the parents being citizens (jus sanguinis) or on the basis of being born within the territory of a state (jus soli). Increased cultural diversity in the context of international migration has, however, challenged such simple distinctions and transformed the criteria of citizenship. Hybrid systems for legal citizenship have thus become more prominent as immigration countries have come to realize that the exclusion of large groups from citizenship has problematic implications in terms of social marginalization, political exclusion, conflict, and racism. In this situation, exclusion and stratified membership in communities of citizens have become key issues in citizenship studies within and outside human geography (Kofman 2006).

Citizenship studies have been marked by a cultural turn that has raised critical questions about cultural differences and cultural politics within the nation. Citizenship rests on assumptions about cultural homogeneity, and the principle of universality means that all members of a political community are granted citizenship on equal terms. It also means that commonality of identity among citizens is privileged at the expense of particularistic group belonging, and that all are treated equally in the sense that laws and rules apply to all in the same way. The liberal perspective on citizenship holds that the principle of universality constructs citizenship in a manner that transcends particularity and difference in favor of equality and justice. Critics argue, in contrast, that universality conceals how citizenship is defined in terms of dominant identities and thus puts other identity groups at a disadvantage, even if everyone is granted equal citizenship in legal terms. While universal citizenship is seen as an instrument of emancipation and justice, it simultaneously masks and
accentuates group oppression in terms of gender, sexuality, class, ethnicity, and so on.

Citizenship studies have drawn attention to contentions over the character of national communities and struggles for inclusive membership. Isin and Wood (1999) describe such politics of membership as “cultural politics” and make a distinction between identity politics revolving around claims on the basis of durable group identities, and politics of difference emphasizing recognition of differences. Identity politics and politics of difference present opposed views on the nature of identities, with divergent implications for political practices.

*Identity politics* refers broadly to political struggles around shared experiences of injustice based on involuntary membership in a particular social group. Conscientization about the mode of oppression that a group experiences is thus central in challenging stigmatizing representations and in demanding group-differentiated rights. Recent years have also seen the emergence of a *politics of difference*, focusing on the constructed character of identity and differences within any imagined community. This is in marked contrast to identity politics, which sees groups as defined by objective relations of oppression.

The question of membership in communities of citizens has thus produced two modes of cultural politics, separated by a divide between essentialist and constructivist views on identity. Whereas identity politics builds on essentialist notions of identity and seeks a transition from oppression to social and political inclusion, the politics of difference is based on a constructivist view of identity, critical attention to difference, and a broadening of what issues are considered relevant to citizenship.

Geographers have paid increased scholarly attention to the policies and politics of inclusion/exclusion in cultural membership and formal citizenship, including a critical focus on different forms of partial citizenship between noncitizens and full citizens. The prevalence of hybrid and stratified citizenship blurs the idealized image of binary distinction between citizens and noncitizens, and of equality among citizens. Differentiation at the level of *becoming* a citizen is also mirrored in diverse and stratified experiences of *being* a citizen. Renewed attention to citizenship has thus provided new opportunities for geographic scholarship on changing and contextual links between the state and communities.

Transformation of the nation-state model of citizenship

The nation-state model of citizenship has come under pressure as a result of increased diversity and cultural politics within presumably homogeneous nations, but also from the transformation of territorial state sovereignty in conjunction with increased globalization.

The modern model of liberal citizenship rests on assumptions about territorially bounded nations and states. The nation-state is seen as the principal site for citizenship, because of its sovereign authority to grant legal status as a citizen within its territory and to define the extent and content of rights and political participation. This territorial model of citizenship has come under pressure in the context of various forms of globalization. Increased economic globalization has reduced the sovereignty of the state and contributed to the emergence of multiscale forms of governance and citizenship. Global neoliberalization of governance also means that citizenship rights and participation are defined not only by the citizens’ relations to the state, but also by the market and civil society. Finally, increased international mobility has produced a growing number of people with dual citizenship or
transnational belonging, challenging the territorial nation-state model of citizenship. It can thus be argued that economic globalization, globalized neoliberalism, and international migration have introduced and reinforced tendencies toward cross-scale, multisited, and transterritorial citizenship. Citizenship has become increasingly complex in geographic terms, and the substance of membership, rights, and participation has come to be defined through multiple and relational scales and spaces (Desforges, Jones, and Woods 2005).

Citizenship has been decentered in regard to the territorial nation-states, although the state remains a prominent domain of citizenship, leading some scholars to the observation that citizenship is being transformed in postnational, denationalized, and transnational directions (Sassen 2002). A postnational trajectory means that citizenship comes to be located outside the framework of national communities in the sense that it rests on new forms of community and that it transcends the institutional framework centered on the nation-state. Denationalization, in contrast, refers to a transformation of citizenship away from the national scale that nevertheless remains within the general framework of nations and states. Such a denationalization trajectory is especially visible in the emergence of multilevel citizenship.

The most obvious example of multilevel citizenship is found in federal states, where individuals are citizens with rights and responsibilities both at the level of the component states and within the overarching federal state. Devolution of power to semiautonomous regions in a quasi-federal state or to municipalities and cities in a decentralized state structure provides additional examples of multilevel citizenship. Such subnational forms of citizenship can be characterized as scaled down versions of the nation-state model of citizenship. At the opposite scalar end, there are also examples of citizenship at the supranational level based on the nation-state model. The foremost example here is citizenship at the scale of the European Union, which also includes formal legal status, rights, and political participation.

The postnational trajectory is a more radical departure from the nation-state model of citizenship since it involves constructions of communities of citizens and rights outside the framework of the nation. In the past, citizenship was broadened when previously excluded groups (e.g., workers, women, children) were included in the national polity. In the contemporary period, some argue that rights that used to be reserved for nationals are increasingly granted to resident foreigners (denizens). This means that membership has come to be based on discourses of personhood and that rights are framed as human rights. It does not mean, however, that the state has become irrelevant. While universal personhood and human rights have become a legitimating basis for claims to rights, the realization of such rights is still tied to state institutions.

A third trajectory is found in the form of transnational citizenship. Transnational citizenship means that legal status and rights are situated in national institutions, while citizenship as membership (belonging) and participation (social, cultural, and political practices) is embedded in transnational fields. This creates a situation where belonging and active citizenship are with reference to multiple political and communal spaces in countries of origin and immigration as well as the transnational spaces of diasporas.

This brief review demonstrates the continued centrality of the nation-state as a research object in human geography. It also indicates that the questions that are asked and the approaches that are used have undergone important changes,
and especially that citizenship has become an important analytical tool for studying the concrete, context-specific, and changing meaning and politics of state–community relations within nation-states. Cultural and global changes have challenged the nation-state and its model of citizenship, and have been followed by increased attention to postnational, denationalized, and transnational forms of citizenship and to cross-scale, multisite, and transterritorial geographies of citizenship. Contemporary state–community relations in nation-states are thus characterized by an increasingly complex geography as institutions and political struggles for citizenship are constituted within and across multiple scales, spaces, and places.

Natural hazards and disasters

J.C. Gaillard  
*The University of Auckland, New Zealand*

The sharp increase in the occurrence of documented disasters worldwide over the past few decades has stirred growing interest within geography and other cognate social sciences. Geographers have given particular attention to disasters associated with natural hazards, the understanding of which requires blending knowledge of both the physical environment and the social fabric.

The definition and scope of both natural hazards and disasters have been debated. Some, especially within the North American geographical literature, have long considered natural hazards as the possible interaction between people and natural events (Tobin and Montz 1997, 5), while a disaster used to refer to the actual event significantly impacting society. The foregoing understanding of natural hazards, which was still prominent in the 1990s, has, however, progressively been replaced by a more consensual definition limiting natural hazards to natural processes and events which are possibly destructive to people and their resources, and disruptive of their activities (Wisner, Gaillard, and Kelman 2012, 21). In this sense, natural hazards only pose a threat to people who are vulnerable and lack capacities to face them. This interaction between hazard, vulnerability, and capacities mirrors the risk of a disaster or the risk that the occurrence of a natural hazard leads to casualties, infrastructure damage, or livelihood disruption – eventualities which are too important for the affected area and people to deal with on their own.

Such a definition of a disaster emphasizing the interaction between the natural environment and the social fabric has become central to geographical understandings of disasters as it refers to the essence of the discipline. In fact, most geographers’ efforts have been dedicated to better comprehending the causes of disasters, thus involving studies of both natural hazards and people’s vulnerability and capacities. In parallel, sociologists have focused on disruptions to the social fabric caused by disasters and how people actually react faced with these events, while psychologists have largely concentrated on disaster-induced trauma and anthropologists on long-term social and cultural change associated with disasters. All these other fields of scholarship have concurrently developed their own definitions of disasters, mirroring their disciplinary interests.

Apprehending the causes of disasters has stimulated much discussion among geographers who have debated the relative role of natural versus human factors in the increasing, but spatially unequal, occurrence of documented disasters. These debates have had a powerful influence on disaster risk reduction (DRR) as well as postdisaster reconstruction policies and practices.

**Trends in the occurrence of natural hazards and disasters**

All available databases recording disasters associated with natural hazards worldwide show a sharp increase in their occurrence from the
1980s onward. The most trusted database, EM-DAT, compiled by the Centre for Research on the Epidemiology of Disasters (www.emdat.be) records 11,632 events between 1900 and 2013, 9,504 of which have occurred since 1980, including some very high-profile events such as the 2004 Indian Ocean tsunami, Hurricane Katrina in the United States in 2005, the 2008 earthquake in China, the 2010 earthquake in Haiti, the 2011 earthquake and tsunami in Japan, and Typhoon Yolanda in the Philippines in 2013. The surge in the number of disasters is particularly pronounced in the less wealthy countries, especially those in Asia and Latin America, where 59% of the events recorded between 1900 and 2013 occurred. Meanwhile, Europe and Northern America seem to be less frequently impacted – disasters recorded in EM-DAT as 14% and 9% respectively. EM-DAT also shows that 87% of the disasters recorded worldwide between 1900 and 2013 are associated with hydrological and/or climatic events, with no significant disparities in the distribution of hazards across regions of the world. In addition, hydrological and/or climatic events are related to 88% of the casualties.

The severity of the impact of recorded disasters is increasing. The number of people affected has been surging over the past few decades, especially, again, in the less wealthy countries of Asia, Latin America, and Africa. Between 1980 and 2013, more than 6.2 billion people have been injured, forced to evacuate, or lost assets and resources in disasters, of whom 89% live in Asia, 6.5% in Africa, and 3.2% Latin America. In parallel, the number of people killed is also growing. EM-DAT shows that 2.3 million people died between 1980 and 2013, compared to 2.1 million individuals between 1900 and 1979. The economic impact of recorded disasters measured through the sole direct losses in monetary value is also surging. EM-DAT shows that cumulated losses since 1980 have reached US$2.5 trillion against US$87 billion between 1900 and 1979. The trend is exponential, as economic losses recorded since 2000 have reached US$1.6 trillion. Wealthy countries suffer the largest absolute losses, with Japan, the United States, and China topping the list of the most severely affected countries. However, less affluent countries, especially the smallest ones such as the Small Island Developing States (SIDS), record higher relative losses in comparison to their gross domestic product (GDP).

This brief overview of documented natural hazards and recorded disasters only mirrors the scope of existing datasets, which themselves merely reflect the interest of, on the one hand, international agencies involved in disaster response and, on the other hand, scholars engaged in disaster studies. In this regards, most databases recording disasters worldwide focus on large events which trigger international humanitarian attention and are known to a large enough number of people to stimulate research interest. For example, EM-DAT only records events which kill at least 10 people, affect at least 100 individuals, require the declaration of a state of emergency, and/or a call for international assistance.

In parallel with these large disasters, there are also a significant number of smaller events whose cumulative impact is supposed to be higher. These neglected disasters are partly captured in the alternative DesInventar database (www.desinventar.org), now managed by the United Nations International Strategy for Disaster Reduction. For example, DesInventar records more than 40,996 events, and 44,390 deaths, between 1914 and 2013 in Colombia alone. By contrast, EM-DAT records only 158 disasters, and 32,661 people killed for the same period. In Nepal, EM-DAT records 58 disasters between
1971 and 2007, while DesInventar lists 7263 events.

Small disasters are not only important for their cumulative impact and significance in the everyday life of those who are affected. They also challenge the common view of disasters as events which exceeds the ability of those affected to cope using their own resources. Because these events are overlooked or neglected by most institutional actors involved in disaster risk management (DRM), affected people are left on their own to cope and recover. Small disasters, in fact, constitute a category of events which fall between large disasters and the everyday crises associated with maldevelopment, that is, poverty and associated food insecurity, poor health, informal shelter. Figure 1 shows that small disasters, unlike everyday crises and large events, are overlooked by policymakers and people’s response is largely undocumented. They constitute what the United Nations’ 2009 Global Assessment Report on Disaster Risk Reduction labeled as “extensive risks” in comparison to “intensive risks,” which are associated with large disasters.

In addition, all available databases only provide a rather rough overview of the impact of disasters that tends to standardize data at regional and national scales. There is very little data indeed about the impact of disasters at the local level,
including across neighborhoods, genders, ages, and social statuses. This gap leads to an overall generalization of the impact of disasters to the detriment of a wide range of different local realities and experiences. It also affects the way disasters associated with natural hazards are explained and interpreted.

Dominant understanding and the hazard paradigm

Disasters have long been viewed solely through the lens of natural hazards and have thus been seen as prime concerns for physical sciences such as seismology, volcanology, climatology, geomorphology, hydrology, and meteorology. Up until the mid-twentieth century, the responsibility for the occurrence of disasters that include physical phenomena was therefore attributed to external natural forces or to the whims of angry or vindictive deities.

Rousseau was the first person known to attribute a disaster to human responsibility, in a 1756 letter to Voltaire about the previous year’s Lisbon earthquake and tsunami. However, it was not until the 1940s and White’s (1945) pioneering thesis on people’s adjustments to floods in the United States that the human dimension of disasters began to be widely accepted as part of a broader human ecology body of scholarship. However, although it addresses anthropogenic issues, the human ecology approach has continued to emphasize the contribution of natural hazards and has, in fact, further consolidated the so-called hazard paradigm. This paradigm stresses the importance of extreme (in magnitude) and rare (in time) natural hazards that exceed people’s ability to cope with them. Hazards are thus often considered extraneous to people and societies.

The extraneous and extreme dimension of natural hazards has led disasters being considered out of the regular social fabric. Scientists, institutions, governments, and media thus often mention extraordinary, uncontrollable, incredible, unpredictable, and uncertain phenomena, along with unexpected disasters and unscheduled and unanticipated damage. It is claimed that regions affected are unable to face such forces of nature, and such regions are often considered to be underdeveloped, overpopulated, uninformed, unprepared, and unplanned. Therefore, a clear border is delineated between regions of the world which are often struck by disasters and those that are supposedly safe. The construction of this divide is facilitated by the homogenizing nature of data available on the occurrence of disasters.

In this context, earth and climate scientists and engineers tend to focus on monitoring, predicting, and calculating probabilities and parameters for extreme natural hazards. In parallel, social scientists, led by geographers following White’s precedent, are interested in how people and societies perceive the potential danger and how they adjust to possible threats (Burton, Kates, and White 1978). Individuals and societies said to have a low perception of risk allegedly adjust poorly to possible threats. Conversely, people and societies considered to have a high-risk perception are assumed to adjust well to natural hazards. Factors that affect people’s perception of risk are hazard-related too (i.e., hazard magnitude, duration, frequency and temporal spacing, plus the recentness, frequency, and intensity of past personal experiences with hazards) and independent of the social environment.

Proponents of the hazard paradigm further stress the range of adjustment options known to those at risk. The larger the array of opportunities people are aware of, the broader their
portfolio of choices to adjust to natural hazards. Choices of adjustment therefore widen with technological progress and wealth (Kates 1971). Poorer people are therefore deemed to be less able to adjust to natural hazards and, in consequence, suffer the brunt of disasters. In many instances, the poor are said to aggravate the impact of disasters by deliberately choosing to live in hazardous areas and contributing to higher population growth, which leads to more casualties should hazards occur.

The study of people’s perception of risk relies on quantitative research methods, including the use of identical questionnaire surveys conducted in different regions of the world, following similar approaches, so that the outcomes are comparable (White 1974). These allow for the design of universal theoretical frameworks such as the choice tree of adjustment to natural hazard, which has been applied from individual to societal levels (Burton Kates, and White 1978). The choice tree distinguishes incidental adjustments to natural hazards from purposeful adjustments, which are further broken down into passive acceptance of losses to actions to reduce losses and initiatives toward choosing or changing land-use or location (Figure 2).

The hazard paradigm is further fueled by the dominant discourse on climate change. Uncertainties around the evolution of climate conditions constitute a powerful argument for considering “nature” as the major threat. Uncertainties are frequently associated with the probability of occurrence of rare and extreme natural hazards which should be addressed through scientific models and statistical probabilities. The contemporary focus on climate change thus reinforces a paradigm where nature is hazardous (even if exacerbated by human activity, as with climate change and many other hazards). In the face of such changing threats, people are expected to adapt to deal with them, which is very similar to the adjustment approach of the hazard paradigm. The vocabulary has shifted from adjustment to adaptation, but the meaning and scientific justification are largely the same.

The hazard paradigm and study of people’s perception and adjustment to natural hazards has provided a major breakthrough in the study of disasters. However, it has been widely criticized for being excessively deterministic, Malthusian, and technocratic to the detriment of the study of underlying social processes that make people vulnerable.

Alternative interpretation and the vulnerability paradigm

The role of natural hazards and people’s perception of associated risk in the occurrence of disasters has been progressively reconsidered since the 1970s through the work of geographers engaged in both political economy and political ecology research. For example, O’Keefe, Westgate, and Wisner (1976) have emphasized the root causes of people’s unequal vulnerability, or their susceptibility to suffer should potentially harmful natural hazards occur. The bottom-line evidence is that there is no disaster which causes all buildings in a particular place to collapse or all people to die. There are always buildings which withstand and people who survive.

Drawing on the precepts of an array of critical theories associated with the works of Marx, Weber and Sen, the proponents of the vulnerability paradigm argue that people affected by disasters are disproportionately drawn from the margins of society (Wisner et al. 2004). They are marginalized geographically and physically because they live in places exposed to natural hazards, which often coincide with locations
with inadequate services and contested tenure (e.g., informal settlers, shacks); socially and culturally because they often are members of minority groups (e.g., ethnic or caste minorities, people with disabilities, prisoners, and refugees); economically because they are excluded from the market (e.g., jobless); and, ultimately, politically because their voice is disregarded by those with political power (e.g., indigenous people, women, gender minorities, homeless, children, and the elderly). Disasters thus most frequently affect individuals with limited and fragile incomes, reducing their ability to deal with natural hazards, notably their ability to choose the location of their home and to invest in protective measures. Vulnerability and marginality also relate to inadequate social protection and limited social networks.

The unequal impact of disasters and people’s vulnerability to natural hazards reflect a lack of access to resources and means of protection. Lack of access does not mean that these resources and means of protection are not available locally. Most often they are available but access is limited.
to those with stronger economic, political, and social positions in society, thus reflecting an unequal distribution of power and opportunities. In cases of extreme marginalization, homeless people, migrants, traveling communities, squatters, gender minorities, lower untouchable castes, and other social groups whose citizenship and identity are legally and/or socially illegitimate, or at least not properly acknowledged through state identification systems, cannot even claim such access. This constitutes a further obstacle to protection and a driver of vulnerability. Therefore, the vulnerability–marginality nexus here goes far beyond poverty to also include issues of age, physical ability, gender, sexuality, race, ethnicity, caste, and religion.

People’s vulnerability to natural hazards varies in time and space and mirrors the nature, strength, and diversity of their livelihoods. The intimate relationship between livelihood and vulnerability explains why many people often have no other choice but to face natural hazards to sustain their daily needs. In many instances, threats to everyday needs, especially to food security, are almost always more pressing than threats from rare or seasonal natural hazards. The difficulty of meeting daily needs can further lead to environmental degradation, which often manifests itself in increasing natural hazards.

For the proponents of the vulnerability paradigm, people’s vulnerability to natural hazards therefore results from their limited ability to control their daily lives. In that context, disasters highlight or amplify people’s daily hardships and everyday emergencies associated with food insecurity, illnesses, fragile shelter, and poverty at large. Thus disasters cannot be considered as accidents beyond the usual functioning of the society (Hewitt 1983). Instead, disasters generally reflect development failures where the root causes of vulnerability have origins in other, usually contextual, development-related crises.

The root causes of disasters are grounded in an array of structural sociocultural heritages and political economy processes working at both local and international scales. These are further explained by deep-seated historical processes, colonial and postcolonial legacies, and powerful ideological frameworks (Watts and Bohle 1993). Ultimately, the root causes of disasters most often lie beyond the hands of those who are vulnerable and suffer.

Understanding people’s vulnerability requires fine-grained studies relying on qualitative, often ethnographic, research methods through undertaking what Chambers (2007) has called “anthropological particularism.” If the outcomes of the growing number of studies conducted under the vulnerability paradigm over the past three decades are not directly comparable, some powerful frameworks have been designed to confront them. The most influential of these is the pressure and release (PAR) framework popularized by Wisner et al. (2004). PAR tracks down the factors of vulnerability from the unsafe everyday lives of those at risk of dynamic pressures and, ultimately, structural root causes (Figure 3).

The foregoing tenets of the vulnerability paradigm constitute a radical departure from previous interpretations of natural hazards and disasters. It has been criticized for putting too much emphasis on the social to the detriment of the natural component of disasters. In addition, many scholars working in industrialized wealthy countries have found it more applicable to the less affluent regions of the world, where this approach emerged in the first place. In its early years, the vulnerability paradigm was also challenged for overly stressing people’s weaknesses to the detriment of their intrinsic capacities to face natural hazards and disasters.
From vulnerability and suffering to capacities and actions

Those who are vulnerable to natural hazards are neither “victims” nor helpless in time of hardship. They always display some form of ability to face threats and disastrous situations. Late in the 1980s, practitioners coined the term “capacities” (Anderson and Woodrow 1989). Since then it has been widely used through the practice of vulnerability and capacity analysis (VCA) – a core dimension of many DRM projects derived from Anderson and Woodrow’s framework for assessing vulnerability and capacities. However, the concept itself (not in association with other concepts such as in the expressions “adaptive capacity,” “capacity to resist/to face/to recover,” etc.) has been poorly defined in the academic world. Only recently have geographers pushed for its consideration in order to balance the sole negative dimension of vulnerability.

Capacities usually refer to the set of knowledge, skills, and resources people resort to in dealing with natural hazards and disasters. These capacities include, for example, kinship...
and solidarity networks, remittances, traditional medicines, vernacular architectures, experiences and knowledge of past hazardous events, traditional water management, hazard-resistant crops, knowledge of biodiversity resources, ability to hunt and fish, local leadership, and flexible decision-making processes. Figure 4 organizes these forms of knowledge, skills, and resources into arbitrary categories associated with particular strategies and outcomes when confronted with natural hazards and disasters. The concept of capacity further encompasses the ability to claim, access, and use these knowledge, skills, and resources.

Importantly, capacities are not the opposite end of vulnerability on a single spectrum, because highly vulnerable people may display a large array of capacities and vice versa. In fact, while the root causes of vulnerability are largely exogenous to those at risk, capacities are often rooted in resources which are endogenous to them. They are often the extension of everyday practices and roles within the society rather than extraordinary measures taken to face rare and extreme events.

The concept of capacities ultimately recognizes that those at risk take actions in facing natural hazards and disasters. In fact, they are often considered as the first line of responders. In times of disaster, outside assistance arrives, at best, hours or days after the event even though it is well known that the initial few hours are crucial in saving lives and livelihoods. Evidence collected by sociologists suggests that a very large majority of postdisaster survivors are rescued by their friends, kin, or neighbors who are on the spot at the time of an event and who rely on local knowledge and available resources and skills (Quarantelli and Dynes 1972).

Although the increasing emphasis given to people’s capacities emerged as a spin-off from the vulnerability approach and has not led to the emergence of a new paradigm per se, it still marks a significant evolution in the study and understanding of natural hazards and disasters. Because they are often embedded in people’s everyday life and culture, capacities are difficult to apprehend for outside researchers and practitioners. For this reason, the analysis of capacities has largely relied on participatory approaches led by those at risk along the line of what Chambers (2007) calls participatory pluralism, which includes tools, methods, attitudes, and behaviors geared toward fostering the contribution of a large array of diverse and usually excluded local actors in analyzing and finding solutions to problems which affect them.

Yet, much research has still to be conducted on the concept of capacity. Its contours have to be more clearly defined, notably in the context of other cognate concepts. Capacities indeed relate to the concept of subculture put forward by sociologists in the 1960s and the 1970s. Disaster subcultures include cultural patterns existing in particular places for overcoming social and nonsocial problems associated with natural hazards and disasters. Disaster subcultures guide the behavior of individuals and groups before, during, and after the occurrence of natural hazards. The ways in which capacities are mobilized in times of crisis also reflect coping strategies. Coping strategies refer to the manner in which people use available resources to overcome the unusual and adverse conditions of a disaster. Capacities also relate to many interpretations of the broader and controversial concept of resilience, which is increasingly used to similarly emphasize people’s ability to face natural hazards and disasters.

Reducing the risk of disaster

Since the early work of White in the 1930s and 1940s, geographers, more than any other
social scientists, have committed themselves, and significantly contributed, to enhancing policies and practices of DRM, in particular risk reduction, at all scales (Wisner, Gaillard, and Kelman 2012). Recognizing natural hazards as well as people’s vulnerability and capacities is essential for reducing the risk of disaster. In principle, risk reduction must therefore include...
actions to address the root causes of people’s vulnerability as well as initiatives to enhance their capacities. Because these are, respectively, largely exogenous and endogenous to those at risk, risk reduction requires actions from both the outside (or from the top down) and inside (or from the bottom up). Actions from the outside should be geared toward granting access to resources to those who are vulnerable as well as strengthening their everyday livelihoods. Actions from the inside should facilitate and improve the utilization of local knowledge, resources, and skills. In parallel, risk reduction should also consider actions to prevent hazards from occurring or, should they occur, ensure that they do not reach neighboring settlements nor affect people’s livelihoods. These could be both initiated from the inside and outside through bottom-up and top-down initiatives.

Risk reduction should therefore be an integrative process involving a large array of unequally powerful stakeholders active at different geographical scales (Gaillard and Mercer 2013). These stakeholders should include people at risk including the most marginalized, schools, faith groups, local governments, nongovernmental organizations (NGOs), scientists, the private sector, national governments, and international organizations. The role of both those at risk and governments is crucial. Disasters are local events which first and foremost affect local people. No one is, therefore, more interested in reducing disaster risk than those whose survival and wellbeing are at stake. Meanwhile, achieving large-scale outcomes requires appropriate institutional frameworks at the state level and the wide and thoughtful implementation of these by local governments. Internationally, these have been timidly recognized by policy guidelines such as the Hyogo Framework for Action 2005–2015 (titled “Building the Resilience of Nations and Communities to Disasters”) and the most recent Sendai Framework for Disaster Risk Reduction 2015–2030.

In practice, however, the policies and practices of many countries and actors reflect the influence of the hazard paradigm. These policies and practices are primarily geared toward the extreme and rare dimensions of natural hazards and often reflect strategies designed to organize battles in time of war. Indeed, in many countries, disaster policies are handled by the army or civil protection institutions, which rely on military chains of command and treat natural hazards as enemies to fight against. Most often these actions, designed at a global scale, include specific, technocratic, command and control measures such as engineering structures to control natural hazards, technology-based monitoring and warning systems to anticipate the occurrence of hazardous events, hazard-based land-use planning, and unilateral risk awareness campaigns. Such frameworks further rely on top-down transfers of knowledge, technology, and experience from the wealthiest and most powerful regions of the world, which are supposed to be safer because of their larger technological and economic resources, to poorer and less powerful regions, which are considered more vulnerable. These policies and practices draw on the abrupt and overgeneralizing geography of risk, opposing the safe North to the dangerous South (Hewitt 1983). Throughout history, wealthier countries have thus developed policies to assist poorer countries in addressing disaster-related issues because of the latter’s alleged inability to cope on their own (Bankoff 2001).

These dominant, hazard-focused, policies have largely failed to address the root causes of people’s vulnerability. The command and control nature of these frameworks does not yield easily to the amorphous and contextual dimension of people’s everyday life and vulnerability, which requires continuous attention and investments
rather than punctual consideration and sporadic allocation of resources. In consequence, the dominant strategies to reduce the risk of disasters have given paramount importance to large events to the detriment of smaller disasters, thus overlooking a large component of people’s hardship.

Alternative initiatives emphasizing local actions, following bottom-up frameworks, emerged in the 1970s and eventually spread widely in the 1980s and 1990s under the impetus of an increasing number of NGOs and other civil society organizations. These have been referred to as “community-based disaster risk reduction” (CBDRR) by policymakers and practitioners. CBDRR fosters the participation of those who are vulnerable according to both the evaluation of disaster risk and in ways to reduce it. It aims to empower those at risk with self-developed and culturally, socially, and economically acceptable ways of dealing with natural hazards (Maskrey 1989). It relies heavily on participatory learning and actions (PLA), which include all approaches, methods, and attitudes designed to empower those at risk to share, analyze, and enhance their knowledge of disaster risk and to plan, implement, monitor, assess, and reflect toward risk reduction. CBDRR thus gives prime importance to people’s capacities and preparedness in facing possible events through the design of early warning systems as well as evacuation and crisis management plans.

More often than not, CBDRR activities have had only a limited impact on reducing people’s vulnerability, which largely lies beyond the scope of such projects. In some extreme cases, the proponents of CBDRR reject all support from the outside/top down. In addition, vulnerable people’s participation in risk reduction is often skewed to serve the interests of outside actors who need to justify the involvement of local people in activities they have designed beforehand.

In such instances, participation is often conceived as an outcome that is accountable to Western funding agencies, rather than a process where accountability is downward to those at risk.

Ultimately, it is difficult to integrate the needed and positive outcomes of actions from the inside or the bottom up with initiatives from the outside or the top down. This gap is considered a major impediment to sustainable risk reduction. It reflects difficulties in appraising and integrating different forms of knowledge, resources, and skills as well as the continuing dominance of technocratic institutional frameworks, and a scarcity of appropriate tools to foster dialogue and establish trust between all stakeholders. Dialogue and trust are essential for all diverse stakeholders to recognize, value, and integrate the vulnerability and capacities of those at risk, and to make sure that actions to address and enhance these are integrated. Most of those who are vulnerable, including the most marginalized, know what their needs and resources are in facing hazards and disasters. The issue for these groups is usually to make their vulnerability and capacities tangible and recognized by others. In that sense, they should interact with those with power in the larger society, otherwise risk reduction initiatives remain clustered and fail to address the unequal power relationships which lead to disasters.

Postdisaster reconstruction and further opportunities to foster risk reduction

Should risk reduction policies fail and disasters occur, the subsequent process of reconstruction is often expected to provide further room for reducing the risk of future disasters. Opportunities for risk reduction following disasters are said to stem from increased awareness of disaster risk which opens a window for change. It is
therefore recommended to “build back better” (Lyons, Schilderman, and Boano 2010).

Christoplos (2006) identifies pathways which, in theory, favor positive change toward risk reduction in the aftermath of disasters: (i) disasters usually enhance individuals’ and the whole society’s perception of the risk associated with natural hazards, thus providing space for critical reflection on the causes of disasters; (ii) disasters thus often reveal the shortcomings of past development strategies and may lead to a better understanding of the underlying factors of disaster risk; (iii) disasters expose institutional weaknesses such as corruption, lack of human resources, and weak institutional structures, as well as weakening and discrediting those actors whose actions have contributed to creating disaster risk; (iv) in consequence, there usually is a stronger political will for change in the aftermath of disasters; (v) disasters clear away weak and vulnerable infrastructure and create the opportunity to construct stronger buildings; (vi) the frequent influx of financial and other resources which immediately follows disasters often prove important for initiating large-scale reconstruction.

Unfortunately, there is very little available evidence of postdisaster reconstructions which have actually significantly reduced the risk of future disaster. Most often, greater attention is given to short-term needs such as shelter, food, water, and sanitation over longer-term risk reduction. This gap largely results from postdisaster DRR planning allegedly requiring time and outside expertise to implement, whereas meeting survivors’ immediate needs supposedly entails quick, pragmatic, and straightforward actions. In fact, to meet large-scale short-term needs as quickly as possible, postdisaster reconstruction often relies on centralized and top-down policies which overlook day-to-day, collaborative, small-scale actions and local resources which are essential to risk reduction.

Overcoming this gap, again, requires integrating both actions from the outside/top down and initiatives from the inside/bottom up. Rebuilding following a disaster is often considered a long-term process, especially if it is to foster DRR and especially where it relies on external intervention, which requires often lengthy preliminary needs assessment and careful planning. However, a quicker alternative is to rely on local resources, knowledge, and skills, that is, those of affected people and institutions. Local actions need to be supported by appropriate initiatives from outside stakeholders for tasks which cannot be achieved by relying solely on local resources, for example clearing massive debris and reconstructing stronger large infrastructure, including scientific knowledge of hazards.

It is widely acknowledged that three key pathways facilitate the integration of actions from the inside/top down and from the outside/bottom up following disasters (Alexander et al. 2007). First, it is recommended that reconstruction begin immediately after the disaster, simultaneously with relief operations. Rebuilding should also be designed to balance change, which is critical to integrate DRR, with continuity, which is essential to ensure that the links between people and their territory be maintained, thus accelerating the recovery process. Too much change requires time and resources which are often unavailable locally. In this view, geographical relocation away from hazard-prone areas has often failed to foster the recovery of affected people. Integrating bottom-up and top-down actions toward DRR also requires decentralized, flexible, and straightforward decision-making processes. For this reason, the creation of centralizing superstructures dedicated to postdisaster reconstruction, which has frequently followed large disasters, has proved a hindrance for integrating local knowledge, resources, and skills.
NATURAL HAZARDS AND DISASTERS

Following these pathways toward risk reduction proves difficult when reconstruction is planned ad hoc following a disaster. Pre-disaster reconstruction planning is an alternative currently pursued by some local governments. It facilitates the mutual integration of reconstruction within risk and risk reduction within reconstruction, and a concurrent shift from a sequential approach to risk reduction and disaster reconstruction to a more holistic model of DRM which aims to transform development trajectories in line with a more sustainable future.

Future research directions for enhancing disaster risk management

The study of natural hazards and disasters has become a major component of geographical research. The field has grown so large and diverse that, since the mid-1990s, the initially clear divide between the hazard and vulnerability paradigms has become blurred. Some even suggest the emergence of a third, hybrid paradigm fostering the integration of natural hazard research, risk perception inquiries, and vulnerability studies.

Currently, people’s vulnerability, as well as their capacities, are often considered from a taxonomic and quantitative perspective in direct relation to natural hazards though the use of related concepts such as exposure (to natural hazards) and indicators like demographic data. Such an approach to natural hazards and disasters is much less grounded in geographical and broader social theories. It increasingly relies on the use of tools like geographic information systems (GIS) and remote sensing.

In addition, more recent scholarship regarding climate change and its impact on people and societies, which borrows many concepts from natural hazard and disaster studies, has emerged as a parallel stream of research. In this context, the long tradition of natural hazard and disaster research within geography and cognate social sciences has to be acknowledged so that climate change studies does not simply reinvent the wheel. This is of particular importance in the context of policies and practices of climate change adaptation, which are increasingly considered in tandem with DRM. The integration of both streams of research, policy, and practice is one of the major challenges of the coming decades in the aim to foster sustainable development.

The concept of resources occupies a major place in understandings of human environmental relations. Etymologically related to the Latin resurgere, meaning “to rise again,” the term “resource” conveys a sense of (re-)empowerment and opportunity, but also dependence and vulnerability. Without a resource, one may not be able to stand back up after falling. This fear is often reinforced by adjectives attached to resources, such as “critical,” “vital,” “crucial,” “national,” or “strategic.” Frequently deployed in mainstream geopolitical narratives of “resource wars,” these adjectives cast resources as the condition of (continued) “civilization” over which competing groups are bound to fight. Resources vary in their spatial location, relative abundance, physical characteristics, technologies of extraction and transformation, use, social and environmental impacts, and economic value. Resources and their relative availability or scarcity are, in other words, both (physically) material and (socially) relational. A simple example is diamonds, for which desirability, scarcity, and high prices are more functions of cultural construction and corporate control (by companies such as De Beers) than of intrinsic physical properties. Resources are also understood as objects influencing social relations. Such an idea does not mean ascribing a fixed and deterministic sense of agency to resources; oil itself does not declare war. Rather, it is about recognizing what Arjun Appadurai (1988) calls “the social life of things”: that resources both reflect and contribute to material cultures. Demand for resources is driven not simply by human needs but also by the social practices that resources, as objects, enable and influence. Similarly, human conflicts differ widely, and violent forms of conflicts include acts not simply of physical violence, but also of structural and symbolic forms of violence. As such, talking of “natural resources and human conflict” is problematic: first, because it reproduces a dualism between natural and human categories that fails to acknowledge the intrinsically social dimensions of resources, even if these are not obviously socially “produced” in the ways crops (“domesticated nature”) and manufactured goods (“transformed nature”) are; second, because it can deflect attention from human conflicts against nature — not simply the numerous environmental impacts of wars, but also the violence perpetrated against ecosystems by everyday consumption and through a prevalent utilitarian perspective of the nonhuman treating it solely as a “resource.”

**Historical perspectives**

Natural resources have long attracted attention in the study of human conflicts; accounts of resource plunder and destruction within war narratives date back to at least 3600 BCE. From a historical perspective, scholarly studies of resources and early warfare in preagricultural societies have largely focused on the role of material self-interest, the forms of conflict, the organization and the sedentarization of social groups, as well as the relative availability, density,
and predictability of resources. Ethnographic, archaeological, and evolutionary and comparative social ecology studies associate early warfare with the territorial control of abundant resources (mostly food) and uncertainty about resource access. Contrary to neo-Malthusian narratives, higher population densities and resource abundance would result in territorialization, with conflicts over resources occurring as a result of trespass or intrusion, while resource scarcity and low population densities would result in mutually beneficial cooperation rather than conflict. The transition to agriculture and exploitation of resources that reshape relations between human groups and the “natural world” are often understood as one of the main factors in the frequency of warfare. In common with the classical period, contemporary Western geopolitical perspectives on resources have been dominated by the equation of trade, war, and power. Following gold-focused conquest, colonial plantation economies of tropical slave-produced commodities became the core of Western imperial extension. Duties on sugar, tobacco, cocoa, cotton, coffee, and opium provided “modernizing” states with the finances to open up new markets through warfare. Since sea power itself rested on access to timber, naval timber supply became a critical preoccupation for major European powers from the seventeenth century onward, a situation comparable to the case of oil in the twentieth century. Given the strategic role of resources, concerns for resource scarcity and war received considerable attention from contemporary scholars such as Malthus, who saw “vices of mankind and able ministers of depopulation” usefully staving off (rather than resulting from) food scarcity.

The importance of resource flows for industrialization and militarization – most notably coal, iron, and later oil – reinforced an ideology of resource competition between European powers, found notably in the flurry of studies over access to raw material distribution during the first half of the twentieth century, and especially between the two world wars (Westing 1988). The growing assertiveness of “Third World” states during the 1960s and 1970s transformed the political landscape of sovereignty over natural resources and provided a (new) twist on ideologies of resource wars, with, for example, some Arab states leveraging their oil production in the form of an export embargo against some pro-Israeli states.

By the 1970s, broader geopolitical conceptualizations of security incorporated issues such as population growth, environmental degradation, and social inequalities in poor countries. The ensuing concept of “environmental security” came about to reflect ideas of global interdependence, illustrated through the debates on environmental “limits to growth,” political instability supposedly caused by environmental scarcity in the South, and more recently the consequences of climate change. The concept, however, represented for some a skewed and controversial “securitization” of environmental issues, calling for “military” and “international development” solutions, and constructing biased identities and narratives of endangerment in the Anthropocene that often blamed the poor (Dalby 2009).

With the end of the Cold War, a view emerged that violent scrambles for resources among local warlords, regional powers, and international actors were a major feature of contemporary conflicts, particularly given the supposed declining role of ideology in regional or local conflicts. Preoccupations with (militarized) “resource supply security” resurfaced again as commodity prices rose after 2002. China challenged US hegemony, and relations with resource-exporting countries became (selectively) rearticulated in the context of the “war on terror.” Most
contemporary accounts of resource wars are associated with a combination of rapidly increasing demand for raw materials, growing resource shortages, and contested resource ownership (Klare 2008). Many accounts of resource wars tend to pathologize conflicts and politically delegitimize protest and popular (armed) resistance, to criminalize small-scale mineral exploitation by local communities and regional migrants, undermining both livelihood coping mechanisms, and to prioritize certain types of economic growth (such as large-scale mining or logging) over local livelihoods and environmental practices.

Main explanations

Mainstream accounts of natural resource and human conflicts have thus relied on two often intertwined explanations. The first explanation views resources as a motivational factor for human conflicts. Raiding, looting, pillaging, grabbing, capturing, annexing, and conquering all carry a sense of violent dispossession and appropriation of resources. Such a motivational dimension can be mistaken for the consequences of social behavior during or after the conflict; state-led military annexation and house looting by individual soldiers are both violent dispossession, but they differ in scale, intentionality, means, and outcomes. The second explanation is that some resources are crucial factors for the conduct of warfare itself, which thereby achieve “strategic” status. Resources that are strategic for warfare have long preoccupied military planners, notably through anticipating wars to obtain control over those resources. In the extreme, a war would be “pre-emptively” conducted to access resources necessary for warfare. Accessing such strategic resources and denying access to potential enemies have constituted one of the many “great games” of military strategists. But the strategic and security dimension of a resource needs to be considered in light of the corporate interests that can motivate or at least benefit from such association. These two main explanations – resources as loot and resources as military means – continue to dominate much of the media, policy, and scholarly literature on resources and human conflicts, mostly through conventional geopolitical perspectives which define resource wars as armed conflicts revolving around the control of “critical” raw materials. To paraphrase the Prussian war thinker Carl von Clausewitz, resource wars are, from this perspective, the continuation of resource politics by military means. Mostly used in reference to interstate conflicts over the control and supply of “strategic resources,” the concept gives way to a narrow and militaristic notion of “resource security” (and in particular “energy security”). The term also became widely used in the application of the metaphor “trade wars,” such as in the examples of bananas or wheat. Finally, the term has been applied to describe popular struggles against large-scale resource exploitation projects and neoliberal reforms in resources and in public utility sectors.

Four main theoretical perspectives have conceptualized natural resources and human conflicts relations (Korf 2011). The first is Hobbesian, and conceptualizes resource conflicts as rational individualism in the absence of authority. From this perspective, life in the state of nature is not only “solitary, poor, nasty, brutish and short”, but also centered around competitive zero-sum game resource grabs. The second is neo-Malthusian, which combines the Hobbesian perspective with the anxieties of early urbanization, industrialization, and democratization to view “modern” progress and demographic growth as overtaking nature’s pace and resulting in scarcity-induced resource conflicts. The third
is positivist and suggests that resource opportunities affect conflict feasibility. Here *homo economicus* rationalizes the losses and gains of conflict over resources. Finally, the Schmittian perspective views historically complex identities reified in part through resource conflicts, whereby resources and conflicts over resources come to constitute identity narratives and to reproduce conflicts. The neo-Malthusian perspective has by far received the most attention within geography. David Harvey (1974, 256) warned of the “profound political implications” of supposedly ethically neutral scientific discussions of the population–resources relationship, especially a projection of neo-Malthusian views that invited “repression at home and neo-colonial policies abroad.” Contemporary debates about natural resources and human conflict mostly use three distinct yet overlapping concepts to capture different facets of resource-related conflicts (Le Billon 2012). First, the *resource curse* argues that resource wealth and dependence makes a society more vulnerable to conflict by weakening governing institutions, reinforcing authoritarianism, and undermining economic performance. The second, *resource struggles*, suggests that resource control and exploitation tend to increase the risk of conflict, including through competition, dispossession, and grievances over access and control of natural resources, and the distribution of costs and benefits from their exploitation. The third, *conflict resources*, recognizes resources as providing the financial means to sustain armed conflicts and potentially motivating belligerents to pursue hostilities. Overall, resource sectors may contribute to shaping greater vulnerability to, risk of, and opportunities for armed conflicts, most notably high-value resources exploited in resource-dependent countries already affected by ethnoreligious divides.

**Political ecology contributions**

In contrast to most studies focusing on the material characteristics of resources and their relative scarcity or abundance, anthropologist Arturo Escobar (2006, 9) has rightly pointed at the importance of accounting for cultural differences in explaining resource-related conflicts, for “many communities in the world signify their natural environment, and then use it, in ways that markedly contrast with the more commonly accepted way of seeing nature as a resource external to humans and which humans can appropriate in any way they see fit.” In this respect, political ecology approaches have emphasized contextualization and multiscalar relations, pointing also to the specific material and social dimensions of resources. Yielding nuanced and historically grounded analysis of uneven power relations and conflicts around natural resources, political ecology approaches seek to understand violence “as a site-specific phenomenon rooted in local histories and social relations yet connected to larger processes of material transformation and power relations” (Peluso and Watts 2001, 5).

As such, political ecology approaches make several contributions. First, it reconceptualizes scarcity, abundance, and dependence both historically and spatially, by considering how uneven power relations and resource entitlements reflect the antagonizing effects of conflicts on social identities, and by demonstrating how violence reshapes conditions of access and control over resources. Second, it questions not only at which location, but also at what scales, conflicts are occurring, and recognizes the chronic and multiscalar character of many resource-related conflicts. Third, it gives greater attention to both the material and the discursive dimensions of ecological processes and resource sectors, notably the “regimes of truth” that sustain and
seek to legitimate resource-based processes of capitalist accumulation (notably “accumulation through dispossession” in the form of enclosure of commons and other exclusive rights of access). Fourth, it accounts for a broader range of violence than geopolitical and political perspectives, thereby understanding different types of conflicts and multiple forms of violence. Fifth, it recognizes resources as a material object influencing sociomaterial practices, and as a social subject endowed with a set of character(istic)s through “spokespersons” such as campaigners, local communities, or resource companies granting them a voice; this combination of material enablement and social voice constitute a form of (indirect) agency, as recognized in the concept of the actant, from the perspective of actor-network theory. Sixth, it connects temporal and spatial realms, notably through site specificity and multiscalar analyses between resources and conflicts, helping to identify connections, actors and their motivations, and power relations – political ecology approaches allow for some degree of accountability beyond the immediate perpetrators of physical violence. Connections between resources and various forms of violence, in this regard, not only include commodification processes (i.e., how “things” become resources or commodities defined by their use and exchange values), but also fetishization processes (i.e., how imaginative aspects of resource production and consumption affect power relations and associated forms of violence). Many studies of natural resources and human conflicts are moving beyond simplistic conceptions of resource scarcity, abundance, and dependence. Rather, they consider how uneven resource entitlements and patterns of resource exploitation and consumption reflect and exacerbate the antagonizing effects of human conflicts, as well as informing the types of violence that are reshaping conditions of access and control over resources. This suggests mixed methods including historical and political economy analyses, as well as ethnographies of power relations and local perceptions of resources and violence.

Natural resource products are a significant component of the world’s economy. They account for one-third of world traded goods, and their share has been increasing over the last decade (WTO 2013). Natural resource products are particularly important for the least developed economies where they account for 78% of exports and 22% of gross domestic product (GDP) (WTO 2013). Natural resources provide significant nonmarket benefits in the form of ecological services, which are estimated to exceed the total value of the world’s GDP (Costanza et al. 2014). Natural resource development can also be a major contributor to environmental problems such as climate change.

This entry assesses issues and challenges of this important sector of the world economy. Dependency and comparative advantage paradigms and the efficacy of alternative development strategies are assessed. Environmental impacts of resource development are examined and a case study of tar sands development in Canada, which is among the world’s largest resource development projects, is analyzed. The entry concludes by identifying research questions that need to be addressed to better understand the role of natural resources in achieving sustainable development.

Natural resources and economic development

The starting point for understanding the role of natural resources in the development process is the “staple theory.” The staple theory originated with the work of Canadian economic historians Innis and Mackintosh and was developed into a more explicit model by Watkins (1963) and Hirschman (1981) to explain development of regions with a plentiful supply of natural resources. The staple theory bears similarities to North’s export-led growth theory (1955) and to Rostow’s (1960) stages of growth theory.

Staples are defined as natural resources and natural resource-related manufacturing. Traditional staple industries include agriculture, forestry and forestry-based processing such as lumber and pulp and paper, hunting and fishing, mining and mining-related processing, and energy.

Staples stimulate economic development by extraction of the natural resource and by a series of linkages that can be divided into four categories: forward linkages, defined as processing of the natural resources prior to export; backward linkages, defined as the production of inputs such as machinery and infrastructure used to extract the resource; final demand linkages, defined as production of goods and services required to support workers employed in the staple sector; and fiscal linkages, defined as the spending of rent generated by the natural resource.

The fiscal linkage deserves special mention because it is a linkage unique to natural resources.
Natural resources generate rent, defined as a return above normal returns to labor and capital. Capitalized rent is the market value of the in situ natural resource endowment and is a special dividend available to the owners of the resource above what would be generated in other economic development activities. Rent may be received as an ongoing payment tied to the rate of resource extraction or as a lump sum payment for the right to extract an in situ resource.

The rate of development in the staple region is determined by a number of factors that can be divided into endogenous factors under the staple region’s control and exogenous factors beyond the region’s control. An important exogenous factor is the quality and quantity of the natural resource. The quality of the resource determines the cost of extraction, which in turn determines the rate of development and magnitude of rent, while the quantity of the resource determines the longevity of resource extraction. A second exogenous factor is the production function of the staple, which determines the quantity of labor and capital required to produce the product, which in turn determines the linkages. Products such as fish and agricultural products may require little in the way of processing prior to consumption while other products such as minerals and some forestry products may require significant processing. Backward linkages also vary depending on the inputs required to extract and process staples. Another significant exogenous factor is external demand for the staple, which sets an upper limit on the size of the staple industry. World price for natural resources is also largely exogenous, but can be influenced by supply-side cartels such as OPEC (Organization of the Petroleum Exporting Countries).

Endogenous factors affecting the contribution of natural resources to development include resource management policies such as regulations governing the rate of extraction, ownership of the resource, development of linkages, collection and distribution of rent, provision of infrastructure, environmental regulations, and macroeconomic policies such as exchange rates.

The spatial distribution of extraction activities is determined by the location of the natural resource. A distinction is normally made between point resources such as mining and energy that are located in a specific place and diffuse resources such as agriculture and forestry that are spread across larger areas. The spatial pattern of point resources is normally small single industry towns in remote locations, or “fly in” camps if the life expectancy of the resource does not justify investment in long-term infrastructure. The spatial pattern of diffused resources such as agriculture is low-density settlement complemented by a hierarchy of more concentrated urban centers, a pattern that gave rise to central place theory. The spatial pattern of linkages is also determined by exogenous factors such as the production process that determines the optimal economic location of processing. Many forward linkages such as sawmilling, for example, are located close to resource extraction to minimize transportation costs because they are weight-losing activities. Other processing activities such as metal fabrication may be located in larger centers outside the staple region where costs may be lower due to economies of scale and access to other required inputs and markets.

A distinction can also be made between renewable resources that can sustain long run settlements and nonrenewable resources that may not justify permanent settlements. These spatial patterns can change over time with changes in the production function. Agriculture, for example, has experienced increased economies of scale that have led to larger farms and rural depopulation as capital is substituted for labor. Spatial patterns are also influenced by government policies impacting the location
of resource activities such as land-use controls, subsidies, provision of public infrastructure, and other regulations such as policies requiring local processing of natural resources.

Staple theory also helps explain the rise of political and institutional structures and public policy. The creation of countries such as Canada, for example, is often explained by the need to create a larger political unit to control and exploit the vast array of natural resources by building major transportation infrastructure and imposing order and controls conducive to resource extraction. The building of railways, creation of property rights, and the maintenance of social order are all nation-building endeavors necessary for resource exploitation. The location of natural resources is also a major factor stimulating conflict among jurisdictions vying for control of strategic resource deposits (Le Billon 2001).

Challenges of natural resource development

According to staple theory, an abundant supply of staples is an important asset providing regions with a significant advantage in the development process. More advanced regions seeking natural resources can provide demand, capital, technology, and entrepreneurial skills that stimulate more rapid development than would occur in a domestically oriented economy constrained by its internal rate of savings, market, and development capacity. Rent provides an extra return above normal returns to production. Stimulated by external demand and generation of rent, the staple region can prosper and diversify from its initial reliance on natural resources as it passes critical thresholds required to support more advanced industries with higher economies of scale.

Staple theory cautions that development of natural resources can also face inherent challenges that can offset the advantages (Watkins 1963; Auty 1995; Gunton 2003; Ploeg 2011). Development is constrained by the natural limits of the resource base. Nonrenewable resources extraction costs can increase as the most productive resources are exploited. Ultimately nonrenewable resources can run out, resulting in termination of production. Renewable resources can be exhausted by excessive rates of harvesting and, even if they are harvested on a sustained yield basis, extraction is constrained by the upper limit of the renewable resource’s biological productivity.

Resource development is often capital intensive: it requires high fixed costs to develop because the extraction of resources requires expensive geographically fixed investments at the site of the resource and infrastructure such as railways and pipelines required to transport the resource to markets. These “lumpy” and immobile investments create economic rigidity that impairs resiliency of the staple region to adjust to changing market conditions.

The rigidity in staple regions makes them particularly vulnerable to boom and bust cycles that characterize resource commodity markets. Resource booms stimulate a high rate of investment in staples fueled by excessive optimism that stimulates higher cost development, often financed by debt. The boom can create shortages of labor and capital that inflate costs and constrain development of other sectors of the economy. The rise in exchange rates resulting from a resource boom can produce the so called “Dutch disease,” characterized by contraction in nonstaple sectors suffering from reduced competitiveness due to currency appreciation and inflated costs.

The staple boom is followed by an inevitable downturn that can cause long-term economic
NATURAL RESOURCES DEVELOPMENT

stress. Export earnings fall, undermining the viability of high-cost resource development projects and the ability of the staple region to service external debts incurred to finance the investment boom. The recent write-off of $50 billion in uneconomic investments by the world’s major mining companies is a case in point (Koven 2013). The nonstaple sector is unable to compensate for the staple downturn because it has been weakened by the currency appreciation and inflated costs during the staple boom. The result is a legacy of uneconomic surplus capacity and debt that imperils the long-term economic health of the staple region.

Another challenge for staple regions relates to the corporate organization of the resource development. Some staple industries such as farming are smaller-scale locally owned enterprises, sometimes referred to as the entrepreneurial model. But many staple industries are large, capital-intensive, export-oriented industries that can only be undertaken by entities with substantial financial resources and management skills. Consequently, many staple industries, particularly in the energy and mining sectors, are owned and operated by large multinational corporations or state enterprises that control a major proportion of world production. Even the smaller locally owned enterprises may be indirectly dependent on large corporate enterprises that purchase their output. This can impose an additional impediment to development in staple regions because large multinational corporations may be less likely to locate higher-order functions such as processing, management, research and development, and equipment production in the staple region because these activities may already be established in the home location of the enterprise. Large multinational corporations can also extract rent from the staple region by repatriation of profits using intracompany transfer pricing to artificially reduce the export price, thus making it difficult for the staple region to collect rent (Gunton 2003).

The successful development of staple economies is very much dependent on government policies to collect rent and manage development in a sustainable manner. But staple industries are able to use their dominant position in the economy to pressure governments to implement policies to meet the needs of the staple sector, such as subsidizing infrastructure, reducing resource industry royalties, and weakening environmental and other regulations. These policies can retard development by expediting the leakage of rent, increasing the rate of extraction beyond sustainable limits, and impeding diversification by subsidizing the staple sector at the expense of other sectors. Governments may also have a propensity for dissipating rent by funding unsustainable or uneconomic public expenditures at the behest of stakeholders seeking a share of the rent.

Dependency and comparative advantage paradigms

While there is general agreement that natural resources provide advantages and disadvantages in the development process, there is disagreement over the relative balance. This has given rise to two schools: the dependency or resource curse school, and the comparative advantage or what could be termed the resource blessing school (Gunton 2003).

The dependency or resource curse school is decidedly pessimistic about staple-based development. Relying on staples is very risky strategy with a high probability of failure. The comparative advantage school is distinctly more optimistic. It acknowledges the challenges of staple-based growth but concludes that the advantages outweigh the disadvantages. The
comparative advantage school also argues that the problems of staple-led growth have to be compared to the problems of alternative development strategies such as indigenously owned manufacturing and import substitution, which have their own challenges. The conclusion is that regions with a plentiful supply of natural resources should focus their efforts on developing their staple sector. The key to success is not abandoning staples but managing their development properly by implementing policies such as collection of rent and development of economically viable linkages to maximize benefits and overcome challenges.

The debate over the resource curse versus resource blessing positions has spawned a plethora of empirical research evaluating whether natural resources are an advantage or disadvantage. Many studies show a negative correlation between resource dependency and growth (e.g., Auty 1995), while other studies show a positive correlation (e.g., Michaels 2011; Cavalcanti, Mohaddes, and Raissi 2011). The results vary with how development and resource dependency are measured, among other factors. Critics of the resource curse argue that even if there is a negative correlation between staple dependence and growth, this does not mean that slow growth is caused by resource dependency or that there would be more rapid growth if the region did not have natural resources.

While there is no consensus on the validity of the resource curse thesis there is agreement that many countries such as Norway and Canada seem to benefit from staple development while other countries such as Nigeria and Venezuela do not (Torvik 2009; Ploeg 2011). This raises perhaps a more productive focus of research: why are some countries more successful in achieving staple-led growth than others?

According to the research, the key variable determining success is the quality of governance (Torvik 2009; Ploeg 2011). Countries with high institutional quality – defined as clear and stable property rights and low incidence of corruption – exhibit a positive correlation between resource dependency and growth, while countries with a low institutional quality display a negative correlation.

Natural resource development and the environment

With the publication of the Brundtland Commission report in 1987 and the United Nations Conference on the Environment and Development held in 1992, sustainable development emerged as a primary consideration in public policy. The magnitude of the challenge is documented in many “state of the environment” reports such as the UN Millennium Ecosystem Assessment (MEA 2005), which concludes that nearly two-thirds of the world’s ecosystem services are in decline and 10–50% of species are threatened with extinction due to habitat loss and overexploitation.

The environmental damage generated by exploitation of fossil fuel resources is particularly well documented. The Intergovernmental Panel on Climate Change (IPCC) warns that unmitigated climate change will likely exceed the capacity of the natural, managed, and human systems to adapt (IPCC 2007, 73), while the International Energy Agency’s (IEA) 2011 World Energy Outlook concludes that the status quo policy regime will result in an increase in average world temperatures of 6°C, well above the 2°C target adopted by the world community in the Copenhagen Accord in 2009. The principal driver of these increases is increased production of fossil fuels, which is forecast to increase 18% for oil, 25% for coal, and 55% for natural gas by 2035 (IEA 2011, 71).
The environmental impacts of natural resource extraction and consumption, combined with the finite supply of natural resources, are dramatically illustrated by Meadows, Randers, and Meadows (2004) who popularized the limits to growth argument by showing through series of computer simulation scenarios that increased consumption would exhaust the world’s supply of natural resources sometime in the mid-twenty-first-century and put undue stress on the world’s environment. The limits to growth argument was criticized for failing to incorporate market adjustments such as improved productivity in resource extraction, development of substitutes, and changes in demand, all of which would occur in response to higher resource prices generated by increasing scarcity (Bardi 2011). Critics cite evidence of general declining resource prices over the last century and increased or constant reserve-to-consumption ratios as indicators that resources are not in short supply. But even the strongest critics of the limits to growth argument acknowledge that there is no assurance that these trends will continue and that at some point the supply of some natural resources may be exhausted. For example, more sophisticated modeling that incorporates prices concludes that oil and natural gas reserves could be exhausted within 35 and 37 years, respectively (Shafiee and Topal 2009). Further, even if world production is unaffected by supply constraints, production will shift spatially as some regional supplies are exhausted, resulting in significant economic dislocation, and pollution generated by unconstrained natural resource extraction will result in significant environmental damage.

Growing awareness of environmental impacts of resource development has resulted in most jurisdictions implementing environmental impact assessment processes to determine if large projects should be built and, if they are built, how the impacts should be mitigated. Governments have also implemented environmental regulations such as emissions controls and harvesting restrictions to reduce environmental impacts. Canada, for example, significantly reduced acid rain caused by sulphur dioxide emissions from its mining sector by the introduction of increasingly strict regulations implemented over the last several decades, and many jurisdictions are implementing regulations to reduce greenhouse gas emissions.

Environmental impacts of resource development have also spawned public opposition from nongovernmental organizations and aboriginal populations impacted by development throughout the world. In Canada, aboriginal populations and environmental organizations opposed timber harvesting by mounting blockades, legal challenges, and international boycott campaigns in the 1990s (Hayter 2003). The conflict, known as the “war in the woods” resulted in implementation of new timber harvesting practices, more than doubling the land set aside for protection and co-management of timber extraction (McGee, Cullen, and Gunton 2010). In North America there is opposition to the expansion of oil and gas production and the building of pipelines to transport oil to market. In Chile, opposition blocked a major power project and opposition in China over the last decade has blocked the massive hydro development along the Jinsha River.

Stakeholder opposition to resource development has given rise to concepts such as free and prior informed consent and social license, which are based on the principle that resource development must have the support of stakeholders as well as government before it can proceed. A specific tool to facilitate stakeholder support for resource development is the impact benefit agreement (IBA), which is a contract between resource development corporations
and impacted populations that specifies terms and conditions of development beyond those imposed by government. IBAs are common where resource development impacts aboriginal populations, and in some countries such as Canada, signing an IBA with aboriginal groups is a precondition for gaining support needed for project approval.

IBAs normally include provisions for financial payments such as royalties to local populations, profit sharing, co-ownership, provision of infrastructure and services, employment training, hiring, purchasing from local businesses, and protection of the environment. Evaluation of IBAs concludes that while there are challenges in developing and implementing them due to inequality in bargaining power, weak enforcement provisions, and uncertainty, they have the potential to increase benefits of resource development (Fidler 2009). IBAs will therefore become an increasingly common tool for managing resource development.

Case study: Canadian tar sands

Issues in resource development are well illustrated by the development of tar sands in Canada, which is one of the largest natural resource projects in the world. Oil production is forecast to increase almost fourfold to 5.4 million barrels per day by 2035, involving a capital investment of $220 billion (US 2011) plus an additional $30–40 billion in pipelines to transport oil to market (Honarvar et al. 2011). The development will entail dozens of individual development projects located across an area approximately the size of England.

Development of the tar sands is the subject of a major debate in Canada between proponents who argue that the development will strengthen the Canadian economy and critics who argue that development will undermine the long-run health of the economy by impeding diversification, degrading the environment, and relying on a risky nonrenewable resource subject to the vagaries of international commodity cycles.

Proponents cite economic impact studies that show that tar sands expansion generates significant economic activity (Honarvar et al. 2011) and increases per capita GDP in the three most resource dependent provinces (Alberta, Saskatchewan, and Newfoundland) by 40 and 60% above the Canadian average.

Critics caution that the tar sands industry is among the most capital intensive, generating only one job per $2 million of production, compared to manufacturing which generates 20 times more employment and the service sector which generates from 20 to 65 times more employment per dollar invested than the tar sands (Clarke et al. 2013). Although per capita GDP is much higher than the Canadian average for the resource-producing provinces, the differences in income are modest because returns to employees are such a small component of tar sands expenditures (Clarke et al. 2013).

Employment impact is further constrained by the failure to develop forward linkages related to processing of oil prior to export. Almost all future tar sands development will produce and export raw bitumen to foreign markets. Therefore, Canada will lose out on refinery processing employment and on many of the backward linkages such as supply of machinery and equipment, much of which will be imported from the US (Honarvar et al. 2011).

Critics also note that the oil sector in Canada is controlled by large multinational firms: the top 10 firms control three-quarters of Canada’s oil production and eight of these firms are foreign owned, including one owned by the Chinese government. Royalties will collect only 35–65% of the rent (Plourde 2010), leaving the rest to be
NATURAL RESOURCES DEVELOPMENT

retained by oil companies as excess profits, much of which will be leaked from the Canadian economy as payments to foreign-owned shareholders who receive almost one-half of Canada's oil and gas industry profits. The integrated structure of firms selling oil to their own refineries creates the opportunity for firms to reduce royalty payments to Canadian governments by discounting the export price using intracompany transfer pricing. Integrated firms transporting their oil to their own existing foreign-located processing assets are also less likely to build new processing facilities in Canada.

Critics also caution that development of the tar sands will distort the structure of the Canadian economy by inflating costs and the exchange rate and consuming capital and labor that could have been invested in other sectors of the Canadian economy. From 2001 to 2011 the Canadian economy gained 16,500 jobs in the oil and gas sector but lost 520,000 in manufacturing (Clarke et al. 2013). Critics acknowledge that there may be many reasons for the contraction of the manufacturing sector, but the evidence shows that a significant proportion of the contraction is caused by the Dutch disease impacts of natural resource development inflating the exchange rate (Clarke et al. 2013).

Critics also identify economic risks resulting from the cyclical nature of oil markets. Canadian tar sands development is among the most expensive sources of oil in the world and many of the current projects are suffering from significant cost overruns. During the current boom, tar sands expansion is growing so rapidly that it is inflating costs and reducing the export price by overwhelming transportation and refinery capacity, creating what has been termed the “bitumen bubble” (Clarke et al. 2013). The problem facing the tar sands is that because it is among the highest-cost producers, it has little capacity to absorb the inevitable fluctuations in oil markets.

Both proponents and critics agree that the expansion of the tar sands development will have significant environmental impacts. Despite regulatory controls that have helped reduce greenhouse gas emissions by almost one-third per barrel produced from 1990 to 2009, tar sands oil remains high-polluting relative to conventional oil (Grant et al. 2013). Greenhouse gas emissions resulting from tar sands development in Canada will increase threefold, from 45 Mt/year in 2010 to 155 Mt/year by 2030 (Millington et al. 2012) thus making it virtually impossible for Canada to achieve its greenhouse gas emissions targets, while other emissions will negatively impact air, land, and water (Grant et al. 2013).

Development of the Canadian tar sands represents the classic staple dependency versus staple advantage debate and there is evidence to support both sides. No doubt the tar sands will provide a fruitful area of research to test competing hypotheses about the role of natural resources in development.

Conclusion

Economically traded natural resources comprise a significant proportion of the world economy, especially for less developed economies, while noneconomic benefits provided by natural resources exceed the total value of the world’s economic production. The evidence suggests that management of natural resources is seriously deficient. Many countries with a plentiful supply of natural resources, that should provide a significant advantage in the development process, experience slower rates of growth than countries without natural resources. Environmental mismanagement of natural resources is particularly worrisome. The majority of the world’s ecosystems are being degraded, and increased consumption of fossil fuels is accelerating the rate
of climate change. The environmental impacts of some resource development projects may be so severe that society could be better off leaving the resources in the ground, thus turning the development paradigm on its head.

These challenges require a fundamental rethinking of management policies to achieve sustainable development. The priority in future research in the resource policy field should be to develop policies to achieve sustainable resource development and to identify strategies to ensure successful policy implementation. Focusing on policy research to collect rents, develop linkages, and mitigate environmental impacts will help ensure that natural resources are a benefit instead of a curse.

NATURAL RESOURCES DEVELOPMENT

Natural resources

Daniel Banoub
University of Manchester, UK

For many people living in the Global North, capitalist society appears liberated from the material world. Economies are now “postindustrial,” with services, technology, and information replacing manufacturing and resource extraction. The natural world is no longer looked to for survival, but as a place of escape from everyday life for recreation. The combined effects of the 2007–2008 financial crisis, a period of rising commodity prices, and the effects of climate change upset this belief. The global economy is still a vast engine based on the appropriation and conversion of natural resources into a range of commodities and by-products.

The reemergence of the “problem” of natural resources, however, is more a question of perspective than reality. For most people outside the West, the “outdated” problems of resource availability and access have remained central to everyday life. The apparent liberation of the postindustrial economy is exactly that: an appearance. Society’s dependence on Earth as a source of material inputs and as a sink for by-products has only deepened over the past forty years. Ironically, the “liberation” of the economy from the material world is a result of the spatial expansion and intensification of resource extraction and use.

The strange combination of dematerialization and rematerialization, at first, appears to be a paradox. How can society be liberated from, yet more dependent upon, the material world at the same time? This seeming contradiction highlights the need for a geographical approach to the study of natural resources. Summed up concisely, the paradox is a product of uneven geographical development. The geography of natural resources is profoundly uneven as a result of a basic fact: natural resources are not evenly distributed across the globe. Even oxygen is scarce at certain altitudes. Therefore, natural resource availability does not map perfectly onto the geography of natural resource demand. This has two consequences. First, the modern economy is dependent upon long-distance flows of natural resources across space. Second, these flows produce an unequal distribution of positive and negative consequences, at a variety of scales. Spaces of dematerialized consumption cannot exist without (often far-flung) spaces of material extraction.

With this in mind, this entry will examine natural resources through the lens of critical human geography. The first section attempts to denaturalize the “natural resources” category. It concludes that natural resources must be considered relational, dynamic, and irreducibly social rather than simply “natural.” The following three sections are organized around the geographical contradiction between fixity and motion and the way it is experienced in three different registers: “stock–flow” and classification, “circulation-accumulation” and political economy, and “territory-networks” and geopolitics.

Denaturalizing natural resources

The term “natural resources,” at first sight, seems self-evident, almost banal. Natural resources are
any part of the nonhuman, biophysical world that satisfy a human want or need. They are most often understood as the raw material inputs that sustain the economy: minerals, fossil fuels, plant and animal life, soils, water, air, wind, and sunlight. Natural resources can also refer to a variety of ecosystem services, such as carbon sequestration, that help maintain the general conditions of life. Natural resources also provide certain noninstrumental uses, such as the aesthetic, spiritual, cultural, or recreational “consumption” of nature. The broad definition of “natural resources,” then, refers to a wide range of entities: a Douglas-fir tree, a plant’s ability to absorb CO$_2$, a resplendent sunset over a tranquil beach, to name three.

“Natural resources” is a blanket term intended to cover the diverse range of human uses of the nonhuman world. Yet, its conceptual clarity rests upon two subtle, yet questionable, implications that emerge from the use of “natural” as an adjective. Nature, as Raymond Williams famously asserted, “is perhaps the most complex word in the language” (1983, 219). It is so complex because it evokes a wide range of meanings. First, “natural” limits the object of inquiry to the nonhuman world, making a strict division between “society” and “nature.” Second, it naturalizes “human wants and needs,” reducing them to a question of supposedly innate requirements. “Resource-ness,” in other words, is assumed to be an intrinsic quality of the nonhuman world, existing unchanged throughout time, simply waiting to be discovered by resourceful humans.

The discipline of geography has played an historic role in developing applied, instrumental forms of knowledge meant to understand, appropriate, and manage the nonhuman world. For natural resource geographers working in the managerial tradition, the “naturalness” of resources is indisputable. Accordingly, they have devised highly technical, expert-based forms of knowledge predicated on treating natural resources as fixed and stable. These forms of knowledge and expertise are easily reconcilable with state administration and capitalist political economy and form the basis of the conventional understanding of nature.

The managerial approach views Earth as ruled by the law of the conservation of mass. Mass (matter or energy) can be neither created nor destroyed. Earth, therefore, is composed of a fixed stock of resources. The abundance or scarcity of natural resources is a geological or biological fact emerging from asocial processes. The managerial approach emerged in the nineteenth century to protect nature from the destructive tendencies of Western industrialization. From the late 1990s, the modern nature conservation movement extended administrative techniques to natural resources, seeking to improve the productivity of nature through its rational and ordered use. These centralized, hierarchical, and scientific forms of knowledge sought to radically reduce the complexity of nature to satisfy human needs. Nevertheless, this radical process of simplification was never fully successful, being resisted by both natural resource users and the natural resources themselves. In response to these failures, natural resource management has been reframed around questions of complexity, uncertainty, and adaptation. Rather than seeking to reduce complexity, so-called adaptive management embraces uncertainty, promoting active learning and continual modification.

In contrast to the instrumental forms of geographical knowledge, there is also a rich critical tradition in geography. This tradition refuses to treat nature as an ahistorical category and takes issue with the two subtle implications of the adjective “natural.” Critical geographers are located primarily in human geography, but also to some extent in physical geography.
They argue that natural resources are anything but natural. In other words, they contend that “nature” and “society” cannot be treated as discrete domains. Moreover, “resource-ness” is not an innate biophysical quality, but an emergent outcome of social and political work. Rather than pre-existing humanity, natural resources are produced socially. This does not deny the existence of biophysical processes and properties that humans refer to as nature. Rather, it argues that they cannot be divorced from the social means through which they are appraised, appropriated, distributed, used, and discarded. As Erich Zimmermann (1933) succinctly and presciently argued: “Resources are not; they become.”

Critical geographers reject the argument that natural resources are fixed, absolute, and asocial. They treat natural resources as dynamic, relational, and irreducibly social. In other words, what counts as a natural resource is seen as a social appraisal with two preconditions. First, there must be a sufficient level of knowledge to recognize, extract, and use them. Second, there must be an economic demand for services they provide. This helps explain why certain bits of the biophysical world slip in and out of the category of “natural resources” over time. For example, whale oil and guano were once highly valuable commodities. Now, they are no longer considered a profitable investment opportunity. “Resource-ness” does not exist in nature as an essential quality, but is a product of social work. Moreover, it is not immutable, but demonstrates remarkable dynamism over time.

Critical geographers, similarly, treat scarcity as contingent and relational. Scarcity is not predetermined by biology or geology alone. Rather, it is a social appraisal of nature that occurs in a specific historical context. A small shift in knowledge, technology, or demand can radically alter perceptions of scarcity or abundance. Oil, for example, is considered the perfect example of the relationship between scarcity and nature. Recent work in the political economy of oil, however, has shown that oil’s scarcity is not a simple function of geology. Rather, it is a relational outcome of social processes, such as the politics of physical access, control, and land ownership and the internal organization of the oil industry. The more pressing historical problem for oil firms has been to produce scarcity in the context of staggering liquid abundance. With this in mind, the recent narrative of “peak oil,” which posits the imminent exhaustion of finite oil supplies, must be taken with a grain of salt.

Natural resources purportedly satisfy human desires and requirements. There are certain biophysical requirements for the sustenance of human life, such as food, water, and shelter. On their own, however, they have very limited explanatory potential. Human “wants and needs” are fluid and ever changing. For example, sweetness is undeniably and innately pleasing. Nevertheless, the human predilection for sweetness cannot explain the role of sucrose in the modern diet. As Sidney Mintz (1986) has shown, the global adoption of sucrose as a source of calories was the result of social power, not humanity’s inherent sweet tooth. Human “wants and needs” are not reducible to biology. Rather, they are constituted socially and display remarkable flexibility across space and time. They are also riven with social differences, making them the site of intense political contestation.

Critical resource geography reframes the instrumental or managerial forms of geographical knowledge concerning natural resources. Rather than developing technical, expert-based management regimes, critical geographers seek to “denaturalize” natural resources. They demonstrate that the “naturalness” of natural resources is an effect of social processes rather than an innate quality. Critical resource geographers
excavate the deeply political character of natural resources. They broaden the scope of analysis beyond the narrowly circumscribed questions of management. They interrogate the more openly political questions of access to natural resources and the distribution of their benefits and waste. Critical geographers, in sum, seek to denaturalize, and thereby politicize, the study of natural resources by arguing that they are dynamic, relational, and irreducibly social.

**Stock–flow and the classification of natural resources**

As mentioned above, the term “natural resources” refers to a wide range of biophysical properties and qualities that humans find useful. Consequently, a number of classification systems have been developed to reduce the complexity of the biophysical world. Natural resources can be distinguished upon a number of axes. For example, a seemingly basic classification would be between biotic and abiotic resources. Biotic resources are living organisms capable of biological reproduction, such as plant and animal life. Abiotic resources are nonliving entities produced by nonorganic physical, chemical, and geological processes, such as minerals, sunlight, and air. This distinction, however, obscures the fact that biotic and abiotic resources are deeply codependent. Radical biologists argue that an organism and its abiotic and biotic environment are inseparable, existing in a dialectical, co-constitutive relationship. The most common classification system is based on the resource’s ability to regenerate. This system distinguishes between nonrenewable “stock” resources and renewable “flow” resources. Geographer Judith Rees (1991) refined this distinction by dividing stock and flow resources into different subcategories. She divided stock resources into three categories. First, those that are consumed by use, such as fossil fuels; second, those that can be theoretically recovered after initial use, which includes all elemental minerals; and third, stock resources that are recyclable with current technology, such as aluminum and gold. She divides flow resources into two categories. First, flow resources that are capable of exhaustion, if exploitation overwhelms regeneration, are defined as “critical zone resources.” Second, flow resources that human activity cannot affect, such as wind and sunlight, are defined as “noncritical zone resources.”

Yet, as Rees pointed out, the dividing line between stock and flow resources is “very fine.” “Conventional thought” justifies it more than biophysical realities (1991, 240). The stock–flow distinction is a function of the timescales over which they regenerate. Oil, for example, is a classic “consumed by use” stock resource. The decomposition of organic matter under conditions of heat and pressure over millions of years produces oil. In other words, the formation of

---

**Figure 1** Classifying natural resources by their spatial characteristics.
oil is a continual process, not a single event. Its exhaustibility is a relation between the rate of underground production and the rate of its extraction. The “exhaustibility” of oil is not an absolute, essential quality of the resource. It is a contingent outcome of the social relations of extraction and consumption. Similarly, many classic “flow” resources (fish, trees, water in aquifers, etc.) are capable of exhaustion. Like oil, this is a relational outcome of the social relations of production, not an essential biophysical quality. The stock–flow distinction is not an absolute division determined by biophysical characteristics. It is more accurately treated as a “resource continuum” (Rees 1991, 241).

Another way of classifying natural resources is around the contradiction between fixity and motion (Figure 1). This method is explicitly geographical. The system is organized around the spatial, temporal, and biophysical properties of natural resources. Some natural resources are mobile; that is, able to circulate freely through space – migratory animals and water are examples. Others are fixed, accumulating in particular locations – think of coal, land, and trees. The biophysical properties of resources – their phase, density, solubility, volatility, and so forth – can make them particularly amenable or resistant to efforts to fix them in place or make them circulate. This distinction is also dependent upon timescales, because what may appear fixed in space may actually be moving when examined over long periods. For example, while trees might be spatially embedded, forests are remarkably dynamic. Finally, the propensity to circulate or accumulate can be remade through technological or economic innovations. For example, the development of refrigeration, steam–powered transport, and canning increased the capacity of animal protein to circulate the globe by overcoming decomposition.

This distinction, moreover, highlights some of the inadequacies of the conventional stock–flow continuum. Oil and coal, for example, are both within the “consumed by use” stock category, yet they display different spatial characteristics. “Light, sweet” crude oil circulates, whereas coal accumulates in sinuous veins. Even within the category of oil – a “catch-all term that covers a diversity of liquid hydrocarbons” (Bridge and Le Billon 2013, 5) – there is a range of spatial characteristics. “Conventional” oil is far more mobile than the bituminous deposits of Alberta. Bitumen is mixed with sand and clay and requires refining before it can flow through a pipeline. In terms of the fixity–motion criteria, coal (stock) and trees (flow) may share more in common than trees (flow) and certain fish species (flow). The geographical lens of fixity–motion highlights similarities between stock and flow resources and dissimilarities within those categories. Like the classification system outlined by Rees (1991), this system is not a succession of fixed categories. Rather, the fixity–motion lens is best characterized as a continuum.

Accumulation–circulation and the geographical political economy of natural resources

The contradiction between fixity and motion permeates the entirety of capitalist political economy. The expanded reproduction of the capitalist mode of production is predicated on the capitalists’ desire to accumulate. This desire cannot be satiated and has no theoretical upper threshold. Their motto is: “accumulation for accumulation’s sake, production for production’s sake” (Marx 1976, 595). Yet, as Marx points out, the capitalist is not a miser. Rather than hoarding their money, capitalists set it free, throwing it into circulation, hoping that, like a true lover, it will return.
Marx distinguishes between “money as money” and “money as capital.” Money simply gathers dust in the miser’s hoard; capital is set in motion. However, to throw capital into circulation in the hopes that an equivalent amount will return would be as “purposeless as it is absurd” (Marx 1976, 251). Thankfully, as Marx notes, “circulation sweats money from every pore” (1976, 208). The circulation of capital is a process of self-valorization, a continual expansion of value. The initial sum of capital thrown into circulation, it is hoped, will return in an expanded form. The accumulation and circulation is characterized by a contradiction between fixity and motion. The desire to accumulate, to hoard wealth and fix it in place, can only be satiated by the circulation of capital, by throwing it into motion.

The dialectical tension between fixity and mobility shapes the dynamics of accumulation and circulation. As David Harvey argued in his book, The Limits to Capital (1982), it also shapes the geographical organization of capitalism. Capital is constantly striving to overcome spatial barriers, always seeking the “annihilation of space by time” (Marx 1973, 539). However, this can only be accomplished through the construction of immobile infrastructures. Circulation requires roads, communication systems, and cities. In other words, capital must be sunk into the built environment, literally fixed in space, to overcome spatial barriers. These built environments are not an everlasting solution to capital’s confrontation with space. Rather, they will at some point become the spatial barrier to be overcome. The contradiction between fixity and motion emerges as one of the driving forces in uneven geographical development. The mutating geography of capitalism is relentless, overcoming certain spatial barriers by creating new ones.

Natural resource geographers have made a significant contribution to geographical political economy. They argue that the materiality of natural resources shapes the organization of production and the geography of capitalism. They do not treat natural resources as a raw material input or a “free gift” of nature. Rather, they argue that biophysical properties constrain, enable, frustrate, and surprise natural resource industries. In other words, natural resources are not just an external limit to extraction. Every obstacle is an opportunity for capital. The exhaustion of wild capture fisheries creates the possibility of farmed fish. The materiality of natural resources actively constitutes the spatial organization of capitalism. Uneven geographical development does not simply produce effects on nature (depletion, pollution, etc.). It is also produced by natural resources.

Natural resources industries are essentially exercises in securing and controlling flow. Humans try to coax resources into the circuits of capital at the optimal rate for human needs, or at least the logic of capital. For fixed resources, the main difficulty is securing flow, bringing fixed deposits into circulation. For mobile resources, the difficulty is controlling flow, harnessing the mobility of nature for human needs. It is important to remember that these tensions and confrontations are not only encountered at the point of extraction. Rather, the tension between fixity and mobility permeates all phases of the circuit of capital. It affects the “upstream” phase of exploration and extraction, the “midstream” phase of storage and transportation, the “downstream” phase of processing, distribution, and consumption, and the “backstream” phase of waste production and assimilation (Bridge and Le Billon 2013, 37). The material properties of resources can either constrain or enable flow. This fact has profound effects upon the uneven geographical development of capitalism.

The propensity to accumulate or circulate provides the foundation for natural resource industries. Yet, ironically, it often emerges as the
central barrier to accumulation. For example, mining companies dream of finding a high concentration of valuable minerals in a limited area. However, the more concentrated and limited the area, the more difficult it is to find it. Factor in the distance from an economic center, and the efficiency of transportation, and the deposit may no longer be profitable. Likewise, water’s ability to flow is the basis of complex irrigation, hydropower, and drinking water systems. Yet, its innate tendency to under- or overflow can have disastrous consequences. Thus, the fixed/mobile character of resources appears as an external limit to accumulation. But, as Marx points out, in the capitalist mode of production, “every limit appears as a barrier to be overcome” (1973, 408). Accordingly, capitalists have devised many technical, scientific, and organizational innovations to overcome these barriers. Take deep-sea fisheries, for example: for a neophyte, finding large concentrations of fish would be like trying to find the proverbial needle in a haystack. Fish have complex life histories and migratory patterns and live in a dynamic environment. Over time, fishers develop refined understandings of the ocean environment, helping them track and extract fish. The development of scientific knowledge around fish biology and oceanography bolsters this traditional knowledge. Following World War II, the fishing industry adopted a range of new technologies. These include such things as sonar, radar, echo-sounders, synthetic fibers, and refrigeration. These technologies increased productivity and encouraged organizational changes in the industry. Large factory-freezer trawlers owned by large seafood corporations now dominate the industry in developed nations. These technical, scientific, and organizational innovations seek to overcome barriers presented by fish populations. They attempt to control fish mobility and regulate the flow of fish and fishery products around the globe.

The point of extraction seems like the most obvious point for examining the materiality of resources. But, as mentioned above, the different stock–flow propensities of resources shape all phases of capital circulation. For example, William Cronon (1991) showed how the steam-powered grain elevator restructured the grain industry. This invention reoriented grain’s distribution rather than overcoming the material obstacles to its production. Before the steam-powered grain elevator, grain shipments traveled to market in sacks by ship. This guaranteed their unmixed and uncontaminated arrival – a slow, treacherous, and labor-intensive journey. The grain elevator increased the scale and efficiency of Chicago’s grain handlers. It was able to move, sort, and aggregate vast quantities of grain. But it had one caveat: grain shipments had to arrive sackless. “Only then,” Cronon argued, “could corn or wheat cease to act like solid objects and begin to behave more like liquids: golden streams that flowed like water” (1991, 113). This transformation in distribution had profound effects on the entire organization of production. Before the grain elevator, legal claims were placed on a particular sack from a particular parcel of land. After, they were placed on a specific quantity of a particular grade of grain. This severed the connection between grain’s movement as a physical object and its movement as a commodity. It also opened the possibility of speculation and a futures market. Both results increased the pace of accumulation. The steam-powered grain elevator secured and increased the flow of grain by turning the fixed properties of the sack into the “golden streams” of liquid grain.

Natural resources, despite our efforts to secure and control flow, are unruly. They have a tendency to frustrate human desires. Consequently, they must be understood as a source of immense uncertainty and surprise. This problem
NATURAL RESOURCES

is not limited to the failure of human systems intended to secure and control flow, such as a flood caused by the malfunctioning of a dam. Surprises also emerge from the very successes of these systems. Industrial livestock and agriculture technologies have overcome some of the barriers to the regular flow of animal and plant products. Yet, they also produce a range of diseases and parasites that threaten the survival and profitability of the enterprises. Intensive open net-pen salmonid aquaculture produces infectious salmon anemia and sea lice. The large-scale pollination of mono-crops by bees leads to colony collapse disorder. Large-scale poultry farms breed avian influenza.

The transition to fossil fuels radically increased humanity’s ability to secure and control flows of natural resources. For millennia, biological sources of energy powered society: water, wind, and muscle. These sources were gradually replaced by fossil fuels – first coal, then oil. Yet the unearthing of vast lithospheric stores of hydrocarbons produced many unintended consequences. They unleashed many uncontrolled and destructive flows and accumulations that threaten the reproduction of capitalist society. The accumulation of CO₂ in the atmosphere is the most obvious, but these flows also occur on finer scales and micro-geographies. The extraction and processing of bitumen in northern Alberta is a good example. Bitumen is an “unconventional” source of oil comprised of heavy crude mixed with sand, clay, and water. Its extraction unleashes a flow of deleterious toxins in the immediate area and downstream along the Athabasca River. Toxins seep into the river through the storage of wastewater in “tailings ponds,” flowing northward to the Arctic Ocean. On their journey they bioaccumulate in plants and animals. More distressingly, they bioaccumulate in the bodies of indigenous people and settlers in northern Alberta. These uncontrolled flows have a predictable and devastating impact on northern, primarily indigenous, communities. For example, Fort Chipewyan has six recorded cases of cholangiocarcinoma, a rare form of bile duct cancer that typically affects 1 in 100,000 people. For a community of 1200 people this is an impossibly high rate. Despite our best attempts to secure and control the flows of natural resources, they will remain a source of surprise, shaping the organization of production and the uneven geography of capitalism.

Territory-networks and the geopolitics of natural resources

In 2008, the US Army Modernization Strategy listed resource demand and population growth as two of the key security threats in the era of “persistent conflict” (US Department of Defense 2008, 6). The US military’s interest in natural resources is based on a seemingly indisputable and pragmatic logic. Earth’s biophysical resources are limited. Thus, the exhaustion of Earth’s resources is inevitable in a rapidly urbanizing world. Fears over the imminent surpassing of planetary boundaries have intensified over the past two decades. On one hand, the problem of depletion, or “peak” everything, is causing fears of scarcity. On the other hand, the problem of pollution and climate change are causing fears of over-abundance. This logic has inspired terrifying visions of the near future. Poverty, starvation, population migrations, and mass mortalities are mere decades, or years, away. In this context, natural resources have reemerged as a central topic of geopolitical calculation. The negative effects of resource depletion and climate change are certainly lamentable. But the more pressing issue for most Western states is the possibility of violent conflict over resources, such as water, food, and energy. They believe that competition...
over natural resources will inevitably produce geopolitical instabilities. The return of natural resources as a geopolitical problem is far from expected. Indeed, the return of geopolitics as a problem at all in the twenty-first century would surprise many people. Swedish political scientist Rudolf Kjellen first coined the term “geopolitics” in 1899. It was the “science” of state security and interstate competition. The discipline viewed the state as an organic entity. Inspired by Darwin’s theory of evolution, states struggled for survival by imperial expansion. By the mid-twentieth century the openly racist and imperialist problem of state competition was reworked. The more abstract notion of “global” competition between the United States and the Soviet Union became the central preoccupation of geopolitics. With the end of the Cold War, the notion of interstate competition seemed outdated in the era of globalization. The “neoliberal” era emphasized uninhibited international trade and investment. In this context, few expected the return to violent nineteenth-century struggle over resources. It is surprising indeed, if not inconceivable.

Recently, conventional foreign policy experts have located an evolutionary transition from geopolitics to geo-economics. Despite this, geopolitical calculation has not been fully eclipsed by a focus on geo-economic flows. The military interest in natural resources demonstrates the continued relevance of geopolitics. Critical geographers have shown that the contradiction between fixity and motion is central to the social geography of power. The desire to fix and defend borders – to bound space and delimit movement – is one of the paradigmatic features of the modern state. Yet, the state is utterly dependent upon transnational flows of information, capital, people, and natural resources. The act of delimiting a boundary recognizes the inevitability of its transgression by movement. A border would be meaningless if no one or nothing tried to cross it. The territorial logic of geopolitics and the market logic of geo-economics are contradictory, but not mutually exclusive.

Many social scientists have shied away from questions of territory in favor of a focus on networked relations. Fixity and stasis appear to define the concept of territory. Moreover, it is rife with sociobiological connotations, positing animals and humans as biologically “territorial.” This is considered homogenizing, even reactionary. In a world characterized by transnational flows and diasporic communities, it is unacceptable. In response, many scholars turn to the concept of networks, focusing on relations, dynamism, and fluidity. Yet, as some scholars point out, territory and networks are not antithetical forms of spatial organization. Rather, they are dialectically related. The spatial organization of power is historically and geographically specific and inherently dynamic. Thus, the tension between the desire to enclose space and to open it up for circulation is one of political geography’s central contradictions.

Natural resources are one of the principal sites over which the tension between territorial fixity and economic mobility is laid bare. This is the result of a rather banal, geographical fact mentioned earlier. The geographies of natural resource availability and demand are not identical. This ensures that states and firms want to enclose the natural resources within their “own” territory. Yet, they also want to ensure that “foreign” resources are available for transnational mobility. In the “neoliberal” era, some argue that the state is losing relevance through privatization and deregulation. Nonetheless, it is far from irrelevant. There is an equally strong tendency toward the extension of state power. The recent saber rattling by the circumpolar states over claims to the Arctic demonstrates this. Politicians
NATURAL RESOURCES

are planting flags and fervently making speeches in an attempt to secure their nation’s access to the potentially valuable oil, gas, and mineral reserves.

The state has not abandoned its historical extra-economic role as an enabler of capital accumulation, but it has been seriously reworked over time. The focus on geo-economic flows and state withdrawal should not lead us to assume that geopolitics and territory are no longer relevant. Rather, it should highlight the centrality of territorial regimes in capital accumulation. Deregulation is better understood as a form of reregulation. The “free” market is never truly free, but operates within historically and geographically specific bounds. Natural resources are embedded in legal, institutional and cultural regimes of nation-states (Bridge 2008). Territorial regimes determine what counts as a resource. They control who is able to access them and what people can do with them. They shape the distribution of their positive and negative outcomes. The “territoriality” of natural resources still shapes the organization of geo-economic flows. The spectacular rise of the Chinese economy has produced a tectonic shift in the global distribution of geopolitical power. For many years, people considered China as a “developing” or “Third World” country. Over the past twenty years, China has emerged as an important player in the global political economy. For many, China’s emergence as global superpower has elicited considerable anxiety. Natural resources are a central concern. China’s unparalleled economic growth, at an average annual rate of 10% over the past decade, is dependent upon a colossal throughput of natural resources. Conventional foreign policy experts frame China as a nascent threat to American hegemony. They consider China a ruthless new competitor in the zero-sum game of geopolitics. China’s insatiable appetite for fossil fuels and raw materials will lead inexorably toward conflict with the West (Cáceres and Ear 2013). Environmentalists argue that China’s industrialization and urbanization is harmful. Powered primarily (70%) by coal, it is unsustainable and destructive. Others criticize China’s authoritarian domestic policies and “business only” foreign policy. China represses internal dissent and does not discriminate against nations with poor human rights records. Taken together, the negative social and ecological repercussions of China’s growth will be on a truly global scale.

China’s emergence as a global power is often framed in solely national terms. China’s internal, authoritarian conditions, however, cannot explain its economic growth. China’s current economy is export-oriented. It would be unthinkable without foreign markets to buy its cheap commodities. China’s quest for natural resources is a result of broader shifts in both Chinese geo-economic strategy and global political economy (Lim 2010). It is not simply an external “threat” to American hegemony, but inextricable from it. In 1978, the Chinese state “opened up” the economy, encouraging foreign investment within China. In the early 2000s, the state shifted to a “going out” strategy. It began to secure natural resources abroad to feed its export-oriented economy. Firms began investing abroad and the state pursued international trade agreements (Gonzalez-Vicente 2011). Chinese capital is increasingly assertive in securing an adequate supply of natural resources. Private Chinese firms are increasing foreign investments. The Chinese state, through its sovereign wealth fund and state-owned enterprises, is following suit. They are developing economic relationships with resource-rich nations in Africa, Latin America, and Asia. Chinese geo-economic strategy has recently shifted toward a spatially expansive quest for
natural resources. This is reshaping the geographies of natural resources and the distribution of geopolitical power.

Natural resources are geopolitical. The political economy of natural resources does not operate in some abstract Cartesian space. The processes of securing and controlling flow are deeply embedded in specific territorial regimes. Moreover, the geographical distribution of value across the circuit of capital is highly politicized. It is a central site of contestation, conflict, and compromise. For classical geopolitics, natural resources are only examined when they cause international competition. Critical “geopolitics,” in contrast, brings attention to the geographical character of natural resources politics.

Natural resources are conventionally defined as any part of the nonhuman world that satisfies a human want or need. Natural resources may be “nonhuman,” but they are not asocial. For critical geographers they are complex social phenomena. The geographical contradiction between fixity and motion helps parse the complexity of natural resources. First, natural resources are often classified in terms of their regenerative dynamics, but the propensity to circulate or accumulate presents another axis of comparison. Second, these propensities in turn help shape the contradiction between circulation and accumulation in capitalist political economy. Third, the geographical dynamics of capitalism are rooted in the geopolitical contradiction between territorial enclosure and transnational flows. Recent shifts in global politics ensure that natural resources will remain at the center of social debate in the twenty-first century.

Nature and corporeality

Bethan Evans
University of Liverpool, UK

Ideas about (bodily) nature are central to understandings of corporeality and, as Castree (2013) demonstrates, questions about corporeality (race, genetics, DNA, food, bioengineering) are central to our understandings of nature. Since the mid-1990s, there has been a significant growth in work within geography on corporeality, stemming largely from feminist work on the body in the early 1990s. Within this work is an inherent tension relating to ideas of “nature” and the nature and materiality of bodies that has, until recently, been relatively undertheorized within geography. Before outlining some of this more recent work, it is necessary first to consider the entrance of the body into geographical scholarship and address the tension at the heart of geographical work on nature and corporeality.

Much Western thought is structured around a Cartesian dualism between mind and body which maps onto a distinction between culture and nature. These dualisms are central to understanding both the historical absence of work on corporeality within geography and the relative absence of work on nature within geographical literature on the body (and vice versa). As Rose explains, these dualisms have historically informed (and, arguably, continue to inform) hierarchies of knowledge production in which the clause considered closer to “nature” (female, body, private, nature) is subordinate to the masculinized clause associated with the mind and culture. Within geography – as a discipline “implicitly structured around the distinction between Nature and Culture” (Rose 1993, 73) – this dualistic thinking meant the exclusion of the body as an object of study and also the exclusion of those associated with nature and the body (along the lines of gender, age, class, sexuality, race, disability) from knowledge production. This is not particular to geography and, as Grosz (1994, 4) observes, is common across Western philosophical traditions where, “Given the coupling of mind with maleness and the body with femaleness and given philosophy’s own self-understanding as a conceptual enterprise, it follows that women and femininity are problematized as knowing philosophical subjects and as knowable epistemic objects.”

Early work on the body within geography therefore drew on and contributed to broader feminist work which sought to demonstrate how, as Haraway explains, the distinctions between pure and applied science and between nature and culture are versions of the philosophy of science that exploits the rupture between subject and object to justify the double ideology of firm scientific objectivity and mere personal subjectivity. This anti-liberation core of knowledge and practice in our sciences is an important buttress of social control. (1991, 30–31)

Both these elements raised by Haraway are important to understanding how geographers have challenged the distinctions between nature and culture and mind and body.

First, feminist work has sought to challenge the “double ideology of firm scientific objectivity and mere personal subjectivity” (Haraway 1991, 30). The exclusion of subordinate groups from
knowledge production was based on claims that those groups are unable to transcend their embodied natures to achieve objectivity (Rose 1993). Modes of knowledge production within the social sciences therefore valorized disembodied knowledges and ideas of objectivity that resemble a “god trick” – a universal view from nowhere and no body. Donna Haraway’s (1991) work on situated knowledges has been central to feminist geographical work which has challenged this. Instead of objectivity being about “the false vision promising transcendence of all limits and responsibility,” Haraway argued for a feminist account of objectivity which is about “situated and embodied knowledges” entailing “politics and epistemologies of location, positioning, and situating, where partiality and not universality is the condition of being heard to make rational knowledge claims … the view from a body” (1991, 340, 342, 349–350). This has involved recognition of the embodied nature of knowledge production through acknowledging the positionality and embodiment of the researcher. In practical terms, this has meant that, rather than writing as a disembodied voice, research has been written in the first person, directly addressing and setting out the position and situation of the researcher in order to write from a situated body. It has also allowed a pluralizing of bodies considered able to contribute to geographical knowledge production, with particular advances in recent years made in children’s geographies, participatory geographies, and geographical work by and with indigenous communities, partly through challenges to previous ideas that these groups, like women, were limited by their bodily natures.

Second, feminist work on the body has sought to highlight and challenge the ways in which the “anti-liberation core of knowledge and practice in our sciences is an important buttress of social control” (Haraway 1991, 30–31). Here, Haraway is referring to the ways in which essentialist and biologically deterministic knowledge claims within the social and behavioral sciences have been (and continue to be) used to justify social positions of domination and subordination for particular bodies and groups. As she explains, “The union of the political and physiological … has been a major source of ancient and modern justifications of domination, especially of domination based on differences seen as natural, given, inescapable, and therefore moral” (Haraway 1991, 30). Early work on the body in geography, as elsewhere in the social sciences, involved a distancing from “nature” and a focus on the body as socially and culturally constructed in order to challenge the subordination of those groups whose capacities were seen to be limited by their corporeal natures. Thus, early work bringing corporeality into geography was “in contrast to the commonsense understanding of the body as completely natural” (Rose 1993, 29). This work has been, and continues to be, important in challenging the subordination of particular groups via essentialist discourses which evoke the “nature” of particular bodies to justify their subordination (see, e.g. Nash 2003 on antiracist geographies, and Wright 2010 on feminist and queer geographies). Critiques of mind/body and nature/culture dualisms also extend to critical work on the normalization of particular bodily performances, forms, and practices through highlighting the cultural constructions and moral knowledges which position some as able to “correctly” control bodily functions, desires, and “natures” (see, e.g., Colls and Evans 2013 on fat).

While work that challenges essentialist accounts of bodies continues to be important, the dominance of social constructionist accounts of bodies in early geographical work on corporeality means there is a tension within geographical work on corporeality and nature. As Longhurst (1997, 489) explains,
Constructionist feminists argue that bodies are discursively produced and that essentialist discourses – that is, discourses which make reference to the physical, biological body – serve to naturalize what is in fact social difference. For constructionist feminists, references to the biological body are seen to reinforce patriarchal claims that women are naturally incapable of certain kinds of action.

Thus, in challenging the hierarchies of those scientific modes of knowledge production which legitimated the exclusion of women, and in challenging knowledge which legitimates the subordination of those groups regarded as inferior with reference to their bodily natures, early geographical work on the body involved a disavowal of the importance of “nature” to knowledge of corporeality. As Whatmore (2002) explains, there is a similar tension between geographical work which adopts constructivist and realist approaches to questions of Nature/nature. It is important to note here, that as Whatmore recognizes in relation to work on Nature/nature, only the “most vulgar” constructivist accounts focus exclusively on linguistic constructions, and early work on the body within geography was similarly not exclusively concerned with representations and discourses at the expense of lived embodiment. Informed by poststructuralist feminist politics, this early work “is interested not just in the social construction or representation of bodies, but also in ‘real,’ material bodies that occupy ‘real’ spaces and places” (Longhurst and Johnston 2014, 270). However, in disavowing claims to bodily “nature,” such work had left corporeal natures relatively undertheorized. In recent years, however, there have been calls to address critically, and in nonessentialist terms, the relationships between nature and corporeality. The resultant work spans subdisciplinary boundaries and is a literature too vast to cover in its entirety here. This entry therefore signposts two

key themes through which nature and corporeality have been considered within geographic scholarship: corporeal natures, and corporeality in/and nature. Before discussing this work, it should be recognized that, in line with the aforementioned work on situated knowledges, this entry is inevitably partial: the choice of and treatment of these themes is shaped by the author’s own position as a feminist geographer who works on questions of embodiment and health.

**Corporeal natures**

Since the mid-2000s, geographers have built on, and moved forward from, a focus on representations and social constructions to address corporeal natures through two related theoretical developments within the discipline more broadly: first, through work broadly referred to as nonrepresentational or more than representational geographies, and, second, through research concerned with bodily materialities. In the first, as Anderson and Harrison (2010, 7) explain, “the bodies which populate non-representational theory are, for the most part, relational bodies; ecological in form and ethological in apprehension.” Through a focus on the ways in which bodies develop habitual relations to others and environments, on precognitive and affective responses to stimuli, and on the role of our senses in shaping the ways in which we encounter the world, this research offers theoretical approaches through which geographers can question corporeal natures in nonessentialist terms. There have been some feminist critiques of this work, centered on the lack of a differentiated body-subject, but, as Colls (2012) suggests, there are productive possibilities at the intersection between feminist and nonrepresentational theories to develop geographical work here further. This range of theories has been influential in many of the areas outlined in this and the following sections.
Second, geographers have built on social constructionist accounts of bodies in ways that are more open to considerations of corporeal natures through attending to bodily materialities and bodily matter. This work draws on broader feminist theory (see, e.g., Grosz 1994) which challenges the dualisms between mind and body, science and the humanities, culture and nature which, while questioned by work on social constructionism, tend to leave the material body still in the realm of the physical sciences. As such, Longhurst (2001) suggested that, while there had, to that point, been significant growth in work within geography on the body, “the bodies articulated in geographers’ texts have tended to be theoretical, discursive, fleshless bodies,” meaning that “the leaky, messy, awkward zones of the inside/outside of bodies and their resulting spatial relationships remain largely unexamined” (2001, 1, 2). Since then, there has been growth in geographical work which does attend to bodily materialities. For example, Colls (2007, 357) explores fat bodily matter, offering a nonessentialist approach through arguing that “both the material and discursive are mutually implicated in the intra-activity of matter.” Other work, which similarly draws attention to corporeal natures through a focus on materiality, includes work on bodily organs and external and internal bodily surfaces (see, e.g., Colls and Fannin 2013 on placental surfaces); research on food which questions the ways in which ideas about “natural” food and “healthy” bodies are culturally connected through foregrounding the matter which crosses bodily boundaries through consumption (e.g., Guthman 2012); work on (the management of) bodily fluids and the porosity of bodies (Longhurst 2001); and research on environmental citizenship which foregrounds corporeal materiality and challenges distinctions between nature and culture through an approach that Gabrielson and Parady term “corporeal citizenship.” This approach “begins from the fact of humans’ inescapable embeddedness in both social and natural contexts and adopts an understanding of the human body as porous but resistant, plural and connected ... [It] highlights the connectivity of the material world across the nature/culture divide” (Gabrielson and Parady 2010, 382; emphasis in the original).

The corporeal in/and nature

Following from the final point in the previous section, the second (related) way in which geographical work addresses corporeality and nature is through considering the ways in which bodies and “natural” landscapes or environments encounter each other. This work is similarly multiple and there is space here only to signal some of the key areas of connection, many of which draw on the theoretical developments outlined earlier.

First, there is a long history within medical and health geography of considering the relationship between bodies and environments or landscapes. This includes work which adopts a disease ecology approach to consider the effects of environmental toxins on health, work which adopts a more socioecological approach to considering the impact of environments on health (e.g., work on obesogenic environments: see Colls and Evans 2013), and work on therapeutic environments (see, e.g., Conradson 2005). Much of this research explores the relationship between corporeality and nature through considering the proximity of particular “natures” to bodies and their effect on health.

However, as Colls and Evans (2013) argue in relation to work on obesogenic environments, bodies, nature, and the relationship between them have been undertheorized within health geography. Similarly, Conradson (2005, 338) argues that work on therapeutic landscapes is limited by “a tendency to frame such settings
as having intrinsically therapeutic properties … to equate physical presence within a landscape with the unproblematic receipt of its therapeutic influence.” There is, therefore, a need to explore more fully the relations through which “natural” landscapes and environments affect health. One possibility might come from engagement with the areas of work outlined earlier: nonrepresentational geographies and corporeal materialities. Here, for example, there is the potential to connect work on therapeutic landscapes with geographical literatures on sensory experiences of landscapes (see, e.g., Morris 2009 on naturalism). Moreover, Colls and Evans (2013) suggest that a combination of feminist and disability theory would be helpful to think in more nuanced ways about the interaction between bodies and socio–natural environments within work on obesogenic environments. Engagement between health geography and work in political ecology offers the further potential to interrogate nature–corporeal relations here.

Second, there has recently been a growth in work within political ecology which pays attention to bodies. For example, Bakker and Bridge (2006) suggest that engagement with literature on bodily materialities might provide a way for research on resource geographies to question the nature/culture distinction without falling prey to essentialism. Recently there have been a range of calls, in particular, for engagement between political ecology and geographies of health. Here, it is suggested that political ecology might provide a means to think critically about the nature–society question within geographies of health, moving away from an approach which breaks health down into its constitutive parts to think instead in more complex and connected terms (Jackson and Neely 2014). For example, Guthman (2012) suggests that political ecology might provide a means to “open up the black box” of the body in geographical work on obesity; and Mansfield (2008) uses the example of childbirth to illustrate the productive possibilities in health geography engaging with research on nature–society. Recent work on the biopolitics of disease (Braun 2007) also offers a more politicized understanding of corporeal–natural relations in health geography.

However, Guthman and Mansfield (2013) have suggested that, while political ecology has made important strides in problematizing ideas of nature, the same critical lens has not been turned to questions of corporeality (Guthman and Mansfield 2013). They suggest that new epigenetic approaches, which explore how environmental toxins and other stimuli affect phenotypical development, may provide a conceptual framework which does more to “open up the black box of the body” here. In particular, they argue that this approach offers a route for geographers to consider the permeability of the body and to think in more complex ways about the active nature of both bodies and environments, moving beyond simple deterministic models. However, as they acknowledge, there are risks here too and, as geographical work develops in this area, critical attention on the politics of such research needs to be maintained, as well as a wariness of any neoessentialist discourses surrounding race, gender, class, disability, and so on which may be legitimized here. Elsewhere, Greenhough (2010) suggests that adopting the concept of ontological politics may be one way to bridge the gap between political ecology, geographies of bioscience, and geographies of health to allow, for example, further exploration of the ways in which new biotechnologies are refiguring ideas of biological citizenship and the multiple ways in which bodies are connected to (nonhuman) others that are relevant for questions of health and health care. Further potential lies in engagements between feminist work on the body and work in
the subfield of feminist political ecology which is drawing on work on corporeality elsewhere in feminist scholarship, to demonstrate the importance of spatial and material ecologies to the lived and embodied realities of gender and race. More broadly, this work is illustrating that political ecology needs to attend to embodiment since “it is frequently at the level of the intimate that national and international power relations are produced and sustained” (Elmhirst 2011a; see also the other papers in Elmhirst 2011b).

Finally, geographical work on corporeality and nature also includes that which explores hybrid and cyborg bodies and our relations to nonhumans. Work here is interested in challenging the distinction between nature and culture in relation to bodies by demonstrating the multiple ways in which our corporeal being-in-the-world is enabled by connections to other humans and nonhumans. There has been a particular emergence recently of geographical work which considers human relations with nonhuman animals. As Buller (2014) explains, the “animal turn” which has occurred in the past 15 years across the social sciences poses particular challenges to human geography. This work not only destabilizes distinctions between human and animal but also between nature and culture, and mind and body, as geographers consider the agency of animals.

Other work which blurs the boundaries between human and nonhuman bodies concerns new geographical work on hybrid and cyborg bodies and on (bio)technologies (Kirsch 2014). Sarah Whatmore’s (2002) work on hybrid geographies is important here. Hybrid geographies, she observes, draw together thinking through space with thinking through the body “by attending simultaneously to the inter-corporeal conduct of human knowing and doing and to the affects of a multitude of other ‘message-bearers’ that make their presence felt in the fabric of social life” (Whatmore 2002, 3; emphasis in the original). Recent work in this vein is at the forefront of explorations of the production of natures and cultures and of what it means to be a (human) body. For example, Davies’s (2006) work on organ transplantation and stem cells addresses questions about the ways in which biotechnology may be framed as being “against nature.” Elsewhere, work that adopts actor-network theory is enabling geographic work which recognizes that humans are produced through their relations with others. Within urban political ecology the concept of the cyborg (defined by Haraway as an organism–machine hybrid) has been adopted in relation to cyborg urbanism, as a way of conceptualizing “the material interface between the body and the city” (Gandy 2005, 28). This work draws attention to the networks of pipes and wires that support and enable urban life. Much work on cyborg bodies refers to Haraway’s work (1991) which, as Callard (1998) reminds us, is about broad questions of human subjectivity in which Haraway (1991, 30) asserts that “Without question, the modern evolutionary concept of a population, as the fundamental natural group, owes much to classical ideas of the body politic, which in turn are inextricably interwoven with the social relationships of production and reproduction.” The concept of the cyborg thus provides one potential means to draw together geographical work in political ecology which questions ideas of “nature” with feminist work on corporeality in order to develop what Haraway (1991, 35) proposes is a socialist-feminist theory of the body politic which avoids biological determinism, recognizing that “neither our personal bodies nor our social bodies may be seen as natural, in the sense of existing outside the self-creating process called human labour. What we experience and theorize as nature and as culture are transformed by our work.”
Ways forward

There is no doubt that work within geography that questions corporeality and nature is some of the most theoretically and empirically exciting and dynamic within the discipline. New approaches in feminist geography, non-representational geography, political ecology, actor-network theory, material cultures, and hybrid geographies offer possibilities for exciting future work which engages with the multiplicity of human and nonhuman actors to question corporeal natures in nonessentialist ways. Geographies that allow a connection between work on nature and on corporeality are, as Whatmore (2002, 7) argues, important to “keep the promise of the geographical craft alive to the creative presence of creatures and devices amongst us and the corporeal sensibilities of our diverse human being.”

NATURE AND CORPOREALITY

Nature conservation

Paul Jepson
University of Oxford, UK

Nature conservation is a label for a cultural and policy movement that encourages societies to reflect upon, engage with, and govern their relationship with the nonhuman world. Approaches to nature conservation differ between countries due to the interplay of a variety of factors. These include cultural traditions of engaging with nature, what people consider natural and the landscapes, iconic species, and practices that shape this, the level of dependency on natural resources, the type of political order, and the time period during which nature conservation has gained high-level policy attention. There are distinct national and regional geographies of nature conservation. However, since the late 1970s these have interacted with an increasingly influential international conservation regime that formulates and promotes common standards for nature conservation. These have found greatest expression in less developed countries that are recipients of loans and aid from multilateral and bilateral government funds.

The origins of nature conservation can be traced to a group of social movements that emerged during the nineteenth and early twentieth centuries in the colonies and cities of Western Europe and East-Coast North America. They were a response to a major unsettling of beliefs on the human–nature relationship interacting with social agendas responding to industrialization, colonialism, and nation-building. Particularly influential were the debates provoked by Charles Darwin’s theory of evolution by natural selection (1851) and the extirpation of superabundant species, such as the passenger pigeon, at the hands of man. The generally accepted view that God created and destroyed the species on Earth was replaced with the realization that species could decline and cease to exist as a result of human actions. Thomas (1991) sees this as one of the great transformations in Western thought and avoiding extinction has remained at the heart of nature conservation ever since.

It is possible to recognize five distinct nature conservation movements that emerged or consolidated during the late nineteenth and early twentieth century. There was however considerable flow between each of them and across space, facilitated by the culture of letter writing during the Victorian era. These movements led to transnational networks of prominent citizens and organizations advocating distinct yet complementary values that manifested in a coherent body of law and actions to protect special sites, forestall extinctions, and govern the exploitation of wildlife and natural resources.

Briefly the social movements were as follows.

1 The wise use movement, which emerged among government scientists in the colonies of Western nations (eighteenth century onwards) tasked with finding economically valuable natural resources and developing new plantation crops. They identified the link between ecological and social systems and promulgated the value that natural resources should be managed for the greatest good for the greatest number in the long term.

2 The amenity or open spaces movement, which emerged in London and Philadelphia (mid-nineteenth century) among social movements.
NATURE CONSERVATION

reformers active on issues such as slavery, animal cruelty, and workers’ rights. They promulgated the values that access to nature and countryside is necessary for the health and wellbeing of urban dwellers, and that free enjoyment of nature is a human right.

3 The wildlife movement, which emerged in New York in the 1890s among an eclectic group of prominent big game hunters who were witnessing at first hand the impacts of human expansion on the American megafauna. They enrolled European big game hunters and together promoted the values that human conquest of nature carries with it a moral responsibility to ensure the survival of threatened life–forms, and that wanton and unnecessary slaughter of wildlife is cruel and barbaric.

4 The Naturdenkmalmovement, which emerged in West European cities (c. 1905–1925) among prominent citizens active in natural history who were concerned about damage to their favored excursion sites arising from clear-felling policies (Germany) and industrial expansion. They argued that aesthetic and intellectual contemplation of nature is integral to the biological and cultural inheritance of many peoples and that monuments of nature should be guarded from ruin in the same way as great buildings and works of art.

5 The wilderness movement, which was led by writers and philosophers in the United States (late nineteenth century onwards) who were active in forging an American cultural identity distinct from Europe. They argued that magnificent landscapes evoking wilderness should be preserved as a symbol of the vigor of the lands of the New World, as places for spiritual, aesthetic, and physical exploration and rejuvenation and as benchmarks from which to assess urban/industrial modernity (Nash 2014).

These values have found varying expression and emphasis over time and in different places. However, their contemporary versions remain evident in nature conservation policy and practice today. Perhaps the most significant value embraced subsequently relates to the rise of consciousness and activism concerning the rights of indigenous people during the 1980s. In 1989 the Coordinating Body of Indigenous Organizations of the Amazon Basin (COICA) called for Western environmental groups to include indigenous peoples in their vision of the Amazonian biosphere. This struck a chord with American conservation nongovernmental organizations (NGOs) at a time when public interest in the plight of indigenous people was growing as a result of the publicity campaigns of groups such as Survival International and films such as John Boorman’s The Emerald Forest. The social value associated with this development is less clearly articulated in histories of nature conservation but might be summarized by the statement that society has a moral duty to permit traditional peoples inhabiting natural landscapes to choose their own destiny in time frames appropriate to their history and culture (Jepson and Ladle 2012).

The concept of nature conservation may have diverse philosophical and political roots but there is a relatively small suite of causes that define nature conservation in the public mind. One is saving a rare species from looming extinction. A second is the fight to prevent unnecessary and wanton slaughter of wildlife. A third is the protection of places with special natural features or spectacles and/or where the human footprint appears light or absent. A forth is the sustainable use and management of natural resources. Household name organizations such as the World Wide Fund for Nature (WWF), The Nature Conservancy (United States), The Royal Society for the Protection of Birds (United Kingdom),
and Natuurmonumenten (Netherlands) trace their origins to one or more of these causes and the conservation movements outlined above.

During the twentieth century, nature conservation interacted with broader social policy and cultural trends that shaped or reasserted national identities; this was particularly so in North America, Europe, Southern Africa, the Indian subcontinent, Australia, and Israel. The timing and nature of these interactions are country specific. For example, UK national park policy was developed in the 1940s as a component of broader policy to create a national health service and assert a national identity more rooted in country than in empire. Similarly, India’s political leaders launched Project Tiger in 1969 to foreground India’s biological heritage as part of a strategy to construct a nationalist frame separate from British imperialism. The point is that nature conservation has many national variants although the geographies of these are yet to be mapped.

Here it is useful to position nature conservation in relation to other domains of conservation with which it overlaps. The two most significant are heritage conservation and biodiversity conservation. Heritage conservation focuses on the protection and care of tangible cultural artifacts such as artwork, architecture, archaeological sites, and museum collections, but extends to include cultural landscapes many of which have nature conservation value. The overlap between nature and heritage conservation is embodied in organizations such as the National Trust (United Kingdom) and international frameworks, notably the 1972 World Heritage Convention.

Biodiversity conservation is a 1990s scientific agenda within nature conservation. Simply put, biodiversity refers to the variety of life on Earth – ecosystems, species, and genes. Biodiversity conservation emphasizes the maintenance of species diversity for utilitarian purposes such as a genetic library for the development of new compounds, as a local livelihood resource, and as the basis for functioning ecosystems that provide services essential for life – oxygen, water, flood control, agriculture, medicine, recreation, and so forth. Nature conservation, in contrast, embodies a more relational value set that aspires to a better quality of life for humans and nonhumans alike (see Table 1).

Nature conservation policy

Nature conservation, in different guises, attained high-level policy attention at least four times during the twentieth century. Over time, nature conservation has interacted with wider policy goals relating to, for example, rational resource management, public health, urban regeneration, poverty alleviation, and sustainability. This has produced complex institutional legacies and served to embed nature conservation in public policy globally. An overview of these different phases of nature conservation is important for positioning contemporary scholarship, policy, and action.

Practices of natural resource management have ancient roots. They have been practiced by traditional peoples and by royal and colonial administrations for centuries. For instance, between 1764 and 1791 colonial powers established forest reserves in Mauritius and the Caribbean that can be regarded as the antecedents of forestry systems instituted in the Indian subcontinent in the nineteenth century. New cartographic techniques developed towards the end of that century produced powerful spatial visualizations of declining forest resources. These reinforced the strategic policy case for natural resource conservation, notably in the United States under the leadership of Gifford Pinchot.
who, from 1905 to 1910, was head of the US Forest Service. Pinchot understood the importance of popular discussion in creating policy legitimacy. He conducted massive publicity campaigns and debated rational resource use with those who opposed commercialization of nature (notably John Muir, a wilderness movement leader). This, together with the wider uptake of such ideas by colonial governments internationally, served to establish natural resource management as a key area of domestic and international policy. Pinchot’s strongly utilitarian framing of nature conservation has dominated in policy and bureaucratic circles since, not least because governmental competencies for nature conservation were initially assigned to forestry or agriculture ministries (e.g., Indonesia, Ghana, Brazil).

The cause of wildlife conservation attained high-level policy attention towards the end of the colonial era, peaking with the 1933 London Convention on African Wildlife. The wildlife movement, which included among its leadership presidents (e.g., Theodore Roosevelt, United States), foreign ministers (e.g., Earl Grey, United Kingdom), royalty (e.g., Prince Leopold, Belgium), and hunter celebrities (e.g., Frederick Courtney Selous), mobilized to avoid the African megafauna suffering the same fate as the megafauna of Europe and North America. They identified three major threats facing African wildlife: the disease rinderpest; market, sport, and subsistence hunting by white settlers; and the expansion of agriculture. Their policy response was the creation of parks and reserves in sparsely populated areas still rich in wildlife. Future human settlement would be limited in order to separate wildlife from disease-carrying domestic stock and for ease of governance (Hingston 1931). The London convention led to the creation of National Parks and wildlife sanctuaries in Africa, and also British India, the Dutch East Indies (modern Indonesia), and, to a limited extent, French Indochina. The guiding nature conservation ethos of this era can be understood as “nature should be protected to be useful, uplifting, indeed ennobling to mankind” (Winks 1997, 14). Nature conservation was an expression of humanity’s ability to rise above the chaos, opportunism, self-interest, and ignorance that had, for example, characterized the frontiers of the American West.

Nature conservation aligned with high-level policy agendas a third time during the 1960s in the context of rising post–World War II affluence and increased mobility and leisure time. Policymakers recognized that the protection of natural and historic heritage was part of building (or reasserting) national and regional identities and that growing urban populations needed space to play. Outdoor recreation linked these and other policy objectives: it catered for all social classes, provided health benefits, and generated urban–rural economic and cultural flows. This was the era of multi-use conservation or “nature development,” which President Lyndon Johnson identified in his 1964 State of the Union address as one of three pillars of his “Great Society” (Whitaker 1976). This policy frame is closely associated with the US National Park model but nature-development policies were enacted in many industrialized countries globally, for example, through the establishment of national, state, or country parks and urban “re-greening” projects. Given the complex interactions of nature, landscape, culture, and politics, the expression of this policy has many national variants. It is most evident in countries exhibiting a combination of progressive social policy, an active civil society, and traditions of nature-based sport and recreation.

The fourth and perhaps most significant era of conservation policy emerged from the interaction of these earlier nature conservation frames with the sudden forces of environmentalism.

The 1970 Earth Day event in the United States signified a profound shift in public consciousness on human–nature relations and galvanized high-level political responses. Until this time urban publics had largely viewed nature conservation as a moral and rational imperative that happened outside cities and did not directly impact on their lives. Popular books, notably Fairfield Osborn’s *Our Plundered Planet* (1948) and Rachel Carson’s celebrated *Silent Spring* (1962), challenged this view by making explicit the links between resource exhaustion, environmental pollution, and human wellbeing. They had impact because the physical manifestations of their arguments – water pollution, smog, uncontrolled waste disposal, and the collapse of predatory bird populations – were becoming visible to all, urban and rural alike. This was particularly so in the United States but also in many Western European countries.

The new environmental consciousness was emerging in many cities around the world, particularly in Western Europe. For instance,
between 1963 and 1970 the UK government convened a series of consultations on “the countryside in the 1970s” figureheaded by Prince Phillip, and less populist, but nonetheless influential, environmental books were appearing, such as Max Nicholson’s *The Environmental Revolution* (1970). However, histories of the time suggest that this new environmental consciousness gained a greater political and policy saliency in the United States because it was picked up as a key issue in political opinion polls, and because the cause was taken up by a young, well-educated, middle-class generation with an activist confidence instilled by the 1960s. Importantly, however, the Nixon presidency was able to assume sudden and progressive leadership in environmental policy domestically and internationally because nature conservationists had developed the policies, leaders, and networks to support a rapid political response (Winks 1997).

In 1948, Laurence S. Rockefeller (who had been a major philanthropic investor in the US National Park movement) together with Fairfield Osborne (above) had founded The Conservation Foundation (CF) as a high-level Washington-based policy “think tank” to work on formulating a “new conservation” incorporating what we now term environmental ideas. The foundation had links with the Swiss-based International Union for the Conservation of Nature and Natural Resources (IUCN), a body formed in 1947 through the influence of European–US conservation networks and with the status of a United Nations agency. This transatlantic conservation network included astute and eminent members of the political, scientific, and bureaucratic elite. They seized the policy opening created by Earth Day and mobilized their influence and networks to convene the landmark 1972 United Nations Conference on the Human Environment from which emerged a raft of new environmental legal frameworks. CF staff assumed influential positions in the new environmental institutions that resulted: for instance Russel Train became head of the new US Environment Agency and assumed the brief for international issues, whilst Raymond Dasmann became chief ecologist of the IUCN. In this position he assumed the influential role of preparing the first drafts of international conservation policy frameworks and guidelines and helped IUCN exploit the political opportunity to position itself at the center of a reinvigorated international conservation regime. To this end the IUCN leveraged three additional assets: (i) the US National Park ideal that offered an inspiring and populist goal, along with an international network of park managers (the Commission on National Parks and Protected Areas, later renamed the World Commission of Protected Areas); (ii) the emerging science of ecology (and later conservation biology) that provided a scientific justification for policy; and (iii) incipient technologies for metricizing attributes of nature (see below).

The events of this period are recorded and discussed in many excellent histories, biographies, and memoirs (see e.g., Whitaker 1976; Winks 1997). These histories point to a significant shift in the dominant worldviews underpinning nature conservation policy, activism, and public support. Earlier confidence in the ability of humans to protect, manage, and reshape nature was replaced by a sense of despair concerning humanity’s “wounding ways” and an awareness that the biosphere could no longer absorb human impacts. A logic appeared that areas needed to be left alone where nature could take its course, both as scientific benchmarks for restoring and managing Earth systems and because humans could no longer be trusted to treat nature responsibly. Nature conservation came to be seen as an end in itself rather than as
a means of improving the quality of life of both people and nonhuman species.

Such logics are clearly evident in protected area legislation developed subsequent to the environmental crisis in less developed countries such as Indonesia and Brazil during the 1980s and 1990s. These logics interplayed with the US wilderness ethic and the rise of ecological science to create a nature conservation policy that was more biocentric and exclusionary. Some social scientists argue that nature conservation embodies a troubling dualistic concept of the human–nature relationship with eco-colonialist overtones. Given the breadth of conservation such ideas are undoubtedly present; however, histories of conservation policy suggest that the so-called nature–society dualism may have come to the fore more recently.

The European Union (EU) exemplifies some of the political complexity subsumed in the term “nature conservation.” Several, though not all, member states have nature conservation legislation and institutions that pre-date their EU membership and reflect national ways of engaging with nature. During the 1960s, environmental governance started to emerge within the EU as an issue of common trading standards, leading to the creation of a new environment directorate within the European Commission (EC). A campaign by two informal bird-protectionists committees (one German and one Dutch/UK) against migratory bird hunting offered the new directorate a transnational issue where it could justifiably claim regulatory competence in nature conservation: individual member states could not protect migratory birds and the practice of killing tired birds on the way back to their breeding grounds seemed absurd to technocrats and cruel to influential urban publics.

Figure 1 Major milestones and the growth of the world’s protected area estate. Reprinted from Watson et al. 2014 by permission from Macmillan Publishers Ltd. © 2014.

Two directives emerged, both of which were co-drafted by tiny groups of EC and non-governmental organization (NGO) policy entrepreneurs. The 1978 Birds Directive and 1986 Habitats Directive are both examples of “top-down” prescriptive legislation that require member states to incorporate their provision in national law. With EC support, “insider” conservation NGOs built the capacity of national conservation groups across the EU to form partnerships that could assist and/or monitor member state compliance and report back to the
EC. Backed up by a powerful European Court, this simultaneously empowered the EC as a supranational governance entity and contributed to the emergence of a set of conservation NGOs as influential transnational policy actors (Jackson 2013).

The various institutionalizing processes of nature conservation that arose out of 1970s environmentalism assumed a maturity and stability with the rise of the term “biodiversity” in the 1990s. This represents the fifth, and present, era of nature conservation. The main focus of nature conservation policy over the past 20 years has been the protection of the world’s remarkable biological diversity (see Figure 1). The term biodiversity was deliberately introduced in the 1980s to make politicians and bureaucrats aware of the looming extinction crisis, particularly in the tropics. The term quickly rose to prominence and was cemented in international policy at the Earth Summit in Rio de Janeiro 1992 with the formulation of the Convention on Biological Diversity (CBD). This declared the preservation of biodiversity as a major element of “sustainable development.” Biodiversity was framed as a new type of natural resource, providing raw materials for activities ranging from plant breeding to development of pharmaceuticals, that could be systematically surveyed and prospected (Haila and Kouki 1994).

The term biodiversity gave rise to a powerful new policy and scientific discourse: it transformed nature into units that could be measured, modeled, and converted into targets. The Biodiversity Hotspot prioritization scheme developed and marketed by Conservation International galvanized strategic action and investment at a global scale. Less high profile, but perhaps more influential, are the requirements of the CBD for signatory governments to integrate provisions of the convention into national law and to prepare biodiversity action plans at each administrative level. In addition, biodiversity has been “mainstreamed” into other areas of policy, such as international development, and into influential standards, such as those of the International Finance Corporation. Biodiversity emphasizes a technocratic, resourcist approach to nature conservation that has marginalized earlier moral–aesthetic arguments for conservation and the benefits these generate. It is a domain of nature conservation that has assumed a distinct, and in many ways separate, identity.

Whilst the core idea of avoiding extinction through laws and setting aside land are similar, in the biodiversity frame, conservation strategy and policy have been guided by units of biodiversity that can be standardized and thereby quantified, compared, and modeled. Among the more influential units are biological species which gave rise to the notion of mega-diverse countries, Red Lists of threatened species and endemic species (technically termed “restricted-range species”), which have become central criteria for the global identification of Key Biodiversity Areas and ecoregions. The latter construct biota-scale units that aim to provide metrics for comparison and prioritization and for the identification of representative habitats and assemblages (see Ladle and Whittaker 2011 for overview). In the biodiversity frame the conservation of so-called cultural species – those that generate value for humans in the form of wonder, curiosity, identity, outdoor recreation, and so forth – is downplayed. This is because they are difficult to classify in a systematic way.

A fuller treatment of biodiversity is outside the scope of this entry but see for example Gaston and Spicer (2013). There are indications that “biodiversity” is losing traction as a policy frame: government funds for biodiversity in the international arena are declining. This is in part because conservationists have struggled to prove their arguments that losing species will
have significant negative economic and social consequences and in part because other causes have placed new demands on finite budgets. The term “ecosystem services” is gaining traction in policy as a more holistic and communicable alternative to the term biodiversity. Ecosystem services are defined as the benefits (goods and services) provided by ecosystems that contribute to making human life both possible and worth living. The ecosystem services frame aligns more readily with ideas of natural capital than does biodiversity and it enables clear articulation of the social, environmental, and economic returns generated by investments in conservation.

A key point from this section is that nature conservation must constantly adapt and align with changing agendas if it is to retain its policy saliency. This is achieved by a cadre of conservation policy advocates, entrepreneurs, and campaigners (lobbyists) who have secured access to high-level decision forums through the deployment of a suite of influence tactics (Box 1). Maintaining and supporting a strong advocacy force requires an authoritative and robust science evidence base. Further, success translates into laws being passed, guidelines being adopted and lands being designated. Conservation groups have responsibilities regarding the implementation and monitoring of the policies they advocate, for example as technical advisors, partners in management, watchdogs, and public communicators. All of this requires funds, and how to finance nature conservation is a real and pressing issue and the topic of the next section.

Financing nature conservation

Doing conservation requires large amounts of money. A 1999 study (James, Gaston, and Balmford 1999) estimated that a comprehensive global conservation program would cost approximately $300 billion annually, yet the total annual spend from governments and donor agencies was just $6 billion. Finance for nature conservation is generated from several different sources which can be grouped into three general types: (i) funds generated by conservation organizations which they can use more or less as they like; (ii) funds from governments and foundations that are for specified purposes; and (iii) funds “released” through the creation of economic devices such as environmental tax and compensation funds. Sources of income and the emphasis of nature conservation goals interplay: pragmatism dictates that in order to keep staff employed a conservation group may need to adapt its cause to align with the agenda of donors and/or act as a service provider for government and other agencies.

Fee-paying members and subscribers are a key source of income for many nongovernment conservation groups. They provide a relatively stable and “unrestricted” flow of income and a constituency who can be asked for additional donations (including legacies and planned giving). In addition, they act as a core customer base for the development of a retail arm and fundraising products (e.g., adopt an animal) aimed at the wider public. The United Kingdom’s Royal Society for the Protection of Birds generated £90 million in 2013 from a combination of membership fees, legacies, and commercial activities. In countries with strong traditions of philanthropy, such as the United States, donations from high-net-worth individuals are a significant source of income, and cultivating relationships with such people is a core conservation activity. Major philanthropists have created foundations and trusts to hold and manage assets that are to be used for charitable purposes. These vary enormously in size but the larger ones are
Although the goals of nature conservation have changed over time there is remarkable consistency in the influence tactics deployed by people and groups advocating nature conservation. The following approaches appear to characterize nature conservation.

1 **Relationship building** – Developing relationships with officials, bureaucrats, celebrities, and employees of corporations who are conservation minded and/or who see a benefit in siding with a conservation cause.

2 **Expert advice** – Generating and communicating expert and grounded advice and analysis about the state of the natural world, the threats to it, and possible solutions to deal with these threats.

3 **Creating standards** – Developing assessment, categorization, and measurement standards that turn agreements, laws, and commitments into tangible and meaningful practices that can be audited by others.

4 **Framing conservation issues** – Shaping how conservation issues are thought about (framed) and promoting public and media interest in the issues and in preferred solutions and actions.

5 **Direct action and mobilizing constituency** – Acquiring land, managing populations of endangered species, and engaging citizens in campaigns responding to threats to places, species, and ideals.

This is not an exhaustive list. For example, it does not include taking governments to court (used in the United States and EU but rarely elsewhere) if they fail to enforce conservation-related laws. Source: Jepson and Ladle 2012.

managed by professional staff and disperse grants to achieve particular goals. These often relate to broader human development and environmental goals and a conservation group will need to adopt and deliver these goals in order to be eligible for a grant. Grants from multinational agencies may be even more prescriptive and are invariably packaged into a time-limited project that is supposed to become self-sustaining in some way after the initial period.

Given the complexity of the situations where conservation operates, interventions can rarely be packaged into planned and costed three- to five-year work plans with predictable outcomes. The project-by-project mode of conservation delivery has generated inflexibility and inefficiencies and it incentivizes organizations to develop new projects rather than follow through on existing investments. In addition, the major conservation donors want to make fewer grants, but of a larger size, to reduce administrative costs. This favors large conservation NGOs with professional finance, human resource, and project capacity. Over time, smaller conservation NGOs have been “squeezed out” and the landscape of nature conservation action has shifted from a plethora of small, grounded organizations led by conservationist committed to a particular place towards a smaller number of centralized conservation delivery organizations.
Many governments have dedicated nature conservation agencies, and funding for conservation comes from a combination of direct budget support and co-financing from specific governmental programs. For example, the EU’s LIFE Programme has co-financed 3.4 billion euros worth of projects in EU member states since 1992. Since the 2008 Eurozone crisis government budgets for conservation have decreased: the US National Parks operating budget fell by nearly 13% between 2009 and 2013 and science positions in Parks Canada were cut by 13% during the same period (Watson et al. 2014).

As indicated above, underfunding for nature conservation is nothing new and since the late 1970s conservation economists have been innovating with the creation of financial instruments that either release new money or make it easier for people to support conservation. Conservation easements were one of the first such instruments. Developed in the United States, they involve a legal agreement between a landowner and a land trust or government agency that permanently circumscribes the use of the land in order to preserve its conservation value. The landowner benefits from reducing the taxable value of the property. Further, because “easements” remain binding if the property is sold, they empower landowners to protect their land from future development.

Debt-for-nature swaps are another clever financial mechanism. The underlying principle is simple: many less developed countries owe Western governments and banks billions and this “debt burden” is a major obstacle to development and sound environmental management. Such “debt” is traded on secondary markets and can be purchased at a price significantly lower than face value. This sovereign debt can be purchased and a deal negotiated with the debtor government to redeem the debt. This might involve restricting development around a protected area but more normally it involves the debtor country setting up a local currency trust fund to finance an agreed portfolio of conservation projects. The Nature Conservancy and Conservation International have become adept at facilitating and negotiating debt-for-nature swaps that secure redemption values higher than the purchase cost of the debt.

Brazil has pioneered environmental fiscal transfer schemes (EFT) to reward local government efforts toward sustainable development. Specifically, the Ecological Value-Added Tax (ICMS-Ecológico) introduced in 1991 compensates municipalities for land-use restrictions associated with protected areas. By creating the possibility of a new income stream, ICMS-E has put nature conservation on the agenda of public administrations. Unfortunately, its actual conservation impact is less clear. This is because Brazilian tax law provides that taxes are not bound to specific expenditures. This means that it is up to municipalities whether or not they wish to pass complementary legislation that earmarks ICMS-E income for activities to protect and manage the protected areas they have designated. In addition, this instrument is rival, meaning that tax revenues to a municipality are diluted as more municipalities join the scheme and as more area is protected.

The new horizons for conservation are creating mechanisms for payments for ecosystems services (PES) (e.g., forest carbon sequestration and storage) and the development of green bonds. The imperative to turn towards markets to meet the shortfall of public conservation funds is part of a trend towards a wider engagement between nature conservation, corporations, and investment markets.
Science of nature conservation

The science of nature conservation is, like the natural world it seeks to conserve, complex and multilayered. There are many excellent books on the science of conservation. The aim of this section is to briefly introduce the types of science that characterize nature conservation and to introduce key policy and scientific ideas that have influenced the work of conservation scientists.

Broadly speaking, conservation science can be understood as an interplay of: (i) policy-orientated science that constructs attributes of nature as in need of governance and governable. This interacts with high-level policy and provides expert advice on issues requiring policy attention and strategic policy responses; (ii) management-orientated science that informs the management of species populations, habitats, and, increasingly, landscapes. This can be located on two general axes – in situ versus ex situ and passive versus active management (see below); and (iii) a science of biological recording and monitoring, characterized by the involvement of citizens and that underpins (i) and (ii). In addition, conservation science informs, shapes, and is shaped by the scale at which conservation aspires to act. In the past 20 years an earlier focus on species and sites had been expanded to include habitats and landscapes.

The discipline of conservation biology established during the 1980s (Soulé 1985) developed an influential body of scientific theory and evidence that underpins and legitimizes contemporary institutions of nature conservation. However, the spatial and temporal resolution of the data informing conservation science is undergoing something of a step change with the emergence of new bio-informatics, sensing, and recording technologies. This, together with the critical engagement of social, political, computational, and economic scientists with nature conservation policy, is producing a new interdisciplinary conservation science that is simultaneously building reflexivity and prompting innovation in conservation theory and practice.

It is important to note that policy-orientated conservation science has its roots in the systematic heritage of conservation located in museums and herbaria. As a result the species is a key unit of analysis and action: over time conservation science has produced a portfolio of identities for species that combine ecological concepts and applied conservation practice; notable among these are flagship, keystone, umbrella, and threatened species. Flagship species are those with traits (such as charisma) that galvanize action; keystone species are those that play an important role in the structuring and functioning of ecosystems. The concept of umbrella species bridges the two and describes prominent species with large-range requirements whose conservation will provide protection for other species using the same habitat.

The threatened species identity formalized in the IUCN Red Lists is without doubt the most influential species construct in conservation. The first effort to systematically assess species at risk of extinction was published in 1958. Subsequent interactions developed a set of science-based criteria against which species are assessed and placed into one of six extinction risk categories (Mace et al. 2008). The Red List created a standard that enabled a more systematic approach to conservation prioritization and the development and enforcement of species protection laws at the international and national level. In so doing it reinforced the role of the IUCN as the expert intergovernmental authority on nature conservation.
An important concept for predicting the rate of extinctions is known as the species–area relationship (SAR). As a rule of thumb, theoretical models of the relationship between species numbers and area developed from studies of islands predict that a 95% reduction in habitat area will eventually result in a loss of half of the species that live within it. MacArthur and Wilson’s (1967) influential *Theory of Island Biogeography* provided a theoretical explanation of the causes of variation in the form of SARs that can generate predictions on the impact of habitat loss and fragmentation. The relationship has been used to predict future extinctions over a large scale. For example, in 2007 the NGO Conservation International created a constantly ticking “extinction clock” by combining extinction estimates based on habitat destruction with the latest models of the impacts of climate change on biodiversity. This science constructs the notion of a “sixth extinction” event that provides a powerful argument for the protection of natural habitats and at the same time serves to raise mass awareness of global conservation issues.

The species–area relationship led to an important applied debate concerning the merits of opting for a strategy of protecting a single large or several small reserves of the same total area (SLOSS) (Diamond 1975). The SLOSS debate was never fully resolved, but many commentators lent towards the large reserve end of the debate, and this legitimated the creation of vast reserves in many less developed countries during the 1980s, often exceeding 1 million hectares or more.

The SLOSS debate interacted with the so-called “representation principle,” a guiding goal of international conservation policy (first articulated in 1976, see Simberloff and Abele 1976) that aims to create global networks of reserves that together represent within their boundaries the variety of habitats and species found on Earth. It resulted in the design of protected network systems in less developed countries with a few very large reserves, often in excess of 1 million hectares, representing major habitat types (Sumatra in Indonesia is a good example). The representation principle initiated the science of systematic conservation planning (Margules and Pressey 2000) that seeks to design optimal, efficient, and resilient reserve networks. This science is increasingly interfacing with techniques from computational biology to widen the range of taxonomic and ecological units embraced in reserve network planning and to integrate social and economic spatial data into planning.

Two important and related concepts in conservation management are minimum viable population and the “metapopulation.” The first posits that once animal populations fall below a critical number they risk entering an “extinction vortex” caused by inbreeding, stochastic, and other processes. The metapopulation concept responds to the reality that as habitats become more fragmented populations get broken up into numerous small populations that are often loosely connected to each other through a greater or lesser degree of dispersal. Conservation scientists have developed a range of techniques to study how such populations behave and what the consequences are for species management and conservation. This translates to practical advice on reserve design and building reserve networks, reintroductions and translocations, and the creation of dispersal corridors.

The involvement of nonprofessional scientists is a feature in nature conservation science, particularly in the area of biological recording. The skills and enthusiasm of naturalist were first mobilized in 1927 when the Oxford Ornithological Society organized a national survey of heronries. Organizations such as the British Trust of Ornithology (United Kingdom) and eBird (United States) have developed an authoritative
body of conservation science based on their ability to mobilize citizens, and have developed sophisticated sampling, analytical, and visualization techniques to deal with the data they collect. Citizen recorders make vital contributions to the recording of many taxa and wider environmental issues such as the spread of invasive species, tree diseases, and incidents of road kill. Emerging technologies are widening participation and the contributions of citizen scientists. For example, web platforms such as iSpot and Zooniverse offer respectively “crowd identification” and data curation tasks, whilst smartphone technology enables the automated collection of time, locality, and other data and also the possibility to automatically detect and identify species (e.g., bats and orthoptera) (August et al. 2015).

Conservation citizen science is interacting with the scientific project of creating a biodiversity informatics infrastructure to realize a future whereby decisions and actions are coordinated, comprehensive, and sustain Earth observations and systems. Biodiversity informatics involves developing the computational architecture, data standards, and culture to link diverse biological data in museums, research institutes, and environment agencies in an interoperable data network accessible via platforms (see e.g., Global Environmental Information Facility) (Edwards et al. 2011). Increasingly, citizen-generated data input directly into informatics infrastructures via national gateways and are contributing to the transformation of conservation science from a data-poor to a data-rich science.

As already indicated, a feature of the last two decades has been the emergence of a more interdisciplinary science of nature conservation. One input into this was the alignment of biodiversity conservation and international development in the 1990s and the idea that if both could simultaneously be achieved the interests of both would be served. This led to the field of community-based conservation, which draws on scholarship in the areas of common property, traditional ecological knowledge, and political ecology (Berkes 2004). The engagement of social scientists with conservation institutions and local people, combined with the rise of social justice concerns, has given rise to a valuable critique of nature conservation worldviews, policy, and practice. This initially focused on the impacts and injustices associated with relocating peoples from protected areas: Brockington (2002) coined the phrase “fortress conservation” to describe such practices. Two particular complaints of sociologists, anthropologists, and geographers interested in these issues are (i) that conservation agencies have not adopted clear policy standards to deal with voluntary or involuntary displacement and the negative social, health, and economic costs incurred by the people involved, and (ii) that protected areas and the funding that comes with them impose or reinforce idealized versions of “wild” Africa (and other continents) – further, that portraying nature conservation (in its various guises) as a public good legitimizes the removal and/or marginalization of rural people. Perhaps at the core of such critiques is the reality that the agendas of indigenous peoples invariably begin from the desire to secure legal rights to, and authority to govern, what they see as their land or natural resources. In short, there is a political agenda seeking a degree of autonomy from the state. In contrast, the nature conservation agenda has typically strengthened the power of the state in less developed nations by extending rational and centralized land-use management into remote areas and by generating international funding flows into these areas.

The “fortress conservation” critique is now considered to be an oversimplification of the diverse biophysical, historical, political, and social contexts within which conservation acts and the contingencies that result. This and related
NATURE CONSERVATION

work are, however, giving rise to an insightful and sophisticated analysis of power (state, corporate, and private), of the institutional alliances that make up modern nature conservation and the underlying concepts and terminology that frame action. One strand, led by political scientists, examines the dynamics between “big” international conservation NGOs and other actors (such as the World Bank) involved in transnational governance. For instance, research by Duffy (2006) shows how in Madagascar private conservation NGOs have become part of powerful networks involving international and state government actors that act as conduits for global conservation interest at the national scale. In so doing, Duffey reveals the complex institutional arrangements and drivers of nature conservation acting internationally and raises questions concerning the representation and influence of national (Madagascar) ways of doing conservation in these networks.

A second strand, arising from environmental lawyers, philosophers, and political ecologists, examines the ideology and biases of the agendas with which nature conservation has aligned (or is aligning). An area of active scholarship is framing and critiquing the trend towards neoliberal conservation. One question being asked is whether conservationists are embracing the force that is responsible for the degradation of the natures they hold dear. By revealing and explaining the raison d’être of market-based policy and rhetoric, articles such as Penca (2013) promote reflexivity and accountability in nature conservation, particularly among biologically trained conservationists, who hold most positions of influence.

A third strand, popular among human geographers, is problematizing perceived dualisms in conservation, such as nature/society, which they argue have shaped the development of nature conservation policy and management. This academic agenda is concerned with promoting a more “hybrid” and “cosmopolitan” approach to nature conservation. Whilst it produces thoughtful insight, this strand of scholarship is sometimes constrained by its ahistorical approach and universalizing tendencies (e.g., belief that wilderness is a dominant natural archetype globally) and its insistence on dismantling binaries that may have only limited presence given the multifaceted character of conservation (see, e.g., Sundberg 2014).

The rise of a multidisciplinary conservation science is giving new vigor and depth to debates about the underlying ideology and purpose of nature conservation. For instance, the debate on whether the purpose of conservation is to protect nature for its own sake or for the benefits it provides to humans has gained renewed salience. Proponents of a so-called new conservationist science and new environmental pragmatism argue for an approach to nature conservation that seeks to protect or restore natural habitats in areas where people live, that is open to experimentation and the creation of novel ecosystems (those without examples in present or past nature), and that engages business and investors to generate forms of nature-based development (see, e.g., Kareiva and Mariver 2012). Traditionalists retort that claims that their approach has an undue focus on pristine and fragile natures, that they disregard human welfare, and that they have dwindling public support as being poorly evidenced. Furthermore, they argue that “refashioning conservation into a set of goals that primarily advance human interests means selling nature down the river, serving neither the long term interests of people nor the rest of the species with which we share this planet” (Doak et al. 2014, 82). Others such as Marris (2014) feel that new thinking on assisted migration and ecosystem restoration, which is blurring the native/nonnative species boundary
and producing novel species assemblies, is being unfairly aligned with the human-benefit side of the argument. She argues that these approaches are meant to complement and expand, rather than replace, traditional conservation and that they can equally serve anthropocentric and eco-centric conservation goals. In a powerful and comprehensive retort, Spash and Aslaksen (2015) accuse those associated with this new wave of conservation pragmatism of reducing “moral considerability [for nature] to instrumental usefulness” and of “being oriented towards the continued expansion of a market-based economic system of capital accumulation” (251). At the time of writing, conservation science appears to be entering a period of active discursive struggle.

**Nature conservation futures**

The interdependencies between international agencies, governments, academia, and civil society described above have created influential nature conservation institutions that have been relatively stable over a period of three decades or more. However, various developments suggest that we may be entering a period of “unsettling” with uncertain outcomes.

Continuing the themes of the last section, influential new research areas in ecology and Earth systems science are working to understand past and present ecosystem function to support resilience and adaption. Such research is enabled by step changes in data, computation, and associated analytics. It is generating a new “functionalist” agenda for nature conservation – the restoration of functional ecosystems – that is bringing into focus the “compositionalist” paradigm (conserve an example of each unit) that underpins contemporary nature conservation institutions. More radically still, new knowledge on the function of past ecosystems is posing fundamental questions concerning the baselines for nature conservation. For instance, is it still relevant and feasible for EU policy to focus on the maintenance of remnants of biodiverse habitats produced by preindustrial agricultural practices? Should the management goal of the Emas National Park in Brazil be to maintain an example of the impact of Holocene extinctions of mega-herbivores or to restore as far as is feasible the lost ecosystem functions (through introduction of functional analogues)? (Galetti 2004). The Oostvaardersplassen, a large-scale ecological experiment in the Netherlands, has given such questions practical expression by (in part) restoring a European mega-herbivore assemblage that has created a “Serengeti behind the dykes”: a radical alternative vision for nature conservation that has generated huge interest and controversy.

Such debates and the ideal of nature restoration are assuming the label “rewilding” (Lorimer et al. 2015). For many young conservationists rewilding offers an inspiring and positive conservation vision: one that engages with fresh and exciting questions and that encapsulates a positive environmentalism. For those who aspire to being a conservation hero, the age of charismatic conservationists working to document and save wild things in wild places has passed. The new conservation heroes are slated to be those who restore systems through recreating trophic cascades. To achieve this vision they will need to rally against constraints imposed by twentieth-century conservation institutions and those who defend these. In short, we may witness the emergence of a radical younger generation of nature conservationists.

The growing engagement of conservation groups with markets and corporations is also likely to shape the future of nature conservation. This can be understood as a natural progression of the “pragmatic turn” in conservation during
NATURE CONSERVATION

the 1980s that gave rise to a new generation of policy approaches designed to harness the power of consumers and markets to promote pro-conservation behaviors within supply chains of natural resources. Seminal in this regard was the Forest Stewardship Council certification scheme launched in 1994 by a partnership of conservation NGOs and retailers (Klooster 2005). Subsequently, the scope has broadened to include ecological footprinting tools that benchmark the ecological performance of firms, sectors, and cities, offset mechanisms that enable firms and projects to attain “not net loss” (e.g., of biodiversity), and new conservation finance and investment mechanisms. The combination of declining governmental support for nature conservation, globalization, awareness of the transformative power of markets, and professional conservation employment opportunities at this nexus is creating a new conservation governance, one that deploys “soft law” and gains influence through a blend of reputational risk, “best in class,” and business case logics. Such neoliberal conservation is increasingly operating in dynamic relation to the older state-centric regime and is creating points of friction and innovation.

Finally, new technological forces – the Internet, computing as a utility, and low-cost, miniaturized sensors – look set to transform the science and practice of nature conservation. The conditions of the late twentieth century required a centralized organizational form of nature conservation and led to an influential community of international and state agencies and “big” conservation NGOs. This organizational form served conservation well but it also restricted participation in conservation policy and action to those with the professional qualifications necessary to secure jobs with a conservation agency. Technology is democratizing access to knowledge, data, data analytics, networks, and fundraising and making once expensive research tools affordable to (nearly) all. New specialist conservation consultancies and services providers are forming at the conservation–industry nexus and technology seems likely to widen this trend. It may result in a more “situated conservation” involving groups pursuing agendas and visions tailored to their beliefs, interests, and socioecological setting. In short, the ordered institutional form of nature conservation may become unruly and messy, and challenge the late twentieth-century ideal of a rational, coordinated international management.

Nature conservation politics
and disconnects

The organizational, institutional, professional, and ideological landscape of nature conservation is diverse. Whilst there are many areas of common ground there are deep-rooted tensions which may be intensifying in response to social, scientific, environmental, and technological change outlined above. The following five axes offer a useful framework for understanding these tensions.

1. **In situ versus ex situ.** Many field conservationists are uneasy with wildlife being kept in zoos and worry that captive breeding consumes a disproportionate amount of conservation resources, has a poor track record of success, and lets politicians “off the hook” by providing an attractive alternative. Zoo conservationists recognize that zoos are part of the cultural makeup of many cities, play a vital role in reasserting connections between people and the natural world, and view captive populations as an important insurance policy for conservation.

2. **Animal rights/welfare versus wildlife management and hunting.** Many citizens supporting nature
NATURE CONSERVATION

conservation are animal lovers for whom the welfare (and sometimes rights) of individual animals is paramount. Conservation managers and hunters are primarily concerned with the health of specific animal populations and view culling of competing species and/or sustainable hunting as legitimate practices.

3 Passive versus active management of nature. Some conservationists subscribe to the ideal of a pure and pristine nature where natural processes (e.g., fire) should be allowed to take their course without human intervention. Others believe either that, given the restricted size of remaining natural areas and populations, such an approach is too risky, or that most natural landscapes are shaped by human intervention so it is appropriate to actively design and manage natural areas.

4 State versus market governance also expressed as centralized versus situated conservation. One group of conservationists holds to the ideal of strong centralized governments embedding the conservation rationale in laws that are effectively enforced. Another group sees the world as having moved on; they recognize the declining power of government and the rise of market logics and more networked modes of governance. In their view, conservation must embrace market-governance instruments and techniques such as certification, standards, and risk management to retain its relevance and influence.

5 Moral absolutism versus moral pragmatism. This axis conceivably underpins everything. It is the distinction between those who believe that certain actions are right or wrong regardless of the conservation context or purpose, and those who believe that whether a conservation intervention is right or wrong needs to be measured by the outcome it produces for nature conservation and human society.

The issue of international wildlife trade has long been an arena where such tensions and disconnects are fought out. The issue gained renewed media and policy profile in 2014 as a result of a speech by US secretary of state Hilary Clinton that framed illegal wildlife trade as a security issue. This was followed by a high-profile conference in London convened with royal patronage. Action to curtail wanton slaughter of wildlife and market hunting is an old and enduring cause within nature conservation. The story of the extinction of the passenger pigeon – the devastation of unimaginably large flocks by market and sport hunters, white farmers, and Native Americans between 1830 and 1880 – is deeply embedded in the Western conservation psyche. The species’ plight retains mobilizing power as a shocking illustration of the impact of market forces emerging from the expansion of commerce and infrastructure into remoter regions. The conditions that led to the demise of the passenger pigeon seem to be repeating in regions of Africa and East Asia. The hunting of elephants, rhinos, and pangolins appears to be out of control and there are real fears that, a century on, these species may go the way of the passenger pigeon.

A sense of urgency pervades the campaign against wildlife trade and this is producing a tense politics. One camp argues a prohibitionist stance: elevating wildlife crime to a serious crime, banning trade in wildlife products, and imposing strict enforcement. Another camp argues a situated, pragmatic approach that blends market and regulatory approaches according to context. It supports, or is relaxed about, the principle of selling ivory from managed herds, rhino ranching, and trophy hunting so long as they are effectively governed. The former position appeals to those who lean towards the in
situ, animal welfare, passive management, state, and/or moral abolitionist poles, and the later to the ex situ, wildlife management, active management, market, and/or moral pragmatism poles of the five axes above. The “enforcement” position is far more influential politically than the sustainable use position. This is because it appeals to urban publics who often have less understanding of the context but are more politically and financially empowered. During the 1990s, national organizations within the WWF federation moved their position from the sustainable-use to the more prohibitionist position.

These debates on conservation governance approaches are increasingly extending to debates on the morality of what actions are legitimate to avoid the extinction of a species. Political economists question the so-called militarization of conservation, pointing out that the framing of wildlife trade as a form of trafficking involving international crime syndicates and as a source of finance for terrorist organizations is based on flimsy evidence and legitimates lethal intervention against people labeled as poachers (Duffy 2016). As a consequence, nature conservation is becoming a core element of a global security project, especially in areas of US geostrategic interest in sub-Saharan Africa.

More generally, there is a growing disconnect between applied and academic conservationists. These two wings operate in different institutional cultures with different incentive structures. Applied conservationists sometimes assume that the role of academic conservation is to provide evidence in support of their causes and management challenges. In contrast, academic conservationists see their role as furthering the theory of conservation science and, increasingly, to study and critically appraise the practice of applied conservation. In some areas of nature conservation, particularly the management of conservation landscapes (see rewilding above) progressive academic conservation thinking increasingly poses a radical challenge to the institutionalized practices of nature conservation formalized a generation ago. In short, the nature conservation community is increasingly both divided within and exposed to external academic critique.

Wildlife trade apart, there are concerns that objectives of higher-level nature conservation policy – biodiversity and ecosystem service conservation – are becoming disconnected from those communicated to lay publics by the media, conservation groups, and nature enterprises such as zoos, and furthermore, that older conservation approaches that foreground flagship species and iconic landscapes are being downplayed or abandoned without critical evaluation of their cultural agency and impact. The historic, institutional, and scientific dimensions of conservation foregrounded in this entry are but one component of nature conservation and may be unknown or irrelevant to the many everyday practitioners working and volunteering for conservation groups.

In many countries around the world nature conservation remains primarily a practice conducted by civil society groups, nature-based enterprises (e.g., zoos), communities, and private individuals. Many frontline employees and volunteers are vocationally minded individuals whose conservation activities are steered by a mix of belief, experience, mentoring, and organizational polices. There is a level of disconnect between these “grounded” conservationists and their professional policy and science colleagues, and between the latter group and their colleagues in marketing, fundraising, communication, and campaigning who tend to portray versions of nature conservation that play to emotion, sentiment, cultural stereotypes, and fear. A small group of eight conservation NGOs have grown into major organizations in terms of turnover, employees, brand, and reach and are led by
executives recruited for their organizational management aptitudes rather than conservation knowledge. A corporate nature conservation is emerging that is able to assume high-level policy influence and act at larger scale, but this may weaken the social movement and democratic legitimacy of conservation.

**Conclusion**

Nature conservation can be understood as an interaction of complex social, scientific, and managerial visions of the human–nature relationship that manifest in different ways in different places and at different times. It is a dynamic concept that reformulates in different spaces as a result of both synergies and tensions between interest groups within and outside conservation, and forces of alignment and appropriation that manifest through the engagement of conservation ideals with other powerful political and policy agendas. As a result, nature conservation has multiple facets and identities such that it is unwise to discuss or study it as a unitary thing. Furthermore, the geographies of nature conservation are poorly mapped and understood, in part because of universalizing tendencies among both natural scientists working to develop a body of theory and evidence to legitimize and guide conservation policy and social scientists seeking to ask critical questions about the power and influence of conservation. This account has outlined key trends in nature conservation over time and the causes that define it as a domain of public life. It suggests that future directions are uncertain due to the combined influence of advances in ecology, new technological forces, the ageing of first-generation regulatory frameworks, deeper engagement with markets, and the increasingly polarized and fractious debates within the nature conservation community.

Nature, art, and aesthetics

Deborah P. Dixon

University of Glasgow, UK

Both art and aesthetics have been crucial to the making of the modern-day geographic discipline as a set of ideas and practices concerned with understanding, and engaging with nature. Art, understood as a creative practice that reworks materials as a means of affording them an expressiveness, continues to be an object of analysis for geographers interested in the role and value of the creative industries, the unfolding of creative practices and their products in the making of place, the everyday embodiment of creative energies, and so on. Historically, however, art has been a stalwart methodological practice underlying physical as well as human geographic research. Similarly aesthetics, understood as the making sense of sensory information, has played a key role across the discipline, particularly with regard to the import of geographic fieldwork. Though this historic role is difficult to discern in the contemporary practice of physical geographers, there is a renewed interdisciplinary interest in how art and aesthetics might be a productive means of bringing together human and physical geographers in their framing of nature as a highly complex site for critical investigation. Key here is a shared interest in multisensuous encounters with nature, and how these are perceived, experienced, and cognized, as well as in how the emotive dimensions of such encounters can help to reanimate the communication of geographic knowledge to a wide range of audiences.

Art and aesthetics have long and complex historical trajectories, manifest in other disciplines as well as geography. This wide-ranging presence stems in large part from the fluidity of Enlightenment thinking and practice, wherein the sharply observed disciplinary boundaries operative today were in the process of being posited, shaped, and reshaped. The work of Alexander von Humboldt (1769–1859), for example, often noted as one of the founding fathers of a modern-day geography, is representative of an expansive mode of inquiry into the form and workings of nature that consisted of systematic measurements of particular landscape features, hypotheses as to their construction, and also meditations on the role of an aesthetic sensibility. Here, art was by no means a rarified practice that took place under the aegis of expert cohorts such as the members of the Royal College of Art (established 1769), but it was a crucial component of the research process itself. Field sketches and paintings were an important means of getting to grips with the balance of forces (represented in Humboldt's design of the isoline, for example) that animated terrestrial phenomena, and that undergirded the universe. Humboldt's enrolment of artistic practice, and his appreciation for the sublime, as well as his desire for measurements of sensible phenomena, were both key to his philosophy of a holistic nature (Buttimer 2001). In similar vein, the work of G.K. Gilbert, often described as an inspiration for the mid-twentieth century's quantitative revolution in geography, illustrates an expansive mode of inquiry that draws on field sketches and photography as a means of making sense of a multisensuous engagement with nature (Dixon, Hawkins, and Straughan...
For both scholars, artistic practice was a critical component of scientific fieldwork and knowledge building. Notwithstanding this common grounding in artistic practice and aesthetics, the conceptual and methodological cleaving of the discipline in the twentieth century has largely placed both outside the remit of current physical geography research. Sensuous encounters with nature remain an important part of the fieldwork process, but are very much cast as the source from which systematic, methodological, and technically mediated procedures can produce data. Such data are of value insofar as they lend themselves to hypothesis testing. Furthermore, while this approach to aesthetics sees some value in artworks, it is their supposed accuracy in rendering the world they are understood to mimic that enables them to function as proxy datasets. As some physical geographers have observed, the emotive dimensions of wonder and curiosity that were so explicit in earlier eighteenth- and nineteenth-century geographic writing have largely been written out of the field (Baker and Twidale 1991).

It is unsurprising, then, to find that much of the debate on art and aesthetics has been carried out by human geographers, particularly those interested in cultural phenomena and practices, and that some have argued that such an interest is a useful, even necessary, antidote to an arid formalism that underlies physical geographic renderings of nature (Tuan 1993). For the most part, such geographers have sought to understand how art and aesthetics have been deployed by particular cohorts to frame and engage with nature. For some, this is primarily a matter of inquiring into how landscape has been creatively portrayed and shaped, insofar as this object of analysis has long been configured within the discipline as an interface between nature and society. Landscape paintings and literatures, as well as landscape design, are considered as testament to the diverse manner in which nature is perceived and interpreted. Techniques drawn from the formal arts and humanities, wherein emphasis is placed on the expert decoding of an artwork (according to style, genre, and the artist’s intention) resonate here with geographers’ accounts of reading the landscape with an “expert eye” and the role of human agency in affording meaning (Duncan and Ley 1993).

By the 1990s, however, as the deconstructive possibilities of Marxism, feminist theory, and poststructuralism teased apart nature as a contested term, landscapes were inserted into broader social relations of power and inequality (Daniels 1989). Moreover, other objects of analysis, such as sites and bodies, were to become a matter of interest to geographers working on art and aesthetics. In part, this was because sites were regarded as offering more complex and nuanced accounts of a nature that was not separate from society, but thoroughly entangled with it, such that a myriad of asymmetrical relations between and across species, as well as between and across organic and elemental domains, were seen to operate through, and to help comprise, such sites. In similar vein, bodies were no longer considered so readily distinguishable as human or nonhuman according to set taxonomies. Seemingly different bodies could have shared capacities that undercut the notion of agency, and even artistry, as a thoroughly human endeavor. But, also, the character of the relations between various bodies, such as symbiosis, was often considered as more important in a given context than shared biological antecedents. Such an approach belies the easy categorization of nature as composed of individual creatures rendered distinctive by their biology and occupying varying ecological niches. At the same time, in the humanities, the traditional, formal distinctions that maintained art and nature as separate
spheres were also giving way to more entangled understandings of the creative process, and the role of the nonhuman therein.

As what came to be termed a “postnatural” approach has become more prominent across academia, so the traditional figure of the “dis-attached” expert has largely been replaced with that of the immersed scholar undertaking research as a form of practice. Sensuous geographies, emotional geographies, and affective geographies, for example, have all foregrounded aesthetics as a matter of exploring how a “felt” experience of the environment is shaped, and with what import. Part and parcel of such accounts is an attentiveness to the doing of research that draws geographers close to debates in the arts and humanities on ecology, performance, creativity, and experimentation (Hawkins 2013). Indeed, an emerging trend within the discipline has been for geographers to collaborate with artists on specific projects using diverse mediums and with diverse venues and audiences in mind. What is more, there is a burgeoning series of “in the field” collaborations between physical geographers and artists focused around the mutual exploration of landscapes, and the harnessing of the emotive dimensions of such body–environment encounters in the production and communication of geomorphological knowledges.

At the moment, such efforts are heavily invested in a more traditional framing of human–environment relationships, wherein both individual human agency and meaning-making remain a central concern. Looking forward, however, there is substantial room for physical geographers to incorporate more critical accounts of the “nature” of human being and, in the process, reassess the practice of fieldwork as well as their understanding of how physical processes impact on, and are shaped by, people and groups. Likewise, there is room for human geographers to pay more attention to nature not as a bundle of forces, materials, and events awaiting human perception, experience, and analysis, but as existing in and for itself.

NATURE, ART, AND AESTHETICS

The nature of geography

“Nature,” by definition, includes but also exceeds the meaning of “environment.” To consider how geographers have studied nature is, necessarily, to consider the discipline of geography in its entirety (rather than just some of its sub-branches). Why so? First, in various ways the first university geographers saw their task as the study of human–environment relations – with humans perceived as more or less responsive (in a physical and psychological sense) to natural stimuli issuing from their immediate surroundings. For decades, academic geography was in some measure about “Earth writing” in a literal sense: that is, the analysis of how the Earth materially inscribes itself on humans, and vice versa. Second, even though geography splintered into a largely nature-free “human geography” and an environment-focused “physical geography” after 1945, nature necessarily served as a “shadow concept” organizing the former. In other words, by presuming that something called “society” was different in kind from something called “nature” (human and nonhuman), human geographers were able to justify a largely exclusive focus on the spatial organization of people’s activities and creations. This focus was only possible by believing that the biophysical world could be “bracketed-out” and left to physical geographers to study – making it what some theorists call a “constitutive outside” or “absent presence” in a semantic sense. Third, in recent years many human geographers have taken a deep interest in the more-than-human dimensions of the world, while others have concurrently challenged conventional understandings of “the social” and “the human.” Though it has rarely involved collaborations with physical geographers, it has helped to dissolve the nature–society dualism that has for decades organized the academic division of labor in geography. Fourth, also in recent years so-called environmental geographers, who position themselves between human and physical geography, have increased in number. In large part this is because of the “global environmental change” research agenda now central to many funding agencies and intergovernmental organizations like the United Nations. But it also reflects the growing number of people who live in areas prone to perennial or periodic biophysical threats, like wildfires and floods. In short, whether our focus is on the discipline’s past or present, to write about the analysis of nature in geography is to contemplate the nature of geography. Despite this, there is no detailed history of how the two things have evolved over time (though see Castree 2005 for a sketch).

Since we cannot possibly cover such a large and complex terrain in a single entry, a parsimonious approach is required, with all the risks of oversimplification this entails. We begin in the obvious place by defining nature and offering some wider considerations about its place in Western understandings of the world. We then highlight ways in which nature was a central object of description and explanation in the early decades of academic geography, before summarizing developments after 1945, when it
became the almost exclusive preserve of physical geography’s various sub-branches. The fourth section focuses on the recent period in which, it is shown, “naturalist” and “denaturalizing” approaches developed side by side in geography, often without much contact.

Overall, we will discover that “nature” provides an illuminating conceptual lens through which to view both the evolution of geography and current fault lines (analytical and political) in the discipline. It will be suggested that geography has always had a “problem” with nature. Disagreements over what is and is not natural, who should study it, and how, have, it will be shown, been flashpoints for the successive reconstitution of geography as an academic enterprise since the discipline’s inception. Today, arguably, we are at a point where the ontological “obviousness” of nature’s existence is so widely doubted that the nature of geography may (again) be changing quite significantly. Far from “solving” the problem, this “nature skepticism” in its various current forms is symptomatic of ongoing struggles in geography to capture the hearts and minds of practitioners, students, and nonacademic stakeholders of various stripes. It only constitutes “progress” in how geographers think about nature seen from a certain viewpoint. Accordingly, we give previous approaches their due rather than rushing past them to focus mostly on recent developments, as if they eclipse all prior contributions. Most of these previous approaches share a philosophical commitment to nature’s naturalness (a commitment we will call “traditional”). As will be seen, more recent research aims to be post-traditional by questioning nature’s naturalness in various ways. Readers should note that there is a bias toward Anglophone research in what follows, and the analysis does not cover developments in continental Europe or elsewhere.

**What is nature?**

Nature is a very old word in the English language, and its meanings have varied in the detail through time. It refers to a wide range of phenomena in a plurality of different ways – this is why it is an unusually complicated word; some would argue the most complex of all. As a linguistic philosopher might say, it is a “signifier” (word, symbol, or sound) that has more than one “signified” (a specific meaning) and these signifieds are attached to an astonishing number and range of material things (“referents”), both human and nonhuman. Today, the term has four principal meanings which have endured through many decades. First, it designates the nonhuman world, especially those parts untouched or barely affected by humans (“the natural environment”); second, the entire physical world, including humans as biological entities and products of evolutionary history (or, as some would have it, a deity); third, the power or force governing some or all living things (such as gravity or the conservation of energy); finally, the essential quality or defining property of something (e.g., it is natural for birds to fly and fish to swim). As a shorthand, we can (respectively) call these meanings “external nature,” “universal nature,” “superordinate nature,” and “intrinsic nature” (see Figure 1).

Clearly, depending on the context of usage, the idea of nature can function as a noun, a verb, an adverb, or an adjective; it can also be characterized as object or subject, passive or active. As geographer Neil Smith once put it, “Nature is material and ... spiritual, it is given and made, pure and undefiled; nature is order and it is disorder, sublime and secular, dominated and victorious; it is a totality and series of parts, woman and object, organism and machine. Nature is the gift of God and ... a product of its own evolution; it is a universal outside [human] history and also the product of history, accidental
and designed, wilderness and garden” (Smith 1984, 11). In short, the word nature is – and has long been – promiscuous: not only polysemic and polyreferential, but utilized in a wide array of everyday and more specialized situations. We might therefore say it is a keyword rather than a buzzword.

Keywords, as cultural analyst Raymond Williams (1976) argued in his famous book of this name, have three characteristics. First, they are “ordinary,” which is to say used widely and frequently by all manner of people in all manner of contexts (private, commercial, and civic). Second, they are enduring rather than ephemeral – they do not come and go in a way that buzzwords like “globalization” or “post-modernism” do. Finally, keywords possess what cultural critic Tony Bennett and colleagues, in their update of Williams’s book, call “social force” (Bennett et al. 2005, xxii). In other words, because their various meanings become normalized in a given culture they are able to govern (i.e., steer or direct) not only our thinking but also a wide range of practices resulting therefrom. A simple measure of the importance of “nature” as a signifier is to imagine us dispensing with the term and its meanings altogether. The “hole” in our language would be enormous. We would be rendered both inarticulate and incapable in large areas of our thought and action. In sum, if we did not already have the term in our present-day vocabulary, we would probably have to invent it.

This becomes even more obvious if we consider two other things. First, Williams rightly referred to “particular formations of meaning” (1976, 13; emphasis added) when explaining to readers how they might interpret a signifier like “nature.” His point was that in any given society at one historical moment there are likely to be a family of keywords whose meanings bleed into, and borrow from, one another. We can say that the concept of nature is not exclusively associated with the word “nature.” Instead, the meanings are routinely signified by a range of other words that are (or have become) part of our collective vocabulary. In this sense, “nature” is something of a “ghost that is rarely visible under its own name” (Olwig 1996, 87). Its meanings often appear as collateral concepts (Earle, Mathewson, and Kenzer 1996, xvi). That is to say, they are signified by different keywords which refer us to similar or additional referents.

In the early twenty-first century nature’s collateral terms include the following, among others: “environment,” “wilderness,” “gene,” “genius,” “biology,” “race,” “sex,” “biodiversity,” “animal,” “life,” “intelligence,” “human,”

| Figure 1 | The principal meanings of the word “nature” in contemporary Anglophone societies. Source: Reproduced with permission from Castree (2014, 10). |
“instinct,” “blood,” “reality,” “climate change,” “mind,” and “ecosystem.” Some of these terms are relatively old; others relatively new. Some appear semantically simple and straightforward (though, in actuality, they are not); others more evidently complex. The precise ways in which they partake of the meanings of “nature” varies, according to both the word and the context of reference. Most of them feature in discussions of both human and nonhuman nature, but some are used more exclusively. Most of them are also freighted with meanings that go beyond those connoted by the term “nature.” These collateral words are thus only partly – rather than exclusively – synonyms for the last. It depends entirely on the circumstances of their invocation and usage (see Figure 2).

Second, circumstances aside, nature and its collateral concepts are members of a fairly select family of antinomies that can be said to structure Western thinking about the nature of reality. These antinomies include urban–rural, raw–cooked, wild–civilized, and authentic–artificial. Their meanings are best understood relationally rather than separately. Together they comprise a “semantic rule book” that at some level governs specific acts of verbal and visual representation. They are the epistemic means by which Westerners have assured themselves that there is a measure of inherent order to the world. The binaries create boundaries and differences that are presumed to be hardwired into reality, in part “by nature,” in part by design (see Box 1).

If all this seems to complicate matters too much, there are some signals in the noise. Arguably, whenever we use the word “nature” and its proxy terms, we typically think we are making (or anchoring) ontological statements of a cognitive, moral, or aesthetic kind. That is to say, we believe we are making (or vouchsafing) statements about a biophysical reality that exists independently of the words, concepts, and terms we use to make linguistic sense of it. In this respect, we are apt to assume that “nature” and its filial terms are “mimetic concepts”: that is,

---

**Figure 2** Nature and its collateral concepts. The principal meanings of the word “nature” (i.e., what it signifies) are routinely attached to all manner of material referents by way of other words (i.e., collateral terms). The words and meanings become conjoined in often complicated ways. However, these collateral terms may also signify meanings beyond the four signified by “nature.” Source: Reproduced with permission from Castree (2014, 18).
Box 1 Fundamental dualisms of Western thought since the European Enlightenment. Depending on the precise context of their use in acts of communication, each of the terms in one column can imply its opposite term in a “hard” or “soft” way. Some of the terms, again depending on the context of use, have ambivalent meanings, slipping and sliding between and across both columns. Reproduced with permission from Castree (2014, 24).

ones whose meanings capture in words actually existing phenomena that are “out there” (or “in here” if we are discussing our own physiology and neurology).

As we will see below, there is ample evidence of this being the case in academic geography across the decades. However, despite its apparently “obvious” existence, there is another
way of understanding what we call nature. Consider that some cultures have neither the word nor all (or even some) of the four meanings itemized above. For instance, in his study of several aboriginal societies, anthropologist Tim Ingold (1996) came to the following conclusion: “[H]unter-gatherers,” he suggested, “do not, as a rule, approach their environment as an external world of nature that has to be grasped conceptually and appropriated symbolically within the terms of an imposed cultural design …; indeed, the separation of mind and nature has no place in their thought and practice” (p. 120). Ingold’s conclusion chimes with that of Williams. As Williams (1980, 67) put it:

Some people, when they see a word, think that the first thing to do is to define it. Dictionaries are produced … and a proper meaning is attached. But while it may be possible to do this, more or less satisfactorily, with certain simple names of things, it is not only impossible but irrelevant in the case of more complicated ideas. What matters in them is not the proper meaning but the history and complexity of meanings.

Following Williams, we can suggest that all four meanings (signifieds) of the term “nature” are purely conventional, not once-and-for-all “correct.” Likewise, we can argue that there is nothing “natural” about the fact that the term refers to all the particular things it does, and not to others. If we want to know what nature is, and why we value or exploit it in the ways we do, we should, perhaps, look not to nature itself but to our ideas about what we call nature. When we talk about “nature,” Williams famously opined, we are talking about ourselves (whoever “we” happen to be) without necessarily knowing it or admitting it.

This is why I have devoted this section to discussing the concept of “nature,” rather than assuming that it is secondary to the material world it is intended to depict. Is this to suggest that “nature” does not exist, only the concept and its proxy terms? In one sense, yes. This is not the same as arguing that the material things to which the concept refers do not exist: they assuredly do. But it is purely a matter of habit to call them “natural” in the various ways and contexts that we choose to; indeed, it is arguably a matter of convention to divide the world into words and things, symbols and reality, mind and matter. For many (perhaps including some readers of this entry), this is no doubt a difficult argument to accept. It accords a lot of importance to language, its social origins and its practical effects, and it challenges the conventional idea that many or most concepts are semantic “mirrors” that faithfully represent the material world. As noted above, nature, by definition, seems to be that which lies outside of, and is irreducible to, linguistic frameworks. But appearances can be deceptive. In the end, some (like Ingold and Williams) would argue there is nothing “natural” about our habit of designating certain things as belonging to “nature,” nor about using those things as a reference point to secure our ethical or aesthetic beliefs. Conversely, it follows that any new habits, for example, ones that would dispense with concepts like “nature” and “society” altogether, cannot simply be justified with reference to the “realities” they supposedly respect. They too can be seen as contingent creations rather than necessities. This sort of “denaturalizing” approach to understanding nature has, as we will discover later, loomed large in human and environmental geography in recent years.

**Geography and nature: the early decades**

It is fair to say that the early university geographers took the ontological existence of nature as a given – it was considered “natural” in one or more of the four senses identified above. Their
concern was with phenomenal nature, rather than nature at the micro or cosmic scale. For academic geography’s founders, the interesting question was the various ways that this nature affected different societies across the globe. From the outset, geography was to be a “bridging subject” devoted to intellectual synthesis. This was abundantly clear in a key 1887 address by the young Halford Mackinder to the Royal Geographical Society in London. Entitled “On the Scope and Methods of Geography,” his lecture explained how and why geography should take its place alongside other disciplines within the academic division of labor. His strategy, at once simple and audacious, was to call that division of labor into question. Geography, Mackinder argued, can “bridge one of the greatest of all gaps,” namely, that separating “the natural sciences and the study of humanity” (1887, 145). He was not alone in defining geography as “the science whose main function is to trace the interaction of man [sic] in society and so much of his environment as varies locally” (Mackinder 1887, 145). At points east and west others were doing much the same, such as William Morris Davis in America, Paul Vidal de la Blache in France, and Friedrich Ratzel in Germany. The four men soon occupied important university positions and were followed by similarly vigorous proselytizers who quickly built on the foundations their forebears had laid.

So began geography’s career as a university subject and what historian of thought David Livingstone (1992, 177) called “the geographical experiment.” This was the attempt to keep nature and society under “one conceptual umbrella” in the face of “the incipient Balkanization of knowledge that accompanied the professionalization of scientific specialities” (Livingstone 1992, 177). There were two aspects to this. First, the likes of Mackinder, de la Blache, Ratzel, and Davis saw the need to study nature as a whole, not as a set of discrete parts. Where subjects like chemistry, physics, and botany specialized in investigating select elements of the natural world, geography would study all these elements in combination (as Alexander von Humboldt had famously sought to do early in the nineteenth century). This is what “physical geography” was, according to earliest proponents like Mary Somerville. In her 1849 book of the same name, she defined it as “a description of the Earth, the sea and the air, with their inhabitants the distribution of these beings, and the causes of their distribution” (p. 1). Her successors, influenced in part by Charles Darwin’s path-breaking theory of evolution by means of natural selection (1859), were sometimes given to discussions of “human nature” and how it varied geographically in response to the conditions of regional physical environment. Second, this commitment to studying nature as an integrated, multifaceted system was accompanied by a desire to explore its two-way (“vertical”) relationships with human societies in different places and regions (“horizontal” differentiation). For Mackinder and the other early geographers, it was important that nature be studied in context as something that forms the basis of (and is affected) by human practices of an economic, cultural, and political kind. In this sense, the study of human geography was to be deeply materialist, with its roots – quite literally – in the soil. The resulting investigations of “human–environment” relations could be conducted at a range of geographical scales from the local right up to the global.

Clearly, geography had high ambitions in its fledging years as a university subject: it was, in terms of subject matter and scope, very much a “world discipline.” But it became increasingly clear that its “bridging” aspirations were difficult to realize satisfactorily. The major problem was a practical one. Geography’s perspective
on the world was so comprehensive, and its subject matter so compendious, that it proved very difficult to demonstrate causal connections between the component parts of the nonhuman world, let alone all these parts and various societies worldwide. Some, like Mackinder and Ratzel, had hoped that a geographical equivalent (or version) of the theory of evolution might be developed. But this hope was in vain. It was time-consuming enough to provide mere descriptions of different societies and their physical environs, never mind plausible explanations. As a result, most early research publications by geographers were beset by what—with hindsight—were serious intellectual weaknesses. For instance, monographs that focused on specific places or regions were often impressionistic by present-day standards and filled with unverified speculations about how and why nature and human society were as they were in given situations. At worst, this shaded into what we would now regard as racism founded on supposed “natural differences” between humans rooted in biophysical conditions and their evolutionary imprint. For instance, in the United States, geographers like Ellen Semple and Ellsworth Huntington were apt to argue that certain physical environments produced human “races” less intellectually or physically capable than Europeans. These arguments were presented as descriptions of “historical accidents” that had blessed some races but not others. Indeed, both Semple and Huntington on occasion claimed that even “Europeans” would “decline” if they had evolved in a region like West Africa.

Such beliefs were consistent with certain versions of evolutionary theory—such as the work of Jean Baptiste Lamarck (1744–1829)—though certainly not with Darwin’s. With hindsight, they appear as academic attempts to justify the colonialism and clientalism—military, economic, politician and social—practiced by West European countries and the United States of America in Africa and elsewhere. Through all this, nature was understood as both universal and external, intransigent and enabling, restrictive and productive, in ways that were ultimately contradictory. Where an apparently “hard” environmental determinism was operative on some societies in some places, other societies elsewhere seemingly experienced only a “soft” determinism. Here environmental conditions were said to produce either a “superior” human nature or else “civilizations” that had, in effect, built a rich house of “culture” atop the inherent genetic and physiological universals of human biology. Intellectually, it was an approach that allowed Anglophone and continental European geographers to have their colonial cake and eat it too.

Post-1945 fragmentation: the emergence of a nature-free human geography, an environment-centered physical geography, and a small disciplinary middle ground

World War II was a turning point for geography and its approach to the study of nature–society relations. Many who would subsequently gain positions in university geography departments served in the military between 1939 and 1945. The experience was formative for most, instilling a belief that precision, measurement, and rationality were virtues to which one should aspire. Aside from the skills of mapping, surveying, and close field observation, pre-war geography struck many observers as offering precious little to the war effort. At the same time, three other developments were significant. First, the discipline had failed to produce major books or intellectual innovations comparable to, say, John Maynard Keynes’s 1936 General
Theory of Employment, Interest and Money. This became a cause for concern. Second, many outside geography had successfully argued that the physical sciences and the social sciences (with the humanities) had to be different by virtue of their subject matter. There could be no overarching analysis of people and nature, it was argued, because the former possessed ontological properties quite different from rocks, rivers, or ravines. For instance, humans are self-reflexive, linguistic, tool-making beings able to make their own history and geography – so argued philosopher Wilhelm Dilthey, among others. This argument drove a wedge between the two spheres – society and nature – that the original geographers had sought to bring together in a single intellectual frame. Finally, the embarrassment of “environmental determinism” – the pre-war argument made by Semple, Huntington, and others that some human “races” were mere reflexes of climate, soils, and resources – made some geographers determined to “raise their game” intellectually.

After 1945 academic geography progressively splintered into two major halves (human and physical), with each fragmenting into relatively discrete “systematic” subdisciplines. Consider some of the new studies of the natural environment published at the time. Bagnold’s (1941) The Physics of Blown Sand and Desert Dunes inquired into physical process-phenomenal form connections in arid environments (Bagnold’s British military service had been in dryland regions). R.E. Horton (1945) used his engineering background to argue that the action of water over and through different types of soil and rock had consistent physical consequences that could be measured empirically – and even predicted. Finally, Strahler’s (1952) “Dynamic Basis of Geomorphology” argued strongly that physical geographers should measure and explain how processes defined by universal laws create specific sorts of landforms, given a certain set of “initial conditions.” Together, works like Bagnold’s, Horton’s, and Strahler’s laid the groundwork for a physical geography where explanations were derived from the testing, by way of repeated observation and measurement, of refutable hypotheses. This was an altogether more specialized, more rigorous, less descriptive approach to the physical environment than almost anything found in pre-1939 geography. Within a decade key texts like Fluvial Processes in Geomorphology (Leopold, Wolman, and Miller 1964) were making this new kind of physical geography a serious proposition.

The turn to specialization was undertaken in the hope that human and physical geography could become “spatial sciences.” Scientists would discover – through careful measurement, experimental control (where possible), proposition testing, and use of statistics – laws explaining spatial patterns (such as the common tendency of rivers to meander, or migration flows to be inversely proportional to the size of destination cities). This implied a splitting of geography’s subject matter into two, with intellectual unity (many hoped) maintained at the level of the perspective taken on the subject matter (rather than subject matter per se). Accordingly, human geography increasingly abstracted the analysis of political, economic, social, and cultural practices from their biophysical integument. The pre-war fondness of some geographers for discussing “human nature” (in the biological sense of mind and body) was also quickly abandoned. On the other side, physical geographers produced increasingly “scientific” descriptions, explanations, and even forecasts of Earth surface phenomena. Specialization, new databases, new remote sensing capabilities, and new computer technologies made this possible. But lingering aspirations to synthesis paid the price: physical
geographers divided nature (in the sense of the planet's physical environment) into the five areas that comprise the field to this day (namely, geomorphology, biogeography, climatology, hydrology, and Quaternary environmental change). There was also a progressive move toward small-scale, short-time horizon studies because hypothesis testing was very difficult for macroscale analyses of (say) whole ecosystems or river basins. Where macroscale physical geography persisted, it was often hived off to other academic subjects – as happened with meteorology and climatology. Indeed, physical geography's major post-1945 branches bled into cognate subjects – such as ecology in the case of biogeography. This made them increasingly interdisciplinary and reflected their inability to police their own turf once the idea of a unified physical geography was progressively abandoned after 1945. Finally, all of the above meant that the study of human–environment relations became a minority pursuit, with “spatial analysis” and the search for general laws, models, and theories geography’s new modus operandi.

These changes together bolstered geographers’ intellectual self-esteem and improved their external image within the world of higher learning. Ironically, though, geography was effectively abandoning the study of human–environment relations at the very moment when the title of William Thomas’s 1956 book, *Man’s Role in Changing the Face of the Earth*, was becoming as obvious as it was profound. The Brit C.P. Snow’s famous complaint about the estrangement of “the two cultures” – one literary–humanistic, the other scientific–rational – was (ironically) applicable to postwar geography, the one subject that had made intellectual unity its *raison d’être*. The long shadow cast by pre-1945 environmental determinism made many younger geographers wary of inhabiting the “middle ground” between a newly scientific physical and human geography.

Notwithstanding all this, a number of geographers did try to occupy this terrain in ways that eluded the shadow. For instance, after World War II, many Western governments adopted a more hands-on approach to public welfare. This included a new desire to protect people from the effects of natural hazards, such as hurricanes, droughts, and landslides. In this context, the American geographer Gilbert White pioneered an approach in which people’s perceptions of hazards became the major focus. In *Human Adjustment to Floods* (1945) and subsequent works, White argued that many individuals and communities living in high-risk locations did not necessarily perceive themselves to be vulnerable and so failed to take adequate measures to mitigate the effects of hazard events. In this way, people’s cognition was granted a degree of independence and flexibility rather than being assumed to bear the “objective” imprint of their environs. Ian Burton and Robert Kates, among others, built on White’s approach and sought to identify different forms of “cognitive rationality” specific to certain groups in certain hazardous locations (Burton, Kates, and White 1978). The presumption was that people’s perceptions of hazards, however inaccurate or distorted, could be typified and rationally explained, leading to tailored policy solutions that might better protect them and their livelihoods. This kind of geographical research was important in US and Canadian geography, with natural hazards researchers being directly involved in public policy agendas for hazardous regions in both countries.

Meanwhile, cultural ecology came to prominence by the early 1970s. Situated on the marchlands between cultural anthropology and cultural geography, this approach to society–nature study was pioneered by Julian Steward, Andrew Vayda, Roy Rappaport, Marvin Harris,
and Clifford Geertz. It was a critique of anthropology’s mid-twentieth century “culturalism” – wherein cultural habits were thought to develop sui generis – and pre-war geography’s muscular naturalism. Typically focused on land and water-based communities in the Global South, cultural ecologists sought out those aspects of cultural belief and practice that seemed to be “functional” adaptations to local ecology. In this way they re-materialized culture to its biophysical base, without succumbing to environmental determinism or racism/cultural chauvinism.

The typical cultural ecologist would undertake detailed, long-term fieldwork into environmental usage and modification in one locality, as well as everyday and ritualistic cultural practices. The result was a set of holistic studies in which the metaphor of “homeostasis” – borrowed from systems theory – loomed large, and in which “culture” and “ecology” were regarded as codependent, mutually adjusted, relatively stable, and internally complex domains of process, relationship, and event.

Though cultural ecology was synthetic and hazards geography more specialized, they both prioritized immersion in local situations and eschewed the macro-focus of earlier human–environment geographers. Yet they also both, in their own way, held fast to the realism of their predecessors: “nature” was taken as an independently existing domain that could be studied carefully to ascertain the threats, constraints, and opportunities it afforded different people in different locations. This realism they shared with the newly scientific branches of physical geography. Though this conformed to the common sense of the time, the cultural ecologists, and hazards geographers’ efforts did not arrest the growing human–physical divide described above, and nor did they intersect with the Western environmental movement – which first gathered momentum in the late 1960s.

By then it was clear to many that population increase, economic growth, and mass consumption were having a profound effect on natural resource availability and the integrity of ecosystems. Mercury poisoning at Minamata Bay, Japan; the Torrey Canyon oil tanker spill; Rachel Carson’s (1962) bestselling account of how herbicides and pesticides got into the food chain – these and other events inspired the first Earth Day, the founding of Greenpeace and Friends of the Earth, and other seminal early 1970s environmental initiatives. Geography had a golden opportunity to make “human impact studies” its main business – a possibility foreseen in 1956 in the earlier-mentioned Man’s Role in Changing the Face of the Earth and foreshadowed a century earlier by geographer George Perkins Marsh (1965/1864).

Quite why this opportunity was missed is hard to say. Although it was grasped at the teaching level, this was not really the case at the research level. Richard Chorley’s (1969) Water, Earth and Man – which called for a new focus on human–environment interactions – was arguably among the exceptions that proved the rule. Geographers conspicuously failed to analyze the anthropogenic local and global “environmental problems” that became ever more apparent from the early 1960s. Morally, the discipline also virtually ignored the pro-nature (or eco-centric) arguments being made within the wider environmental movement. Instead, a relatively small number of geographers complemented the natural hazards work of White and associates with a rather anthropocentric focus on resource management. This resource analysis was usually empirical, quantitative, and conducted in what geographer Tim O’Riordan (1976) called a “technocentric” mode. In other words, this research looked at how best to conserve resources for present and future human
needs. It rarely took issue with the fundamental causes of resource depletion and was very human-centered. Relatedly, a number of physical geographers became interested in the impact of human activities on the parts of the environment that interested them (and vice versa) (e.g., Hollis 1975). Like resource management studies, their research had a policy dimension because environmental management needed to be based on a proper understanding of its objects (e.g., rivers, soil erosion, predator–prey relationships). Yet despite its apparent “ethical-neutrality,” this sort of research was arguably value-laden because it did little to challenge the institutions, human actions, and rule systems that generated environmental degradation in the first place. It was very much “status quo” research.

The 1980s, 1990s, and early 2000s: “re-naturalizing” human geography, denaturalizing an enlarged environmental geography, and finessing the nature of physical geography

By the mid-1970s, then, nature was a key object of analysis in geography but in a different and more circumscribed way than a century earlier. A decade later things began to change. A significant development was that “critical human geographers” – those politically on the left of the subject – began to take a serious interest in not only nature but its collateral terms and referents too. Concurrently, a new generation of environmental geographers (also critically disposed) began to focus hard on contemporary environmental problems, but in ways that challenged the status quo by de-emphasizing the purported contribution of “nature” (e.g., natural scarcity) to those problems. These developments, to be detailed momentarily, were at once unsurprising and novel. The radicalism reflected the formative influence of the worldwide anti-establishment protests that erupted in 1968 and lived on for some years; but the “rediscovery of nature” beyond physical geography was not, in fact, a delayed mirror image of the “green movement” whose heyday was the 1975–1985 period. As we will now see, many human and environmental geographers sought to de-objectify “nature” and were relatively unconcerned about things like “environmental limits to growth” or the “rights of nature.” In other words, and for reasons to be explained, they chose not to make geography the discipline of analyzing and trying to reduce “the human impact” on the nonhuman world (so continuing an existing trend). Their interest in nature took other forms and had other motivations.

Let us look first at developments in environmental geography, of which two are worth highlighting during this period: namely, the rise of (developing-world) “political ecology” and of “vulnerability” approaches to understanding natural hazards. Cultural ecology, for the most part, adopted a resolutely local focus and tended to treat cultural groups and their biophysical milieu in isolation from the national and global scales. But this began to change from the mid-1980s onwards. The reasons were presaged in cultural ecologist Barney Nietschmann’s study of the Miskito Indians of the Nicaraguan coast. A field trip in the early 1970s made Nietschmann aware that his chosen field area was beginning to be drawn into national and global commodity markets and was losing some of its former independence (Nietschmann 1973). A decade later, Piers Blaikie and Harold Brookfield formalized this insight in the germinal books The Political Economy of Soil Erosion (Blaikie 1985) and Land Degradation and Society (Blaikie and Brookfield 1987). For them, cultural ecology’s focus on homeostasis and the relative autonomy of different cultures were increasingly being rendered unrealistic by two things: first, the growing reach
of state power at the national level, and second, the internationalization of commodity production, distribution, and consumption. “Political ecology” was thus tasked with understanding how local resource use was being affected by wider social forces, and the accent was on asymmetries of power between ordinary people and the various actors (e.g., national states and multinational companies) affecting those people’s lives. A new generation of researchers, especially in North America, was inspired to uncover the complex chain of connections tying local land and water use decisions by (say) peasant farmers to global shifts in commodity prices, trade agreements, and so on. Political ecology was thus “political” in that it was critical of the actors and processes that were destabilizing local land-use practices. For instance, land users who degraded their local resources were typically seen in this approach as relatively blameless victims making difficult decisions in highly constrained circumstances explained by “external drivers” beyond their immediate control.

If political ecology radicalized cultural ecology and expanded its analytical horizons, so too did a new approach to natural hazards geography from the mid-1980s onwards. The studies of White and fellow travelers tended, like cultural ecology, to bracket off the local scale from its wider geographical context. They also abstracted people’s perceptions of hazards and the process of cognition from any broader consideration of social relations and social identity. This began to change when Kenneth Hewitt – a former adherent to the White approach – edited *Interpretations of Calamity* (1983). A decade later, Ben Wisner and colleagues published the important book *At Risk: Natural Hazards, People’s Vulnerability and Disasters* (Wisner et al. 2003). These texts had an international impact on Anglophone hazards geography. They suggested that “vulnerability” to hazards was not simply a question of living in a naturally hazardous location; it was also a question of wealth, power, identity, and social location. Drawing, like the political ecologists, on the radical ideas that flowered in the Western social sciences from the early 1970s onwards, Hewitt, Wisner, and others argued that vulnerability was (i) variable in degree and kind within populations, and (ii) explained by the positions people occupied in regional or national social structures and in world politics and economics more broadly. This kind of research directed policymakers’ attention away from people’s perceptions and conceptions of hazards (with associated public education programs), and from technocratic policies like building flood walls to defend against storm surges. Instead, attention was focused on how poverty and powerlessness are socially produced, and on how vulnerable communities can be better protected against the problems triggered when hazardous events occur, like a tsunami. Protective policies should, the argument went, be focused as much on social welfare as on physical engineering solutions. Vulnerability was seen as a *societal* problem whose downsides were starkly exposed when natural hazards (seen as “proximate,” not “root,” causes) occurred.

As these intellectual innovations were occurring, a disparate group of human geographers began to take an interest in nature. Their aim was not to understand its “real character” and how it materially affected people. Instead, they sought to *denaturalize* understandings of nature and its collateral terms. Publications by scholars influenced by “poststructuralism” and by Marxism respectively stand out. The former were part of a wider “cultural turn” in Anglophone human geography during this period, one that focused on the origins and effects of various forms of social “discourse.” The latter were part of Marxism’s consolidation as a major approach in
human geography. The denaturalizing perspective that became de rigueur had three broad aims: first, to show that claims made about nature contained culturally specific assumptions about how the world is and ought to be; second, to show how references to nature were a means of furthering specific social agendas; and third, to show how these references actively concealed the two things just mentioned. Together these aims defined a “nature-skeptical” attitude in the specific sense that, while the concept of nature was taken to be real, so too was the physical world it designated, but the concept was seen to be “unnatural,” as was its role in societal discourse (lay and expert). It is this attitude that was flagged in the latter half of the section “What is nature?” as an alternative to the presumption that “realism” is the only sensible attitude toward those things we, by convention, call “natural phenomena.”

Out of many key contributions to the new “cultural studies of nature” in the 1990s, human geography let us focus on just two authors. In a now classic essay and related book, Canadian geographer Bruce Braun (Willems-Braun 1997; Braun 2002) applied poststructuralist Jacques Derrida’s ideas to the topic of nature and wedded them to postcolonial theory. The latter proposes that colonialism lives on culturally even though it has largely disappeared economically and politically. Braun’s empirical focus was the early 1990s clash between environmentalists and a commercial logging company over whether to fell an area of “old-growth” temperate rainforest in British Columbia called Clayoquot Sound. The former saw Clayoquot as one of the last remaining spaces of “pristine nature,” while the latter regarded it as a valuable economic resource that should be logged in a responsible way for the good of the Canadian economy and those communities dependent on forestry jobs. In a detailed analysis of both sides’ representations of Clayoquot, Braun shows how the region’s “realities” were made to appear quite different, depending who was doing the looking. There was a clash between representations that made Clayoquot appear wild, intricate, threatened, and special on the one side, and those (on the other side) that made it appear as one more “resource zone” to be rationally harvested by high-tech logging firms. In both cases, the authors of the representations claimed to be depicting Clayoquot as it actually was. But Braun’s point was that these representations – which comprised books, pamphlets, press releases, and newsletters – reflected the specific agendas of those promoting them. In other words, one could not adjudicate between them by testing their veracity against the “nonrepresentational actualities” of Clayoquot’s old-growth trees.

Arresting though this insight was, Braun’s research contained a further surprise. Notwithstanding the differences in content and message between the environmentalists’ and forest company’s representations, Braun argued that they ultimately shared the same symbolic universe: a specifically Anglo-North American one that reflects the linguistic conventions and cultural assumptions of those colonists who spread through the United States and Canada from the seventeenth century onwards. He makes this point with reference to Clayoquot Sound’s small groups of remaining “native” or indigenous peoples. These groups had, historically, lived a peripatetic existence and had used forest, lake, river, and shore for generations to meet their material and symbolic needs. Yet both the environmentalists and the logging company fighting over Clayoquot’s future assumed that the region was largely empty. This, Braun argued, constituted a geographical expression of a specifically Western belief that nature and society are two separate things.
indigenous peoples, he concluded, were thus victims of symbolic violence, even in the supposedly postcolonial conditions of modern Canada. Their history and present-day claims to control of Clayoquot simply did not register in the unthinking assumptions made by the descendants of the original European colonizers. Even when seemingly “progressive,” Braun showed, references to nature can serve as politics by other means.

Around the same time as Braun was writing, Australian geographer Kay Anderson was reinterpreting one of nature’s oldest and most socially potent collateral concepts, “race.” In the 1980s, ideas about race as biological differences between groups of Homo sapiens made something of a reappearance in Western discourse, having been discredited in the 1940s and 1950s for reasons we cannot go into here. In part this reappearance was linked to progress in the various sciences of human biology, which led to an international attempt to “map” the human genome and an eventually abortive attempt to also map genomic diversity among humans. There was also, again courtesy of new scientific findings, a resurgent “nature versus nurture” discussion in the West. Within the disciplines of human biology, physical anthropology, neuropsychology, and the young field of sociobiology, a debate has raged over whether people’s mental and physical capacities are mainly a function of genes and the like, or a product of their sociocultural environment. As this debate has unfolded, new biotechnologies have been invented that promise to alter “human nature” so that behavioral “disorders” or congenial diseases can, potentially, be engineered out of existence. In this context, many people worry that we are witnessing a new biological determinism to rival the eugenic beliefs popular in some Western countries in the 1920s and 1930s. The concern is that beliefs about the supposed links between a person’s genes and their behavior or appearance will be used to target those with a supposedly “inferior” or “abnormal” genetic constitution.

Writing in this context, Anderson explored how discourses about the supposed “actualities” of a group’s “race” were used to exclude them from the rest of a society, both socially and spatially. In her 1991 book, Vancouver’s Chinatown, Anderson showed how, from the late nineteenth century, a majority white population of British descent in Vancouver stigmatized Chinese immigrants. She demonstrated how this majority fixated upon phenotypical and cultural differences between themselves and Chinese settlers, coding them in “racial” terms and hierarchically too. This coding then served to hold the settlers at a distance in key arenas like employment and housing, reproducing European privilege. A later book on the origins of ideas about significant differences between human beings, Race and the Crisis of Humanism (Anderson 2007), also focused on the way culturally specific ideas are often conflated with the physical world of which they seek to make sense. Anderson’s monograph explored the challenge Europeans faced in understanding aboriginal societies in Australia from the late seventeenth century. Though holding Enlightenment concepts of humanity as a singular species and of all humans as biologically similar, new arrivals to Australia struggled to fit aboriginal people into their schema. Over time, Anderson shows, it was believed that these people were somehow closer to nature, almost animalistic, and thus not “human” in the same way as Europeans were. Yet, far from being a “factual” corrective to the Enlightenment idea of a “universal human nature,” Anderson demonstrates that this idea was itself culturally infused with certain European perceptions of what it means to be “properly human.” The implication is that even contemporary ideas about human nature and
intrahuman group differences cannot escape the imprint of cultural preferences and dislikes.

Studies like Braun’s and Anderson’s paid careful attention to the origins, content, and effects of various forms of “nature-talk” and of representations of “natural phenomena” more generally. However, they paid little attention to the material referents invoked or to the political economic realm wherein people wrest goods and services from the Earth. The former oversight perhaps reflected a fear of reintroducing environmental (or biophysical) determinism by the back door. It underpinned publications focusing on how nature might be said to be a “social construction” (see, for instance, Demeritt 2002). By contrast, one of human geography’s leading Marxists, the late Neil Smith (1954–2012), focused on both things. His influential book Uneven Development (1984) argued that capitalism – the dominant system by which goods and services are today produced – generates geographically uneven development as a constitutive feature, not as a random occurrence or accident. This is because capitalism is inherently contradictory: its compulsion to increase wealth incessantly leads it to scour the Earth for new investment opportunities, new markets, new raw materials, and new labor forces. According to Smith, the generation of profits and their deployment on a vast scale not only explains the rise and fall of cities, regions, and whole countries; it also underpins what he called “the production of nature.” This, as Smith himself observed, is a counterintuitive idea: “We are used to conceiving of nature as external to society … or else as a grand universal in which human beings are but small and simple cogs. But … our concepts have not caught up with reality. … [C]apitalism … ardently defies the … separation between nature and society, and with pride rather than shame” (1984, xiv).

What did Smith mean by “production”? Capitalism, Karl Marx argued, is an historically specific mode of making and exchanging commodities that began in Europe during the early eighteenth century. What makes it distinctive, he argued, is that commodities are produced not for their use value (i.e., their practical utility) but their exchange value (i.e., how much money they can command upon sale). Since they do not sell in order to get the same monetary sum back as it cost to produce their commodities, capitalists are fixated on “accumulation for accumulation’s sake,” employing workers to do their bidding and facing competitive pressures from rival capitalists. These pressures, Marx argued, necessarily force all capitalists to innovate and to seek a competitive edge by making new products, hiring more or less workers, employing “smart machines,” relocating factories, and so on.

What has this got to do with “nature”? A great deal. According to Smith, capitalism has remade nature over the past two centuries, meaning that such things as genetically modified crops are only the latest in a very long line of material transformations of the nonhuman world. Nature has become a mere means to the end of profit realization, and in the process it has been physically reconstituted into an anthropogenic “second nature.” Though not formally referencing Smith’s book, a brilliant 1991 monograph by historical geographer William Cronon illustrated Smith’s arguments in bracing detail. Nature’s Metropolis tells the epic story of how the rise of Chicago during the nineteenth century was umbilically connected to the formation of entirely new agricultural landscapes throughout the mid-west of the United States. For instance, in a superb chapter on grain production Cronon (1991) shows how money invested in new railways, new storage facilities, and new farm equipment created a vast new geography of fields and fences that replaced the natural grasslands created by evolution and the actions of indigenous/native peoples. Capitalism, in both
metaphorical and literal terms, revolutionized Chicago’s hinterland in a few short decades.

Smith’s arguments may seem somewhat overstated, even in an era where the genetic composition of species is being altered by science and technology. After all, even the “produced” landscapes of modern, commercial farms are “natural” in the sense that the animals, seeds, and crops have not been created by people from scratch. So why did Smith not favor the use of “softer” verbs (like “modification” or “alteration”) when describing the capitalism–nature relationship? The answer is twofold. First, he wanted to challenge those who continued to reference a nonsocial, supposedly pure, external “nature” when advancing their own cognitive, moral, or aesthetic arguments. His PhD thesis supervisor, David Harvey, had already set a precedent back in 1974. Harvey strenuously resisted then-popular arguments claiming that the world was increasingly “overpopulated,” because there were more people alive than the Earth’s natural resources could sustain. He argued that advocates of policies to limit birthrates justified them by talking of “natural limits to growth” that were supposedly fixed. This, Harvey (1974) argued, was an “ideological” move because it neglected the fact that “optimum” population numbers can only ever be defined relative to culturally specific assessments of what a “suitable” standard of living is. Those neo-Malthusians arguing for population control, Harvey argued, were typically developed-world inhabitants using spurious claims about “natural resource scarcity” to imply that developing world poverty was caused by reckless procreation.

Second, Smith arguably favored the metaphor of “production” because he believed that in a capitalist world “nature” and “society” were no longer discrete domains of reality. In other words, they comprise an ontological unity, not two ontological spheres. Terms like “alteration” and “modification” suggest some residuum of “natural nature” untouched by capital. But Smith’s point was that those aspects of what we call “nature” that are germane to our everyday lives are increasingly defined in relation to the needs and actions of capitalists. It is not so much that all of nature is produced “all the way down” physically – the Earth’s molten core, for instance, is hardly “produced” by capital. It is more that so much of what we consider to be “modified” or even “pristine” nature is as it is because it serves the material and discursive demands of capitalist enterprises as they vary in time and space. And where it does not – as in the case of global warming, which is caused unintentionally by atmospheric pollution – this nature is the indirect result of the intentional production of other aspects of nature.

This said, Smith (ironically) said precious little about the material properties and causal efficacy of those things we by convention call “natural,” be they consciously “produced” or not. His was a one-sided materialism that accorded considerable power to capitalism. It was left to others to fill this intellectual vacuum. There were two aspects to this. On the one side, some showed how capitalism was able to physically mold some parts of nature in the interests of profitability. Examples include environmental sociologist Jack Kloppenburg’s First the Seed (1988) and Goodman, Sorj, and Wilkinson’s From Farming to Biotechnology (1987). Both books focused, like Cronon’s, on farming. They showed how science was used by agro-foods companies to break down the physical “barriers” posed by crops and farm animals to enhanced profits – barriers such as crops’ vulnerability to certain pests or a chicken’s inability to grow to adult size in a few weeks rather than months. In both books, the physical malleability of certain components of “nature” was made plain in
a way in which Smith only made theoretical mention.

On the other side, other Marxist researchers interrogated cases where capital (or, rather, certain capitalists) is unable to impose its will entirely and where the agency of “nature” becomes important. Two examples will suffice. Karen Bakker’s (2003) *An Uncooperative Commodity?* showed how the physical properties of water made a huge difference to the way that privatizing British water services unfolded post-1989. Its weight and bulkiness give it a certain insensitivity to which new water market had to adjust. Likewise, Scott Prudham’s book *Knock on Wood* (2005) showed how the Pacific coast forestry industry has, in key respects, had to adapt to the material challenges posed by softwood trees growing in mountainous environments. Bakker and Prudham were not reintroducing a concept of nonsocial “nature,” of which Smith would surely have disapproved. Their point is that what we call “nature” possesses a degree of agency and influence, but this is always defined relationally with respect to the changing needs and wants of capitalist firms, not *sui generis*. It is thus never absolute and is thoroughly contingent and conditional.

The Marxian work on capitalism and nature prioritized economic processes and motivations. As we have seen, the suggestion was that the conventional idea of “nature” has been rendered obsolete (in some or all of its four meanings) because biophysical entities can no longer be understood in abstraction from the influences of capitalist enterprises. As Smith and Harvey also argued, this idea can be used for ideological purposes even as it has outlived its usefulness. This implies a gap between “discourse” and “reality,” wherein the concept of “nature” is used as a smokescreen by those with power or influence. This focus on the concept’s “performativity” is one they shared with the likes of Braun and Anderson.

Compared to all of the above, physical geography altered in quite conservative ways through the 1980s and 1990s. It held firmly on to, while finessing, its commitment to the idea that (nonhuman) nature has objective properties that are amenable to impartial analysis. There were three noteworthy changes of emphasis. First, the balance between pure and applied research arguably tilted slightly in the latter’s favor. According to Gardner (1996), this reflected a growth in the “environment industry” after the first Earth Summit (in 1992) and, particularly, the field of environmental management. Issues such as desertification, water pollution, soil erosion, and deforestation increasingly made it onto physical geographers’ research and teaching agendas (for more on this, see Gregory 2000, ch. 7). These geographers often sought to aid environmental managers by pinpointing the physical changes caused by certain human actions (e.g., Burt, Heathwaite, and Trudgill 1993). Second, at a more philosophical level, physical geography moved away from the “steady-state” and “dynamic-equilibrium” assumptions that had underpinned much of 1970s and 1980s research. Instead, practitioners began to appreciate that the environment is complex, often disorderly, and even chaotic in its operations. As Barbara Kennedy (1979) presciently noted in the late 1970s, physical geographers are confronted with a “naughty world” (see also Kennedy 1994). This change in ontological assumptions was partly inspired by wider shifts in scientific thinking, notably the rise of “transcendental realism,” as well as complexity and chaos theory (see Phillips 1999). Third, the rise of Quaternary studies and a new emphasis on “global environmental change” meant that the study of environmental systems at large spatial and/or
temporal scales underwent a revival. In a sense, physical geography’s historical origins as what Simpson (1963) called a “historical science” were rediscovered, providing a counterbalance to the small-scale, process-form studies that had been so popular from the late 1950s. This meant that its credentials as an idiographic subject focused on novelty and difference were reasserted, not at the expense of a nomothetic (i.e., law or pattern-finding) approach but as a recognition that general laws and processes can have nongeneral (unique) outcomes (as some “critical realists” argue).

The nature of contemporary geography

We have just seen that human geographers had “rediscovered” nature by the turn of the new millennium by way of a seemingly paradoxical “denaturalizing” approach. This approach, we have also seen, animated an expanded domain of environmental geography, leaving physical geography’s branches focused on the nonhuman world and holding fast to a realist ontology. What of the most recent period? How do geographers today understand “nature” and what, therefore, is the current nature of geography?

In human geography the denaturalizing sensibility that existed by 2000 has to some extent given way to a new approach that challenges the idea either that “nature” is a socially constituted representation (or artifact) or that it is something existing regardless of human ideas and practices. This approach rejects the ontological distinction between society and nature that underpins most of the studies cited so far in this entry. It has roots in continental European philosophy and STS (science and technology studies): thinkers like Isabelle Stengers, Michel Callon, Donna Haraway, and Bruno Latour have strongly influenced several erstwhile “human” geographers since the mid-1990s. By the early 2000s two overlapping strands of research were already evident, both prevalent in British human geography: namely, one focused on “hybrid geographies” (closely associated with Sarah Whatmore 2002) and one on “nonrepresentational geographies” (closely associated with Nigel Thrift 2007). Since we do not have the space to explore their subtle differences, we will simply highlight their commonalities.

Hybrid and nonrepresentational perspectives maintain that dividing the world into “social” and “natural” entities simplifies reality to the point of misrepresenting it. The suggestion is that there is no neat Maginot Line that divides the world into two qualitatively different orders that somehow “come into contact” with each other in various ways in different contexts. Instead, Whatmore, Thrift, and like-minded geographers insist that we inhabit one reality, not two, and that supposedly “natural” things and “social” things cannot be separated if we are to understand their character and effects. This chimes with Neil Smith’s arguments, but unlike Smith these geographers do not believe that capitalism is calling all the shots in our syncretic, mixed-up world. They further suggest that human engagements with the world far exceed acts of “representation”: they also involve touch, smell, hearing, and physical interaction. We are multisensual actors, the argument goes, and what we are does not precede our relationship with all manner of other entities.

To flesh out these arguments, there have been numerous recent studies of the almost endless ways in which so-called social and natural things are so entangled as to variously co-constitute, stabilize, or alter one another (depending on the case). These studies are highly attentive to the fine details of different situations and amount to a cognitive, moral, and aesthetic call to attend to what the society–nature dualism has so long
hidden from view. For example, in some of her work on wildlife conservation, Sarah Whatmore has argued that the seemingly unproblematic category “elephant” needs to be called into question. Becoming an “elephant” is, Whatmore and Lorraine Thorne (2000) show, a process that is contingent on the specific network of actors, institutions, and physical environs in which individual pachyderms exist. There is thus, they argue, a notable set of differences between zoo elephants and “wild” elephants, even though they are conventionally regarded as belonging to a single species possessed of stable and singular characteristics common to any similarly named creature. Conservationists, they imply, could usefully pay more attention to the differentiated character of that which they are seeking to conserve, and to the varied networks through which “becoming an elephant” is achieved. To conserve “nature” one needs to understand that it is not a discrete object or site to be protected, but a whole set of differentiated entities bound into complex relationships that might be very extensive in space and time. This obliges us to rethink both what is being “conserved” and how to do it in all nature conservation policies (see also Hinchliffe 2008). More broadly, it means that any future politics must be attentive to the relationships between, and admixtures of, what can no longer be labeled as “social” or “natural” entities. This challenges most major extant political paradigms, be they environmentalist, socialist, liberal, or any other.

Research in this vein has grown in size and diversity since 2000. It is now known, variously, as inquiry that has a “more-than-human,” “postnatural,” or “posthuman” focus. Some of it examines the human body, yet without reintroducing fixed conceptions of “human nature.” It has also been called “neo-materialist” because it shares physical geography’s deep interest in the properties and effects of materials, while challenging the atomist and reductionist assumptions about matters evident in some of its branches. A fine recent example of this expansively relational approach is Lesley Head, Jenny Atchison, and Alison Gates’s (2012) Ingrained: A Human Biography of Wheat.

However, this is not to suggest that earlier strands of denaturalizing research by human geographers are passé. On the contrary, many studies continue to be published of who is speaking about “nature” and its collateral terms, in what ways, with what intentions, and with what effects. Many of these studies have used the analytical lens of “eco-governmentality” (or “environmentality”) to make sense of discourses about everything from global climate change to “green consumption.” This lens derives from French philosopher-historian Michel Foucault’s notion of “governmentality.” Foucault argued that the process of governing people (and non-humans) exceeds the institutions of the modern state and is dispersed among multiple organizations and actors. He further suggested that government not only acts upon people but, as it were, through them by altering their sense of self and world. Governmentality as an analytical concept combines two aspects of governing: namely, “rationalities of government” and “technologies of government” (Miller and Rose 2008, 15). The former specify the division of tasks and actions between authorities (e.g., political, spiritual, military, or familial) and express the ideals or principles that should direct government (e.g., freedom, justice, or entitlements). Such systems of thought also identify the nature of the objects to be governed (e.g., society, the nation, the population, animals, the economy) and characterize the persons over whom government is to be exercised (e.g., a flock to be led, legal subjects with rights, a resource to be exploited) (see Rose and Miller 1992, 178–179).
As Lövbrand, Stripple, and Wiman (2009, 8) express it: “Whereas rationalities of government … render reality into the domain of thought, technologies of government translate thought into the domain of reality.”

How does this connect with issues of “nature”? In recent years three such issues have become ever more prominent in academia, politics, business, and civil society. First, there are widespread concerns about the accelerating pace and heightened magnitude of anthropogenic climate change (“nature as threat”). Second, there are equally widespread worries about natural resource exhaustion and anthropogenic degradation of terrestrial and marine ecosystems (“nature under relentless pressure”). Finally, there is both excitement and concern about genetic modification, artificial life forms, and other science-led attempts to intentionally remake the building blocks of life (“nature denatured”). In this context, what studies of “eco-governmentality” do is trace the ways certain mainstream institutions are enrolling references to things like biodiversity, species extinction, resource conservation, genetic diseases, and carbon dioxide into new rationalities and technologies of government (see Rutherford 2011). For instance, something as mundane and seemingly positive as promoting “ethical shopping” can be seen as a contestable attempt by certain organizations (e.g., supermarkets) to govern the thoughts and actions of millions of people – in the process closing off other possible ways of responding to global environmental change.

This kind of research, like that done earlier by Braun, Anderson, and Smith, pays little attention to how the material world existing beyond rationalities and techniques of government might matter “in itself.” This may seem foolish in light of what many scientists tell us is the “dangerous” magnitude of anthropogenic environmental change coming at us in this century and beyond. Accordingly, some human geographers, and many environmental geographers, have been very focused on the following issues: how the science of environmental change is communicated to and interpreted by ordinary people (e.g., Boykoff 2011); how advanced industrial societies can make a rapid sociotechnical transition to a “low carbon” state (e.g., Bailey and Wilson 2009); how low-income countries can adapt to the biophysical impacts of a warmer, wetter world (e.g., O’Brien and O’Keefe 2013); how low-income communities and vulnerable people can be made more resilient in the face of anthropogenic environmental change (e.g., Wilson 2012); and how local alternatives to an environmentally destructive global capitalism can be fostered (Gibson-Graham and Roelvink 2010). This is an incomplete list, but it speaks to the partial “renaturalization” of both human and environmental geography in light of the end, as some earth scientists see it, of the Holocene (i.e., the 11,500-year period of relative environmental stability coincident with homo sapiens flourishing). The word “partial” is used here because the kind of research just itemized generally does not take a humanly altered “nature” as something whose character and impacts can be defined in absolute terms. In this sense, it carries forward the analytical sensibility first cultivated by the likes of Hewitt, Wisner, Blaikie, and Brookfield many years ago.

However, some environmental geographers now argue for a more profound renaturalization of geographical research and pedagogy. For instance, in his book Inhuman Nature: Sociable Life on a Dynamic Planet, Nigel Clark (2011) claims that the strands of “denaturalizing” summarized earlier in this entry suffer a key weakness. In his view they tend to ignore – or to not take seriously enough – the very largest, inhuman forces operative in and on Earth (like ocean currents and volcanoes). The twentieth century,
he argues, has fooled many Western geographers into believing that “high-magnitude” bio-physical events are low frequency and spatially dispersed. Yet our climate-changed future might assault global humanity with many such events in time and space. In this light, denaturalizing research – be it cultural studies of nature or “postnatural” research – risks being irresponsibly ignorant of the corporeal threats and radical opportunities for a new human future attendant upon the Holocene’s end.

Clark’s belief in the autonomous existence and raw power of “big nature” – albeit one imprinted by centuries of human activity – chimes with recent developments in parts of physical geography (and the wider environmental sciences). Many practitioners have regarded global environmental change as a further impetus to reclaim physical geography’s “big picture” integrative focus (see Clifford 2009). Many physical geographers have seen their research feature in the influential reports of the Intergovernmental Panel on Climate Change (IPCC) and a few are advocating the new idea of “planetary boundaries,” which humanity is said to compromise at its peril. Still others have, at times, lent their name to Earth System Science, a hoped-for super-science of the planetary environment that seeks to understand couplings, feedbacks, and thresholds among the various subsystems of land, air, and water (see Wainwright 2009). Through all this a rather traditional ontological realism prevails: global nature, one changing because of human impacts, is seen as amenable to analysis via remote sensing techniques, sophisticated computer packages, ground-truthing, and logical analysis based on known laws. So it is that the long-standing nature–society dualism is preserved, despite the critical interventions of Whatmore, Thrift, and others. Complementing this, a number of environmental geographers are keen to extend the scientific mindset to both understand and better manage the “human impact” on the world’s land, water, and air masses. Advocates of “land change science” and “sustainability science,” like Billie Lee Turner II (Turner, Geoghegan, and Foster 2004) and Robert Kates (2011) respectively, urge geographers to derive practical solutions to anthropogenic environmental problems by paying close attention to the scientific evidence. These geographers are, perhaps, less enamored of the denaturalizing impulses of many of their professional peers and closer in spirit to most physical geographers. Though in no way neo-environmental determinists, they apparently accept the is–ought dualism that parallels the nature–society, object–subject ones discussed in the section “What is nature?”

There are, however, exceptions. For instance, Mike Hulme – a physical geographer and former lead author of IPCC science reports – argues that the sciences of the Earth environment should be subject to sociocultural analysis. This is especially true now that they may be assuming unprecedented importance in shaping public and political decision-making. In Why We Disagree about Climate Change (Hulme 2010) and related publications he challenges the idea that the environmental sciences deal merely in “facts,” leaving others to trade in debates about values and goals. More than this, though a scientist himself, he worries that the global claims made by the IPCC can too easily underpin ideas of “global government” and “global policy” that are likely to alienate (even harm) many ordinary people whose lives are ineluctably local and situated. A new “climate determinism,” he suggests, may be afoot (Hulme 2011). If so, it comes on the heels of a neo-environmental determinism some detect in the writings of geography’s most famous environmental analyst, Jared Diamond. His popular books Guns, Germs and Steel (1997) and Collapse: How Societies Choose to Succeed or Fail (2005) are part of a genre of “highbrow”...
popular writing that recalls the grand analyses of geography’s founding figures such as Halford Mackinder. But they arguably suffer the same problems in their attempt to establish how the natural environment enables and constrains human flourishing. Gaps of data, questionable inferences, and contestable deductions are glossed over in the search for historic patterns and cross-cultural trends in humanity’s relation to land, water, and sky.

In light of all of the above, it should by now be clear that the various intellectual divisions internal to geography will not be overcome in the name of a holistic analysis of our new environmental era, what some are calling the Anthropocene. Though some geographers hope for a reunification of the discipline (e.g., Herbert and Matthews 2004), it is more realistic to expect greater interchange between certain physical, environmental, and human geographers interested in some aspect(s) of “nature.” This interchange has been interpreted as within-discipline experiments in, variously, “inter-,” “multi-,” “cross-,” and “trans-disciplinarity” (see, for instance, Oughton and Bracken 2009).

Though some of these experiments are intended to combine the expertise of specialists in order to reveal the “total picture,” many are designed to foster mutual learning between diverse perspectives. Hulme (2010), for one, sees the latter as vital for both geography and wider society. For him, current debates about “nature” – what it is, what it does, its value, and its very existence – are not to be resolved. Instead, they are incitements to explore diverse views on the sort of world we believe we inhabit and the sort of future we might want to create. For Hulme, the “problem” of how to understand what we call nature (and its collateral referents) is a productive opportunity, not a hurdle to overcome. It can and should spark democratic debate about the really big questions in our lives.

Conclusion

Despite its length, this entry has not represented the full range of work on nature by geographers past and present. Yet we have still covered an awful lot of ground. As we have seen, the centrality of “nature” to geographers’ inquiries has varied over the past century or more, but has never been marginal to their endeavors. In recent years it has captured the attention of physical, environmental, and human geographers, in contrast to the period 1945–1980, when it largely fell to physical geographers to study and teach about it. This means nature has again assumed the wider disciplinary importance it enjoyed during geography’s early years as a university subject – only now in very different ways than in the era of Mackinder, Ratzel, Semple, de la Blache, Davis, and fellow travelers. Today we can witness the influence of the accumulated history of geographers’ changing perspectives on nature (in any of its four main meanings and its myriad of referents). A traditional realist approach, albeit very different in the detail from a century ago, still persists and looms large in contemporary physical and parts of environmental geography. Meanwhile, two more recent denaturalizing approaches exert influence in parts of environmental and human geography – one focused on representations (images, discourses, signs, etc.) or material transformations (as in agriculture), the other on the dissolution of the supposed ontological divide between society and nature, human and nonhuman. Though we live in an era where many express alarm about the “realities” of humanity’s impact on both nonhuman nature and its own corporeal nature, this has not led to a synthesis of the three approaches or the triumph of one over the others. Instead, intellectual diversity prevails.

Is this a weakness, perhaps a sign of incoherence, or a failure to respond responsibly to...
the “grand challenges” of the early twenty-first century? Some would say so. However, there is another view. By juxtaposing very different perspectives within a single disciplinary matrix, geography today offers opportunities to combine and complicate forms of knowledge about the biophysical world that often exist in splendid isolation elsewhere in academic life. What can realists about “nature” learn from “denaturalizing” critics, and vice versa? What difference might it make to research, public policy, or scholar-activism? These questions challenge geographers and others to appreciate that, like all of the really crucial issues in life, there is no such thing as a “right answer.” Instead, there should always be struggles and disagreements over the way issues are framed and responses thereby delimited. Answers are thereby revisable, debate thereby stilled only for a period of years.

Necrogeography

Hamzah Muzaini
Wageningen University, Netherlands

Necrogeography, or the study of “deathscapes,” is the inquiry into spaces associated with the mourning, management, and remembrance of death, dying, and the dead, of humans as well as animals, particularly how these are physically and symbolically constructed, negotiated, and sometimes contested.

Various aspects define its research parameters. The first pertains to the role of “place” in human mortality and end-of-life processes. This strand considers how rituals associated with such processes transform “places,” and the ways in which “places” in turn influence experiences of death and dying. The second relates to the critical mapping of the logic behind the planning and design of “deathscapes,” such as within cemeteries and crematoria. This applies to the processes and issues to do with how dead bodies (and animal remains) are spatially disposed of and managed.

Influenced by trends within the “new cultural geography,” a third strand focuses on the meanings invested in such spaces, and the co-option of these meanings for a variety of purposes (e.g., for identity-building, dark tourism, or bereavement). Underlying this strand is also how “deathscapes” mirror society, not only in its constitution but also its divisions, where contentions may arise over multiple uses of these spaces, and how they can embody exclusions (e.g., in terms of gender, ethnicity, and class).

A fourth strand is the analyses of death and “deathscapes” as these are depicted through art and other media. Of particular interest here is how such representations serve as a lens to reflect upon societal norms and beliefs.

Following more nonrepresentational lines of thinking, recent research strands include the study of the material and affective agency of corpses, emotional geographies of dealing with death, and everyday practices of engaging with the dead. From traditional sites like cemeteries and monuments, research has also moved to “new” spaces for handling remains and remembering the dead, such as through natural burial sites and virtual memoryscapes. In line with the emphasis on the notion of “practice,” there is also increasing interest in liminal spaces associated with the labor of taking care of dead bodies (e.g., within funeral homes). Cutting across many of these strands of research are the following common observations: that “deathscapes” reflect the sociocultural and political contexts in which they are found, that they are susceptible to cultural politics, and that they reveal as much about the living as they do about the dead.

NECROGEOGRAPHY

Neighborhood, conceptual

Christian Freksa
Arne Kreutzmann
University of Bremen, Germany

The notion of conceptual neighborhood was introduced in the context of research in qualitative temporal and spatial reasoning to describe direct discrete transitions between temporal or spatial relations in dynamic worlds (Freksa 1991a, 1991b). As a simple example, consider the relative position of two (time or space) points on a directed line. The points P and Q can be positioned in one of three relations: P before Q (P < Q), P at Q (P = Q), or P after Q (P > Q). Under continuous motion of the points direct transitions are possible from P < Q to P = Q and from P = Q to P > Q; a direct transition from P < Q to P > Q, however, is not possible; a transition will go through the intermediate relation =. The relation before (>) therefore is called a “conceptual neighbor” of the relation at (=) and the relation at (=) is called a conceptual neighbor of the relation after (>), whereas the relations before (−<) and after (>−) are not conceptual neighbors, as no direct transition between them is possible (Figure 1). Spatial or temporal entities connected through relations form spatial or temporal configurations.

The role of relations

Qualitative relations are abstract concepts that correspond to discrete classes of continuous-valued relations. If one variable is fixed, qualitative relations either correspond to a single, precise value (e.g., P = Q), or they subsume a whole range of values that are not further distinguished (e.g., P < Q).

Qualitative relations play an important role in conceptualizing spatial, temporal, and other configurations. They are robust with respect to small distortions that do not affect critical aspects of the configuration. Depending on the relations chosen to represent configurations, critical aspects may refer to topological properties (e.g., disjoint, touching, overlapping, inside), to orientation properties (e.g., left, right, front, back, up, down), to angles (acute, right, obtuse, straight), to distance (near, far), or others.
Informal definition of conceptual neighborhood

The notion of conceptual neighborhood was first introduced for temporal relations (Freksa 1991a).

Two relations between pairs of events are (conceptual) neighbors if they can be directly transformed into one another by continuous deformation (i.e., shortening or lengthening) of the events.

This notion can be interpreted for spatial relations as follows.

Two relations between pairs of spatial entities are conceptual neighbors if they can be directly transformed into one another by continuous transformation.

This definition of conceptual neighbors addresses binary relations; it can be extended to ternary relations or to relations of higher arity in a straightforward manner.

The definition of conceptual neighborhood intentionally leaves room for interpretation. First, it does not specify exactly which continuous transformations are to be considered; second, it does not specify whether relations can be conceptual neighbors of themselves; and third, it does not specify what is considered to be a continuous transformation. In his book *Qualitative Spatial Change*, Galton (2000, Chapter 7) examines the implications of different types of spatial change, given various notions of continuity; this results in different answers as to whether or not a two-dimensional region can be continuously transformed into a line segment.

In early days, the terms “closest-topological-relationship-graph” (Egenhofer and Al-Taha 1992) and “continuity network” (Cohn and Hazarika 2001) were used synonymously with conceptual neighborhood graph.

Formal definition of conceptual neighborhood

In this section, the term “domain” refers to a mathematical structure. In geographic information systems the typical domain used is the domain of two-dimensional polygons extended to allow the inclusion of points and sometimes also of line segments. However, a circle or circle segment can only be approximated in such a domain.

In this section, the term “domain” refers to a mathematical structure. In geographic information systems the typical domain used is the domain of two-dimensional polygons extended to allow the inclusion of points and sometimes also of line segments. However, a circle or circle segment can only be approximated in such a domain.

Given a finite set of $n$-ary relations $R$ over a domain $D$, then two distinct relations $r_1$ and $r_2$ are called conceptual neighbors if, and only if, there exists a continuous function $f : C(D^n)$

\[
\begin{align*}
  f &: R \rightarrow D^n, \\
  f(0) &\in r_1, \\
  f(1) &\in r_2, \text{ and} \\
  f(t) &\in r_1 \cup r_2 \text{ for all } t \in [0, 1].
\end{align*}
\]

In the literature, concepts usually are not considered to be conceptual neighbors of themselves; therefore the above definition contains the requirement, that $r_1$ and $r_2$ are not identical. Further, conceptual neighborhood is often
regarded as symmetric, which also directly follows from the above definition with $f'(t) = f(1 - t)$. However, applications usually only allow a subset of all possible continuous transformations due to the semantics in the domain, geometric or physical laws, dynamic properties, and so on.

### Semantics

As conceptual neighborhoods are derived from transitions in the represented domain, they depend on structural and dynamic properties of the domain and of the entities in the domain. To illustrate this, this entry will look at a slightly more complex example: rather than considering (zero-dimensional) points on (one-dimensional) lines it will now look at extended one-dimensional spatial objects: line segments, which can move with respect to a directed line. Equivalently, time intervals (rather than one-dimensional spatial objects), which can be related to one another, can be considered. Thirteen qualitative relations can now be distinguished (Figure 2).

For each configuration of two intervals on the directed line there is exactly one qualitative relation; that is, the relations are jointly exhaustive and pairwise disjoint (the so-called “JEPD property”).

In the one-dimensional world of linear extended objects/events we can conceive of different kinds of dynamics depending on physical properties of the entities involved and on the forces that act on these entities. For example, objects may be assumed to be fixed in location, or mobile, they may be rigid (i.e., nondeformable), elastic (deformable), divisible, or mergeable, and these operations may be symmetric or asymmetric; some of these properties may be combined in various ways. For example,

Figure 2 Thirteen qualitative relations between two linear extended objects on a directed line (or equivalently: two temporal intervals on the directed time line). Adapted from Freksa 1991a. Reproduced with permission of Elsevier.

(i) individual objects may expand or shrink at one end at a time; (ii) objects may be rigid (fixed size), but able to move relative to one another; or (iii) objects may be fixed in location but expand or shrink on both ends.

From a physical modeling, a cognitive, and a computational perspective, it may be desirable to consider exclusively those relations that can be physically realized; however, obtaining conceptual neighborhood in a formal system in the case of restrictions on the domain poses a difficult challenge and generally results in more complex structures. This is due to the fact that abstract formal systems are not structurally constrained in the same ways as physical systems are. Therefore, formal approaches often use a more general notion of conceptual neighborhood for practical applications that does not take into account the restrictions of specific domains; these restrictions then are taken into account at a later stage of modeling.

It frequently happens that, in domains where different perspectives such as empirical, theoretical, or practical may become relevant, these perspectives impose different desiderata on the concepts employed, as each perspective may employ a
different reference system. This is why some flexibility may be needed in order to relate these perspectives in a productive fashion. As applications generally require more information than those encoded in typical conceptual neighborhoods, various extensions have been proposed.

Adding further transition knowledge

Besides restricting the set of continuous transformations on the basis of structural properties of the domain, taking into account restrictions due to specific tasks or actions to be performed as well as implications from earlier processing can be of great value in applications. For example, in a control setting it is important to know which actions could result in a specific change on the qualitative level.

Action-augmented conceptual neighborhoods

Conceptual neighborhood allows the description of mandatory and possible changes but does not specify the cause or actions leading to such change. Assuming that all changes are caused by actions performed by the involved agents, the set of continuous functions can be divided into subsets such that each subset corresponds to a tuple describing the corresponding actions. For each tuple of actions the induced conceptual neighborhood can be determined. Dylla (2008) calls the resulting extension action-augmented conceptual neighborhood.

The asymmetrical nature of actions carries over to the action-augmented conceptual neighborhood. Further, due to abstraction, actions might not result in a change on the conceptual level (see the section “Perceptual uncertainty and coarse reasoning”) or could lead to different neighboring relations. Consequently, the resulting action-augmented conceptual neighborhood structure is complex and requires additional reasoning methods to be used for active agent control.

Dominance spaces and topological mode spaces

From a more theoretical point of view it is interesting to know what occurs at the transition from one relation to another and whether a relation can hold over an interval or only at a single instant of time. An example is the motion of a pendulum that reaches its extreme deflection only at a single instant where its speed is zero. This kind of knowledge is not only important when estimating what might be observable and what might not, but also when simultaneously employing conceptual neighborhoods from different relations.

A relation $u$ is said to dominate a relation $v$ if the relation $u$ has to hold at the transition point for relation $v$. Consequently, the relation describing a pendulum’s extreme deflection dominates the relation that describes a rising pendulum. A conceptual neighborhood structure extended by the notion of dominance is called dominance space. Topological mode spaces combine both dominance and possible temporal extent of relations. Galton (2000) proved a product theorem for topological mode spaces, which allows for directly computing the product of topological mode spaces. This is an important result for applications, as only basic topological mode spaces need to be determined, for example for single pairs of entities, to be able to calculate the topological mode space describing the simultaneous motions of arbitrarily large numbers of entities.
Conceptual neighborhood graphs

Depending on the ontology of the domain and the specific laws that rule the environment, different conceptual neighborhood structures will be obtained. Nonetheless, all of these structures form a graph, either directed or undirected. As an example, imagine two people looking into an aquarium seeing and describing the changing relations of two of the fishes. Essentially, they established a conceptual neighborhood structure, which is visualized as a graph in Figure 3. The observed relative size might change as the fish move in three-dimensional space while the viewer only perceives a projection. See also Figure 4.

Relation between conceptual neighborhood and spatial neighborhood

Tobler’s first law of geography states that “everything is related to everything else, but near things are more related than distant things.” This insight suggests that near things may deserve a different treatment than distant things. Qualitatively, we may distinguish near things from distant things through the attributes “directly connected” versus “not directly connected.” The special role of nearness and neighborhood is a particular property of space; it carries over to the domain of time, to which space is closely connected through the laws of physics.

Similar insights exist in pattern recognition and scene analysis: as a rule of thumb, it is a good heuristic to assume that a pixel (say on a satellite image) maps the same land-use category as the neighboring pixel; this rule is violated only at the (one-dimensional) boundaries of (two-dimensional) land-use regions. Dealing with these – comparatively few – exceptions is considerably cheaper than treating each pixel without prejudice.

Accordingly for conceptual neighborhoods: just as land use or other attributes are not randomly distributed over spatial regions, qualitative relations are not randomly distributed over conceptual spaces (Gärdenfors 2000). The rules for conceptual neighborhoods are even stronger than for attributes of spatial neighborhood: while attributes of spatial neighbors are merely a heuristic rule of thumb, the rules for conceptual neighborhoods correspond to intrinsic properties of spatial (or temporal) structures and processes. In these structures, there is no way that the neighborhood structure could be violated. This fact is exploited in conceptual neighborhood-based reasoning.

Conceptual neighborhood-based reasoning

Spatial reasoning in general can be reduced to the following inference pattern for three locations A, B, and C and two given relations r1 and r2: if A is in relation r1 to B and B is in relation r2 to C then A is in relation R to location C (Freksa 1991b). In this way we can compose each element of a set of relations with itself and with each other element of the set to obtain a complete set of composition rules that govern the respective domain; this has been done, for example, by Allen (1983) in his famous paper on Maintaining Knowledge about Temporal Intervals. By composing each of the 13 JEPD relations that may hold between two temporal intervals (Figure 2) with each element of the same set of relations, we obtain $13 \times 13 = 169$ relations that describe the knowledge we can infer by applying two of these relations in sequence. For example, when an event A takes place before an event B and the
event B takes place before an event C, we can infer that event A takes place before event C.

Not all of the 169 compositions are as straightforward as in this example: for certain compositions, the inferred relation differs from both constituent relations; for other compositions of constituent relations the inferred relation is ambiguous. For example, if event A overlaps event B and event B takes place during event C, then event A either overlaps or takes place during or starts event C; but other relations are not possible.

In the case of the 13 JEPD relations between temporal intervals, 72 compositions yield such ambiguous results. Three of these compositions do not permit any useful inference; for example, if event A takes place before event B and event B takes place after event C, any of the 13 base relations between event A and event C may hold.

Allen observed that compositions that involve the equal relation yield trivial inferences that are identical to the second constituent relation involved; he therefore reduced the $13 \times 13$ composition table to a $12 \times 12$ matrix (which he called the “transitivity table”).

But the structures of time and space exhibit much more regularity that can be exploited for reasoning. Specifically, if we arrange the composition table in such a way that neighboring entries correspond to conceptually neighboring constituent relations, we will observe that the inferences in the table behave in a rather regular and smooth way; this structure can be used to guide the inferences. Most notably, we will observe that only a small fraction of theoretically conceivable combinations of JEPD relations will actually occur as inferences in spatial and temporal reasoning. Upon further analysis, we will observe that the inference sets of relations (i.e., the sets of possible resulting JEPD relations that cannot be disambiguated through the inferences) consist of conceptually neighboring relations, that is, they correspond to situations that are obtained through continuous transformations in the domain.

This insight is not surprising if we analyze the reasons for the ambiguities in inferences: in qualitative temporal and spatial reasoning over temporal intervals or spatially extended objects the ambiguities in inferences are due to the fact...
that the premises yield coarse information with regards to the potential configurations of the entities as the boundaries of the objects are only partially fixed. As a consequence, only neighboring relations corresponding to the ambiguous sides of these boundaries are in question.

This consideration leads to a feature of qualitative spatial reasoning that is highly relevant for cognitive processing or, more generally, for processing incomplete information in benign environments. Here “benign environment” means an environment in which changes happen gradually rather than abruptly. In qualitative (categorical) views of the world, gradual changes correspond to smallest steps (transitions between conceptual neighbors) whereas abrupt changes would correspond to jumps between non-neighboring relations.

Distances between relations

The distinction between conceptually neighboring and other relations gives rise to the question of whether further distinctions between relations may be useful. In particular, a neighbor of a neighbor may be considered closer than a non-neighbor. This becomes computationally relevant if we exploit conceptual neighborhood for reasoning. Thus, we can define a conceptual distance between relations. Based on the conceptual neighborhood graph, a minimal distance between relations can be defined as the minimum number of neighborhood transitions between two relations (e.g., Goyal and Egenhofer 2001) for distances between cardinal direction relations.

Egenhofer and Al-Taha (1992) applied the notion of conceptual neighborhood to reasoning about gradual changes of topological relationships; for example, rising water levels of a lake that will cause a lake that originally is disjoint from the house first to meet and then to overlap the region of the house. The authors looked at conceptual neighborhoods within the framework of the 9-intersection model of topological relationships. The 9-intersection model describes topological relations between spatially extended objects in terms of the configurations of relations between their respective interiors, boundaries, and exteriors; this results in 9 subrelations, each of which can take the value “empty” or “nonempty.” They observed that certain topological relations are distinguished by only a single subrelation whereas others – including some conceptual neighbors – are distinguished by a larger number of subrelations. Consequently, they defined distance between topological relations by the number of distinguished subrelations in the 9-intersection model. Neighboring relations with the shortest distance were designated as the closest topological relationship.
NEIGHBORHOOD, CONCEPTUAL

Egenhofer and Mark (1995) used conceptual neighborhoods to describe topological relations between lines and regions; they confirmed that conceptual neighborhoods correspond largely to the way humans conceptualize similarity of spatial relations. Egenhofer also analyzes spatial relations on spheres in terms of conceptual neighborhoods.

Coarse relations

Conceptually neighboring relations, which are distinguished only through gradual transitions between semantically very close entities, lead directly to the concept of a coarse relation. A coarse relation can be defined by a set of fine (base) relations in which small distinctions (= transitions between neighboring relations) are ignored. The usefulness of coarse relations is twofold: (i) coarse relations can be used to represent incomplete knowledge (here, knowledge in which distinctions between certain details are missing); (ii) perceptual and conceptual knowledge frequently are structured in such a way that fine distinctions may be missing while the big picture is preserved. This seems to be particularly the case for knowledge relating to “benign” domains such as time and space, which are conceptualized as continuous domains in which changes happen gradually to a large extent. Such a type of “incomplete” knowledge frequently can be represented through coarse qualitative relations on the basis of conceptual neighborhoods.

Reasoning based on coarse relations

The next obvious step of what can be done with conceptual neighborhoods is to reason on the basis of coarse relations – particularly if they correspond in a natural way to the type of knowledge that is available through perception of space and time and through the conceptualizations we may have of them.

A classical approach to dealing with incomplete knowledge in artificial intelligence is to form disjunctions of hypothetical completions of this knowledge; in other words, the potential alternatives that may hold under the incomplete specification would be enumerated. Reasoning over disjunctions is a computationally expensive process, as each disjunction may result in new sets of disjunctions; this leads to an exponential growth of complexity. Furthermore, replacing incomplete knowledge by disjunctions of complete knowledge is intuitively not very plausible for the most part. It is a form of reasoning a detective may use to solve a puzzle with missing pieces; but for everyday tasks of dealing with coarse knowledge, what is looked for are computationally cheap approaches that can deal with the coarse level of knowledge directly and yield results on a comparable level of precision (or resolution) as the premises.

This is an area of application for which coarse relations based on conceptual neighborhoods work very nicely: reasoning can be carried out directly on the basis of the coarse relations rather than on the more precisely specified JEPD base relations. In principle, it may be possible to maintain the JEPD property on a coarser level; in practice, this may be neither natural nor necessary. In fact, by choosing coarse relations in such a way that their applicability overlaps for certain temporal or spatial configurations, advantages may be generated that have benefits similar to those of coarse coding techniques in biological and technical systems: by forming conjunctions between overlapping coarse relations the precision of inferences can actually be increased.
and the grain sizes reduced, provided that appropriate coarse knowledge is available. Freksa (1992) showed for the case of Allen’s interval calculus that a suitable choice of coarse relations (semi-interval representation) based on conceptual neighborhoods allows for calculations on the same level of precision as the high-resolution interval approach used in the Allen calculus. The conceptual neighborhood-based composition tables are much more compact than composition tables using base relations as they exploit inherent structures of time and space to a much larger extent than the finer relations.

Conceptual neighborhood-based spatial problem-solving preserves some of the special properties of time and space that make problem-solving in space as efficient as it is; this efficiency disappears when spatial structures are disintegrated by describing them on the level of atomic relations, as is preferably done in formal reasoning.

Perceptual uncertainty and coarse reasoning

The spatial resolution of visual perception in the eye or in a camera is limited by the granularity of the receptive fields in the eye or in the camera, or, as Zadeh (1973) succinctly puts it, “The closer one looks at a real-world problem, the fuzzier becomes its solution” (Zadeh’s Principle of incompatibility). As a consequence, certain conceptual distinctions between spatially similar situations may be difficult or impossible to perceive. For example, from some distance, we may not be able to visually distinguish whether two objects are almost touching one another but being spatially separated or whether they are actually touching, thus being spatially connected; similarly, we may not be able to distinguish perceptually whether two objects touch or barely overlap. All three conceptually distinct situations form a conceptual neighborhood of closely related spatial topological relations.

Interestingly, from a larger distance borders are perceived more clearly and look more orderly than from close by. For example, when we look down to Earth from an airplane or when we view satellite images of the Earth, certain spatial structures manifest themselves much more clearly even though the spatial resolution has been reduced. As transition zones between large regions become narrower they can be categorized more easily as lines at which the neighboring regions meet. This is a similar effect to that observed when looking at sketch maps or schematic maps that abstract from detail that is not informative for certain purposes.

Coarse spatial relations are more stable than fine spatial relations, as it typically requires many fine changes to change coarse spatial relations. When coarse spatial relations change, fine relations inevitably must have changed.

These observations are quite significant for information processing: anything that can validly be inferred on a coarse level of representation should preferably be inferred on a coarse level, as this (i) requires less information, and (ii) will be more stable.

Role of conceptual neighborhoods for perception and cognition

A crucial human ability to deal with perceptual and with conceptual information is to move between different object sizes (size constancy), different levels of granularity (resolution), and different levels of conceptualization of objects in a scene. For visual perception, this ability is
NEIGHBORHOOD, CONCEPTUAL

facilitated through physical/geometrical properties of space, motion in space, and optical projection: when visually perceiving cognitive agents move towards a scene, objects are projected at a larger size, more details can be differentiated, and entities that were perceived as single objects from a distance will appear as aggregates of smaller constituent objects from nearby. In other words, in our everyday spatial experience, “vertical neighborhoods” (Freksa and Barkowsky 1996) in a hierarchical or heterarchical representation that characterize relationships between visual objects and aggregates of objects that form new visual objects, are quite common and familiar to us from everyday experience.

The transitions between objects and aggregate objects have direct implications on spatial neighborhoods and on conceptual neighborhoods: obviously, only spatially neighboring objects will be optically separated/aggregated by moving towards/away from a scene; similarly, conceptually neighboring spatial relations between objects in a scene will be the first to be separated/aggregated as perception transforms between aggregates and their constituent objects. In other words, conceptual neighborhoods have a deep cognitive reality for our understanding of how parts and wholes relate to one another.

The relations between spatial entities and larger entities formed by them have significant implications on geography, map making, and map interpretation. An example is map generalization where individual houses are aggregated to make up residential areas, residential areas are aggregated to make up towns, and so on. On the level of paths and roads, minor routes need to be eliminated at coarser resolutions without violating certain connectivity constraints. Maintaining correct topological relationships is an issue that can be dealt with by means of conceptual neighborhood.

Similarity: conceptual neighborhood versus fuzziness

Conceptual neighborhoods have a distinct relation to fuzzy sets: conceptual neighborhoods can be considered discrete analogs to fuzzy sets. Whereas compatibilities of fuzzy relations typically change gradually as a relevant feature changes, the selection of a spatial or temporal relation changes in a transition to a conceptually neighboring relation in a discrete step. This corresponds to the way people typically talk about spatial and temporal relations: we select a label for a relation that appears to be appropriate, being well aware that a neighboring label also might fit. This awareness helps us to interpret semantically neighboring relation labels that may have been chosen by others due to subjective preference and/or due to not quite identical reference contexts.

Applications of conceptual neighborhood-based reasoning in artificial intelligence

There are a variety of applications of conceptual neighborhood; this entry will present four rather distinct examples.

Commonsense reasoning

When describing events, such as a car overtaking another car, humans abstract to a few key configurations assuming that it is clear how to fill the gaps. Commonsense reasoning focuses on methods to describe how “trivial” inferences
can be achieved, instead of saving reproducible inferences explicitly. Addition and subtraction are examples for such a kind of “inference,” as one could create a lookup table or describe the process of adding two numbers. Conceptual neighborhood-based reasoning fills a similar role in event recognition and planning (see the section “Conceptual neighborhood-based reasoning”), as often a key configuration cannot be observed directly but its occurrence can be inferred, for example, that a pendulum had reached its highest position.

Learning event models

Learning of event models is used in the case of complex domains or where no previous knowledge about the domain is present. In such cases, events and models are learned either unsupervised or semisupervised, that is, a teacher or ground truth is generally available. Often models can be simplified by exploiting the conceptual neighborhood. As discussed in the section “Perceptual uncertainty and coarse reasoning,” some relations are hard to distinguish using sensors, for example, if two objects are truly touching each other. Making the learning system aware of such uncertainty allows for more robust as well as more compact models.

Data integration and conflict resolution

When integrating data from various sources, such as database or sensors, usually conflicting information exists. Further, the resulting data should not violate consistency constraints, for example, two lakes cannot overlap. Using conceptual neighborhood combined with a valid distance measure allows to first determine the required changes on the conceptual level, called relaxation, before calculating the changes on the lower level.

Finding tractable subsets of calculi

Conceptual neighborhoods generally play an important role when determining tractable subsets of calculi. A generalized relation in a tractable subset only contains those relations that are pairwise conceptual neighbors. This has been shown by Nebel and Bürckert (1995) for the case of Allen’s interval algebra. As a result, conceptual neighborhood can be exploited to reduce computation from nontractable exponential to tractable polynomial complexity classes.

Concluding remarks

Conceptual neighborhood is a fundamental notion in cognitive systems. It reflects how cognitive agents including humans, animals, and autonomous robots perceive, describe, and perform changes in spatiotemporal environments. The notion relates to psychology of perception, cognitive geography, and artificial intelligence, as well as to cognitive modeling and process control. It has implications for visualization, autonomous robotics, and theoretical computer science. It is related to robustness, to switching between coarse and fine representations, and to efficiency. Consideration of conceptual neighborhood may play an important role in the design of future reliable technology.

Further reading

The concept of a neighborhood refers to the localized network of everyday social relations and senses of identity that form among residents and businesses that constitute that network. As an object of analysis, however, there has never been consensus among scholars on a specific definition of “neighborhood.” This uncertainty is reflected by the less than precise definition given by the Merriam-Webster Dictionary: “a section of a town or city” and “the people who live near each other.”

Neighborhoods are widely seen to come into existence through the formation of community organizations. These organizations consist of community members to represent interests of residents (based on housing, education, culture, identity, etc.) perceived as shared among most residents and businesses located within identified spatial boundaries. Here, more than just local networks of social relations, neighborhoods often become “politicalized” sites to the extent that members actively come together to mobilize resources in the name of preserving, enhancing, or changing particular neighborhood characteristics. In unison with other local institutions – churches, schools, community centers – these are the venues of social activity that work to organize everyday life and consolidate a sense of areal cohesion, control, and identity.

The boundaries and identification of neighborhoods are also frequently contested and debated. For example, the “community areas” officially recognized by the City of Chicago do not always overlap with the neighborhoods identified by the people who reside and/or work within these city-designated community areas. Chicago’s Bronzeville district signifies to local residents a loosely defined area of historical and cultural identity that actually encompasses four community areas (although some residents argue it is not this large), but is not included as one itself. The city, however, has designated a section of this loosely defined area as the “Black Metropolis Historic District,” an act that does recognize Bronzeville’s existence as a present and historic site in the city.

In this context, neighborhoods are not objective realities or passive creations, but social constructions which are often contested and negotiated by residents and vested interests. Rather than static entities, neighborhoods and their boundaries are porous, fluid, and evolving social formations, rendering any precise or broadly agreed upon definition elusive. There is also immense variation in the social and physical form of neighborhoods, both through time and across different cultural settings. It is in this sense that the neighborhood, as a concept and sociospatial phenomenon, has long been treated as an important object of analysis among urban geographers, planners, sociologists, and historians. The remainder of this entry briefly chronicles the evolution of neighborhoods through the modern period with emphasis placed on this entity as a spatial unit in urban geography and urban planning and its conceptualization in academia and beyond.

It has long been considered that humans have historically organized everyday social interaction and local identity within what can be
called geographically bounded areas, identified as neighborhoods or otherwise. In short, once human living patterns moved from nomadic to more stationary settlements (underpinned by increasing agricultural surpluses), the formation of distinct local-scale “communities” has likely existed in some shape and form (Mumford 1954). Through the premodern period, neighborhoods would have formed in compact, high-density spatial units featuring mixes of street-side businesses and apartment-style residences. The local market place is often considered as the adhesion that brought people together, and through which spatially bounded networks of social, political, and economic relations crystalized. While the physical appearance and layout has certainly varied, these foundational elements are considered to have been more or less standard.

These “traditional” neighborhoods were characterized by tight-knit social bonds, mixed populations in terms of class and ethnicity, and a vibrant street life. This spatial structure, however, was irrevocably ruptured by the industrial revolution, a process that has profoundly transformed pre-existing human settlements. In short, the preindustrial city erupted into the large-scale industrial metropolitan regions that have come to mark the modern period. This emergent scale of urbanization disrupted the material foundation that underpinned premodern or “traditional” modes of organizing everyday life (although this still persists in many rural villages across the world). The modern urban landscape, in contrast, is marked by a complex mosaic of districts organized by industrial, commercial, and residential land uses.

It is in this context that the concept, “neighborhood,” first emerged, to identify, almost exclusively, residential areas marked by increasingly homogenous population groups, such as “working-class,” lower-class, upper-class, and ethnic neighborhoods. In the modern industrial city of eighteenth- and nineteenth-century Europe, increased population densities, congestion, and innovations in transportation allowed the wealthy to relocate away from the emergent industrial districts and the community of workers that congregated near them. As a result, neighborhoods became increasingly segregated by economic class, employment type, and establishments that cater to particular population groups. While not all traditional neighborhood characteristics have vanished, they have increasingly been restructured to reflect this modern form in most metropolitan regions across the Global North and South.

This internal ordering of land uses and neighborhoods in the modern city, however, while rational to industrial capitalists, resulted in problems. Most notably, with few public services and little infrastructure (i.e., water, sewage) the living conditions in working-class neighborhoods declined horrifically as famously chronicled by Frederick Engels in The Condition of the Working Class in England, originally published in 1844. The rise of “slums” led to serious problems – starvation, crime, disease – and provided the basis for modern urban planning and consideration of the neighborhood as an important spatial unit of urban life.

**The neighborhood unit in urban geography and planning**

Urban geography and urban planning have been around for a long time. The spatial organization of medieval cities and villages around the town square, cathedral, and marketplace serves as an example of a precursor, with similar manifestations in Islamic, East Asian, and Ancient Greek, Roman, and Egyptian contexts as well. But the concept, “neighborhood,” was not explicitly identified or substantively incorporated into
planning theory and practice until the early twentieth century. Its origins can be traced to Ebenezer Howard's vision of the “garden city,” proposed as an ambitious vehicle aimed at resolving the increasingly prevalent problems associated with “slum formation” and inequality in the industrial city, particularly London (Hall 2002).

Howard envisioned the reorganization of city structure based on radiating concentric rings of avenues, housing, and businesses, which revolved around a civic center. There was no place for large-scale industrial factories, but rather small-scale, individual enterprises that would foster close interpersonal relationships among residents and constitute a kind of “collective” social identity. This was the “garden city,” limited to around 30,000 people, on 1000 acres of land, and surrounded by green belts of rural land uses. This would serve as the principle spatial unit of Howard’s broader vision of a polycentric metropolitan fabric constituted by many garden cities, functioning as individual collectives, and linked through rail transit.

This vision, with the goal of engineering more equitable social processes through physical planning, never came to fruition. But many of these ideas have influenced planned communities across Europe (England, France, and Germany) and, later, the United States. In the process, however, the driving force behind Howard’s vision – social justice – was lost, with planned communities (e.g., Hampstead in England and Riverside, IL, in the US) resembling more garden “suburbs” or “villages,” and safe havens from the worsening congestion, pollution, and poverty in the city.

The neighborhood unit emerged in this context, identified by the sociologist and planner, Clarence Perry. Inspired by the ideas of Jane Addams and his own experience living in Forest Hills Gardens, a garden suburb of New York, Perry advocated for the importance of design in fostering a strong neighborhood identity in planned communities. For Perry (1929), the neighborhood was what made these planned communities work in a socially volatile, rapidly changing, and increasingly auto-centric modern city. Perry emphasized community planning that safeguarded the neighborhood as a “political and moral unit” marked by strong local leadership and “intimate face-to-face association and cooperation” (Cooley, cited in Hall 2002).

In 1928, led by architects Clarence Stein and Henry Wright, Perry’s ideas were manifested in the design and development of Radburn, New Jersey, the first and perhaps best known garden city inspired planned community in the United States. In terms of building Perry’s neighborhood unit into the community, the key was the distinction between higher-volume arterial streets and intimate networks of local streets. The wider arterial streets were to provide the physical boundaries of the neighborhood by discouraging through (or unwanted) traffic. This hierarchical road system has since become the definitive component of the “Radburn layout,” with widespread implementation across urban America. As a result, neighborhoods in the United States have generally formed within the boundaries of arterial, commercially lined streets.

In this context, the planning for neighborhoods had exclusionary underpinnings. And after a few years, most Radburn residents were white and middle-upper class, a far cry from the socioeconomically mixed “garden city” envisioned by Howard. Moreover, the mixed land use component of Howard’s vision, inspired by the medieval town/village, was further complicated by the parallel advent of land-use zoning. While less an issue in Europe, where the pre-existing urban fabric has proved more amenable to preserving and crafting higher-density and mixed-use neighborhoods, the now standardized segregation of residential, commercial, and
NEIGHBORHOOD

industrial land uses via zoning has given way, in the United States, to the neighborhood understood primarily as a residential unit.

The commercial lining of arterial roads has provided walking access to businesses by interior neighborhood residents; but in the rapidly proliferating suburbs, the greater spatial separation between residential and commercial zones has prevented the cultivation of the kind of vibrant and necessary “street life” considered by Perry, Mumford, and others as definitive of healthy and cohesive neighborhoods. To these critics, the automobile and an emergent menace – modernist planning – was the culprit, as the mass suburbanization of American cities was producing a mode of residential life void of face-to-face interaction and, consequently, neighborhood spirit and identity. Here, zoning should cultivate, work through, and enhance, rather than obliterate, the neighborhood unit as the basis for social life.

By the 1950s, Howard’s “garden city” was a thing of the past, and the neighborhood unit lost its luster given the increased dominance of modernist planning principles. This loss was reflected not only in the “sprawling” American suburbs, but in the central city as well. The federal urban renewal program was demolishing large expanses of “blighted” urban spaces to pave the way for two things: limited-access expressways and public high-rise housing. These urban features not only marked the restructuring of American cities, they became ubiquitous features of modernist planning and architectural design around the world. The neighborhood was no longer the foundational unit of city making.

This dominance, however, did not go uncontested, with critiques coming from Lewis Mumford and urban activist and scholar, Jane Jacobs. For Mumford and Jacobs, one of the chief complaints of this proliferation of high-speed expressways and towering high-rises was the perceived obliteration of neighborhoods, and with it, the social and moral health of urban society. Mumford attributed many social urban problems to the loss of the neighborhood unit under the onslaught of suburban sprawl and urban renewal. Mumford emphasized the importance of neighborhood design in urban planning and advocated for a centrally planned “regionalism” of Radburn-type neighborhoods, mixed land uses, and mass transit systems that would link neighborhoods together in a vision inspired by Howard’s “garden cities.” Like Howard, the medieval city was also Mumford’s source of inspiration.

Jacobs levied a similar critique in the context of New York. Jacobs observed the disruption, if not obliteration, of the social networks characteristic of established neighborhoods by urban renewal demolition, new expansive expressways, and Corbusian-inspired high-rise towers that paid no attention to the importance and design of “traditional” neighborhoods. For Jacobs, the development of positive social relationships is based on close proximity between work and home, higher density living, and a vibrant and walkable “street life.” This new emergent city, however, was understood as the antithesis to this ideal vision of urban life. While Mumford and Jacobs are often discussed as oppositional figures, Jacobs taking a more bottom-up approach than the broader “regionalism” of Mumford, both have provided the inspiration for the increasingly popular “neotraditional” design principles of the more recent New Urbanism movement.

The modernist planning paradigm remained dominant through the 1960s, 1970s, and 1980s. But in the 1990s, amid the broader postmodern turn in architecture and planning, this direction began to shift as suburban sprawl and the design of public high-rise housing came under scrutiny. The public housing of the urban renewal era, which was now considered plagued by gang
violence, drugs, and crime was now treated as a horrific failure. Suburban sprawl was also increasingly demonized as wasteful, auto-dependent, and “unsustainable.” The monotony of large subdivisions, cookie-cutter homes, and lack of anything to walk to, prompted the accusation that this landscape had an antisocial effect and fostered an individualist mindset not conducive to the development of strong, cohesive neighborhoods.

The New Urbanism movement, led by architect and planner Andres Duany, arose as a response to the problems of both the “soulless” suburbs and poverty-stricken inner-city areas perceived as void of healthy, sustainable “communities.” Here, the neighborhood unit returned as an emphasis in urban planning and design. As an emergent and increasingly dominant planning paradigm, many new developments – across urban America and beyond – are now adopting “neotraditional” design elements, that is, increased housing density, mixed land uses, socioeconomic diversity, walkability and access to rail transit, access to civic centers and/or “town squares,” and close proximity between job and home. Inspired by Mumford and Jacobs, these design principles have become widespread, and are once again considered the basis for positive human relations.

Although modernist planning principles remain prevalent in many parts of the world, the New Urbanism now informs both suburban growth agendas and central city revitalization efforts in a wide variety of contexts.

The neighborhood unit in urban theory

The neighborhood also has been a fundamental object of analysis in urban studies through the twentieth and twenty-first centuries. As the social and spatial constitution of neighborhoods has continued to evolve, much research has sought to identify, describe, and make sense of the factors that drive change. During the early twentieth century, the Chicago School of Urbanism, led by Robert Park, Ernest Burgess, and Louis Wirth at the University of Chicago, presented a conceptual framework for describing and understanding urban life in the modern city, including the role and function of neighborhoods.

In this school of thought, neighborhoods are conceived as functional units within a broader, “organic” city. Not only is the constitution of neighborhoods of interest, but so are the flows and relations between them. During the early twentieth century, North American cities were experiencing an influx of immigration (i.e., from Europe and East Asia) as well as the Great Migration of African Americans from the American South to northern cities. Through this process, neighborhoods increasingly took an “ethnic” form, that is, black neighborhoods, Chinatowns, Italian, Polish, and Irish neighborhoods, and so on. This “ethnic” neighborhood formation has also marked many cities across the Global North and South.

Among Chicago School scholars, the emergence of “ethnic neighborhoods” informed what would become an influential model of neighborhood change: invasion-secession theory. Neighborhood change was propelled by a supposedly natural process: the “invasion” of one ethnic group moving into an already established neighborhood inhabited by another population. Invariably, the current population is forced to relocate elsewhere in the city to reestablish their neighborhood identity, constituting another invading force elsewhere. Typically, it is a lower-status (and lower class) ethnic group that invades and forces the secession of higher-status
NEIGHBORHOOD

groups, a seemingly inevitable process as immigrants continued to flood North American cities at the time.

The wealthy are first to vacate and reestablish new affluent (and typically white) communities, thereby creating a new ring of residential development around the central city. This process is reflected in the commonly referenced concentric-ring diagram of Chicago, where the outer ring of the city is characterized by higher-income residential areas while the “zones of transition” mark the older neighborhoods experiencing change. As the housing stock ages, older neighborhoods are seen to go through a cycle of successive population groups moving in and out, each one lower in status, which explains why, at the end of the cycle, lowest-status groups are observed to inhabit the least desired urban spaces, the so-called ghettos.

This model, however, was challenged in the 1970s by scholars working in a different paradigm: urban political economy. The Chicago School purportedly presented more of a descriptive than explanatory framework. Influenced by French Marxist scholars (notably Henri Lefebvre), those working in urban political economy emphasized a dimension of this process previously downplayed: segregation. For scholars such as David Harvey and Manuel Castells, the urban mosaic of ethnic neighborhoods formed via the power of structural barriers (legal, economic, political). The evolving differentiation of residential landscapes was not a “natural” process, but was shaped by discriminatory practices (i.e., redlining) designed to preserve existing social structures, power relations, and elite interests in the city.

Critical of the Chicago School, these scholars explained the patterning of residential differentiation as a necessary condition for reproducing the basic social relations of a capitalist society. In this view, the neighborhood is understood as the principal site for social reproduction by maintaining a social and spatial division of labor consistent with the dynamics of capitalist development. Life in a lower-income, working-class neighborhood is likely to lead to the reproduction of the same lower-income (and necessary) workforce in the future. Conversely, life in an affluent neighborhood, far removed from the realities of the inner-city, ethnic “ghetto,” immerses the next generation of elites into the upper echelons of the social structure.

At the same time, as metropolitan regions continued to suburbanize, creating sprawling landscapes of monotonous residential subdivisions, large swaths of central city areas were bulldozed to accommodate an evolving modern city. The erosion of the “traditional” neighborhood unit was now mourned by commentators who identified not only the modernist planning paradigm denigrated by Jacobs and Mumford, but also a new neighborhood-destroying force: globalization. During the 1970s and 1980s many geographers were linking this unraveling of local communities (which was being experienced across the advanced, industrial world) to a world-homogenizing globalization (Tuan 1977). The distinctiveness of neighborhoods was being eroded and replaced by a globalizing, monolithic culture, characterized by new massive shopping complexes, cookie-cutter subdivisions, and rampant consumerism.

A series of debates ensued, in geography and beyond, wherein local communities and identities were considered by some as less destroyed than transformed. While the social and spatial attributes of “traditional” neighborhoods were indeed disrupted, a new kind of neighborhood emerged, reconfiguring, rather than dissolving, the social networks and relations of communities. Here, supposedly, was the transformation of “traditional” communities to “modern” communities where the material conditions
that underpinned “traditional” communities no longer existed (Cox and Mair 1988). New conditions were underpinning the formation of different kinds of communities which now revolved around the workplace and sites of civic engagement rather than face-to-face interactions and tight-knit relations among neighbors.

For others, neighborhoods were conceived more as “concentrations of capital” than distinct cultural formations, whereby particular ensembles of local cultures and sociospatial networks form in relation to local employment conditions (Harvey 1989). But as employment conditions change, as they often destructively do during periods of economic restructuring, so does the social, cultural, and political constitution of the very local communities and neighborhoods that define places. In this setting, neighborhoods are understood as always evolving in response to the temporal rhythms of the broader, global economy.

Others have noted the reinforcement, rather than erosion, of local community cohesion and identity. In response to threats to their community or neighborhood identity, people are also seen to turn inward, seeking out new insular and increasingly balkanized forms of neighborhood and community development. This tendency has been observed in many contexts, such as the increasing presence of affluent “gated communities” in both urban and suburban contexts; Homeowners Associations, which function to organize civic engagement and neighborhood identity within an increasingly “placeless” landscape; and the new suburban frontier, which increasingly incorporates the principles of New Urbanism by modeling the design of new subdivisions on the neighborhood unit.

The neighborhood concept has also played an important role in urban redevelopment strategies, particularly in the context of gentrification. For proponents, “bad” neighborhoods are portrayed as being “revitalized,” a process often touted as reforming the social bonds and relations that make what are often simply called “good” neighborhoods. Gentrification, where a higher class displaces a lower class, is typically portrayed, among both proponents and critics, as unfolding at the scale of the neighborhood. Scholars engaged in gentrification research (Lees, Slater, and Wyly 2008) frequently debate the definition and role of the neighborhood within this process.

Among proponents, gentrification does improve neighborhoods by attracting more resources, jobs, and investment. For critics, this argument privileges the neighborhood as a spatial construct, as the process typically does little to benefit pre-existing residents, many of whom become displaced. For these scholars, the physical space of the neighborhood may have been improved, but it is typically a new population group that inhabits it, one that replaces the social fabric of what previously existed in favor of that which is deemed more desirable for generating revenue and attracting resources. The act of defining the neighborhood becomes an act of politics.

The neighborhood has historically been conceptualized and studied in myriad ways by urban geographers, policymakers, and planners. It has also taken many social and spatial forms. And while the neighborhood is primarily documented in the Anglo context, research is increasing across the Global North and South. Despite such diverse treatment, the common thread unifying conceptualizations of neighborhood is the scale of interpersonal interaction and social identity as dynamic and constantly evolving. The neighborhood will undoubtedly continue to represent an important analytical object among a wide range of social scientists.

Neighborhoods and health

Karen Witten
Massey University, New Zealand

That geography matters to health is not a new idea. In “Life and Death over the Millennium,” Margaret Whitehead records fluctuating population trends in the United Kingdom, tracking the impacts of famine, diseases, and epidemics for over 900 years (Whitehead 1997). She draws on data published in the *Lancet* in 1843 that illustrate enormous differences in life expectancy between occupational groups, residents of rural and urban areas, and people living in different parts of the country. For example, laborers and artisans in Bath had a life expectancy of 25 years compared to 15 years in Liverpool. Gentry and professionals averaged 55 years at death in Bath and 35 years in Liverpool. These variations in mortality between places were attributed to varying exposure to hazardous living and working conditions associated with industrialization (Whitehead 1997).

In recent decades, in a number of industrialized countries, gains in life expectancy and living standards at a population level have not been equitably distributed across groups within populations, and health inequalities have widened. This situation has stimulated renewed policy and research interest in the social and spatial determinants of health inequalities. A notable example was the Commission of Social Determinants of Health established by the World Health Organization to collate evidence on how to achieve health equity (CSDH 2008).

Where a person lives has a profound impact on access to opportunities and the routines of daily life, many of which have implications for health status. For example, residential location determines access to educational and employment opportunities; the availability of public transport or cycling infrastructure may influence whether the trip to work or school is made by car or active transport; ready access to fresh and healthy food supplies can affect food consumption practices; and the social environment of a neighborhood can impact the breadth and depth of social networks and support available. All these factors have downstream consequences for people’s health status.

Investigating the relationship between place, or neighborhoods, and health poses a range of conceptual and methodological challenges: defining and operationalizing “neighborhood”; defining and measuring neighborhood effects; theorizing the pathways through which neighborhood environments affect health; identifying what aspect of health may be affected and for whom. Study in this field has benefited greatly from advances in geographic information system (GIS) technologies and statistical modeling. Virtual databases such as Google Street View can now be used to conduct street audits that have in the past required in situ observational methods.

Neighborhoods have spatial and social aspects. Most people have an intuitive understanding of where their neighborhood lies and if asked will likely define an area that encompasses the homes of immediate neighbors and the services and amenities they use on a regular basis. However, as a research construct, “neighborhood” can be difficult to define and operationalize. In quantitative research administrative boundaries or census units have been commonly used to define a neighborhood. They are convenient, can be
aggregated at various spatial scales, and enable the ready integration of other administrative data (e.g., a census). However they may not represent where residents spend time or what they consider to be their neighborhood. A more recent approach has been to define neighborhood as a buffer distance surrounding a residential address. This is termed an “ego-centered” neighborhood and is measured using the distance along a street network (rather than Euclidean or straight-line distance). A neighborhood defined in this way is more likely to represent the places a person spends time and buffer distances can be set according to the health outcome of interest and population group involved (e.g., a child’s neighborhood buffer may be smaller than an adult’s). The social aspects of a neighborhood are still unlikely to be captured by these methods (Chaix et al. 2009). A self-defined neighborhood is more feasible in qualitative studies.

A broad range of neighborhood factors that could affect health have been investigated, with a distinction often made between contextual or compositional effects. Among the contextual effects that have been examined are attributes relating to the neighborhood physical environment (e.g., air or water quality, urban design); institutions and services (e.g., transport, health, and education); amenities (e.g., parks and other recreational facilities); and the social environment (e.g., neighborhood social cohesion). The characteristics of the people living in a place have been termed “compositional effects.” In some areas of interest there is no clear distinction between contextual and compositional effects. For example, housing tenure can be considered a compositional variable when aggregated to a neighborhood level, yet it may have contextual effects if higher levels of homeownership result in increased social and financial investment in an area. Likewise, the aggregate level of educational qualifications held by residents in a neighborhood would be a compositional effect, but it is feasible that educational participation and outcomes may be influenced by the availability and quality of educational opportunities, a contextual effect.

How neighborhood factors influence health has been investigated for an array of health outcomes including heart disease, physical activity and obesity, low birth weight, smoking, and overall mortality. While many studies have found significant neighborhood effects on health, the effects are generally small compared to the effects of individual sociodemographic factors. In light of worldwide concern over rising obesity rates, a topic that has received considerable research attention in recent years has been the relationship between neighborhood design, residents’ physical activity for transport and recreation, and obesity. There is now strong evidence, in particular originating from the United States, Australia, and New Zealand, of associations between built environment characteristics such as dwelling density, mixed land use, and street connectivity and the physical activity and body size of residents. Individuals living in more sprawling, lower-density neighborhoods are more likely to be less physically active and have higher rates of overweight and obesity than those living in more compact urban areas.

Another topic of contemporary interest is the impact of housing and neighborhood interventions, such as urban renewal, on health and health inequalities. A systematic overview of intervention studies in these areas concluded that there is relatively strong evidence for interventions aimed at improving area characteristics and compelling evidence for warmth and energy efficiency for improving health outcomes (Gibson et al. 2011).

Quantitative research paradigms have dominated research on neighborhood effects on health but there have also been a number of
illuminating locality-based qualitative studies. Studies that use administrative boundaries to define neighborhoods in combination with cross-sectional or longitudinal survey databases containing health and sociodemographic variables remain common in this field. However, increasingly, specific neighborhood factors hypothesized to have an influence on a specific health outcome are being measured, aided in many cases by the use of GIS technologies. Associations between the neighborhood effects and health outcomes are modeled using multilevel statistical techniques, which enable an analysis of the extent to which observed variations in outcomes can be explained by differences at the individual and/or neighborhood levels. The direct measurement of specific exposure and outcome variables, particularly where common measurement tools are applied across studies, is increasing the precision and comparability of research in this field. Attention is also being drawn to differences in relationships between neighborhood effects and health for people of different ages, gender, and ethnicity.

Intervention and longitudinal studies are relatively rare in this field but are needed to substantiate understanding of the pathways of influence between place and people. A number of intervention studies have been conducted in the United States in which low-income families have been supported financially to move into more affluent areas, a shift which represents a change in neighborhood context and composition. Anderson et al. (2003) conducted a systematic review of 12 intervention studies including randomized controlled trials, and controlled and uncontrolled prospective studies. The review reported some support for improved household safety and fewer experiences of personal victimization in intervention households and mixed effects on health outcomes and health-related behaviors. Research in these areas is very challenging, as the individual and neighborhood factors that could potentially influence the health of residents are numerous.

Locality-based qualitative studies, involving in-depth interviews with small numbers of participants, are a useful complement to the larger quantitative studies. Residents’ experiences and understandings of the relationships between material and social aspects of neighborhoods and their health practices and wellbeing can be explored in these studies.

A concern for social justice in terms of more equitable health outcomes often underpins policy and research investigating neighborhoods and health. Place effects on health may be modest compared to the impact of individual-level determinants of health such as occupation, income, and education but they are potentially modifiable. Knowledge of how neighborhoods influence health can inform place-based interventions to improve access to positive health-promoting resources in neighborhoods where the chance of illness and premature death are high. To quote the Commission on Social Determinants of Health report: “Social injustice is killing people on a grand scale” (CSDH 2008: 4). It is probable that many of the known social determinants of health such as housing, education, and employment operate, at least in part, through neighborhood pathways.

Neighbourhoods in Eco-epidemiologic Research: Delimiting Personal Exposure Areas. A Response to Riva, Gauvin, Apparicio and Brodeur.” Social Science & Medicine, 69(9): 1306–1310. DOI:10.1016/j.socscimed.2009.07.018.

Neoliberalism and the environment

Harold A. Perkins
Ohio University, USA

What is neoliberalism?

The prefix “neo” of course means new, or young. The root of the word is “liberal,” referring to an Enlightenment political philosophy. Put the prefix back together with its root and the word refers to a new version of a long-established political philosophy. But to understand better just what is meant by neoliberalism, it is necessary to momentarily separate the root from its prefix again and interrogate what each one means in relation to the other. Start first by interrogating “liberalism.” In the United States, political “liberals” are often people who hold political beliefs that lean left-of-center on the political spectrum. Liberals there are most strongly associated with the Democratic Party that historically tends to favor stronger social welfare, economic intervention, and environmental regulation. But, in fact, the application of the term “liberal” in the context of party politics in the United States is at best a conflation, and at worst, contradictory to what liberalism represents in its traditional and more widely practiced philosophical sense. It is important therefore to address the history of liberalism and delineate its deployment beyond the circumscribed context of current-day Democratic Party politics in the United States.

Liberalism as a philosophy was born during the Enlightenment period in the 1700s and diffused throughout much of the Anglophone and Continental European worlds as a dominant political practice in the centuries that followed. Locke, Mill, Montesquieu, Smith, and Kant wrote about and advocated liberal political philosophy. The geopolitical context in which liberal philosophy was conceived and promulgated in political action is an important consideration. Most of the states in Europe during the seventeenth and eighteenth centuries were ruled by monarchies or some equivalent that wielded power over their respective populations. Political and, to a considerable extent, economic freedoms were limited for most people living under feudal conditions prevalent in many monarchical states. The right to speak freely or own property was restricted in most instances to people born into dynastic systems based on heredity.

Liberalism, in contrast with despotism, eschewed hereditary privilege and instead espoused principles of societal equality, political freedom of expression, representative politics, and the individual right to accrue wealth (own property). Liberalism has a utilitarian component in that actions taken to govern society should be fair and maximize benefit for the largest number of people possible (Rawls 1999/1971). All of these positions were meant to seriously check the absolute power wielded by monarchs throughout Europe. Political liberalism expanded in many of the states that emerged from Europe’s colonial system as well. The United States is an example whereby liberal principles heavily informed the establishment of the state and its relation to its citizens and economy. In particular in the United States the central state was originally envisioned and established as a weak state with little power to interfere with the political and
NEOLIBERALISM AND THE ENVIRONMENT

economic concerns of its republic and citizens. This was the embodiment of the notion of a diffuse and individualist, Jeffersonian America. But of course under most liberal political systems, the only “citizens” who could originally participate in the affairs of governing the state were mostly white men who owned property. So from early on in liberalism’s history, it is exercised in haphazard and contradictory ways. Liberalism not only impacted the political realm, however, it was heavily involved in the development of capitalism.

Liberal political philosophy complemented the industrialization of Western Europe and in the United States liberalism’s emphasis on property rights and minimal state interference in economic affairs set the stage for the rapid expansion of industry. Concomitant with the growth of industrialization were its corollaries in free markets for commodity inputs and outputs requisite to the production process. Indeed liberal political philosophy justified laissez-faire economic regulatory policies by the state that facilitated capital accumulation into private hands. Quite important to this process of accumulation is that liberalism and its emphasis on private property rights enabled capitalists to appropriate common resources for their industrial processes. The privatization of common resources was pivotal to the development of a robust capitalism based strongly in the utilitarian notion that appropriation is justified so long as the action benefits the majority of individuals in society. There are, undoubtedly, many problems with how this has played out historically and geographically. Liberalism’s critiques will be discussed at some length later in this chapter. But before this, it is important to examine the prefix “neo.”

“Neoliberalism” implies that it is a new iteration of the old political and economic philosophy addressed above. But what has changed since the industrial revolution? A look back at history better contextualizes the rise of neoliberalism. Much of the blame for the Great Depression of the 1930s is put on the worst excesses of free-market capitalism justified by extreme interpretations of economic liberalism. Laissez-faire capitalism, while making some people extremely wealthy, was choking its own demand for commodities as wealth concentrated into fewer and fewer hands (Harvey 2007). Political economists of the time believed that pure liberalism needed to be tempered by increased state management of economic affairs to avoid another economic depression. The prominent economist Keynes, for example, believed that the state should pursue demand-side economic policies to stabilize the economy while regulating it more closely to prevent the development of future monopolies. This was the beginning of social democracy in Western Europe, the United States, and other states that expanded their powers to tax and redistribute income through social welfare programs. Keynesianism worked well so long as economic growth continued apace.

Crisis again struck the global economy in the early 1970s, however. Declining economic growth coupled with rising interest rates and rampant inflation in the 1970s spurred resurgence in the demand for liberalized market reforms. Firebrand conservatives like Ronald Reagan in the United States and Margaret Thatcher in the United Kingdom brought real power to bear in their shift away from Keynesianism toward what is now referred to as neoliberalism. The neoliberal turn, starting in the 1980s, was supposed to unleash the power of the market to manage economy, society, and the environment better. But what exactly makes this re-implementation of liberalism “neo”? Initially, liberalized market policies were embedded within, or grafted onto, Keynesian regulatory institutions including demand-side economic policy, social welfare programs, and nationalized
NEOLIBERALISM AND THE ENVIRONMENT

industries. “Neo” liberalization had to cannibalize its Keynesian cousin before it could reign supreme. Thus social welfare programs were rolled back while privatization of national industries, supply side policies, and tax breaks for the wealthy and corporations were implemented in the name of bolstering economic growth (Peck and Tickell 2003). Trade barriers like tariffs were greatly reduced between countries to facilitate global economic growth, too.

These shifts could not occur without a fundamental change in the way people view the relationship of the state to economy, society, and environment. With the return of liberalism come laissez-faire principles that once again have widespread appeal and form a major component of the predominant political economic discourse. Accordingly, the state should not unduly impede the workings of the economy. Bob Jessop refers to this as “the hollowing out” of the nation-state as it retreats from its former Keynesian-style obligations to drive the economy, society, and environment (2002, 235). Jessop and others note, however, that it is not so much about the shrinking of state power as it is a rearticulation and enhancement of state power toward creating rationalized metrics for sustained economic growth (Peck and Tickell 2003). In keeping, Moran (2003) suggests that the neoliberal turn in the United Kingdom, rather than diminishing powers of the state, has instead created a more formalized regulatory environment that constantly fosters novel and flexible policy innovations to steer its economy efficiently through globalization’s turbulence. Concomitantly, neoliberal states (especially in the developed world) continue to exercise their power over societal and environmental regulation; however, they do so indirectly through the coordination of civil sector institutions that provide social and environmental services in lieu of direct state provision.

Despite this rearticulation of state power, in a globalized world economy states still struggle to advantageously control flows of capital, information, and people across their borders. Even a neoliberal world economy thus requires rules for economic engagement at the international level that must be established and enforced through formalized supranational institutions and free-trade frameworks. These institutions include World Bank, International Monetary Fund (IMF), and the World Trade Organization (WTO) that coordinate global flows of capital at the supranational scale (Peet 2003). These institutions are orchestrated by wealthy and powerful states like the United States or those in Western Europe; perhaps more importantly, they represent the private interests in these states that have capital to lend to states and firms throughout the world. This is important because states – particularly in the developing world – participate in the global economy according to strict liberal edicts spelled out by these institutions. In fact, participation in neoliberal globalization is predicated on the adoption of comprehensive market and private property-based systems everywhere.

Many states in the developing world borrowed heavily from Western financial institutions, and are having a hard time servicing their debts. The World Bank and IMF lend states more money to repay their extensive obligations, but with certain conditions attached. Debtor states are frequently subjected to structural adjustment programs, or SAPs, in order to get funds from the World Bank/IMF. SAPs are imposed to “align” states’ economies with the global, free-market order. Terms include prioritizing export-oriented policies and the dismantling of social welfare programs and economic/environmental regulations believed to interfere with market expansion (such stipulations are even being imposed on debt-ridden,
developed states in Southern Europe). These terms are imposed to facilitate states’ participation in the global marketplace. It is important to remember that philosophically the idea behind liberalism is that marketization is supposed to eventually enhance the wealth and wellbeing of people through capitalist development rather than direct state intervention/provision. In fact, a global middle class (loosely defined) has grown by millions in the developing world with the rise of neoliberal capitalism. Critics point out, however, that liberalization of national economies (especially through SAPs) amounts to the transfer of common resources into lucrative forms of private property that disproportionately benefit investors from far-flung locations (Peet 2003; Harvey 2005a). People are sometimes harmed by these reforms that infringe on their resource base and their ability to make a livelihood. Thus it is important to note that neoliberal reforms and development land differently according to geographical context and therefore have different impacts on people throughout the world. Neoliberalism is therefore not monolithic in its outcomes as its reforms are grafted onto extant political economic landscapes, both material and discursive. One commonality to these reforms, however, is that they usually feature some pain and controversy. Strategies must therefore be deployed to deal with such exigencies.

A typology of neoliberal strategies concerning management of environmental resources

Noel Castree elaborated four interrelated ways in which supranational organizations, states, firms, and individuals seek to manage the environment within neoliberal capitalism (2008). As already noted, the expansion of neoliberal capitalism throughout the world increases prosperity but is also fraught with contradictions and tensions. Thus Castree notes there are ways that neoliberalization of the environment is legitimated in the face of such challenges. He refers to these strategies as neoliberalism’s “environmental fixes.” They have much overlap but are useful in helping articulate the primary forms by which the environment increasingly becomes a part of neoliberal capitalism’s material and discursive basis for existence. As he goes on to suggest, these fixes, too, are only partial and usually laden with contradictions. After briefly outlining the fixes here, examples will be provided to contextualize them in the following section.

Environmental fix 1: free-market environmentalism

In this neoliberal strategy the state steps away from direct environmental management to allow market mechanisms to take over conservation efforts. The notion here is that markets and their related price signals are just as capable of protecting “valuable” aspects of the environment as states with their more rigid practices of “fencing off” entire chunks of the environment. Note that market mechanisms for environmental conservation allow for the flexibility of economic transactions across spaces otherwise precluded under traditional modes of state environmental protection. For example, forests are assigned market value so that rational market participants are incentivized to protect the overall resource while sustainably harvesting some of the timber for sale. The argument here is that the market participants will not cut down all of the trees because they too desire to keep the market for timber products alive.
Environmental fix 2: accumulation by dispossession

Unlike the first fix’s emphasis on eco-capitalism, some iterations of neoliberalism appeal to the need for growth at the expense of the environment (and some people who depend on it directly). Here the plight of the economy is predicated on enhanced access by capital to more of the environment formerly managed by the state or by local communities. Often this requires reduced state protections and also can involve the direct appropriation/transfer of lands and resources by/to firms at the expense of communities and individuals who depended on them in the first instance. The idea is that cheaper inputs to production enhance a firm’s profitability—hence the accumulation of capital by the dispossession of resources from others.

Environmental fix 3: institutions and discourse

Parties involved in the neoliberalization of the environment recognize their efforts can be harmful to the environment and by extension damaging to the resource base on which other people depend. Thus strategies are needed to refute contestations and build consensus around environmental transformations that are in some contexts beneficial to capital alone. The creation of institutional frameworks is highly effective in this regard. The North American Free Trade Agreement is a good example, where the right of corporations within member states to consume and pollute free of state (or civil sector) interference is legally protected. By extension, these frameworks help create a discourse of inevitability that circumscribe alternative antiglobalization discourses including “limits to growth.” In many ways this fix is effectively self-referential. The rules of commerce are already well-established and are not easily challenged by those who feel wronged by them.

Environmental fix 4: state legitimacy

Castree notes this strategy perhaps involves the state more than the previous three. He notes the state must maintain its legitimacy and avoid/manage crises caused by conflicts regarding environmental management and resource procurement under neoliberalism. This is difficult because the state increasingly takes a neoliberal stance that promotes the fixes above, yet has to deal with the inevitable fallout these actions may spark, especially among citizens who feel they have lost access to a resource base they need for their survival. This puts the state into a dilemma: how much should it intervene in the management of its economy, society, and environment? Castree suggests this depends on the state itself. Developed states with a history of direct economic/environmental management increasingly depend on civil sector organizations to do the work of regulating the relationship between economy, society, and environment. Meanwhile, in lesser-developed states with little or no history of direct intervention, the state will often take a minimalist stance and rely mostly on the self-regulation of market mechanisms.

Implications and critiques of the neoliberalization of the environment

Free-market environmentalism?

It is important to recognize the atmosphere has long been imperative to the development of the globalized capitalist economy. It is absolutely essential to economic growth because it is treated as a giant pollution sink that absorbs all the
unwanted byproducts of industrial processes. Of particular concern these days is the carbon dioxide the atmosphere is made to absorb from the combustion of fossil fuels. Scientific consensus is that the planet, on average, is warming because of these kinds of greenhouse gasses (GHGs). For the most part in the market-driven world, however, states have rejected the idea of command and control regulatory actions that would force industries under their jurisdiction to reduce their emissions by a given amount. In a neoliberal political economy such a strategy is viewed as more costly, less profitable, and ultimately hindering economic growth. Polluters would likely push back hard against absolute reductions imposed by states. The neoliberal solution requires environmental protection that does not threaten the global economy. Hence a system is created whereby polluters are encouraged to innovate and reduce their pollution voluntarily through market mechanisms (Bumpus and Liverman 2008).

Treaties like the Kyoto Protocol and more recent Paris Agreement set targeted reductions in GHG emissions rates for participating states. Individual states and the European Union have set their own GHG emissions reductions goals in conjunction with their ratification of Kyoto and also independently of these agreements. Reductions targets are largely supposed to be met through the creation and implementation of a market mechanism known as “cap and trade.” Under cap and trade, states issue a certain number of GHG pollution “credits” that in total will limit the amount of GHG emitted into the atmosphere in a given period of time. Credits are sold on open market exchanges between firms that pollute the atmosphere with their emissions. The idea is that firms that innovate with their technologies will use less credits than they possess, and can then sell them to polluting firms that require more credits to be in compliance with the agreement. The hope is that firms will reduce emissions because they have incentive to profitably sell their unwanted credits.

A credit system under cap and trade treats the atmosphere as divisible into units with pollution absorbing capacity. In essence, polluters are buying and selling “pieces” of the atmosphere as a form of private property that they have the right to pollute. These credits are priced according to market signals (supply and demand). In dividing up the atmosphere, cap and trade places monetary value on its entirety and in doing so creates a common valuation scheme that is supposed to protect it as a whole. By extension the global economy is spared the damaging shock from large and immediate reductions in the combustion of fossil fuels. Indeed emissions under cap and trade, particularly in some developed states, have begun to level off. Cap and trade is not without contradiction and controversy, however. A fundamental concern arises as to how well the atmosphere (and everything that depends on it) is ultimately protected when polluting is still permitted.

It is possible that cap and trade does not limit GHG quickly enough. Some suggest command and control systems where states exercise more power to directly limit emissions from fossil fuels are imminently necessary. Other criticisms contend that cap and trade fails to spur much innovation and instead allows the most powerful and wealthy polluters (particularly in the Global North) to purchase their way out of reductions while making a tidy profit in the process. Another problem is that the United States, one of the largest total emitters of GHG, refused to even ratify Kyoto. A lack of participation by large polluters seriously undermines the effectiveness of such solutions and is a big concern for the future of GHG reductions recently negotiated in the Paris Agreement. Yet another concern is that it is difficult to
NEOLIBERALISM AND THE ENVIRONMENT

quantify, monitor, and enforce these schemes. What this all potentially means is that neoliberal, market-based solutions to emissions may not be enough to prevent catastrophic changes in the global climate that could potentially destabilize the global political economy, too. There is a growing sense this is contradictory in that capitalism may be destroying its productive basis in a previously stable atmosphere and climate regime.

Neoliberalization of the environment as “accumulation by dispossession”?

One of the major drivers of a shift away from Keynesianism toward a neoliberal global political economy was the stagnation of capital accumulation by the 1970s. Firms began to look out on the horizon for cheaper inputs to production that would lower costs and by extension increase profits. This drive to renew accumulation by the late 1970s and early 1980s fueled globalization in the sense that firms raced from the developed world with its high costs of production (materials, labor, regulation) to the developing world with its comparatively lower costs. An offshoot of this process was that the material base for enhanced accumulation needed to be secured amid considerable political and social uncertainty within an array of lesser-developed states. At the same time, many of the states with these untapped resources were highly indebted to creditors based in wealthy states. This proved convenient for capital as creditor states were able to bring power to bear over indebted states through global institutions like World Bank/IMF. These institutions devised and implemented the disciplinary frameworks mentioned above that further opened up the resources within developing states to multinational corporations. The transfer of resources has created an enormous amount of wealth globally and is one of neoliberalism’s most significant accomplishments.

Of course the imposition of market liberalization onto previous collective forms of resource management usually requires state support and intervention so that commons resources like water, forests, and minerals can be sold to private interests. Debtor states in the developing world, for the most part, have been eager to promote their resources on the global marketplace in order to enhance their own coffers and to establish their own primacy on the global economic stage. It is important to remember, however, that the transfer of public resources to the private sector represents a significant transfer of wealth. The recipients of these new forms of private wealth are often multinational corporations (MNCs) and their investors that conduct their business around the world and have enough capital to purchase large tracts of the Earth’s surface and the resources it contains. This process drives neoliberalized development as the logic of marketable, private property is extended into places it did not exist before. It sometimes accomplishes this goal at considerable expense to the people already subsisting on these resources prior to the entrance of globalized capital.

Opponents of neoliberal globalization believe accumulation by dispossession is a result of the global expansion of markets, commodification of the environment, and enclosure of the global commons. Accumulation by dispossession is said to occur when MNCs seek out more profitable investments by cheapening their inputs to production in novel private property arrangements and in turn the people who previously subsisted on those same resources lose their access to them (Harvey 2005a). Take the Congo Basin, for example. Expanding market logic into countries in the Congo Basin by enclosing the land and commodifying the trees potentially
NEOLIBERALISM AND THE ENVIRONMENT

dispossesses the people living off the forest from their resource. It is a profitable relation for firms looking for cheap and abundant sources of high-quality hardwood, but it threatens to sever the subsistence connection local communities have with their trees.

Dispossession, neoliberal detractors go on to claim, frequently requires some form of state violence on behalf of MNCs to subvert formerly collective modes of environmental governance by local and indigenous communities. This is in spite of the laissez-faire stance the state is supposed to take in the neoliberal global economy. State intervention is necessary to secure the market because dispossession (or the perception thereof) frequently sparks intense resentment by adversely affected parties. State power exercised in securing private property markets against local backlash is illustrative of the strong possibility that rather than a weakening of state strength under globalized neoliberalism, the state largely rearticulates its power toward protecting its growing resource markets and thereby enhancing its position and stake in the global economy. The Cochabamba water war in Bolivia is a good example of this possibility.

The World Bank encouraged the corporation Aguas del Tunari, in partnership with Bechtel, to acquire and manage the municipal water supply for Cochabamba and a few other Bolivian cities in the late 1990s. The corporations immediately raised water tariffs to the point where poor Bolivians were spending nearly 20% of their monthly income on their water bills, making it more difficult for them to access water. Increased rates were supposed to fund better delivery systems, but in Cochabamba, there was not more water in the taps after the rate increase. A small series of local protests in early 2000 quickly grew into a national strike when protesters shut down Bolivia’s highways and its economy. The Bolivian president declared a state of siege and prompted the military and police force to violently repress the thousands of protesters. Many protesters were injured and at least one teenage boy was shot and killed by the military during its crackdown. By April of 2000 the Bolivian government capitulated and abandoned its contract with Aguas del Tunari. Cochabamba is a rare instance where protest groups forced the state to back down from its neoliberal stance.

Critics sometimes liken accumulation by dispossession to an enclosure of the global commons (Harvey 2005b). Enclosure is a concept more often applied to seventeenth-century England when the growing capitalist political economy there pushed rural people off their land and concentrated them in cities where they were made into an industrial proletariat. Many other examples of enclosure have since occurred around the world including the removal of indigenous people by force from their lands in the Americas, Australia, Africa, and Asia. While the historical and geographical contexts of enclosure then and now are surely different, there are potential commonalities. Most important, perhaps, is that subsistence cultures dependent on a resource lose access to it when it is privatized and as a consequence must move, adapt, or fight back. Vandana Shiva writes much about how numerous indigenous communities in India had their forests declared as “wastelands” by the Indian state and transferred to multinational capital as private property (2013). Many subsistence cultures in South Asia have been destroyed in the process; some still hold out against the Indian state and capital. Shiva and others contend that neoliberal capitalism relies on enclosure much as colonizing states did centuries ago. Thus they argue neoliberalism is a form of neocolonialism.
Institutions, frameworks, and the discourse of inevitability

Almost every state, perhaps with the exception of North Korea and Cuba, is participating in the globalized free market. While some powerful states, like the United States, largely chart their own course for participation, many developing states have their participation in the global marketplace substantially orchestrated by the World Bank, IMF, and WTO. While these institutions outwardly seek to develop states, they are also trying to smooth the global economic surface for the maximization of capital flows and growth. This has profound implications for the people and environments subjected to SAPs. Again, it is important to remember that SAPs are neoliberal frameworks imposed on debtor states to help them avoid defaulting on their outstanding loans. The threat of default means that many states would otherwise be ineligible for future development aid and risk being further isolated from the global economy. This is a risk most states are unwilling to take, making the adoption of SAP frameworks by debtor states practically inevitable. SAP frameworks are fairly complicated agreements, but there are a few overarching commonalities of SAPs that impact people and their local environment.

SAPs frequently require trade liberalization (Peet 2003). Part of the idea behind trade liberalization is that developing states tax their growing export industries and use those funds to repay their loans. States subjected to SAPs are often expected to make their natural resources available to the global market. In other words they must be willing to open up their commons to private interests for exploitation (and in the process states should generate revenue to repay loans). SAPs encourage states to export tropical hardwoods like mahogany, for example, that command strong prices globally. States may also be encouraged to bolster their production and export of bananas, cacao, teak, palm oil, or coffee. Debtor states must, however, also open up their domestic markets to international competition. For example, small-scale coffee producers in Central American states lose protective tariffs that keep their product domestically competitive and must therefore compete with coffee producers of various sizes located all over the world. These actions bring many more low-cost products to the global marketplace and can thus be considered a success in neoliberal terms.

In addition to SAPs, international free-trade agreements also augment the shift to market liberalization (McCarthy 2004). These frameworks marketize the farthest reaches of member states’ hinterlands with consequences for local people now subject to their principles. Mexico’s participation in NAFTA, for example, was predicated on the Mexican state implementing reform of its land tenure policy long enshrined in its constitution. Essentially the state had to put on the market some of its lands guaranteed to farmers as part of its ejido system. Many small farmers relied on this lost land for their livelihood. This was the basis for the Zapatista Rebellion in the State of Chiapas where indigenous groups violently reacted to the sale of their land to MNCs at the behest of the Mexican state that had to follow NAFTA’s rules. The NAFTA framework also eliminated Mexican tariffs on the import of foreign sources of corn. Subsidized corn produced in the United States flooded the Mexican market, driving many small-scale producers out of business and off of their land. Large-scale protests occurred in Mexico City.
and elsewhere, but resulted in little change in the situation as the rules are encoded in the language of the NAFTA agreement. In these instances the state usually stands behind the inevitability of the legal rules for participation in the free-trade framework.

Liberalization is also finding its way into the developing world through the work of institutions other than the World Bank/IMF and the WTO. United Nations (UN) frameworks like its Millennium Development Goals and its efforts to provide potable water to the world’s poorest residents are a good example. Water security efforts coordinated by the UN frequently rely on liberalized, market initiatives to build and manage water infrastructure in resource-strapped contexts where there is little potential for state provision. Multinational water firms are also encouraged to privatize extant state and municipal water supplies if public utilities are deemed insufficient in their capacity to provide water. Part of the proceeds from the private management of water systems is supposed to fund the construction of new systems by the same corporations elsewhere. While there have been some successes, critics contend that the liberalization of water provision can be a continuing hardship for poor people who cannot afford the water tariffs (Shiva 2002). Violent reactions sometimes occur with water privatization, especially where public systems previously offered water at little cost and the new private managers cut off water supply to those not paying their bills. The Cochabamba water crisis mentioned above is one such example. Advocates of market-based strategies for water delivery insist, however, that other viable options for generating funding to build public systems are lacking. Again, this is another instance of the discourse of inevitability associated with neoliberal reforms.

A problem of state legitimacy?

The management of water provision can again be looked at to help answer this question. A growing human population, climate change, and a global economy predicated on unfettered growth are putting incredible strains on the world’s freshwater supply. A lack of potable water is the most pressing of public health crises and therefore is increasingly difficult for states to ignore. To do so runs the risk of losing legitimacy in the face of unrest/protest. Many states, supranational institutions, and municipalities increasingly believe the best way to regulate and protect the world’s freshwater supply is to turn it into a saleable commodity in an established water market (Bakker 2010). The liberalized idea is that when water is valued at its “true market price,” it will be conserved and delivered most efficiently. The growth of private water provision has thus expanded rapidly in the globalized, neoliberal political economy. A handful of MNCs and their subsidiaries are now responsible for much of the world’s potable water supply. The privatization process, however, plays out differently according to geographical context.

In many parts of the developed world, formerly public (often Keynesian) systems are transferred to the private sector and in essence are turned into private property. Public water systems are privatized in developed states for a variety of reasons, including the decline of infrastructure and the need to expand supplies. Mitigating these problems is expensive for the public sector. Some water systems in the United Kingdom, United States, and Greece, for example, were transferred to private firms. Transfer accomplishes two things. First, it bolsters the state’s reputation for fiscal responsibility; and second, it is a redistribution of wealth in the form of public sector assets transferred to the for-profit
private sector. These results provide states with legitimacy from a neoliberal perspective.

In lesser developing contexts, by contrast, states may be eager to expand water provision but political economic realities make it extremely difficult to afford the construction of systems. States, sometimes with UN cooperation, encourage corporations to build new water procurement and distribution systems in places where none previously existed, or perhaps where the extant public system is deemed to be insufficient (Cochabamba). The idea here is that firms use their investment capital to build new systems and thereby leverage more capital through the sale of water to newly connected consumers. The firm can then build new systems elsewhere. This is a particularly common strategy for solving water provision problems in sub-Saharan Africa. From a neoliberal, market-based standpoint, this is a win–win situation. Companies make money from water tariffs while more people gain access to safe drinking water. But there are problems with making water into a marketable commodity, particularly in the developing world, as the Cochabamba example makes clear.

Under neoliberalism people are treated as customers who have to pay to access it. This is probably acceptable for people who have enough money to pay their water bill in the United States or United Kingdom, but herein lies the potential contradiction. As critics suggest, the architects of these privatized water systems in the developing world sometimes underestimate the degree to which new customers have a difficult time paying their water bills. Evidence suggests that poor people often cannot afford the rates charged to them. Thus they end up walking to get water somewhere else, or they sabotage the new system and gain access to the water illegally (Loftus and Lumsden 2008). Overt acts of violence between residents and corporations/states do occur as a result of the contradictions of the privatization process. As was clearly the case in Bolivia, neoliberal fixes like water privatization can sometimes lead to further legitimacy crises for states.

**Concerns about environmental injustice**

Neoliberalism is controversial. In the developed world, the establishment of market liberalization requires the erosion of statist environmental protections won during the Keynesian era. Environmental justice advocates contend the rollback of environmental regulation and defunding of public environmental goods may benefit the overall economy and state budgets, but they say it also leads to a polarization of society where some people live in increasingly degraded environments. As already demonstrated, neoliberalism manifests differently in the developing world and as such it has created a different range of concerns about environmental injustices there.

It is true that millions of people living in the developing world are entering into some kind of middle-class lifestyle with the rise to prominence of market liberalism. Yet neoliberalism is fundamentally at odds with many communities’ (indigenous or otherwise) traditional modes of governance over resources and opponents suggest it will assimilate or dismantle anything that stands in its path (Shiva 2013). The lack of democratic capacity in relation to local communities’ control over the neoliberalization of their environment is well understood. A lack of local governance is important because there is little doubt that the world is a more polluted place than ever before. Intensified production, marketization, and associated consumerism in the name of global economic growth have led to severe environmental damage in the remotest corners of the world where people are subsisting.
From the fields of soya encroaching on the rainforest in the Amazon, to the petroleum polluted Niger Delta estuary, the world’s most productive biomes (and the human communities that live there) are often irreparably damaged by market expansion (Watts 2008). Such damage will be extremely difficult to remediate.

Critics contend there is little recourse for losers in these kinds of scenarios to make meaningful change in their respective states, let alone at the global scale. Neoliberal institutions like the World Bank/IMF and the UN as well as the MNCs that benefit from their frameworks all wield enormous amounts of power to coordinate global market relations. Negatively affected people will continue to protest the actions of these powerful interests and their market reforms. As is the case in Cochabamba, they will turn the tide against privatization of public resources in a few instances. But the cost of violent protest against neoliberalism and its supposed liberation of the individual is often a loss of human life in places like Bolivia and Nigeria. This is one of globalized neoliberalism’s most deep and intractable contradictions.

Neoliberalism

Jamie Peck
University of British Columbia, Canada

Neoliberalism is an umbrella term applied variously to a programmatic bundle of pro-market, pro-corporate, and pro-choice policy measures; to a rationality of small-government transformation, modeled on the principles of entrepreneurialism and competition; to the political-economic philosophy and belief system of “market fundamentalism”; and to a historically ascendant ideology (and pattern) of capitalist development, linked to globalization, financialization, and the hegemony of “market rule.” Signature policies associated with neoliberalism include privatization (the sale of state assets, the outsourcing of government services, and the reallocation of functions from the public to the private sector); deregulation (the diminution or recalibration of state control in favor of more competitive, market-based, or choice-oriented approaches); various forms of marketization (the adoption of market-like principles and subjectivities, based on competition and choice, across a wide range of governmental and nongovernmental spheres); structural adjustment (the enforcement, by way of loan requirements, of neoliberal restructuring measures by multilateral agencies, usually in the context of currency or debt crises, or “bailouts”); and austerity (the imposition of public expenditure cuts and strict fiscal discipline, especially since the 2008 financial crash).

Iconic figures of neoliberal thought include the philosopher-economist Friedrich Hayek, whose 1944 book, *The Road to Serfdom*, is considered by many to be a founding text in the movement for free markets, and the Nobel Prize-winning economist from the University of Chicago, Milton Friedman. Vanguard politicians especially associated with the neoliberal cause include Margaret Thatcher (UK prime minister, 1979–1990), Ronald Reagan (US president, 1981–1989), and General Pinochet (Chilean president, 1974–1990), although centrist, “third-way” politicians like Bill Clinton (US president, 1993–2001), Fernando Henrique Cardoso (Brazilian president, 1995–2003), and Tony Blair (UK prime minister, 1997–2007) also played important roles in the mainstreaming of neoliberal positions and policies, including those of free trade, privatized governance, and labor market/welfare reform. In institutional terms, the propagation and enforcement of neoliberal principles is closely linked, some would say organically, to the trio of Washington Consensus organizations – the World Bank, the International Monetary Fund (IMF), and the World Trade Organization (WTO) – together with an expansive system of free-market think tanks.

A slippery, contested, and polysemic word, “neoliberalism” is very much a critics’ term, one that is principally associated with the critical social sciences (where its explanatory reach and status are often questioned) and with activists and social justice movements working in opposition to corporate rule, financialized capitalism, and socioeconomic inequality. Neoliberalism has very little official currency per se. Politicians will only invoke the term, very occasionally, in order to distance themselves from it, as in the case of the declaration by Nicholas Sarkozy (French president, 2007–2012) that self-regulation, “laissez-faire,” and free-market deregulation...
were “finished” as a result of the Wall Street crash of 2008. (Only rarely will politicians even brand their opponents in these terms, as this would certainly beg the question of how far they, too, share in the neoliberal “consensus.”) In everyday usage, the word tends to be in much wider circulation in regions associated with wrenching experiences of structural adjustment, like Latin America, than it is in the supposed home of the Washington Consensus itself, the United States. As a result, neoliberalism represents, at the same time, a strong signifier in political and ideological terms, and an ambiguous and disputed term in both academic and popular discourse.

Positing a positive program for market freedoms – in the shape of an idealized, small-state, competitive order – neoliberalism is also very much defined by its antipathies, to socialism and statism, to public-sector solutions and government bureaucracies, to social collectivities like labor unions, and to programs of progressive redistribution. The prefix “neo” underscores the character of neoliberalism both as a successor to the influential strand of nineteenth-century political economy known as laissez-faire (against which it offers a sympathetic critique) and as an alternative to the various forms of state-centric government that rose to dominance after World War II, including Keynesian welfare states, state socialist systems, and developmental states (against which it offers a decidedly unsympathetic critique). In this respect, neoliberalism comes after, and refers back to, the laissez-faire vision of economic liberalism (based on freedom of exchange and trade, individualized rights, minimalist government, the spontaneous order of competitive markets, and an antipathy to state intervention beyond the enforcement of property rights), against which is advocated a more purposive but still constrained role for states as the active enablers, protectors, and propagators of markets, entrepreneurialism, and competitiveness. Neoliberalism also represents a historically “new” method for the regulation of capitalist economies, both as an ideological cum institutional alternative to Keynesian welfarist models and state-led approaches to development and, most fundamentally, as a Cold War antithesis to communism and socialism.

If the prefix “neo” serves a range of preformative (not to say performative) purposes, the stem “liberal” is not so easy to fix either. In the first instance, it should be taken to index an affinity to classical liberalism (freedom of thought and contract, equality before the law, the primacy of private property rights) and to liberal traditions in orthodox economics (deference to free markets, methodological individualism, and atomized competition; opposition to government interference), rather than liberal politics per se, at least in the received North American usage, where the label “liberal” usually applies to the politics of the center left and the traditions of New Deal and Great Society (welfare) liberalism. Even though some of the more conspicuous origins of neoliberal programs of government are to be found on the right of the political spectrum, with various conservative and “new right” traditions in North America and Western Europe, with authoritarian regimes in Latin America, and with the advocacy of pro-corporate positions more generally, the roots and reach of the project have long exceeded this. And, certainly in the contemporary context, neoliberal impulses, inclinations, and imperatives are yet more politically promiscuous, dominating the broad center (or mainstream) of the spectrum in many parts of the world, from the pragmatic left (notably, stemming from the Third Way movements of the 1990s) to various configurations of the corporate, establishment, populist, and radical right, while also fusing and interacting, in a usually more conditional and selective fashion, with an array of statist, authoritarian,
and neodevelopmentalist regimes, in China, Russia, India, Singapore, Brazil, and elsewhere.

In light of these complex geographies and genealogies, it should come as no surprise that “neoliberalism” can be a somewhat confounding and perplexing term – as a descriptor, as a signifier, and as an analytic. The influence of market-oriented politics may seem to be pervasive, and on some accounts even ubiquitous, yet no two manifestations of neoliberalism are the same. Since neoliberalism is a utopian vision, it cannot exist in “pure” form. Actually existing manifestations of neoliberalism must therefore always coexist with other social forms and political-economic tendencies – even where market rule is dominant or hegemonic. Its traces, furthermore, can only be found in complex hybrids, amid context-specific conditions, and in contradictory formations, where contradictions arise both from “internal” tendencies in neoliberal development (e.g., problems of market failure, or the experimental adaptation of strict privatization schemes into public–private partnerships and regulated privatizations) and from jarring relations with its coexistent others (e.g., conflicts with public sector unions and service users, differences with alternative conservative positions on issues like immigration).

Inevitably, then, idealized or shorthand representations of neoliberalism, as a generic condition of more market/less state governance, belie more complex and contradictory realities of hybrid coexistence, polymorphic state/market reorganization, and path-dependent restructuring. Nonetheless, the pervasive, “global” presence of neoliberalizing tendencies is commonly (mis)read as an indicator of incipient convergence or as a premonition of imminent conformity, when “total neoliberalism” remains a logical impossibility (and utopian fantasy) and as the reproduction of uneven geographical development is an endemic characteristic of “market rule” (Brenner, Peck, and Theodore 2010). Since all manifestations of neoliberalism are not only incomplete but also situated and context-specific (and not template reproductions, variants, or corruptions of, say, Thatcherism), it can only exist in the world in hybrid or “alloyed” form, while it also follows that neoliberalization functions as a tendency rather than an end state or equilibrium condition. Those that hold onto the term (and the concept) of neoliberalism, despite these challenges of conceptualization and operationalization, tend to do so not because it offers a blanket “explanation of everything,” but because it draws attention to complex connectivities, mutual relations, family resemblances, overlapping rationalities, repeating patterns, asymmetrical articulations, and dense relays between localized manifestations of variegated market rule.

A brief(er) historical geography of neoliberalism

The best-known introduction to the worlds of neoliberalism is David Harvey’s (2005) A Brief History of Neoliberalism. Underscoring the ideological integrity of the neoliberal project – for all its unevenly developed, actually existing forms – Harvey defines neoliberalism “in the first instance [as] a theory of political economic practices that proposes human well-being can be best advanced by liberating individual entrepreneurial freedoms and skills within an institutional framework characterized by strong private property rights, free markets, and free trade,” while at the same time recognizing that...
then, both Clinton and Blair could easily have reversed Nixon’s earlier statement and simply said, “We are all neoliberals now.” The uneven geographical development of neoliberalism, its frequently partial and lop-sided application from one state and social formation to another, testifies to the tentativeness of neoliberal solutions and the complex ways in which political forces, historical traditions, and existing institutional arrangements all shaped why and how the process of neoliberalization actually occurred. (Harvey 2005, 2, 13)

This is not to say that the idealized vision of neoliberalism had no part in these more haphazard, real-world experiences of neoliberalization, but rather that ideological (mis)representations of market freedom “primarily worked as a system of justification and legitimation for whatever needed to be done to achieve [the] goal” of restoring high(er) rates of profitability and returns to wealth, while securing the dominant positions of elites (Harvey 2005, 19).

The roots of neoliberalism as an explicit (and named) set of ideas go back to the middle of the twentieth century, and to two gatherings of prominent liberal intellectuals, first at the Colloque Walter Lippmann in Paris in 1938, and then at a Swiss mountaintop resort in 1947, the founding moment of the Mont Pèlerin Society. Hosted by the French philosopher Louis Rougier, the first meeting focused on the contributions of the American journalist and pioneering cold warrior Walter Lippmann, bringing together prominent representatives of various European liberal traditions, including Wilhelm Röpke and Alexander Rüstow of the German Ordoliberals (who maintained that a prerequisite for the effective functioning of free markets was a strong and well-organized state) and Austrian School adherents to a rather more classical, or paleoliberal, position, notably Ludwig von Mises and Friedrich Hayek. It was at this meeting that Rüstow made the case for a “new liberalism,” a purposeful reconstruction of the laissez-faire tradition, fit for contemporary conditions, and based on a principled repudiation of socialism, collectivism, and statism.

These plans to lay down the intellectual foundations for a new liberalism were disrupted by World War II. But the project was soon to be revived by Hayek in Mont Pèlerin, the Austrian serving as an interlocutor between an upstart cadre of Chicago-based economists, including a young Milton Friedman, who were beginning to define their “school” in opposition to the Keynesian mainstream (and the strongholds of New Deal economics on the East Coast of the United States), and the generally less buccaneering Europeans, including an Ordoliberal contingent with a hand in German reconstruction after the war. Echoing the line of argument sketched out in Hayek’s polemical defense of free-market reason, The Road to Serfdom (which had been a surprise bestseller at the end of the war and was promptly abridged by the Reader’s Digest magazine), these defenders of the liberal creed maintained that collective provisioning and state action, left unchecked, would lead inexorably to totalitarianism. As the founding statement of the Mont Pèlerin Society read:

The central values of civilization are in danger. Over large stretches of the Earth’s surface the essential conditions of human dignity and freedom have already disappeared. In others they are under constant menace from the development of current tendencies of policy … developments [that] have been fostered … by a decline of belief in private property and the competitive market; for without the diffused power and initiative associated with these institutions it is difficult to imagine a society in which freedom may be effectively preserved.

Believing that what is essentially an ideological movement [toward statism and collectivism] must be met by intellectual argument and the reassertion of valid ideals … The group does not aspire to conduct propaganda. It seeks to
As if to affirm their pessimistic reading of “tendencies of policy,” if not their alternative vision of a “free society,” the Mont Pèlerin group and its allies would spend most of the next quarter century at the intellectual margins and in an ideological wilderness. A cluster of Keynesian and developmentalist orthodoxies came to dominate not only the economics profession and the corridors of power, but also the “common sense” of mainstream political parties of all stripes across the Western capitalist countries, reflected in a bipartisan embrace of principles like full employment, social welfare entitlements, and the “mixed economy” of public and private provision, along with measures like price controls, countercyclical spending, and industrial policies. A line borrowed from Milton Friedman and frequently attributed to Republican president Richard Nixon, in the early 1970s, reluctantly acknowledged the status quo of the time: “We are all Keynesians now” (quoted in Harvey 2005, 13).

Far from idle during these years of isolation, however, those associated with what intellectual historians would later term the “neoliberal thought collective” (Mirowski and Plehwe 2009), even as they desisted from using the word “neoliberalism” itself sometime in the early 1950s, had been hard at work on the foundations of their “flexible credo.” This included a biting “monetarist” critique of inflationary tendencies in the Keynesian system, spearheaded by Milton Friedman and the Chicago School, which would later play a decisive role in the (very public) battles over the “stagflation” crises of the 1970s (the coincidence of high inflation and high unemployment, which exposed a mortal flaw in both Keynesian theory and practice). Alongside his achievements as a technical economist (recognized with the Nobel Prize in 1976, two years after Hayek, in the wake of which the field which has been dominated by Mont Pèlerinians and Chicago types), Friedman was by the late 1960s firmly established as one of the most prominent public economists in the United States. He was a formidable exponent of the argument–clinching sound bite, not just in the seminar room but also in the TV studio. A widely read magazine and newspaper columnist, Friedman also wrote some very successful mass market books, such as *Capitalism and Freedom* (1962) and *Free to Choose* (1980), the latter being serialized on public television in the United States in the year that ended with Ronald Reagan’s path-altering election.

Underlining the point that these were very much strategies of distribution and dissemination, rather than intellectual invention per se, the period between the mid-1950s and late 1970s was also a decisive one for what would grow into an expansive and tightly integrated ecosystem of free-market think tanks. The taproot of this system can be traced to a 1947 meeting between Hayek and Antony Fisher, a would-be conservative member of parliament turned businessman, who went on to devote both his life and personal fortune to the cause of economic liberty. On Hayek’s advice, Fisher put his financial and organizational skills to work in a pioneering effort to construct a quite new form of ideologically aligned think tank, at arm’s length from the universities but closely plugged into media circuits and a growing network of allies in the policymaking world. The first of the “Fisher think tanks” was the Institute of Economic Affairs (established in London in 1955), which fought a lonely fight for almost
two decades before the broader turn toward free-market ideas in the 1970s.

This decade saw the foundation of the most influential free-market think tanks, including the Heritage Foundation, established in Washington, DC in 1973 by conservative activists disillusioned with what they saw as Nixon’s excessively moderate policy positions. On the eve of President Reagan’s inauguration in 1981, Heritage would publish its Mandate for Leadership, anticipating both the general direction of (and specific measures within) the radical policy program of the new administration, into which several of its key staff members would promptly move. Rather more purist, the libertarian Cato Institute was founded by conservative billionaire Charles Koch in Wichita, Kansas, in 1974, later to relocate to San Francisco and then to Washington, DC. For his part, Antony Fisher was instrumental in founding the Fraser Institute (established in Vancouver, Canada, in 1974), the Centre for Independent Studies (established in Sydney, Australia, in 1976), the Manhattan Institute (established in New York City in 1978), the Pacific Research Institute (established in San Francisco, in 1979), the National Center for Policy Analysis (established in Dallas, Texas, in 1983), and the Atlas Economic Research Foundation (established in Washington, DC, in 1980), the latter with a mission to propagate free-market think tanks around the world, the extended network of which now consists of close to 500 affiliated organizations.

The underlying purpose, political orientation, and historical timing of the construction of this infrastructure of free-market think tanks might lend credence to a neat and tidy tale of linear, supply-driven ideational innovation. It is almost as if all that it took to win the battle of ideas was to reprocess the distilled spirit of Mont Pèlerin at the University of Chicago, and then to blend and dilute this in accordance with policymaking appetites and local tastes down the supply chain to the think-tank branch plants. The story, of course, more complicated, and it is significantly marked by fortuitous events and opportunistic openings. Constructing the think-tank delivery system may have been necessary, but on its own it was not sufficient. For his part, Hayek certainly believed that the new breed of free-market think tanks would have vital roles to play as “second-hand dealers in ideas”; since the basic principles of restrained government and liberalized markets were well understood (not to say, in these circles, beyond dispute), the downstream challenge was the continuous political and policy work of “permanent persuasion,” to borrow a Gramscian phrase (Peck 2010). As Antony Fisher liked to write in his fundraising letters, “the echo is more important than the message.”

Fisher was writing these letters, almost without exception, to wealthy business leaders and financiers. By the 1970s, some members of the business community in the United States were willing to write increasingly large checks to fund battles against burdensome taxes and bothersome regulations, against infringements of the corporate “right to manage,” and against creeping bureaucratization and social state expansionism, in order to defend the free enterprise system. But it had not always been so. After relocating to the United States in 1950, Hayek, Friedman, and their friends at the University of Chicago had struggled for years to raise adequate funds from the corporate sector and from private donors. The free-market cause had its supporters, but these were generally on the fringes of the business community. In the early 1970s, however, things began to change.

The turning of the tides was symbolized by the so-called Powell Memorandum of 1971, a confidential missive delivered to prominent members of the US Chamber of Commerce by Lewis F. Powell Jr, a corporate lawyer soon
to be appointed to the US Supreme Court. Entitled “Attack of American Free Enterprise System,” the memo traced the source of what was portrayed as a sustained and systemic assault on capitalist values and institutions to a “chorus of criticism … from the college campus, the pulpit, the media, and intellectual and literary journals, the arts and sciences, and from politicians,” in the face of which the business community had mistakenly adopted an implicit policy of appeasement. This had to change:

There should be no hesitation to attack the Naders, the Marcuses and others who openly seek destruction of the system. There should not be the slightest hesitation to press vigorously in all political arenas for support of the enterprise system. Nor should there be reluctance to penalize politically those who oppose it … The threat to the enterprise system is not merely a matter of economics. It also is a threat to individual freedom. (Powell 1971, 29–30, 32)

This is not to suggest that the Powell memo was the single smoking gun cause of the subsequent “strategic politicization” of the US business class, but it is widely credited as a germinal factor in (and portent of) the subsequent build-out of the free-market think-tank infrastructure; the ascendancy of organized assertion of shareholder values and interests; the massive expansion of business, financial, and “right channel” media; and the formation of conservative corporate policymaking operations like the American Legislative Exchange Council (ALEC), the influence of which did not fully come to light until well into the organization’s fourth decade of under-the-radar activities (see Block and Somers 2014; Peck 2014).

Few of these sparks would have led to any larger conflagrations, needless to say, absent the kindling of propitious cultural, social, and political-economic circumstances. In the pivotal decade of the 1970s, however, conditions began to favor, if not impel, the kind of concerted action advocated in the Powell memo and long anticipated by the free-market evangelists in Chicago. Sustained downward trends in corporate profitability, in labor productivity, and in the US share of world trade were contributing to an environment of macroeconomic insecurity, while a wide range of social movements (including organized labor; movements for civil, welfare, and women’s rights; and causes like environmental and consumer protection) had been achieving legislative traction as well as (re)shaping public opinion. The Powell memo had sounded the alarm that legislative and cultural incursions onto the corporate terrain had crossed the line to system-threatening status, arguing that the movement toward progressive taxation had gone too far and that increasing inflation would further erode the position of the holders of capital.

What some commentators would call the Great Inflation (the roots of which were traced to rising governmental and wage expenditures in the 1960s, not least as a result of the Vietnam War) was to prove catalytic for the subsequent turn toward neoliberal governance, the carrier of which was Friedman’s monetarist doctrine of tight control of the money supply (see Samuelson 2008). This turn echoed the way in which macroeconomic collapse and mass unemployment of the 1930s, the Great Depression, had provided the historical impetus (and the opportunity, if not necessity) for the rise of New Deal politics, for the establishment of the postwar social welfare settlement, as well as the foundations for the capital–labor accord of Fordism–Keynesianism (see Gordon, Edwards, and Reich 1982).

If these conditions described the path toward neoliberalism in the United States – culminating in the Reagan presidency and what would prove to be a long-run shift toward inflation control, tax restraint, and light-touch regulation – this is
not to say that they are replicated in each and every turn toward neoliberal politics and modes of governance. To be sure, there are recurring themes in neoliberal transformations around the world, such as preceding periods of aggravated macroeconomic stress (as reflected, for example, in currency, debt, or balance of payments crises), and the rise to power of “reformist” administrations (see Fourcade-Gourinchas and Babb 2002), but there is much more than analytical sophistry in the claim that neoliberal “transitions” are contextually and conjuncturally specific.

This point is underscored by what many regard as the “original” neoliberal counterrevolution, in Chile in the wake of the military coup of 1973. Under the dictatorial rule of General Augusto Pinochet, Chile was to become what Naomi Klein (2007, 53) has called, with requisite irony, a “laissez-faire laboratory” for Chicago School economics. True, there had been an experiment with neoliberal-style “shock treatment” in Germany, right after World War II, but Chile would become the most notorious case, and a forerunner to similarly severe applications of macroeconomic medicine in Central and Eastern Europe after the fall of the Berlin Wall in 1989 (see Yergin and Stanislaw 2002). In Chile, an elite cadre of US-trained economists — many of whom studied under Milton Friedman and his colleagues as part of an exchange scheme established in the late 1950s — were appointed by Pinochet to drive an unprecedented program of monetary restraint, privatization, deregulation, union suppression, trade liberalization, and tax reform aimed at taming runaway inflation and restoring economic competitiveness.

While Friedman and Hayek defended the economic record of the “Chicago Boys,” their enduring notoriety stems from the perverse political demonstration effect of Chile’s neoliberal turn: this program of economic liberalization was prosecuted through state violence, authoritarian governance, and repression of democratic institutions, undercutting the claim to an irreducible link between political and economic “freedom.” The embrace of neoliberalized modes of economic regulation would later be witnessed across a wide range of political regimes, including robust democracies and “reforming” state socialist systems. In some cases, neoliberal reformers can justly claim an electoral mandate, but there is increasing evidence that deepening neoliberalization is associated less with democratization and empowerment than with a long-run drift toward insider dealing, money politics, and technocratic management. In turn, this reflects established tendencies in neoliberal governance for upward expropriation over downward redistribution, for private gain over the common good, for shareholder value over social benefit, for speculative growth over sustainable development, and so forth.

Arguably, nowhere is the discrepancy between neoliberal economic reforms and democratic consent greater than in the case of structural adjustment programs (SAPs) managed by multilateral agencies like the IMF and World Bank, with the support of the US Treasury department. Beginning in the 1980s, these Washington Consensus organizations started to impose increasingly strict “conditionalities” on loans advanced to middle- and low-income countries in the context of macroeconomic (and especially debt) crises, conditionalities that essentially mandated the introduction of a range of neoliberal policy measures, including privatization, deregulation, financial liberalization, and public spending reductions (see Peet 2003). These policy prescriptions were later summarized by John Williamson (1990), an economist with close links to the IMF and the World Bank, in a manner that would pass into neoliberal lore:
1 fiscal policy discipline, focused on debt reduction;
2 shifting public spending from “subsidies” to pro-growth investments in skills and infrastructure;
3 tax restraint;
4 control of interest rates, which should be market-determined;
5 competitive exchange rates;
6 trade liberalization and the removal of tariff protections;
7 liberalization of inward foreign direct investment;
8 privatization of state enterprises;
9 deregulation;
10 legal security for property rights.

There has been a tendency, since the late 1990s, to apply structural adjustment measures in a less brazenly unilateral manner, with an increased emphasis on “good governance” and “pro-poor” policymaking, in the context of what has sometimes been dubbed the “post-Washington Consensus” – not least as a result of social protests triggered by earlier rounds of SAPs and by the (at best) mixed record of these programs themselves (see Craig and Porter 2006). There has been a resumption of stricter forms of structural adjustment, however, in the period since the global financial crisis of 2008. New rounds of “austerity” measures have been imposed not only on developing countries, but across the eurozone, especially in the Mediterranean states, and in bankrupt cities like Detroit – in some cases involving the formal or de facto suspension of established democratic procedures (Laskos and Tsakalotos 2013; Peck 2014).

Analytics of neoliberalization

The invocation of neoliberalism and its processual variant, neoliberalization, as analytical devices, mostly in the critical social sciences, exhibits a historical geography of its own. This overlaps with, but in other ways is quite distinct from, the evolution of its actually existing forms. Early explorations of the explanatory and conceptual (as well as political) status of neoliberalism can be found in Latin American development studies (see Colclough and Manor 1991), in the neo-Foucauldian governmentality approach (see Barry, Osborne, and Rose 1996), and in neo-Marxist debates around Thatcherism (see Jessop et al. 1988), although there were few connections between these islands of theoretical practice. In geography, the encounter with neoliberalism was principally associated with work in regulation theory (see Peck and Tickell 1994). The initial premise here was to question, in the British context at least, the status of the Thatcherite form of neoliberalism as a viable “successor” to Keynesian welfarism as a mode of social regulation in its own right, and as an effective enabler of an enduring pattern of post-Fordist macroeconomic development. Instead, the interpretation in these early regulationist treatments, which were largely concerned with the macro form(s) and consequences of neoliberalization, was that Thatcherism was more of a creature of the protracted British crisis than any meaningful guide to its resolution, being freighted with unmanageable contradictions and disabling externalities.

Regulation theory rejects economically functionalist conceptions of modes of social regulation (like Keynesianism, developmental statism, and would-be successors like neoliberalism), which are seen to possess relative autonomy from the needs of capital. Yet capitalism (and markets) cannot exist independently of social and institutional supports of different kinds. Markets and institutions are therefore found in (various states of) contradictory coexistence. It follows that the search for new institutional
NEOLIBERALISM

fixes (e.g., along the path of neoliberalization) is marked by a wide range of failed experiments, crisis-managing compromises, and “chance discoveries,” as well as more deliberative projects, putative models, and power plays. Over time, however, it became increasingly clear that various stripes of Anglo-American neoliberalization were beginning to evolve synergistically with deepening financialization, as they also became ever more profoundly entrenched with elite interests. These would soon be shaping the rules of the game more widely, even as this game was being played differently in different places.

Meanwhile, somewhat overlapping understandings of “neoliberalism,” as a synonym for corporate rule and free-market globalization, were emerging in various activist circles, beginning with the Zapatista uprising in Chiapas, Mexico, in 1994, resonating through the anti-WTO protests in Seattle in 1999, and provisionally uniting (albeit in opposition) the diverse array of social movement forces assembled at the World Social Forums, initially in Porto Alegre, Brazil, in 2001, as the dialectical other to the mobilizing slogans “Another World Is Possible” and “One No, Many Yeses” (see Fisher and Ponniah 2003).

This newfound political currency coincided with the recognition that, for many critical social scientists, the term “neoliberalism” had utility as a means to (re)politicize orthodox understandings of globalization, which had been ascendant during the 1990s, following the fall of the Berlin Wall and hubristic announcements of an “end of history” victory for US-style capitalism. (In mainstream usage, “globalization” was often portrayed as an uncontrollable process, like the weather, and somehow above politics itself.) Different conceptions of neoliberalism were soon being widely invoked, especially in geography and urban studies (see Brenner and Theodore 2002), in radical political economy and cultural studies, and rather more tentatively in sociology and anthropology, although still hardly at all in the more orthodox fields of political science or economics. Something of a step change occurred in the wake of the global economic crisis of 2008, however, which, even as it vividly and publicly discredited the model of “deregulated” finance, soberingly affirmed the grip of neoliberalism’s political hegemony in the uncomprising form of social state retrenchment and austerity programming (Brenner, Peck, and Theodore 2010; Hall, Massey, and Rustin 2013).

Notwithstanding the increasingly close attention that has been paid to the form and consequences of neoliberalization, it is notable that the basic definition, the explanatory status, and in some quarters even the very existence of neoliberalism all remain, to varying degrees, subjects of contention. In political rhetoric, the term retains polemical connotations. It is associated with a range of more precise meanings in the social science literature, but these often remain matters of dispute. Some of the theoretical currents include a Marxist depiction of neoliberalism as a (new form of) ruling-class hegemony tied to deepening financialization, as an ideological offensive or “revolution from above,” and in a more general sense as a synonym for the prevailing historical form of capitalism (see Harvey 2005); a (neo-)Foucauldian strand of governmentality studies, in which neoliberal impulses take a much more dispersed and socially complex form, as they are implicated in the enrolment and (re)constitution of enterprising and “responsibilized” subjects (see Barry, Osborne, and Rose 1996); and, working across and between these, various approaches to neoliberalism and neoliberalization as a variegated policy complex, as a restructuring paradigm or regulatory front, and as a prevailing rationality of government (see Brenner, Peck, and Theodore 2010).
In their different ways, all of these critical theorizations of neoliberalism must contend with the many discrepancies and slippages between, on the one hand, the reductionist and idealized discourse of neoliberalism (small state + free economy), which posits an essentially zero-sum relation between governmental withdrawal and the animation of (naturalized) markets, and, on the other hand, the much more prosaic, compromised, and contradictory forms (the plural being deliberate here) exhibited by actually existing programs of neoliberalization. Rarely, if ever, anything resembling the (constitutive) fairy tales of shrinking states and spontaneous markets, the wide array of actually existing neoliberalisms tends to be characterized by, in addition its idiosyncratic features, a tendency for complex reregulation rather than simple deregulation, shaped by recurring crises, policy failures, and opportunistic experiments; a significant degree of institutionalized path dependency, reflecting the specificities of those antithetical institutions targeted, and variably rolled back in neoliberal reforms, as well as the particularities of those rolled out in evolving programs of market-oriented reconstruction; and new forms of uneven geographical development, rather than convergence or standardization toward a generic or template form.

Disputes remain, however, around the utility and scope of neoliberalism as an explanatory device. Those skeptical of the term(inology) typically point to its normalizing effects, as an ideologically coherent “big story,” drawing attention instead to the diversity and vitality of lifeworlds outside the ostensibly all-encompassing ambit of neoliberalization, to local exceptions and alternatives, and to the irreducible social surplus beyond the instrumental reach of market rule. Those attentive to the variegated and sprawling form(s) of neoliberalization, on the other hand, tend to see recurring patterns, family resemblances, and constitutive connections, even as they recognize that neoliberalism’s totalizing tendencies will always be thwarted and exceeded. These different ways of “seeing” neoliberalism, or not, arguably reveal as much about theoretical predispositions as they do about social worlds in change. It is almost as if an analytical version of the Rorschach test is at work: some will focus on the menacing black shapes, while the eyes of others will be drawn to the open spaces beyond.

NEOLIBERALISM

Netherlands: Koninklijk Nederlands Aardrijkskundig Genootschap (KNAG) (Royal Dutch Geographical Society)

Founded: 1873
Location of headquarters: Utrecht
Website: www.knag.nl
Membership: 3000 (as of 2013)
President: Eelko Postma
Contact: e.postma@knag.nl

Description and purpose

The Royal Dutch Geographical Society is the professional association of academic geographers, geography teachers, geography students, and professional geographers in the Netherlands with about 3000 members. The main tasks of the society are the promotion of geography in general and the improvement of its position in primary, secondary, and higher education as well as in scientific and applied research. It also offers opportunity for discussion and activities among geographers in professions in commercial research, education, management, policy, and so forth. Members come from both the public and the private sector and they operate at national as well as international level.

Journals or major publication series

Geografie. www.geografie.nl

Current activities or projects

The society hosts the KNAG Onderwijsdag where about 800 geography teachers attend this annual national congress on geography education. The society gives pupils between the ages of 10 and 15 the opportunity to work with soil, water, and digital map technology while visiting businesses and government during GeoWeek. The society has educational programs that offer advice on curriculum and examination. The society also plans several excursions every year in the Netherlands and abroad, for example, northern Germany and Indonesia.

The society copublishes several monumental atlases on historical cartography, for example, the Grote Atlas van Nederland 1930–1950 (Comprehensive atlas of the Netherlands 1930–1950), Grote Atlas van Nederlands Oost-Indische compagnie (Comprehensive atlas of the Dutch East Indian Company) in seven volumes, and Grote Atlas van de West-Indische compagnie (Comprehensive atlas of the West Indian Company) in two volumes.

Brief history

The Royal Dutch Geographical Society (KNAG) was founded in 1873. Initially, the main aim of the society was to increase the scientific knowledge of the world and the Earth. Expeditions were organized into unknown territories. The members of the expeditions also had an eye on the commercial possibilities of the areas they explored. Artifacts from these expeditions – like authentic maps and original expedition equipment – are lent to various museums in...
the Netherlands where they are put on display. In total, around forty expeditions have been organized under the auspices of the society. All the map making, production of inventories, and the collection of samples has resulted in an impressive cultural heritage.

When the need to explore dwindled, the society turned its focus to geographers and geography in the Netherlands. Modern-day KNAG stresses the distinctive and useful characteristics of geography as an academic discipline, a school subject, and a profession. In addition, the society provides services for its members and functions as a physical and digital meeting place to share ideas, knowledge, and information.

Network analysis

Kevin M. Curtin  
George Mason University, USA

Network analysis is one of the earliest and most persistent subdisciplines within the science of geography, and it has an extraordinarily broad reach across both theoretical and applied research areas. The networks analyzed in geography can be either natural (e.g., river networks) or human in origin (e.g., road networks), and they can consist of either physical structures or conceptual constructs. Networks represent a spatial domain over which an enormous variety of activities take place, from daily transportation to message communication to the flow of goods, services, and ideas. Activities that occur on geographic networks employ a diverse set of modes: cars, trucks, trains, airplanes, pedestrian traffic, and digital messages, among many others. Although the differences among the variety of geographic networks that can be modeled allow for the great diversity of research and applied study, it is the similarities in the network structure that provide the basis for analysis.

The history of network analysis in geography

Even the earliest practitioners of geography recognized the importance of networks in their descriptions of the world around them. Many of the earliest examples of cartography contained representations of rivers, canals, or pathways between and along important features. The ancient Greeks provided descriptions of network geographic features including shipping lanes, and the historical record contains maritime policies designed to protect them. It is well documented that Roman roads were considered vital to the building and maintenance of the empire.

The age of exploration brought with it a revolution in network analysis in geography. In the early part of this period long-distance transportation was dominated by sea travel, and the knowledge of transportation routes and the network of ports for supplies constituted a critical and highly valuable set of knowledge. Maps termed Portolan Charts showed the sea routes that could be exploited from and to a number of origins and destinations. In the later period, a tradition began of constructing series of maps that showed descriptions of routes travelled by explorers, frequently accompanied by directions that later travelers could follow, and pictorial or text descriptions of the sites they would find along the way. This tradition in travel cartography has persisted to this day.

With the advent of the modern university system, geography was recognized as a “mother discipline”; that is, one that is so intellectually broad that it tends to spawn other disciplines as they develop significant bodies of thought in their own right. This process held true for network analysis, as seen in the primary influence of transportation costs on land rent in Von Thunen’s economic location model (Von Thunen 1966). The distorting factors of transportation on the theoretical isotropic plane on which Christaller’s central place theory was posited resulted in a separate transportation principle for areas where the most efficient transport network was the primary locational consideration. Transportation
science itself became a separate discipline with research foci as broad as transportation network construction, to theories of traffic flow and queuing, to the science of urban travel demand modeling using transport networks as the domain for analysis.

The analysis of the movement of goods and services across networks took on new importance during World War II, when the field of military operations research demanded that transport networks be used to efficiently transport supplies and personnel based on operational objectives. This logistical approach to systems management entered the private sector after the war and became more broadly known as operations research. When an operations research problem contains location elements, including the location of objects on networks, or the locations of network elements themselves, this bridges operations research with geography in a subdiscipline termed location science. Location science remains a flourishing research subdiscipline of geography to this day.

During the period known as the quantitative revolution in geography (1950s and 1960s), network analysis became both a focus of research and a supporting concept in many of the most influential theoretical advances in geography of the time. Networks were considered the conduits of interaction in the area of interaction (or gravity) modeling. Diffusion models depended, in some cases, on hierarchical networks of places through which the goods, people, or ideas were moving. Investigations into the nature of the structures of networks and how networks can grow or evolve in different geographic contexts began to appear during this period (Haggett and Chorley 1970), and were tied particularly to economic analyses of regions. The related field of regional science embraced networks as the source of paths across which migrants traveled (and delineated the routes they chose to take on their migration), the conduits for commodity flows, and the connecting threads in interregional analysis (Isard 1960).

During this period transportation science itself developed into a discipline with strong ties to geography. This field encompasses elements of civil engineering (design of transportation network features), operations research (network flow modeling), and urban planning and design (transportation system integration, placement, and design), among others. The element of transportation most closely associated with network geography is that of urban travel demand modeling (Oppenheim 1995). The classic form of this model has four sequential steps, most with fundamentally geographic foci. The trip generation step determines the spatial origins of trip demands, usually through a combination of travel surveys and regression analysis using spatial demographic information as the independent variables. The trip distribution step employs variants of classic interaction modeling to determine likely trip destinations. The modal split step allows analysts to experiment with demand for the road network versus public transport networks based on costs and utility. Finally, the traffic assignment step associates trips with particular paths through the available transport networks. More broadly, transportation science is concerned with transport network design, routing across transport networks, queuing of objects traveling across transport networks, and other related transportation issues. However, since it is widely recognized that transportation applications are not the only research area that benefits from the flexibility and power of network structures, a broader science of network analysis has developed.
The science of network analysis

Network analysis in geography developed in concert with the development and growth of many other scientific disciplines in the modern university system. In particular, several subdisciplines of mathematics provided a quantitative theoretical basis for network analysis to complement the growing body of pure geographic theory. Those subdisciplines – graph theory and topology – examine the properties of connected sets of edges and vertices (in the case of graph theory), and connected spaces more generally (in the case of topology). Within these contexts networks or graphs (the terms are synonymous here) exist as a general class of spatial domain for geographic analysis. Thus, the properties of any network, regardless of the particular application or function, can be described, measured, and proven. Techniques for each of these levels of network analysis have developed over time.

Describing the properties of networks requires describing the elements that make up those networks (edges and vertices), describing the relationships among those elements, and describing the nature of the network as a whole. Among the most intuitive descriptive measures of networks are simple counts of the number of edges and vertices, and measures of the attributes of those network elements, such as the maximum, minimum, or total length of the edges, or the count of population or other demand that is presumed to exist at the vertices. These simple descriptive measures allow the most basic comparison of the size of the network under examination.

A very different means of describing networks consists of categorizing networks into idealized types based on the relative placement of features, the regular pattern of features in the network, or the topological properties of the network. Examples include the Manhattan network type, which consists of edges crossing at right angles creating rectangular “blocks.” As the name suggests, this network type (or an approximation of it) is frequently seen in more modern urban street networks. Distance measures across a network of this type are termed “Manhattan distances” and for some applications – such as pedestrian travel cost in a city – are perceived as much more realistic than other forms, such as Euclidean or “as the crow flies” measures. Hub and spoke networks, with the radial extensions that the name suggests, are a network type that has been widely used in distribution networks, including in some airline routing applications. When a network has branching edges, but no cycles, it falls in the category of tree networks. River networks and many types of hierarchical process networks are frequently modeled as tree networks. The “Bus” network type is a special case of a tree network consisting of a single main line with branches off to either side. In contrast to the name, this network type is frequently used in utility applications (electricity, water, and gas distribution, or telephone and cable television lines). Other types that are often used in more theoretical network analysis work include line and ring networks, or complete networks (where every vertex connects to every other vertex with a unique edge). Often these special cases of network models have distinctive properties that can be proven, and can be relied upon as the networks provide a platform on which network analysis takes place.

Another basic measure that considers the interaction of edges and vertices is the degree of vertices – simply a count of the number of edges incident to the vertex. The maximum, minimum, or average degree of the vertices in the network can then be recorded. These give some measures of the complexity of the interactions among the network elements. A series of more complex indices has been developed to specify
the level of connectedness of network elements (Kansky 1963). The beta index is simply the ratio of edges to vertices, where – intuitively – a larger number of edges associated with the same number of vertices represents a more highly connected network. The gamma and alpha indices represent a ratio of the number of links in a network to the largest number of possible links in that network (if it were a completely connected network), and the number of cycles compared to the maximum number of cycles, respectively. The maximum number of links can be determined based on a well-known proof, while the maximum number of cycles in a graph must be estimated.

These last network measures depend on graph theoretic proofs of the properties of the network in order to make comparisons across different networks. Further proofs of the properties of networks lead to a more robust set of network measures. Perhaps the most widely used proof of a network property is Dijkstra’s algorithm for shortest paths across a network (Dijkstra 1959). This efficient algorithm allows the guaranteed shortest path between any two points in a network to be computed, and variants of this algorithm allow all shortest paths between all vertices in a network to be computed. This, in turn, allows the determination of the diameter of a graph, defined as the longest shortest path between any two nodes in the network. This is a measure of the spatial spread of the network. As the Euclidean distance between any two nodes of the network is easily computed algebraically, the shortest path allows for a comparison of the network shortest path with the Euclidean shortest path between any two points. The ratio of the latter to the former is termed the detour index, and represents the efficiency of the network in overcoming distance. These are only a few of the most common network measures; new ways of measuring networks and their properties are entering the body of knowledge on a continual basis, from across a range of disciplines.

The measures discussed above allow analysis of a network to be performed but other research questions may require analysis on a network. There are many procedures that can allow routes across a network, paths among elements of the network, or optimal activities across a network to be determined. A limited sample of such procedures includes minimum spanning tree algorithms that find a least-cost tree network connecting all vertices in a network, maximal flow algorithms that determine the ways in which the largest possible amount of goods can be moved through a capacitated network (Ford and Fulkerson 1956), and methods to solve the transportation problem on networks where a set of supplies must satisfy a set of demands across the network with minimal system cost. The development of additional solution procedures for network analysis has moved forward rapidly as the technology of geographic information systems (GIS) has matured.

Network analysis in geographic information systems

As with much of the discipline of geography, network analysis has been revolutionized by the advent and growth of GIS. The extent to which network analysis has been integral in this growth stems from a combination of research interest in the community and fortuitous good luck. The latter element is an outcome of the needs for linear features and boundaries in the earliest GIS applications, and therefore their instantiation in the earliest GIS data models.

The earliest computer-based systems for automated cartography attempted to mimic the role of the cartographer in generating pictorial representations of linear features. Using a
series of consecutive symbols from a dot matrix printer, and later sets of individual lines drawn independently on a line plotter, the analyst could create maps showing a range of linear features. The structure of these independent yet adjacent geographic features came to be known as the “spaghetti” data model, as there were no formal connections between the features. In this data model each feature was stored individually, usually with an identifier and a list of coordinates that defined its shape. Because this data model does not preserve topological properties such as incidence or connectivity, it cannot readily be used for network analysis. The spaghetti data model persisted in computer-aided design software for several decades, where the shape of features was of primary importance for the generation of diagrams and drawings.

Although the idea of using topological information to store features developed independently in several places, it was the acceptance of a topological data model by the U.S. Census Bureau that indirectly led the way for significant advances in network analysis. Although generating maps for field work and for the location of addresses to which questionnaires could be mailed was of importance, the Census Bureau was primarily interested in a means of generating well-defined polygons that would represent the Census Tracts, Census Blocks, Counties, and other enumeration areas with which even casual users of GIS are now familiar. In order to meet this need researchers at the US Census Bureau developed a topological data model named the dual incidence matrix encoding (DIME) model (Cooke 1998). “Dual incidence” refers to the storage of topological information among nodes (which nodes are incident creating lines) and among lines (which lines are incident creating polygons). The DIME databases evolved into the topologically integrated geographic encoding and referencing (TIGER) files, and this data model for a time became the standard for vector representations in GIS.

While the goal of the Census Bureau was not to generate network data, the act of digitizing census block boundaries – many of which were roads, railroads, or streams – allowed for the rapid creation of network databases under the direction of (and with the resources of) a federal government agency. At a time when data for use in a GIS were not readily available and required time consuming and costly manual digitizing, the creation of these network databases was a great advantage for researchers pursuing network analysis. Shortly thereafter some of the analytical measures that had developed over many decades (described previously) began to appear as functions in GIS software.

However, because this data model was designed to support a set of hierarchical polygons it constrained network analysis techniques. More specifically, in order to maintain complete polygonal coverage, the data model had to enforce planarity. Planar networks are those that have no edges intersecting without a vertex at that location. In contrast, in real-world transportation networks it is common to have edges which cross in planar space without any connection between the edges. These include overpass–underpass crossings, bridge crossings, and even at-grade railroad and road crossings. No connectivity exists between the edges at the coordinates of the crossing. This limitation has necessitated the development of network-specific data models in GIS. These models variously allow for nonplanar intersections, for modeling flow across the network, and for identifying specialized features such as junctions or turn elements that restrict movement across the network. It has been found that networks can be more efficiently stored in structures that differ from standard relational database structures and, therefore, over time network data models have come to rely on
structures such as the forward star data structure (Evans and Minieka 1992).

Advances in network analysis in geography

With the full integration of network models into GIS the advance of network analysis in geography has seen a rapid move forward. These advances have taken the form of networks as the foundation for location referencing systems, networks as the basis for advanced location modeling, and networks as the spatial domain for new spatial statistical techniques.

A fundamental tenet of geographic analysis writ large is that a well-defined spatial domain must be chosen prior to analysis with some justification, and there must be a means of determining locations across that spatial domain. When the analysis consists only of specifying locations, the domain is frequently an ellipsoid representing the Earth, and the means of identifying locations is through latitude and longitude coordinates. When computations of spatial properties such as distance, area, or direction are part of the analysis, good practice requires that a surface be chosen onto which locations are projected, where it is known what properties are preserved or distorted through that projection. Further, a planar coordinate system is then used to determine locations on that flattened surface. However, it has been accepted in some application areas – particularly transportation science – that a flat planar space is not the spatial domain over which some phenomena occur; rather the network itself is the operational space. In these cases there must be a method of specifying locations across the network. The process of linear referencing provides these locations using the network as the spatial domain (Curtin, Nicoara, and Arifin 2007). A widely recognized application of linear referencing is the mile marker system along US highways. The mile markers represent a distance along a network feature from a well-defined starting point, just as a traditional coordinate represents a distance east and north of a well-defined origin in a traditional coordinate system. There are several benefits to using linear referencing for network analysis, including intuitive locations for work in the field, the ability to define features (sometimes termed routes) that are not limited by the storage parameters of the underlying spatial data model, and the ability to maintain many sets of network attributes using the network only as the underlying datum rather than as the storage set for attribute information.

The acceptance that network phenomena must be analyzed in the network spatial domain has led to significant advances in the realm of spatial statistics. It is now recognized that the spatial statistical determinations of density, clustering and dispersion, and interpolation (among others) of network phenomena cannot be treated as if they operate in the plane. Instead, a related but distinct subdiscipline with spatial statistics – network spatial statistics – has developed; this permits the justifiable analysis of network-based events (Okabe, Okunuki, and Shiode 2006; Okabe, Yomono, and Kitamura 1995). Examples of such phenomena include traffic accidents along roads, pipe breaks along water mains, or pollution samples along river networks.

Just as the prevalence of network data models in GIS has encouraged advances in location referencing and in network spatial statistics, it has encouraged the development of widely available tools for more advanced location science methods. In addition to the optimal routing procedures that have long been integrated, heuristic solutions for highly combinatorially complex decision problems are widely available. These include solution tools for the traveling salesman
problem, the vehicle routing problem (which is effectively a series of traveling salesman problems solved simultaneously), the P-Median problem (which seeks the optimal locations for P facilities on the network such that total cost between demand and the nearest facility is minimized), and the maximal covering location problem (which seeks to locate facilities in such a way as to cover as much demand as possible within a specified service distance across the network). When optimal solutions are needed, specialized software exists to generate such solutions, dependent on problem size. While only a small sample of the solution procedures that have been developed in network analysis have made their way into off-the-shelf GIS software, more are migrating to that user-friendly environment all the time.

The future of network analysis in geography

There is every reason to believe that the future advances in network analysis will continue to reinforce the importance of this subdiscipline within the science of geography. By examining current literature the increasing interest in network analysis across a broad range of applications areas can be seen. For example, a rapidly growing interest in social network analysis has led to contributions including additional network measures of closeness (average distance between nodes), betweenness (number of paths that go through nodes), and centrality (position within network neighborhoods) — all of which are fundamentally geographic concepts. Increased interest is being seen in the development of techniques for network-based spatiotemporal analysis, with the recognition that patterns that suggest an underlying process in both time and space are different from those that appear in only one dimension alone (Eckley and Curtin 2013).

It is likely that the past research on static measures of networks and deterministic analysis on networks will be complemented by more research into dynamic movement through and across networks. While network flow models have existed in the literature for decades, additional means of describing, visualizing, and measuring flow may come from work regarding the simulation of movement across networks. Advances in tracking objects as they move through space will likely support this area of research. There are also avenues for innovation in network analysis related to behavioral geography and the movement of teams across networks where they are seeking some group goal. As these problems become more computationally complex, the advances in computing power (e.g., massively parallel computing, cloud computing) may allow researchers to pursue problem instances that were not previously possible.

In summary, network analysis in geography is a major research area, with a strong theoretical history, a solid mathematical foundation, and wide range of methodological approaches. It is an area with broad interest across disciplines. Perhaps most importantly it is a vibrant and dynamic research area with both growth and refinement of existing methods, and the development of new methods over time. It is likely to remain a significant component of the larger area of geographic analysis for the foreseeable future.

Networks, social capital, and development

Martin Hess
University of Manchester, UK

Development is a moving target. The 1980s saw a crisis in development studies, often referred to as the “development impasse,” when both development theories and real-world developments posed serious challenges to existing models of development at the time. Today, the latest indicators underpinning the 2015 United Nations Millennium Development Goals show that while progress has been made in tackling extreme poverty and a range of other areas of development, any improvements are highly uneven socially and geographically. Such uneven development outcomes occur against a backdrop of neoliberal economic policies, the roll-back of the state and the rise of increasingly fragmented global production networks in what Manuel Castells (2003) calls the network society. As conventional, top-down and state-led forms of development have failed on many accounts, albeit with some notable exceptions especially in East Asia, new forms of alternative development strategies and networked forms of development activism (nongovernmental organizations (NGOs), grass roots movements) have come to the fore. Since the 1990s, this has brought ideas of social capital into the spotlight both in academia and policy circles, often viewed as a development panacea and championed by global organizations such as the World Bank (Potter et al. 2012).

Critics, however, argued that the increasing focus on networks and social capital only helped to obscure some fundamental insights from political economy with regard to poverty and inequality and lead to a de-politicization of the development discourse and practice. Consequently, social capital as a concept has received a very mixed reception in human geography and cognate disciplines ever since its inception by Pierre Bourdieu and its subsequent formulations by James Coleman and Robert Putnam, with the latter becoming especially influential in framing the debate. The next sections will in turn address the role of networks as organizing principle underlying economic, social, and spatial development; Bourdieu’s ideas of social capital and the reproduction of power relations; Putnam’s concept of social capital, trust, and collective action; and the uptake of social capital in development discourse and policy, before offering some concluding thoughts.

Networks, geography, and development

The notion of networks has become almost ubiquitous, in academia as much as in public discourse and the media. Today, it seems an almost universal mode of social, political, and economic organization, from global sub-contracting networks and global production networks to terrorist networks like Al Qaida and Islamic State (IS), from transnational migrant networks and local ethnic business clusters to community unionism, activist networks, and NGOs. Networks are the primary structures and organizational forms through which the flows of goods, services, people, capital, and information
are organized and orchestrated (Grabher 2009). In human geography, since the 1990s, the rise of networks as analytical focus, ontological basis, and methodological foundation for research has found its expression in the so-called relational turn. This approach views networks neither purely as structures nor organizational forms situated between atomistic individual action and hierarchies, but as relational processes that produce observable patterns and outcomes in society and economy (Dicken et al. 2001). Network thinking and analysis has since then gained currency in a variety of subdisciplines, not least economic geography and, to a lesser extent, development geography.

Interest in networks was triggered in no small part by Mark Granovetter’s (1985) seminal article emphasizing the social embeddedness of economic action. Stressing the importance of concrete personal relations and networks of such relations for the generation of trust between actors, he laid down a foundation for the analysis of networks, their governance, and associated economic and developmental outcomes (Hess 2004). All networks share some fundamental characteristics. First, they are based on reciprocity. Any exchange processes (of materials, money, information, etc.) take place within the context of mutual relationships and network embeddedness is determined by the architecture, durability, and stability of these reciprocal relationships. Second, and in contrast to other forms of organization like markets or hierarchies, networks are held together by a multiplicity of interpersonal and organizational ties of different strength, from strong and durable connections to what Granovetter calls “weak ties” allowing for greater flexibility and openness thus avoiding the danger of lock-in and network inertia. Third, actors in networks are mutually interdependent, and such interdependency impacts on the stability and durability of collaboration between network agents. Fourth, networks are shot through with (asymmetrical) power relations that govern them and shape the economic and developmental outcomes of network activities for various actors and the places they inhabit.

Network formation takes place at a variety of scales, from the local to the global, connecting some places while bypassing others. Contemporary networks are made from a complex addition, crossing and entanglement of economic activities, of social and intellectual communities with considerable developmental consequences for the places in which global production networks “touch down” or local networks emerge in situ. There is now a plethora of literature that addresses regional development processes through the lens of networked forms of social and economic organization. Studies of economically successful regions, like the so-called Third Italy, Silicon Valley in California, or clusters of economic activity in the German state of Baden-Württemberg, identified formal and informal network building as main drivers of development. Dense networks at the local scale have been referred to as producing “institutional thickness,” creating the conditions for sustained economic growth, innovation, and development. Institutional thickness refers to a strong institutional presence, high levels of interaction in various political, social, and economic networks, defined governance structures of domination and patterns of coalition, and the mutual awareness of being involved in a common “regional” enterprise. Such conditions have been identified as key ingredients in creative milieus or innovative/learning regions, and, more recently, the thickness concept has been conceptually enhanced to theorize social innovation and community development (Moulaert and Nussbaumer 2006). Moreover, attempts to recreate such geographical clusters and emulate their success have become a policy
mantra in many regions across the Global North and the Global South. However, there also has been a growing recognition that such regions do not exist in isolation and developmental outcomes are also increasingly dependent on transregional networks and the nature of connections with global production networks (Coe and Hess 2011). In other words, development in any place is determined by a variety of local and translocal networks and the associated flows of people (through migration), materials, capital, and knowledge.

The distribution of power among the various agents constituting social and economic networks is clearly paramount for developmental outcomes and the distribution of any benefits from network activities. However, it has been argued that the network concept and metaphor provokes a one-dimensional understanding of power (Prey 2012). Referring to the work of Castells, network thinking has led to an emphasis on exclusion and inclusion as a fundamental form of exercising power. Indeed, much of the recent literature on economic and social upgrading for firms and regions has highlighted the importance of engaging with global networks in order to capture value as a means for development. But such a focus on inclusion and exclusion – following Prey’s argument – obscures the problem of exploitation, a still prominent feature of many global and local networks. What is needed, therefore, is a better understanding of the relations between processes of exclusion and exploitation, as well as inclusion and privilege. To this end, the following section turns to one conceptualization of social capital as developed by Pierre Bourdieu.

Social capital, class, and habitus

Societies and communities are not conflict-free or harmonious social structures, but made up of complex sets of asymmetrical power relations in various social fields such as class, gender, or race/ethnicity. Rooted in a structuralist tradition of social sciences and the sociology of conflict, Pierre Bourdieu was interested in understanding society and inequality, and more specifically the ways in which society and social relations are produced and reproduced. Understanding society as a plurality of social fields, he argues that the control of various forms of capital defines an actor’s position within social networks and society more broadly (Sissiäinen 2000). These forms are identified as economic, cultural, symbolic, and social capital and which need to be seen not in isolation but in relation to each other in order to understand how social relations are reproduced. The positions of actors in social space are conceived of as both the cause and the effect of capital accumulation in its different guises and particularly social capital. Bourdieu (1986, 249–250) defines social capital as:

the aggregate of the actual or potential resources which are linked to a possession of a durable network of more or less institutionalized relationships of mutual acquaintance and recognition – or in other words, to membership in a group – which provides each of its members with the backing of the collectively owned capital, a “credential” which entitles them to credit, in the various senses of the word.

This definition highlights two important components of social capital. First, it is a resource based on social networks and group membership and therefore is a collective phenomenon rather than the result of individual efforts even if actors are actively exploiting its potential. Within a social network or association, each actor occupies different positions and consequently varying possibilities to activate social capital as a resource as well as appropriating related benefits in the form of economic, cultural, and symbolic capital. Actors’ predispositions are fueled by inequality
which is rooted in the differential distribution of capital in its various forms. These predispositions in turn are mobilized to legitimate the differential structure of society and the inequalities in capital accumulation between members (Tzanakis 2013). Second, and following from this, social capital is based on mutual cognition and recognition, thus taking on a symbolic character in the form of symbolic capital. Social classes formed on the basis of uneven access to resources and capital only become meaningful when accepted and internalized by members of society, normalizing and legitimizing existing uneven distribution of capital within and between classes and individuals. In other words, social, cultural, and economic capital becomes socially effective only through the process of translation into symbolic capital and the exercise of symbolic power.

In Bourdieu’s account of social capital, social structures and institutionalized behavior are paramount (Bebbington 2009). Individual agency has to be accounted for in the context of structural constraints, which he theorizes through the concept of “habitus.” As an embodied materialization of an actor’s resources, or “internalized capital,” habitus puts an emphasis on the nonreflexive aspects of practice beyond the conscious, or the habitual element of human agency (Holt 2008). Similar to the role of symbolic capital, habitus acts as a key mechanism for reinforcing views and perceptions of social structure and context as legitimate and obvious. Acquired during the process of socialization from early childhood onwards, habitus describes an actor’s predispositions and forms the basis for the generation of practices within particular social fields. Consequently, the ways in which people engage in social networks and realize social capital can only be partly explained by rational choices or conscious decisions and is to a considerable extent influenced by individual dispositions and habitual practices of which the person may not be aware.

Social capital as developed by Bourdieu arguably provides an important contribution to the study of development by establishing a conceptual framework that helps to explain how social networks can contribute to the reproduction of socioeconomic inequality. Such a conceptualization has not been without its critics, however. Questions still remain about the explanatory power of social capital and the danger of succumbing to economic reductionism, underplaying the transformational potential of social capital. There are also unresolved theoretical and methodological issues of agency/habitus and aggregation in the form of class/class habitus. Despite these problems, social capital and habitus are useful analytical lenses through which to better understand the structural mechanisms as well as embodied practices of social network formation and the struggles over the appropriation of capital(s). Somewhat surprisingly, within human geography and development studies Bourdieu’s ideas about social capital, class, and habitus have been taken up quite reluctantly so far, albeit with some exceptions, for instance, in studies of inner city gentrification, rural communities, and transnational migration. Rather, it was another concept of social capital that from the 1990s onwards attracted the attention of geographers, development scholars and, importantly, policymakers and development practitioners.

Social capital, networks, and trust

In 1993, Robert Putnam published a study of institutional performance, civic society, and economic development in Italy titled *Making Democracy Work*. Like other observers, he was intrigued by the divergent economic development trajectories of different regions of Italy,
with a burgeoning economy in what became known as the Third Italy (northeast and central regions) and markedly lower growth rates or even decline in the old industrial heartlands (First Italy) and the Mezzogiorno in the south (Second Italy). Putnam’s conclusion based on his institutional analysis was that the north displayed much higher levels of collaboration than the south. Putnam (1993, 130) summarized the key empirical findings as follows:

In the North the crucial social, political and even religious allegiances and alignments were horizontal, while those in the South were vertical. Collaboration, mutual assistance, civic obligation, and even trust – not universal, of course, but extending further beyond the limits of kinship than anywhere else in Europe in this era – were the distinguishing features in the North. The chief virtue in the South, by contrast, was the imposition of hierarchy and order on latent anarchy.

Economic prosperity and development in Italy’s north were thus understood as an outcome of social capital emanating from networks based on three main components: trust, shared norms and social obligations, and civic engagement in the form of voluntary associations.

For Putnam, trust is a crucial element of and contributor to civil society. Essential to facilitate social cohesion, trust is also a prerequisite for political institutions and governments to be perceived as legitimate. Such an understanding of trust goes beyond immediate interpersonal relations and assumes a more generalized form, where citizens trust that their involvement in producing a common good for the wider community and society will be reciprocated through the development of positive communal relations (Siisiäinen 2000). In Putnam’s own view, such generalized trust creates reciprocity and various forms of civic engagement, which in turn produce and strengthen trust, in effect constituting a virtuous circle of social capital formation that ultimately fuels socioeconomic development. In line with other conceptualizations of trust (see Murphy 2006), it is also indispensable to reduce risk and lower transaction costs in a complex and contingent environment. In that sense, trust serves as the lubricant for mutually beneficial social relations in the form of bridging and bonding forms of social capital. Bridging social capital establishes connections between geographically and/or socially distant groups and expands social networks, while bonding social capital increases cohesion within geographically and/or socially proximate groups. Unlike Bourdieu, Putnam’s work provides a more contextual or “ecological” idea of social capital based on trust and mutual cooperation, instead of focusing on networks utilized for individual benefit and/or those that reproduce class structures and socioeconomic inequalities.

A second important element of social capital, and closely related to trust, is the role of norms and mutual obligations. Without a set of values that is shared by the members of a network or community, with the expectation of reciprocity, civic engagement erodes and becomes increasingly futile. Rather than resulting in a virtuous circle of social capital for the benefit of socioeconomic development, the absence of shared norms and values will result in a downward spiral of growing distrust and ultimately the disintegration of networks, community, and society. Voluntary associations constitute Putnam’s third central element of social capital, and to him they are a major source of trust generation, along with establishing interpersonal ties. Civic activism and voluntary associations are theorized as the cornerstones of civil society and democratic systems, in line with earlier work by social theorists like Niklas Luhmann and, in particular, Alexis de Tocqueville. The latter’s studies of American society in the nineteenth century – published in 1835 as
“Democracy in America” – were highly influential for Putnam’s own work on voluntary associations, democracy, and social capital in the United States for which he became famous after the publication of “Bowling Alone” (Putnam 2000).

What Putnam has developed, then, is a concept of social capital that represents a decidedly functionalist approach compared to Bourdieu’s sociology of conflict. Putnam’s emphasis on trust and shared norms portrays a notion of community based on common interest and he by and large ignores the unequal power relations inherent in any social relation. What is more, his approach to social capital tends to conflate the concepts of Gemeinschaft (community) and Gesellschaft (society) as developed by Ferdinand Tönnies, obscuring any social and economic tensions and struggles found even within successful regions. Instead, social capital is attributed to aggregate entities like regions, or even countries, without much consideration for social struggle between actors within these spaces. The strongest criticism leveled against theories of social capital, especially in Putnam’s formulation, is their propensity for circular reasoning and tautology without establishing clear causal relationships. Social capital is at the same time cause and effect of positive socioeconomic development. As Tzanakis (2013, 7) puts it, “[a]ll features of public life purported to reflect high social capital are accounted for by the high stock of social capital in that region.” And yet, Putnam’s work has had considerable influence on policy formulation in the realm of (international) development.

Development practice and social capital

The first major international organization to enthusiastically endorse the concept of social capital as a guide for policy formulation was the World Bank (Bebbington 2009). Against the backdrop of the highly problematic and counter-productive structural adjustment programs by international financial institutions during the 1980s and amidst increasing calls for more participatory forms of development as opposed to the prevalent top-down development strategies, social capital came to be seen as a possible route toward a more socially “grounded” approach to development. Such an approach also chimed with the emerging discourse of sustainable development, following the report by the Brundtland Commission in 1987, “Our Common Future,” as it offered a new metric in support of the so-called triple bottom line goals of sustainability: economic growth, social justice, and environmental protection. During the 1990s, social capital became one of the most popular development concepts, embraced by donors and development agencies in the Global North as much as by actors, activists, and NGOs in the Global South. Increasingly seen as “capital of the poor,” the possibilities of promoting social relations at the grassroots level were seen as both progressive and empowering.

One result of efforts by international agencies to mainstream social capital approaches for development has been the livelihood assets framework, aiming to address, in particular, the problems of rural poverty and vulnerability (Potter et al. 2012). New methods like participatory rural appraisal were deployed in order to understand development at the local level better, and to integrate the voices of the people which often had been considered as “objects” of development intervention instead of active subjects following their own strategies and objectives. Social capital was a vital conceptual ingredient in producing such participatory frameworks and the language of “capital” also resonated well with the overarching narrative of “inclusive” capitalism that could make it work for the poor. Critics therefore argue that mobilizing Robert
Putnam’s concept in development policy and intervention entails adopting a “Pollyanna”-style conception of society that ignores the fundamental political-economic problems of unequal access to assets, property, and resources. As Radcliffe (2004, 522, emphasis in original) notes: “Ironically, when social capital is placed at the heart of development projects they can in fact backfire, causing the destruction of local “social capital” or sociopolitical clout and knowledge.”

Applying social capital theory in a rather uncritical way to development policy and practice, then, has contributed to some serious shortcomings in mainstream livelihoods research (Sakdapolrak 2014). First, the incarnation of Putnam’s concept often aids in reproducing imbalanced consideration of the structure–agency relationship given that power and politics are not given the necessary attention. Second, social capital – like other forms of capital – is perceived as stock that can be utilized for economic and material benefits, without proper acknowledgment of the contested nature of assets. Third, while being useful in focusing on the local dimension of development there is a danger of neglecting translocal and transnational structures and dynamics and the ramifications of global processes for individual and collective livelihood strategies. A careful geographical, multiscalar approach to livelihood research and social capital formation is therefore essential.

Finally, the global financial crisis that has engulfed global society since 2007 has brought home the vulnerabilities of citizens not only in the Global South, but also an increasing polarization in the industrial and postindustrial countries of the Global North. Here, too, ideas of social capital have been mobilized by different groups with often incompatible goals. On the one hand, civil society and voluntary association are championed by some political elites as a means to compensate for the retreat of the state (for instance, the current British government-led “Big Society” discourse), while at the other end of the spectrum alternative forms of civil association are experimented with, as illustrated by the Occupy movements that have sprung up in numerous cities, from New York and London to Hong Kong. These examples illustrate the political and contested nature of social capital, its role in reproducing unequal social relations, but also its transformative potential.

Concluding thoughts

Networks and social capital have become important and influential concepts of understanding socioeconomic development in space. At the same time, both notions are highly contested with regard to their usefulness and explanatory power and in terms of their implications for the politics of development, economic, and social change. In geography, the surge of relational thinking has provided a strong basis for network analyses across various scales, from the global to the local, and the differential power relations that emerge from and are exercised within social and economic networks. While network ontologies and methodologies have made inroads in various subdisciplines of human geography – along with many other social sciences, the concepts of social capital as developed by Bourdieu and, in particular, Putnam have resonated most notably with development studies and geography, not least because of the uptake of Putnam’s ideas in policy circles. This has created an ongoing controversy between academics who see social capital as formulated by Putnam as yet another theoretical justification for neoliberal development and the retreat of the state, and others who perceive it as a way of thinking that takes civil society actors seriously and helps promote
more democratic societies and civic engagement (Bebbington 2009). Some observers have indeed reflected on the imminent “death” of social capital as a theoretical and heuristic tool (Radcliffe 2004). But rather than throwing out the baby with the bathwater and abandoning social capital theory altogether, there exists an opportunity to reframe the discourse of social capital and development in a way that sheds light on structural, political-economic conditions as much as social networks and civil society. A way forward therefore might be what Rankin (2002) called a “Marxian approach to social capital,” critically (re-)engaging with Bourdieu’s ideas of various forms of capital, habitus, and theory of practice. Sakdapolrak’s (2014) recent attempt to re-energize livelihoods research in development studies and development geography – drawing on Bourdieu’s theory of practice – can serve as an example of how networks, social capital, and development might be re-imagined in a more critical, constructive, and progressive way.

The new cultural geography’s emergence in the 1980s represented more than the revitalization of a sidelined subdiscipline, as “culture” became increasingly central to thinking about the world and, perhaps, to the world itself. Culture materialized in the most unexpected of places (e.g., airports, laboratories, the trading-floors of the world’s stock exchanges) and encompassed topics geographers had previously neglected (e.g., footwear, fascism, furniture, feng shui, film). Globalization, postcolonialism, and a plurality of socially constructed identities (tackling what it means to be a woman, gay, black, or disabled in an increasingly fluid world) underpinned renewed attempts to understand how cultural differences comprise the human world. The sense in which that world is shaped “discursively” – meaning that the human world is not distinct from (or at least not independent of) its representations – became a mainstream concern: culture was constitutive, performative, always-already in the making. Despite some outstanding debts to the Berkeley School of cultural geography – notably an abiding interest in landscape – the new cultural geography owed more to the growth of cultural studies than to any home-grown antecedents.

The new cultural geography shaped the entire discipline, spanning topics as diverse as nationalism and landscape painting, competitive masculinity and global finance, popular culture and geopolitics, subcultures and territoriality, and dance traditions and tourism. Yet it became an umbrella term for a heterogeneous mix of approaches rather than resolving any obdurate dualisms. Postmodernism’s influence on geography’s “cultural turn” saw accusations of structural factors being neglected in favor of free-floating identities. A lingering humanism, coupled with deconstructive tendencies, saw allegations that the new cultural geography privileged representations, eviscerating reality of its (material) substance – prompting calls for “non-representational theory.” Although such
charges typically attacked straw conceptions, they demonstrate the checkered history of the new cultural geography – from which the sobriquet “new” has long since been dropped.

Cook, Ian, David Crouch, Simon Naylor, and James R. Ryan, eds. 2000. Cultural Turns/Geographical

The term “new economic geography” refers to a range of approaches that have emerged in economic geography since the early 1990s that share a central concern with the links between economic action and social and cultural practices in different places. These approaches derive theoretical inspiration from various sources, including postmodernism, poststructuralism, cultural studies, anthropology, economic sociology, and institutional economics. In general, they have served to direct attention towards questions of agency, difference, identity, language, and performance that were previously marginalized and neglected within economic geography. As Wills and Lee (1997, xvii) argue, “the point is to contextualize rather than undermine the economic, by locating it within the cultural, social and political relations through which it takes on meaning and direction.”

To a considerable extent, this “new” economic geography has been defined against the “old” economic geography of spatial analysis and Marxian political economy, which have been variously criticized for ignoring the wider social and cultural practices that shape economic life and for viewing individual and collective economic agents in essentialist and reductionist ways. Despite their initial counterposing, new approaches in economic geography have not always remained separate from work in geographical political economy as important areas of overlap and cross-fertilization have developed, reflecting the increasingly hybrid and fast-moving nature of the field. These include cultural political economy and efforts to develop a more institutionally – and relationally – sensitive geographical political economy. Crucially, the new economic geography that is the subject of this entry is not to be confused with the “new economic geography” developed by a group of geographically minded economists led by the Nobel Prize Winner Paul Krugman. While this program of research has successfully appropriated the term, it is a very different beast, based upon the application of mathematical modeling techniques to questions of industrial location and regional agglomeration. The remainder of this brief entry is structured around the discussion of three new economic geography approaches that are labeled cultural, institutional, and relational.

Cultural approaches have sought to reframe the economic in particular ways, demonstrating how economic relations are saturated with issues of identity, meaning, and representation. Four main strands of culturally inflected work can be identified. First, studies of consumption that have often focused on the creation and experience of particular landscapes of consumption such as shopping malls, supermarkets, and heritage parks. Second, research on gender, performance, and identity in the workplace and labor market, such as Linda McDowell’s account of work cultures in merchant banks in the City of London. Third, work on the importance of personal contact and social networks in financial and business services. Studies of financial centers such as the City of London, for example, have shown the importance of social networks and trust, encouraging geographical concentration...
NEW ECONOMIC GEOGRAPHY

through the need for regular face-to-face contact. A fourth strand of research is concerned with corporate cultures and identities, particularly in terms of how managers and workers create distinctive corporate cultures through particular discourses and day-to-day practices. Of particular interest here is Erica Schoenberger’s work on large American corporations such as Xerox, DEC, and Lockheed, showing the limitations of such cultures in dealing with a turbulent and unpredictable economic environment.

New economic geography has also drawn upon concepts from institutional economics and economic sociology, which also emphasize the social context of economic life and the role of institutions in shaping and “embedding” economic action. Here, institutions are broadly defined as the “rules of the game,” incorporating both formal and tangible rules and laws, and more informal and intangible conventions and norms. A related set of ideas from economic sociology, particularly Karl Polanyi’s conception of “the economy as an instituted process,” has been utilized to argue that the economy is always grounded in social relations. Characteristically, geographers have “spatialized” the sociological concept of “embeddedness,” emphasizing how particular forms of economic activity are not only grounded in social relations, but also rooted in particular places and regions. One particular area in which the notion of embeddedness has been applied is in studies of transnational corporate investments in particular localities and regions and the scope for local actors to embed these investments by, for example, fostering links with local suppliers and training providers. Institutional approaches are associated with the rise of a “new regionalism” in economic geography that examines the effects of social and cultural conditions within regions in shaping economic development. Successful regions such as Silicon Valley in California, North Eastern and Central Italy, and Baden-Württemberg in Southern German have attracted particular attention, as economic geographers have attempted to identify the social and cultural foundations of economic growth and prosperity.

Another strand of new economic geography research has been influenced by the rise of relational thinking. According to Doreen Massey, the relational approach to space is grounded in three basic propositions about space, viewing it as the product of interrelations, multiple, and always changing and becoming. Relational economic geography focuses on the relationships between economic actors and broader processes of change, informed by the institutional and cultural approaches discussed above. It is particularly associated with the study of networks, defined as “socio-economic structures that connect people, firms and places to one another and that enable knowledge, commodities and capital to flow within and between regions” (Aoyama, Murphy, and Hanson 2011, 181). In this respect, it overlaps significantly with work on the role of socioeconomic practices in economic geography, defined as “the stabilized, routinized, or improvised social actions that constitute and replicate economic space and through and within which diverse actors (e.g. entrepreneurs, workers, caregivers, consumers, firms) and communities (e.g. industries, places, markets, cultural groups) organize materials, produce, consume and/or derive meaning from the economic world” (Jones and Murphy 2011, 367). For example, a study of cultural embeddedness in Utah’s high-tech economy found that Mormon religious values were upheld by a range of day-to-day practices within firms. These include the reinforcement of group norms through routine associations with other employees, observation of fellow workers, the group ratification of culturally informed corporate decisions, and the recruitment of Mormon employees.
Relational conceptions of space have fostered a new concern with “the relational region” that re-imagines regions as open and discontinuous spaces, defined by the wider social relations in which they are situated. They are created for particular purposes by particular actors, meaning that they have no essential character or fixed identity. These arguments were illustrated by an analysis of South East England, the emblematic growth region of neoliberal Britain in the 1980s and 1990s. Within the South East, areas of economic decline and deprivation exist, complicating and confounding the overarching image of growth and prosperity, while the boundaries of the region can be seen as open and porous. This relational theory of the region has been accompanied by a critique of “new regionalist” thinking, rejecting its portrayal of regions as internally coherent and externally bounded.

As outlined above, “new economic geography” research is concerned with the relationships between economic action and social and cultural practices in different places. While the term is rather specific to the mid-to-late 1990s and not widely used today outside of its appropriation by geographically minded economists, it embodies a key moment in the reorientation of the field. This relates to the widening and diversification of economic geography beyond the narrower approaches of the past as it came into contact with new theories and literatures. The underlying concern with the relationships between the economic and the social and cultural spheres of action is central to the ongoing development of cultural, institutional, and relational approaches in economic geography. These approaches look set to continue to animate and inform research in the field over the next decade or so.

The concept of “new industrial space” was developed by Allen Scott in 1988 to describe the agglomeration of highly specialized firms that took place in various parts of the world in the late 1970s and the 1980s. Scott argues that these small firms cluster in one place because proximity to one another allows them to reduce transaction costs. The concept was often considered as a part of the “flexible specialization” thesis proposed by French regulation school scholars, who argued that capitalism has undergone a profound transformation since the 1970s, from “Fordism” to “post-Fordism.” Here, “Fordism” refers to the system of mass production in search of economy of scale. It is characterized by vertically integrated global firms, Keynesian welfare states, and unionized labor. In contrast, “post-Fordism” is a more flexible form of production that seeks to achieve economies of scope. It is characterized by vertically disintegrated firms engaging in batch and specialized production, neoliberal regimes of governance, and the emergence of informal, contract-based, or self-employed workers. While in the 1980s regulation school scholars had interrogated issues such as vertical disintegration (Piore and Sabel 1984) and the emergence of flexible labor (Brusco 1982), Scott points out that transformation to post-Fordism has a spatial dimension: that the big factories that used to dominate the industrial landscaping are now giving way to industrial districts.

One of the cases of new industrial spaces that Scott examined was the “Third Italy.” The term refers to the central and northeast regions of Italy (including Tuscany, Umbria, Marche, Emilia-Romagna, Veneto, Friuli, and Trentino-Alto Adige/Südtirol), which in the 1970s and 1980s witnessed the clustering of small artisan firms and workshops. Each region specialized in a range of loosely related products and each workshop usually had 5–50 workers (often less than 10). The wide range of products in each cluster suggested a shift from economies of scale to economies of scope. Additionally, these small firms and workshops were known for producing high quality products and employing highly skilled and well-paid workers. The workshops were also very design-oriented and multidisciplinary, involving collaboration between entrepreneurs, designers, engineers, and workers. This unique industrial structure was in sharp contrast to the large-scale mass production systems seen in Turin, Milan, and Genoa (the First Italy) and the underdeveloped South (the Second Italy). Scott also pointed out that, because these vertically disintegrated firms often do not need to have direct contact with established industries, and because they prefer places without the presence of big unions, new industrial spaces often appear either in depressed urban enclaves (e.g., the clustering of high-tech firms in Paris’s southern suburb) or in underdeveloped regions (e.g., the Third Italy and Silicon Valley).

Industrial agglomeration is certainly not a new issue in economic geography. In the late nineteenth century, Alfred Marshall, in Principles of Economics (1890), had examined the agglomeration of textile manufacturers in England. He argued that textile manufacturers
NEW INDUSTRIAL SPACE

tended to cluster in certain regions because these places offered common pools of resources that were important for textile production, such as skilled labor, land, capital, and transportation infrastructure. In other words, firms cluster because it is easier to find qualified workers and to exchange commercial and technical information through informal channels. Marshall’s study was followed by a series of research that examined agglomerations in many other parts of the world (e.g., Perroux 1950; Hirschman 1958; Chinitz 1961; Vernon 1960). Allan Scott’s approach to agglomeration, however, is quite different from that of Marshall and his followers. In emphasizing the external benefits provided by the “common pool,” Marshall assumed local economies as collections of atomistic competitors, being aware of one another solely through the intermediation of price signals. By contrast, Scott’s transaction cost thesis emphasizes the interdependence between firms, flexible firm boundaries, cooperative competition, and the importance of trust in the formation and reproduction of industrial districts (Harrison 1992). In other words, the theory of new industrial spaces posits a strong attempt to embed economic relations into a deeper social fabric, highlighting the importance of “trust” that is built in production networks. If trust can best be built through learning about the idiosyncrasies of the actors, and if this requires repeated human interaction, then such interaction is likely to be facilitated by personal contact, and that contact is in turn enhanced by geographical proximity. In this respect, Scott’s thesis of new industrial districts coincided with Granovetter’s (1985) attempt to “bring sociology back in” to the study of the economy: acknowledging the relevance of customs, interdependent preferences, or cognitive processes in the shaping of economic structures.

One of the major criticisms of the new industrial space theory is that transaction cost alone could not explain why firms agglomerate in certain places rather than in others. One important issue in subsequent discussions about the agglomeration of specialized firms is thus the territorial dynamics of agglomeration. In “The Resurgence of Regional Economies, Ten Years Later: The Region as a Nexus of Untraded Interdependencies” (1995), Michael Storper introduced the concept of “untraded dependencies.” He argued that interdependency between firms is based on collective tacit knowledge that cannot be removed from its human, cultural, and social contexts. In other words, since knowledge is place specific, agglomeration is unlikely to take place anywhere. In Regional Advantage: Culture and Competition in Silicon Valley and Route 128 (1994), Anna-Lee Saxenian proposed the concept of “competitive advantage,” which offered an alternative explanation. Saxenian argued that the organization of Silicon Valley’s industrial system is embedded in a local culture that accepted failure and encouraged risk-taking, and that this milieu of innovation is an important reason for the development of high-tech industry in Silicon Valley having been more successful than that of Route 128 in the Boston metropolitan region.

The proliferation of literature about industrial districts in economic geography in the 1990s drew concerns from some scholars, who questioned the extent to which the thesis of new industrial space helped grasp the dynamics of post-1970s capitalism. Some pointed out that some global forces, such as innovation in communications and transportation, the invention of information technology, and interregional migration, are not considered in new industrial space theory (e.g., Bathelt, Malmberg, and Maskell 2004). In addition, scholars such as Goodman (1989) criticized new industrial space for being overly silent on the role of multinational corporations. They point out that scholarship about new industrial space tends to
ignore the flexibility and innovation abilities of big corporations. Furthermore, new industrial space was criticized by scholars such as Markusen (1991) for being ignorant of the role of state and other institutions (such as nongovernmental organizations) in shaping post-1970s capitalism. Last but not least, scholars such as Peter Daniels (2004) pointed out that the research about new industrial space had paid little attention to the rise of the service sector in advanced economies.

Since the 1990s, large cities in Western Europe and America have been witness to the clustering of small business engaging in the production of cultural products. This particular kind of geography resembles many of the characteristics that Scott describes about new industrial space: specialized firms engaging in batch production, flexible labor, and interdependency between firms. However, Scott himself did not categorize these agglomeration economies as a form of new industrial space. Instead, he argues that a “cognitive-cultural economy” is now taking shape and it has reconfigured the contour of capitalism in Western economies (Scott 2000). Capitalism itself, he suggests, is moving into a phase in which the culture forms and meaning of its outputs have become critical elements of production strategy, and in which the realm of human culture as a whole is increasingly subjected to commodification. This transformation is represented by the emergence of industries such as high-tech, services, neo-artisan production, media and entertainment, and tourism. Scott argues that this transformation is made possible by the introduction of digital technology, which, on the one hand, allows many routine labor tasks to be replaced or reconfigured, and, on the other hand, enhances cognitive and affective work. Scott also points out that because creativity and innovation rely on mutual learning and personal interactions, cognitive-cultural systems of production and work come to ground pre-eminently in large urban regions. At the same time, the cognitive-cultural economy in contemporary cities is invariably complemented by large numbers of low-wage, low-skill jobs, and the individuals drawn into these jobs are often migrants from developing countries. In other words, the cognitive-cultural economy comes with a widening of social divides. In yet other words, even Scott himself has recognized the explanatory limitations of the concept of new industrial space.

NEW INDUSTRIAL SPACE

New Urbanism

Matthew B. Anderson
Eastern Washington University, USA

New Urbanism refers to an urban design movement that highlights the importance of traditional neighborhood principles in community planning. Its goal is to design communities that are less auto-dependent and walkable, that incorporate multiple modes of transit (i.e., rail, car, pedestrian), and feature a mix of commercial and residential land uses, socioeconomic diversity, increased housing density, access to civic centers, and close proximity between job and home. Such communities are thought to facilitate healthier, more “eco-friendly” and sustainable lifestyles, and tighter social bonds between local residents and businesses. The movement has gained considerable momentum and influence among urban planners and architects since the Congress of the New Urbanism, the central organizing community of New Urbanism supporters was founded by Andres Duany in 1993. At first an alternative vision of “sustainable” urban design and development, the movement has now proliferated across North America and beyond, and increasingly represents a dominant planning framework informing both suburban growth agendas and central city revitalization efforts.

The New Urbanism movement unfolded within the broader environmental movement during the 1990s in the United States as a planning initiative specifically designed to ameliorate the social and environmental consequences of “sprawl,” such as air pollution, loss of agricultural land, community-eviscerating insularity, teen alienation, and environmental degradation (Kunstler 1994; Duany, Plater-Zyberk, and Speck 2000). In this context, New Urbanism has represented a direct response and challenge to what had become a dominant regime of planning, land-use zoning, and development in the immediate postwar period, and the sprawling suburban world this regime had fostered (Duany, Plater-Zyberk, and Speck 2000). The term “sprawl” is typically invoked pejoratively in the context of denigrating this landscape – marked by low-density, mass-produced residential subdivisions, and expansive shopping complexes – as wasteful, auto-dependent, and “unsustainable.”

New Urbanism has its philosophical roots in the classic work of earlier critics, particularly Jane Jacobs and Lewis Mumford. Mumford, an urban historian and sociologist, attributed many social urban problems of the postwar city to the emergence of sprawl, and called for a more centrally planned “regionalism” to guide the horizontal development of metropolitan regions (Mumford 1962). To Mumford, important connections must be made between local-scale communities and the broader metropolitan fabric that engulfs them. The medieval city was a source of inspiration for Mumford, who argued for mixed-use, walkable communities linked by mass transit as the ideal vision for urban planning and design. Disregarded in this vision is the penchant of modernist planning to privilege the detached single-family house and segregate residential and commercial land uses.

Similarly, Jane Jacobs, urban activist and scholar, observed the parasitic relationship between suburbanization and urban decline, and sharply criticized “urban renewal” in her now classic text, Death and Life of Great American
Cities (1961). For Jacobs, writing about New York, the building of modernist high-rise public housing projects and expansive auto-centric avenues and expressways destroyed the integrity, vibrancy, and social fabric of neighborhoods. Here, urban life is understood to flourish thanks to the close proximity between work and home, higher-density living, and a vibrant and walkable “street life.” While Mumford and Jacobs are often discussed as oppositional figures – Mumford thinking more at the metropolitan scale than Jacobs – both provided poignant critiques of suburban America and advocated for the “neotraditional” design principles that New Urbanism has come to embody.

Despite these early critics, sprawling suburban growth remained the dominant vision among developers, builders, realtors, and mortgage-lending institutions through the 1960s, 1970s, and 1980s. This dominance, however, has since slowly eroded. In short, growing fears of impending resource scarcity and anthropogenic climate change now underpin myriad multiscalar policies geared toward “sustainable urban development” as an increasingly important global objective. It is in this context that “smart growth” emerged, in the 1980s, as a regulatory framework designed to curtail the negative effects of sprawl and foster more “sustainable” communities that promote and encourage efficiency in energy consumption. Neotraditional ideas of community planning and design subsequently informed many of the policy prescriptions promoted within this broader planning agenda.

One of the first, and most influential, communities planned around New Urbanism design principles was Seaside, Florida, which was featured in the movie The Truman Show (1998). The movie garnered national attention for the community and, with it, a significant boost to the New Urbanism movement. This was a pivotal moment, as knowledge of New Urbanism was now widespread among city governments, architects, and developers. Since the 1990s, many suburban developments across urban America have adopted New Urbanism principles as a means of not only (or necessarily) encouraging healthier lifestyles, social bonds, and energy conservation, but also to maintain demand within an increasingly demonized suburban landscape among potential consumers seeking the benefits of the suburbs (safety, good schools, etc.) without the drawbacks of traditional “sprawling” attributes (Anderson 2010).

Many urban revitalization agendas have also been influenced by New Urbanism, particularly in older, postindustrial central cities where abandoned warehouse districts have been targeted for redevelopment (i.e., inner-city Pittsburgh and Denver’s Lo Do district). In these places, New Urbanism is often melded with historical preservation efforts that seek to restore an older district’s “historical integrity.” This has been accompanied by many new downtown shopping and entertainment districts which often emulate an “old town square” and feature condominiums above storefronts (i.e., Atlanta’s Atlantic Station). The movement also influenced the federal HOPE-VI program to demolish and replace America’s most distressed public housing. Since the 1990s, demolished public housing projects have typically been replaced with “mixed-income” developments designed around New Urbanism principles as the presumed solution to concentrated poverty. The redevelopment of Chicago’s infamous Cabrini Green, Henry Horner, and Robert Taylor Homes are perhaps the most well-known examples.

New Urbanism, however, has been severely criticized. Many have noted its excessive reliance on consumer preference as a social force; others have identified the movement’s commitment to a nostalgic, mythologized past; and still others view it as reproductive of an exclusionary class-based
insularity rather than generative of increased diversity (see Harvey 2000). Many studies also now report mixed results at best at many of the HOPE-VI redevelopment sites, implicating the limitations of planning and design in fostering better social conditions, while others have charged HOPE-VI – and New Urbanism by implication – as a program mobilized by urban elites to facilitate gentrification. Here, New Urbanism is criticized as a component of the neoliberal city, a criticism only amplified by the favorable treatment of gentrification by some New Urbanism promoters, who view it as a benign vehicle for the movement’s realization.

Set against this, advocates insist that New Urbanism is the antidote to society’s myriad social ills: that is, poverty, inequality, alienation, and consumptive waste. In this context, New Urbanism has emerged as an increasingly dominant planning paradigm and certainly marks one of the latest chapters in the history of urban planning and theory in urban America and beyond. Its examples and applications are now increasingly widespread. To its advocates, it is an important step in the right direction, whether viewed as a “pragmatic” response to fifty years of woefully unsustainable urbanization or as a genuinely “progressive” movement capable of creating more healthy, socially vibrant, and equitable communities and ways of life.

New Zealand: New Zealand Geographical Society (NZGS)

Founded: August 1944  
Location of headquarters: Palmerston North  
Website: www.nzgs.co.nz  
Membership: 281 (as of October 10, 2014)  
President: Ann Pomeroy  
Contact: ann.pomeroy@xtra.co.nz

Description and purpose

The NZGS aims to promote geography by fostering the subject in secondary and tertiary educational institutions across New Zealand and by supporting geographic research. The society functions as a networking and communication node for New Zealand geographers by making original geographical research available and by liaising with the New Zealand Board of Geography Teachers, geography departments of New Zealand universities, and geographers involved in the private sector, Crown agencies, and community organizations.

Journals or major publication series

Current activities or projects

The NZGS has a core membership of 200–300, but is involved with a much larger group of geographers (more than 900) in New Zealand and internationally through emails and the NZGS website. Monthly newsletters and information specifically of interest to New Zealand geographers are sent through a geography community email list. The society’s activities are carried out by six local branches (Auckland, Waikato, Manawatu, Wellington, Canterbury, and Otago), a highly motivated executive committee and postgraduate network, and in partnership with the New Zealand Board of Geography Teachers. Experienced members that have made a significant contribution to geography in New Zealand can be elected as “Fellows of the NZGS.”

New Zealand Geographical Society conferences are held biannually and attract geographers internationally. Conferences are jointly held on a regular basis with the Institute of Australian Geographers (IAG). The society supports focused geographical research in special study groups. Outcomes of these are presented in seminars or symposia and are regularly published as special issues in the New Zealand Geographer journal. The NZGS is fortunate to have an active postgraduate network which has contributed to a variety of specialty sessions at conferences and quality publications in the New Zealand Geographer. The New Zealand Board of Geography Teachers is equally strong. One of their best contributions is the Network Magazine, an online newsletter that is published on the NZGS website and electronically distributed to all school teachers. Every year at their annual general meetings, the society awards outstanding geographers with distinguished awards and also acknowledges exceptional contributions by postgraduates.

The NZGS is registered as a charitable entity and is governed by an elected council, currently comprising 19 members, which elects the executive committee and specialized subcommittees. The NZGS is a member of the Royal Society
of New Zealand, the International Geographical Union (IGU), and the New Zealand Geographic Board.

**Brief history**

The first separate university geography department was established at Canterbury University College under geologist George Jobberns in 1937 (Auckland, Otago, and Wellington followed in 1946). In 1939, Kenneth B. Cumberland and a group of enthusiastic New Zealand geographers initiated an overseas branch of the English Geographical Association at Canterbury University College, although this lapsed in 1941. Efforts in 1943 led to formal incorporation of the New Zealand Geographical Society in August 1944, supported by the New Zealand Ministry of Internal Affairs, with Ben J. Garnier as secretary. Auckland and Otago branches followed in 1945, and Manawatu and Waikato in the 1960s.

The first issue of the *New Zealand Geographer* was published in August 1945 with three issues per year published electronically since 2005. NZGS conferences began in 1955 and have been held biennially since 1992, periodically together with the Institute of Australian Geographers (IAG). NZGS has co-organized regional conferences of the IGU (Palmerston North, 1974) and jointly with the IAG in Brisbane (2005).

New Zealand’s location in the Asia-Pacific region and its diverse physical features have continued to attract geographers that are energetic, highly motivated, and strongly committed contributors to the New Zealand geographical community. The NZGS remains a vibrant and invigorating society carrying out activities locally and nationally with annual general meetings, conferences, regular webinars, and quality publications in the society’s journal.

Newly industrializing economies (NIEs)

Shiuh-Shen Chien  
Liang-Chih Chen  
Dong-Li Hong  
National Taiwan University

The term “newly industrializing economies” (NIEs), also known as “newly industrializing countries” (NICs), refers to countries and regions undergoing rapid industrialization and economic growth, particularly following World War II. Generally speaking, NIEs have enjoyed largely continuous growth mainly because of export-oriented industrialization, which is characterized by (i) export policies focusing first on primary commodities, followed by manufactured goods, (ii) financial controls, including on currencies and interest rates, and (iii) a cheap and stable labor supply. The best-known NIEs in Asia are Hong Kong, Singapore, South Korea, and Taiwan, collectively referred to as the “Asian Tigers,” which averaged annual gross domestic product (GDP) growth rates in excess of 6% between 1970 and 1990.

There are at least three different, but interrelated, approaches to explain the development of NIEs. First, the liberal market approach considers the changing global economy as a main driving force, including the liberalization of international trade and investment. This approach focuses on the impact of free trade and market mechanisms on economic development. Second, the developmental state approach focuses mainly on the strong role played by the nation-states and their adoption of policies to promote economic development. Third, the technological upgrading approach is concerned with how NIEs learn and innovate to catch up with their industrialized counterparts. Although this distinction helps us to form a general picture of NIEs, it should be noted that, while these three dimensions are theoretically distinguishable, they are empirically intertwined in practice.

Explanations for NIE growth

The liberal market approach

This approach argues that the industrialization of NIEs is closely related to the relocation of industrial and manufacturing sectors from advanced economies in the context of global economic liberalization. In the 1930s, trade protectionism was widely seen as contributing to economic recession, which was a major factor in provoking World War II. In 1948, the General Agreement on Tariffs and Trade (GATT) was established as the first international governmental organization aimed at eliminating international trade barriers, followed by the International Monetary Fund (IMF) and the World Bank (WB).

Trade liberalization was followed in the 1960s by the lifting of restrictions on international investment. Labor-intensive and routine production tasks began to shift out of industrialized countries, initiating a further large-scale international campaign of deregulation and liberalization of cross-border investment. Moreover, capital investment also shifted from developed to developing counties for two main reasons: first, falling profits forced companies in labor-intensive manufacturing sectors (e.g., garments, shoes,
and plastics) to shift production to lower-wage countries; second, technological and organizational advances decreased the importance of geographical proximity and allowed Western manufacturers to divide complicated production processes into separable steps which were then moved offshore.

This trend brought about the emergence of a new international division of labor (NIDL). In the “traditional” international division of labor (starting in the nineteenth century), less-developed countries exported their raw materials for industrial production in the developed countries. In the NIDL, on the other hand, Western manufacturers were attracted to certain developing countries offering low-cost production conditions (including low-cost labor). Those countries adopted policies specifically to attract overseas trade and investment in a bid to accelerate industrialization and economic growth.

The development of the Asian Tigers is a case in point. In the 1960s, Taiwan and South Korea opened up their borders to attract overseas capital and production, mainly from Japan and the United States. By doing so, Taiwan and South Korea started to develop domestic labor-intensive light industries. Accelerated liberalization led to faster industrialization and more development. Similarly, a second wave of Asian NIEs, including countries such as Malaysia, Thailand, and Vietnam, began liberalizing their economies in the 1980s, attracting capital and production from Taiwan and South Korea. This pattern, with development flowing from Japan to the Asian Tigers and then to Southeast Asia, later became known as the “Flying-geese model.”

In sum, the liberal market approach posits that the new international division of labor plays a key role in the development of NIEs, and that states seeking to accelerate development should liberalize policies to facilitate international trade and cross-border investment. Although the liberal market perspective highlights the importance of economic liberalization as a key for NIEs, it does not explain why some countries benefit more than others from implementing such economic liberalization policies. To answer this question, we turn to the developmental state approach.

The developmental state approach

In the late twentieth and early twenty-first century, the Organisation for Economic Co-operation and Development (OECD) and the World Bank classified Greece, Portugal, Spain, Yugoslavia, South Africa, Mexico, Brazil, Indonesia, Malaysia, and Thailand as NIEs, but these countries generally did not experience the same level of economic growth as the Asian Tigers from the 1960s to the 1980s. The developmental state approach, mainly derived from the experience of the Asian Tigers, focuses on the positive role of the state in supporting industrialization through domestic policy. Scholars find that, instead of pure liberal policies, appropriate state inventions and extensive related regulations should play a part in NIE development. According to this approach, industrialization involves five dimensions.

The first dimension in this approach is the development of agricultural support, with the state initiating rural land reforms to offer farm-land ownership or long-term leases to private individuals, who are therefore motivated to increase agriculture productivity. Agricultural surpluses are tacitly extracted by the state to support industrial development. Farmers are encouraged or forced to use fertilizer to increase agricultural productivity, thus driving the development of other industries, which lay the foundations for early-stage industrialization. In addition, after raising productivity, fewer farmers are needed to generate the same agricultural yield, releasing labor resources to...
migrate to cities, thus triggering urbanization and industrialization.

The second dimension focuses on industrial policy. The state strategically selects certain industries for priority development, providing temporary subsidies, trade barriers, and related import substitution policies to support their protected development. State-owned enterprises and associated public research institutes are also established to facilitate the expansion of these strategic industries.

The third dimension concerns the spatial industrial policy. To attract investment, the state establishes special development zones with quality infrastructure and preferential policies such as cheap lands, low taxes, and loose enforcement of labor and environmental regulations. Such zones are also referred to as “export processing zones,” “science parks,” “industrial zones,” and so on.

The fourth dimension is the development of market-friendly labor policies. Labor union activity is restricted, keeping wages low and attracting incoming investors. The state also provides investors with an educated workforce.

Fifth, the state provides an appropriate capital environment. For example, the state can peg its exchange rate to a foreign currency (e.g., the US dollar) at a relatively low level, thus increasing the competitiveness of exports. In addition, the state strongly encourages households to save money in domestic banks, providing a source of funding for domestic investment. Finance policy also allows firms to retain a high proportion of their profits for reinvestment.

It must be noted that these market-friendly state-led development policies were implemented by far-sighted technocrats under authoritarian leaders. Those technocrats formulated policies that favored economic development, and the authoritarian leadership had an upper hand to implement these policies with no, or very limited, opposition. The state was also able to act autonomously to collaborate with private enterprises in the implementation of these policies, a practice which is referred to as the embedded autonomy of the developmental state.

In other words, unlike the liberal market approach (which argues that the state should refrain from intervening in the market), the developmental state approach emphasizes the need for a strong interventionist state to promote economic liberalization. And these two perspectives offer complementary understandings of the rise of NIEs.

The technological upgrading approach

The final approach is specifically concerned with technological capacity, asking how NIEs catch up with their advanced counterparts in terms of technological knowledge and expertise. The “latecomer advantage” thesis argues that the path of technological development in advanced economies serves as a useful reference for latecomers, allowing them to avoid redundant trial-and-error processes and risks. But not surprisingly, the learning process is found to differ widely between different NIEs and between industrial sectors within a single NIE, thus explanations must be found at the regional, and even firm, level.

At the firm level, at the outset of the globalization process, multinational corporations (MNCs) from advanced economies drive the emergence of NIEs. These MNCs diffuse their technologies to NIEs via direct investment or by subcontracting their production chains to local NIE firms. In the case of Singapore, for instance, its industrial development benefited greatly from technology transfer through foreign direct investment (FDI) from the West. In other NIEs, such as South Korea, policy is centered around
large-scale domestic firms in which the government directly subsidizes conglomerates (e.g., the Chaebol) to vertically integrate production in specific industries, thus fostering technological upgrading within complex production and supply chains.

In addition, in some NIEs, such as Taiwan, small- and medium-sized enterprises (SMEs) are key business agents for economic development. These firms are more flexible and dynamic, and excel at using informal channels (e.g., imitation, reverse engineering, casual counseling, etc.) to achieve technological advances. Finally, the interactions between MNCs, large domestic firms, and SMEs are highly dynamic and intertwined with other firms in so-called global production networks (GNPs) in various industries. In some high-tech industries, engineers who are born in NIEs but educated in the United States move frequently between the two economic spheres, serving as agents for the transfer of tacit knowledge, capital, skill, and know-how between Silicon Valley and their home NIEs. This means that technology upgrading is based not only on the NIEs, endogenous assets but also on their complex exogenous relationships and the strategic coupling of economic actors working in different regions.

At the regional scale, state-built development zones in NIEs provide diverse opportunities for innovations among spatially clustered firms and individuals. First, in NIEs the state establishes relevant universities and research institutes near such zones. Geographical proximity of these different organizations minimizes infrastructure costs and maximizes access to specialized information and talent pools, which collectively drives the development and diffusion of technological and business innovation. Second, such spatial concentration increases the likelihood of social interaction among firms, thus facilitating knowledge spillover and learning.

Challenges facing NIEs

The transformation of NIEs from “industrializing” economies to “industrialized” ones entails certain challenges, which can be also categorized as belonging to three different scales. First, the situation of the international political economy has changed. The development of the first wave of NIEs in Asia lasted from the 1960s to the 1980s, and occurred in the historical context of Cold War capitalism. NIEs were able to export their industrial products to the United States, the biggest consumer market at the time, because the United States strategically included NIEs as a part of its Cold War strategy of containment for China and the Soviet Union. After the end of the Cold War, this relatively stable international structure was replaced by a new, more dynamic global power structure characterized by the decline of US and European hegemony, further macroregional economic integration, and the rise of China and other developing countries (e.g., India) as emerging global consumption markets. These developments forced NIEs to periodically adjust their position in the changing international division of labor.

Second, the developmental state in NIEs also encountered challenges from within. Citizens who had enjoyed the fruits of economic development chafed under authoritarian rule, demanding democratic reforms including free and fair elections, media freedom, the independence of the judiciary, and the legalization of civil society organizations (CSOs). These challenges reduced the autonomy of state actors, and gave voice to concerns, such as environmental protections, social inclusion, human rights, or even anti-growth alternatives and so on, which potentially clashed with the state’s priority of economic development.
Third, NIEs face challenges in maintaining the pace of technology upgrading. NIEs developed from agrarian societies to industrial economies through the use of received technologies, but the next stage of development requires NIEs to innovate on their own. For example, in the current arrangement, many NIE firms are relegated to the role of original equipment manufacturers or designers, giving them little negotiating leverage when dealing with MNCs, and leaving them with limited resources for further technology upgrades. MNCs are reluctant to allow the development of potential competitors, and use international intellectual property law to prevent NIEs from making further technological advances through imitation.

Niche theory and models

Jennifer A. Miller
Paul Holloway
University of Texas at Austin, USA

The niche concept is one of the most fundamental ideas in ecology, and in spite of the fact that it has been a topic of books and journal articles for the past 100 years, several different niche theories and definitions have evolved. Within geography, recent attention to the importance of niche theory has increased in the context of developing inductive models to describe species–environment relationships that can subsequently be used to generate predictions for a number of biogeographic applications related to, for example, biodiversity inventory, risk of invasive species, and consequences of climate change.

The concept of a species’ ecological niche and its response to environmental gradients provides an important theoretical basis for quantifying species–environment relationships using these models. While these types of correlative models have been known by different names in the approximately 20 years that they have been used (e.g., “habitat suitability models” and “bioclimatic envelope models”), the terminology has more recently been split between “niche models” and “species distribution models.” Although these two terms have often been used interchangeably, there has been considerable debate about the fundamental and semantic differences between them, the types of data used to fit them, and the products they are used to generate. The main ways in which niche theory has been used to conceptualize these inductive models are discussed in more detail below.

In addition to the semantic differences associated with the development of niche models, the concept of an ecological niche has been heavily debated in terms of what it is, how it is defined, and how it can be used. Of the many different concepts and distinctions associated with niches, one of the main differences involves defining them in terms of the direction of the species–environment relationship: the effect of the species on the environment (“impact”) versus the effect of the environment on the species (“requirements”). This distinction is also implicitly tied to spatial scale: both the impact concept and the requirement concept are necessary at finer scales, while the requirement concept is more important at broader scales (species impact on its environment is also more difficult to measure at broader scales). These categories are also consistent with different definitions of niche that have historically been associated with the ecologists who first wrote about them in the past 100 years. Three of the main “author-ian” niche theories that are most important to the practice of niche modeling are described below. Many of the authors who originally wrote about niche theory incorporated similar ideas independently, and instead of summarizing them chronologically, they are summarized in terms of their contributions to niche modeling, with the most relevant contribution discussed last.
NICHE THEORY AND MODELS

Niche theory

Eltonian niche

The two main classes of niche theory have been described as “Eltonian” and “Grinnellian.” Elton’s (1927) original concept of a niche was related to a species’ functional role and the impact it had on its environment. It was characterized by ecological factors related to biotic interactions and resource consumption and was generally explored only with the aid of detailed field studies. Elton considered biotic interactions, specifically competition, to be a main driver of species composition and distribution. To test the importance of competition, Elton suggested comparing the observed species to genus (S/G) ratios for a location to the ratio that would be expected under randomness. Presumably intraindividual competition would prevent many similar species from occupying the same niche, therefore resulting in a lower S/G ratio. Subsequent studies that compared these ratios produced mixed results, some related to the confounding effect of diversity, and one of the main criticisms was the lack of an appropriate null model against which to compare the observed ratios.

Factors related to competition and resource dynamics are difficult to measure at the spatial scales at which most niche models are developed. This attenuation of importance of biotic factors as spatial scale decreases has been referred to as the “Eltonian noise hypothesis” (Peterson et al. 2011), although this hypothesis has been refuted in some macroscale studies. While original Eltonian niche theory is generally outside of the realm of the type of niche modeling discussed here, the importance of biotic interactions to species distributions has been incorporated in the concept of bionomic factors (see Hutchinsonian niche discussion below), which generally refer to dynamic resources that can be consumed, and for which competition may become an important aspect.

Grinnellian niche

Although he was not the first person to use the word “niche” in a biological context, Grinnell (1917) is generally credited with the original development and formal definition of the ecological niche of a species. Grinnell’s definition of a niche comprised all of the conditions necessary for a species’ existence, ranging from environmental factors associated with physiological tolerances to interactions with other species. Although he emphasized predator interactions over competition, the origins of the “competitive exclusion principle” – that two species must have different traits related to their fitness in order to coexist locally (also known as the “Volterra–Gause principle”) – can be traced back to experiments conducted by Grinnell.

Both Elton’s and Grinnell’s niche concepts were somewhat geographically abstract yet still considered to be an attribute of a place and fit in with a community ecology conceptualization of species composition (e.g., Grinnell’s exemplar California thrasher species was part of the chaparral community). A vacant or empty niche could exist where a particular habitat was unoccupied. While Elton’s concept was more related to a species’ functional role in its community or biotic environment, Grinnell’s concept was more analogous to what is considered habitat, and therefore involved factors that are important to species distributions at spatial scales that are more relevant to niche modeling, although some niche factors suggested by Grinnell such as “food size” are not easily conceptualized as occurring along gradients.
Hutchinsonian niche

Hutchinson (1957) advanced upon these niche concepts to provide a framework for quantifying the species–environment relationship inherent to niche theory and the basis for niche models. Similar to Grinnell’s niche concept, the Hutchinsonian niche is more related to a species’ environmental requirements rather than to its impact on the environment, but unlike both Grinnell and Elton, Hutchinson was the first to define a niche as an attribute of a species or a population instead of a place. The idea that a species had a niche was consistent with the individualistic theory in plant ecology as proposed by Gleason (1926) and extended by Whittaker, and led to the development of methods that quantified species responses to environmental gradients such as gradient analysis and ordination (Whittaker 1967).

Hutchinson’s most important and transformative contribution to the development of niche modeling was his characterization of a species’ niche in terms of environmental space. A Hutchinsonian niche was defined as a function of a species’ requirements (limiting factors) that were represented as gradients or axes along which a species’ tolerance could be plotted. In his seminal paper, Hutchinson (1957) considered limiting factors to be those which permitted a species to survive and reproduce, or more broadly, “to exist indefinitely” (416). The resultant $n$-dimensional hypervolume represented the sum of tolerable conditions across all factors in environmental space.

Hutchinson further distinguished a species’ niche as being fundamental or realized. A fundamental niche comprises a species’ full range of tolerable environmental conditions, the $n$-dimensional hypervolume, while the realized niche describes the subset of environmental conditions to which it is restricted as a function of interactions with other species.

Hutchinson formalized the link between environmental space – in which a species’ fundamental niche was defined – and the biotope, or the physical environment in terms of a species’ requirements. A species’ fundamental niche is defined in abstract environmental space and it is likely that only a subset of the requirements exist in geographic space; any point in niche space could correspond to many different (and geographically disparate) locations in biotope space, or none at all. It is this translation of a niche defined in abstract environmental space to geographic space – what has been referred to as “Hutchinson’s duality” (Colwell and Rangel 2009) – that provides the foundation for niche modeling.

Hutchinson also introduced the terms “scenopoetic” and “bionomic” to distinguish between environmental factors with which individuals did not interact and did, respectively. These factors are similar to the distinction between Grinnell’s niche, which would be defined by noninteracting scenopoetic factors, and Elton’s niche, which would be more closely related to bionomic factors. It is important to note that traditional niche theory generally accounts for only negative population interactions such as competition and predation, while positive interactions such as mutualism were part of what Hutchinson originally considered to be the fundamental niche.

Niche modeling combines aspects of all three niche concepts described above. Figure 1 illustrates the general process involved in formulating a niche model using presence/absence data for *Yucca brevifolia* and three environmental variables in a portion of the Mojave Desert in California. Data on species occurrences are combined with environmental factors (Figure 1a) to quantify the species’ hypervolume in environmental space (Figure 1b, in this case three dimensions: precipitation, temperature, and southwestness), which
Figure 1  Illustration of niche modeling process. Species and environmental data are shown in (a) (red is species absence; green indicates species presence); species data are plotted in environmental space; the relationship established in environmental space in (b) is then projected to geographic space to produce a map of predicted presence/absence (c).

is then applied to geographic space (Figure 1c) using the appropriate digital environmental layers in a geographic information system (GIS). This relationship between environmental space (species’ niche) and geographic space (species’ distribution) is described in more detail below.

Niches and distributions

Soberón (2007) introduced a framework useful for examining the three types of factors that determine the distribution of a species. The “BAM” diagram (Figure 2) can be used to visualize the individual and combined effects of biotic factors (B; biotic factors that affect resource use, e.g., interactions (similar to, but not synonymous with, Hutchinson’s bionomic factors)), abiotic factors (A; scenopoetic factors, e.g., temperature), and movement factors (M; e.g., accessibility based on dispersal capacities). Each circle represents the geographic space in which those conditions – biotic, abiotic, or movement – are suitable for a particular species. The entire circle represented by A can be thought of as the fundamental niche expressed in geographic space, or the potential distribution (Hutchinson’s biotope) of a species. A species’ actual distribution is represented by the intersection of all three factors (bam). The effects and limitations of each of these factors can shift in relative importance in a niche model application, depending on a particular study’s objective or goal.

In geographic space, the potential distribution and actual distribution are generally analogous to fundamental and realized niche, respectively. A distinction between the fundamental niche and potential distribution is that the fundamental niche exists in environmental space, and when it is translated to geographic space, not all of the environmental conditions exist at a particular time, and therefore the potential distribution is a subset of the fundamental niche.
A species’ fundamental niche is relatively static, but because the availability of suitable environmental conditions can change with time, a species’ potential distribution can expand or contract in future projections. These factors are conceptualized as occurring in geographic space, so the areas they represent can change as their respective suitabilities change. For example, a species would not be expected to be observed where only abiotic and movement factors are suitable (\(am\)) because of competition or a similar negative interaction factor. If negative competition was no longer a restriction, those areas could be reclassified as \(bam\) and become occupied. The intersection of suitable biotic and abiotic factors, but beyond suitable movement factors, (\(ba\)) represents areas where a species could survive, if they were accessible. Locations that were within this \(ba\) area could be targeted for translocation or reintroduction studies, or to investigate the risk of species invasions. Studies focusing on projecting future distributions as a function of climate change would generally aim to describe all of \(B\).

### Niche models

Considerable debate addresses what exactly these inductive models used to translate environmental niche space to geographic space should be called. Although terms ranging from “predicted habitat distribution models” to “bioclimatic envelope models” have been used in the past 20 years, the terminology has converged, but not coalesced, on the terms “species distribution model” (SDM) and “(environmental or ecological) niche models” (ENM). While both of these models are firmly rooted in niche theory, SDMs are used primarily to generate a prediction of a species’ distribution in geographic space rather than in environmental space. The use of the term “niche models” is more problematic because they are rarely formulated with data on species interactions, which suggests that they should be used only to predict the fundamental niche as opposed to the realized niche. In practice, however, the data on which they are calibrated were collected in the field and are therefore necessarily representative of the realized niche. The type of data (both species and environmental), as well as the statistical method used to quantify the species–environment relationship, also influences whether it is more appropriate to consider the technique an SDM or an ENM.

### Species data

The response variable of interest in species distribution and niche models can be represented by a variety of measures of species importance such as abundance or richness, but the most commonly used variable is presence-absence or...
NICHE THEORY AND MODELS

presence-only data. Species’ presence should be observed in the intersection of the biotic, abiotic, and movement circles (bam) in Figure 2. A species will most likely be absent outside of that intersection, although sink populations may be detected in other parts of the circle described as movement suitable (M). A species would be absent in areas outside of the B circle as a result of negative interactions and outside of the A circle as a result of unsuitable environmental conditions.

Keeping in mind the limitations inherent in using empirical data in niche models, a model calibrated with presence-only data would be more appropriate for predicting a result closer to the fundamental niche (A), while absence data would be necessary to distinguish between areas that were biotically suitable (e.g., ba, bam) from those that were unsuitable (A, am) in order to predict a result closer to the realized niche. Given that most niche models are developed using only abiotic factors, the information contained in observations of absence may be used indirectly to distinguish between abiotically suitable but biotically unsuitable and abiotically and biotically suitable locations.

Environmental data

Environmental factors vary in importance across species and predictor variables should be selected based on ecological relevance. The limits of several species are often coincident with particular combinations of climate, and abiotic climate variables such as temperature and precipitation, as well as more complex biophysical variables such as growing degree days and potential solar radiation, are often included in species distribution and niche models. These factors generally fall into Hutchinson’s scenopoetic variable category, although there are exceptions; for example at a broad spatial scale, solar radiation would be considered scenopoetic and noninteractive, while at the scale of a forest floor, competition for light could modify its designation to bionomic.

If modeling a species’ fundamental niche is the objective, abiotic factors such as climate should be sufficient. If the objective is to model a species’ realized niche, information on biotic interactions should be incorporated into models, although this has proved conceptually challenging. There is little empirical data on how one species directly influences another, and interactions can differ between populations of the same species. The most commonly used method of incorporating biotic interactions is to include the probability of finding another species alongside these abiotic conditions. In addition, the spatial scale will also affect the subsequent importance of interactions such that the signal of biotic interactions is often lost at coarse spatial scales (the Eltonian noise hypothesis).

Including information on mobility (M from Figure 2) has only recently been addressed, typically in the context of modifying predictions based on changing climate conditions. When it is incorporated, “movement” has been represented by using a measure of dispersal ability. The two most widely used involve the extreme scenarios of “full” dispersal ability, in which a species can access any future suitable locations, and “no” dispersal ability, in which a species is restricted to future suitable locations only within its current distribution. Dispersal ability can also be empirically derived. Data used to measure accessibility can also take the form of a separate movement model (i.e., dispersal kernel or cellular automata), which is then coupled with distribution and niche models.

Statistical methods

Many statistical methods have been used to fit ecological niche models and the specific method
used is often based on both the research objective and the type of data available for modeling. Environmental envelope and similarity are conceptually the most simplistic type of methods used in ENM, and they are also one of the few types of methods that are appropriate when only presence data are available. Envelope models define the hyper-rectangle that encompasses the species response data in multidimensional environmental space and represent a more direct implementation of Hutchinson’s concept of a species’ fundamental niche. In general, the statistical methods that use presence-only data tend to overpredict or result in high commission errors (“false positives”; locations that are predicted to be suitable or contain a species presence, but where the species was not actually observed). This output may be desirable if the objective is to identify potential locations for translocation or reintroduction, in which case areas where commission errors occurred could describe abiotically suitable locations that are currently unoccupied (e.g., as a result of inaccessibility) but could be occupied.

Another class of models that can be used with presence-only data compares the environmental factors associated with observations of presence to the entire range of environmental conditions within the study area. The “available” habitat or background data are also sometimes sampled as “pseudo-absences.” Maximum entropy (Max-Ent) is the most widely used of these methods, and in comparisons with envelope methods such as those described above, MaxEnt generally performs better and results in fewer commission errors.

When data on species presence and absence are available, regression-based models are still the most widely used technique in ENM and they extend the envelope method by modeling variation in the response data within the occupied environmental space and selecting predictor variables based on their observed importance in the final model. There has also been considerable progress in the application of machine learning methods such as decision trees and artificial neural networks in niche modeling applications. Newer ensemble versions of decision trees (bagging, boosting, random forests) have been shown to be of particular promise in quantifying more complex species–environment relationships that may be nonlinear, hierarchical, or involve interactions.

If the objective of a study involved selecting a reserve area, excessive commission errors would be problematic; therefore, a regression or machine learning method using presence/absence would be more appropriate. In general, the more complex statistical methods used with presence/absence data produce a result closer to the actual distribution/realized niche end of the spectrum while more simplistic envelope models used with presence-only data produce a result.

Model evaluation

Ecological niche models can be used for two main purposes: explanation or prediction. Understanding the environmental factors associated with a species’ niche is the main driver behind evaluating a model for its explanation. Niche models are intended to describe suitable conditions in environmental space, and therefore should be robust for predicting across space and time. This is particularly important in the context of climate change projections (see below).

These two distinctly different aims of an ecological niche model strongly influence the metrics used in model evaluation. When explanation is the aim, models are often assessed using model fit diagnostics, and an information criterion approach is becoming more widely implemented.
NICHE THEORY AND MODELS

When prediction is the aim, classification accuracy is assessed using an independent test dataset or a data resample. Several evaluation metrics are currently widely used (e.g., area under the curve (AUC), kappa, sensitivity, specificity) and as such it is considered good practice to report several metrics in evaluation. As with data and statistical method considerations, accuracy assessment metrics should be selected based on the study objective. When the selection of an area for potential translocation or reintroduction is the goal, many commission errors would be acceptable, but omission errors (“false negatives”; locations that are predicted to be unsuitable or contain absences but which really contain a species) should be minimized. Observations of “absence” may not be necessary in the assessment process, whereas in the reserve design example, absence data would be crucial for assessment.

Niche model applications

Several niche modeling applications are described in more detail below. It should be noted that while the niche theory and gradient analysis concepts on which niche models are based involve (plant or animal) species’ responses, the methods have been used to study the distributions of similar biogeographic phenomena such as biodiversity, fire, and vector-borne diseases.

Climate change impacts

Climate change studies are one of the most long-standing application areas for niche models. When used in niche models, abiotic variables are assumed to be somewhat static, but climate variables can change and, while this should not affect a species’ fundamental niche in short time periods (≈10–50 years), a species’ potential distribution in geographic space can change considerably. This can also induce changes in biotic interactions, and limitations associated with dispersal can result in substantial changes in a species’ actual distribution as well. By understanding which factors define a species’ current ecological niche, predictions can be made about the resilience of certain species in the future by extrapolating species responses in environmental space into future geographic space (under various climate change scenarios). Using niche models to assess extinction risk requires explicit modeling of changes in variables that define the actual distribution (bam). Ecological niche models can estimate habitat reduction using current environmental data, which can be used solely or coupled with population models, to estimate extinction risk. Studies focused on species reintroductions are more interested in the intersection between areas of favorable biotic and abiotic conditions (ba), as for some reason (e.g., local extinction, barrier to movement) the areas are not currently accessible to species. This modeling can then identify suitable locations for these species to be reintroduced or translocated.

Invasive species risk

The geographic spread of invasive species is also a phenomenon with global biological and economic consequences. Niche models have been used in this field of research to identify geographic areas that are currently unoccupied by the species but are susceptible to invasion if dispersal limitations are removed (i.e., the species in introduced). Niche models to predict spread of invasive species are fit typically using species and environmental data from one region (usually the native region) and then projected into new regions, where the species may be currently invading or where they could potentially invade. In terms of assessing the accuracy of
predictions from invasive species niche models, commission errors could be used to identify potentially invaded areas, while omission errors would be far more problematic and should be minimized.

Niche conservatism

One of the newest application areas of niche models so far examines the rate of change of niche characteristics both for closely related species and across time. In the niche model studies discussed here, relevant timescales could range from 10 years to several hundred years. Closely related species that share similar niche characteristics even if they are not close in geographic space provide evidence for “niche conservatism.” While niche conservatism would require that all three areas represented by BAM remain unchanged simultaneously, it is a prerequisite for several niche modeling applications such as projecting the impacts of climate change and determining invasive species risk. For example, determining niche conservatism with respect to climatic conditions can have important consequences for potential range expansion. It has also been noted that ignoring \( B \) can obfuscate studies that test for evidence of niche conservatism.

Conclusion

Niche models based on species–environment relationships have become a crucial tool in biogeographic research. While firmly grounded in niche theory and gradient analysis, the application areas in which niche models have been applied are continuing to grow. It is important to understand the assumptions and requirements associated with the niche concepts on which they are based in order to use these models appropriately.

NICHE THEORY AND MODELS

Nonrepresentational theory

Paul Simpson
Plymouth University, UK

Nonrepresentational theory refers to a diverse body of work that emerged in human geography in the mid-to-late 1990s and has since attempted to transpose a range of key concerns for human geography into diversified registers of thought and action. This movement of transposition originated primarily from a series of publications written by Nigel Thrift, but also evolved through the work of a number of his doctoral students from the University of Bristol and a range of interested others (see Anderson and Harrison 2010). As well as coming out of a variety of theoretical, technological, and social developments gaining momentum around this time, nonrepresentational theory also developed as a response to the perceived prominence of “representational” modes of thought in human geography. It was felt that the emphasis on seeing the world as “text” to be deconstructed provided a somewhat limited window onto a range of phenomena relevant to geographic inquiry. By way of contrast, nonrepresentational theory is concerned with the practical and improvised unfolding of the everyday that exceeds the representations that can be made of it but through which much of the world’s consistency, meaningfulness, and legibility come to be (re)produced and maintained.

Two immediate stumbling blocks that have impeded the reception of nonrepresentational theory are the words “nonrepresentational” and “theory.”

For many, the negativity of the “non” in “non-representational” meant (or at least implied) a move away from concerns with representations and texts altogether (see Representation). This impression is understandable given the tenor of some of Thrift’s early outlines and the way in which these positioned themselves very strongly in opposition to New cultural geography (Thrift 1996). This reaction in turn led to the suggestion of “more-than representational theory” as a more inclusive nomenclature that would soften some of this oppositional tone (Lorimer 2005). These debates aside though, nonrepresentational theory is in fact interested in representations. Within this work representations are considered for what they do, as being performative and so playing a part in the ongoing shaping of daily life (Dewsbury et al. 2002). Therefore, the critical target of the “non” is more a form of “representationalism” that reduces the world to, and fixes and frames it within, text or discourse alone, and not at representations in and of themselves.

Furthermore, nonrepresentational theory is not an actual “theory.” Rather, it constitutes a style of thinking that values practice and process. This means that it is better to think of nonrepresentational theory in the plural, as non-representational theories. Within this, a range of ideas from Poststructuralism/poststructural geographies, vitalists, Phenomenology, pragmatists, Feminist geography, and a collection of relational and constructivist social theorists mix in varying concentrations and combinations producing quite diverse and at times seemingly contradictory accounts of this happening of the world.

Nonrepresentational theories try to attend to the “onflow” of everyday life (Thrift 2007).
This attention lays emphasis on the processual registers of experience that exceed our ability to theorize or fully attend to them. Nonrepresentational theories thus openly acknowledge the partial and incomplete nature of our accounts of the world and so act against the reductive “vampirism” inherent in trying to fix the world within particular structures, models, orders, and frameworks posited by the researcher (Dewsbury et al. 2002). This acknowledgement has been manifest both in the required modesty of the researcher in the claims they can make about the world, and also in the way these accounts are produced and presented, as can be seen, for example, in Derek McCormack’s “A Paper with an Interest in Rhythm” (2002). Here McCormack deploys performative modes of writing in an attempt to animate the paper’s discussion of his encounter with a specific somatic movement practice and so avoid representing this practice in an overly fixed way. Inspired by developments in the performing arts, such work aligns itself with a sort of experimentalism that does not shy away from providing an open-ended account of the world.

Nonrepresentational theories have highlighted the importance of the pre-individual to such a process-based understanding of life. As such, this work has been concerned with the practices of subjectification that bodies undergo rather than with already formed subjects or demarcated identity positions. This subjectification arises out of the world being composed of a complex ecology of human and nonhuman things – objects, people, technologies, texts, ideas, discourses, norms, and so on – that are perpetually encountering and shaping one another. This means that nonrepresentational theories are often interested in the human body and its coevolution with the world (see Bodies and embodiment). As can be seen in John Wylie’s auto-ethnographic accounts of walking in the landscape, and particularly in the ways that embodied registers of experience and subjectification are foregrounded within these, the body is not counted as separate from the world but rather it is argued that the human body-subject is an emergent product of its interactions with the environments it moves through.

Being interested in the relations between various bodies/things leads to another key area of interest for nonrepresentational theories: Affect, sensation, and the precognitive aspects of embodied life. This has been a key area of development for nonrepresentational theories and a particularly contentious one given the relationship of this to other key areas of geographic inquiry, such as emotional geographies. While many interpretations exist, here affect does not refer to a personal feeling, but rather to a “pre-personal intensity” that corresponds to the evolving capacities of a body to act and be acted upon. Significant here is that capacities to affect and be affected emerge in the relations themselves, in the “in-between,” and so do not belong to the subject and/or object prior to that encounter. This emergent nature of affect means that affective registers of experience can become an explicit target in the design of various forms of social space. As James Ash has shown in the context of video games, for example, game designers are able to manipulate the affective experience of gamers by experimenting with the spatial and temporal characteristic of the game. Altering the responsiveness of controls, the speed of the “re-spawning” of characters, and so on, can then produce and/or suppress certain affective – and so relatively unreflected upon – interaction with the architecture of the game “world.”

Nonrepresentational theories also acknowledge the vibrancy of matter and so, rather than viewing the nonhuman as an inert supplement to the human world, give a more equal weighting to both the human and things.
(Anderson and Wylie 2009) (see Geophilosophy). Such theories then view the world as a multiplicity of heterogeneous networks and connections needing to be maintained, which in turn decenter the Cartesian notion of agency as belonging solely to the human. Anything from the microscopic infectious pathogens discussed by Steve Hinchliffe and others to the illuminated atmosphere present in urban spaces discussed by Tim Edensor have the capacity to impinge significantly upon the unfolding of human (and more than human) life. In addition to the strong influence of the work of Actor-network theory and “New Materialisms” here, work on Object Oriented Ontology and Speculative Realist philosophies, which seeks to pay attention to the existence and interaction of objects (or “things”) outside of the necessary presence of a human subject, has recently played an increasingly prominent part.

Finally, nonrepresentational theories have been concerned with the ways in which politics and ethics can be considered in light of the shifted and shifting points of reference outlined above. In particular, nonrepresentational theories have sought to consider how difference can be made and new ways of being in the world can be achieved when the parameters of the political and the ethical are expanded beyond solely representational realms (Anderson and Harrison 2010). Thus far, work has focused on notions of the event as a key site for change to emerge and considered how the agency of matter beyond the human is, in part, constitutive of human difference. Ultimately, the key theme here is uncertainty – over what counts and what might come to be – rather than the presentation of a legislative political program. For ethics, there has been a similar shift away from a normative understanding of what constitutes (im)proper conduct towards others towards a more “situated” ethics. Rather than stipulating how we should act towards others, emphasis is laid upon a consideration of how we negotiate the present with an ethos and a sensibility that is attentive to how we affect, and are affected by, the world and others.

The pursuit of these themes has touched a number of nerves within the discipline. One of the clearest indicators of the impact non-representational theories have had is the range, and vehemence, of the critique and criticism that have been made of it. For example, there have been suggestions that nonrepresentational theories are guilty of an ethnocentric universalism in the way they consider (or rather fail to consider) social difference through their movement away from collective identity-based forms of politics. Further, others have argued that nonrepresentational work embodies a form of masculinist rationality in its movement away from subject-based emotions and personal feelings towards a more reasonable language of “engineering.” Here it has been suggested that talking in terms of networks, junctions, pipes, cables, relays, and so on in the tracing of affective relations risks distancing research from important issues of being “human” – namely, our ongoing constitution as specific and often categorized “emotional subjects” in social spaces. Finally, it has also been said that nonrepresentational theory’s account of agency and subjectivity, and the inherent anti/posthumanism of such accounts, does not leave sufficient space for the acknowledgment of differing capacities to engage in political action or provide a ground from which such action can take place.

Arguably though, these critiques are products precisely of the challenge nonrepresentational theories present to the way in which geographic research is undertaken and what counts for knowledge. Nonrepresentational theories do not necessarily deny the importance of identity politics, collective action, and so on. In fact, work here has made substantial contributions to
understanding how racialized bodies are constituted, for example. Nonrepresentational theories also point, however, to the emergence of a range of new political techniques and technologies that act on pre-individual registers of thought and action. To do so requires the development of new vocabularies for expressing these emerging politics and new arts of political action for intervening into them. The extent to which such development is deemed sufficiently “political” though is an entirely different question.

Description and purpose

The NGS is an association for geographers, students, and others interested in the discipline of geography. The society disseminates knowledge concerning geographical topics through meetings for members and others interested in geography. The objective of the society is to provide a collective forum for members and to contribute to the exchange of knowledge and experiences between various institutions where geographers work in teaching, research, administration, and other practical occupations. The society aims to further geographical knowledge and arouse interest for the discipline by arranging seminars, lectures, and field excursions for members and by publishing the Norsk Geografisk Tidsskrift – Norwegian Journal of Geography.

Journals or major publication series

Current activities or projects

Both the Oslo and Trondheim branches of the NGS arrange thematic meetings with lectures and discussions on current topics of interest, for example, climatic warming, permafrost, physical planning, polar explorations, and ongoing geographical research projects. The Oslo branch arranges an annual field excursion. The society organizes a national geographical conference every second year aimed at researchers, lecturers, teachers, planners, environmental administrators, cartographers, statisticians, and other professions. The society has recently published in Norwegian a history of its activities from its foundation in 1889 until 2000 (Jens Fredrik Nystad, 2012, Det Norske Geografiske Selskab 1889–2000, Oslo: Fram).

Brief history

The NGS was founded in 1889 in a wave of national enthusiasm greeting the return of Fridtjof Nansen (1861–1930) to Oslo after skiing across Greenland. It became an important arena of support for subsequent Norwegian exploration and research in polar regions and other parts of the world. Expedition reports and plans were presented at the society’s meetings, often with royalty and members of the government present. The society’s first chairman was Henrik Moen (1835–1916), founder of the Norwegian Meteorological Institute in 1866. Besides Nansen, prominent members included polar explorers C.A. Larsen (1860–1927), Carsten Borchgrevink (1864–1934), Roald Amundsen (1872–1928), Gunnar Isachsen

http://www.tandfonline.com/toc/sgeo20/current
NORWAY

(1868–1939), and Otto Sverdrup (1888–1957). Other explorers included Helge Ingstad (1899–2001) and Thor Heyerdahl (1914–2002). A committee of the society drafted Norway’s first Nature Protection Act in 1910. The society’s research promoted Norwegian sovereignty of Svalbard (annexed 1925), claims to East Greenland (rejected by the International Court of Justice in 1933), and annexation of islands and Queen Maud Land in Antarctica in the 1930s. By 1960, the era of exploration was over and geography became more professionalized and specialized. The Norwegian Geographers Association amalgamated with the society in 2000.

Submitted by Michael Jones
By the middle of the nineteenth century, marine biologists began to realize that the ocean was inhabited by species that appeared to be peculiar to certain geographic areas. This realization stimulated an interest in the regions that could be identified by the presence of endemic species, that is, species that were confined to a given area and found nowhere else. Our present knowledge of marine biogeography and evolution is based primarily on investigations of the biota of the continental shelf and the epipelagic zone, each extending from the surface to a depth of 200 m. This relatively shallow area is penetrated by sunlight, generates most of the primary productivity, and supports the highest level of biodiversity.

Our modern concept of marine biogeographical regions began with the work of James Dwight Dana, an American geologist, mineralogist, and naturalist. As a young man, Dana joined the United States Exploring Expedition to the South Seas. He served four years (1838–1842) as a geologist but also undertook much of the zoological work. As the result of his discoveries on the corals and crustaceans, he was convinced that sea surface temperature was the important factor that determined distributional patterns. Dana used isocrymes (lines of mean minimum temperature for the coldest month) to explain the geographical separation of species groups, and published (1853) an Isocrymal Chart (map) that illustrated the worldwide distribution of marine animals. He was the first to observe that the latitudinal distribution of marine animals was restricted by the cold of winter, not the average temperature. Dana’s chart laid the foundation for the biogeographic regions that are recognized today.

Edward Forbes, the English naturalist who first explored the depth distributions of marine organisms, also drew a map of horizontal distributions that was published (Forbes 1856) in Alexander K. Johnston’s The Physical Atlas of Natural Phenomena. In it, Forbes divided the world’s oceans into 25 provinces located within a series of nine “homoizoic belts.” In his posthumous book, The Natural History of European Seas, Forbes (1859) pointed out the evolutionary significance of zoogeographic provinces. He observed that: (i) each province was an area where there was a special manifestation of creative power, and that the animals originally formed there were apt to become mixed with emigrants from other provinces; (ii) each species was created only once, and individuals tended to migrate outward from their center of origin; and (iii) provinces, to be understood, must be traced back, like species, to their origins in past time.

Samuel P. Woodward published his classic work, Manual of the Mollusca, (1851–1856) but the part devoted to geographical distribution did not appear until 1856. Woodward described 18 marine provinces and located them on a world
map together with the names of typical genera. He was the first to characterize provinces by numbers of endemic species and suggested that endemics constituted more than 50% of the species in each province. Several of Woodward’s molluscan provinces are identical to those that are currently recognized. The next comprehensive work on marine distributions was Sven Ekman’s 1953 book *Zoogeography of the Sea*. This work was an updated English edition of a book originally published in German. It contained a review of all research accomplished until that time. Ekman recognized four climatic zones (warm, warm-temperate, cold-temperate, cold) under various names, and within the zones, he divided the marine world into regions and sub-regions. He discussed regional relationships in detail, paid particular attention to endemism, and speculated on the history of the various faunas. For the following 20 years and beyond, Ekman’s book was the primary reference for marine zoogeography.

The next book to analyze faunal distributions was *Marine Zoogeography* (Briggs 1974). The author’s intent was to continue the work of Ekman, but the enormous amount of new information needed to be organized in a more systematic manner. Within each of the four climatic zones, one or more biogeographic regions were described, and each region consisted of one or more provinces. Provinces were defined as geographic areas containing a minimum of 10% endemic species. So provinces, as Forbes pointed out, were geographic units with evolutionary significance. It was determined that the 20°C isocryme marked the latitudinal limits of the tropical faunas. The faunas of the adjoining warm-temperate provinces were viewed as primarily of tropical derivation. The major zoogeographic barriers and their influence on migration and colonization were identified. Although this volume was based primarily on fish distribution, the described patterns proved to be applicable to several invertebrate groups.

**New developments**

In recent years, numerous volumes on biological oceanography, marine biology, and general biogeography have been published but little attention was paid to the importance of marine provinces and the barriers that separate them. However, continued collecting and analysis (systematic and phylogeographic) produced information of considerable value. The continued migration of species from high-diversity centers to less diverse areas appeared to be a global phenomenon. But phylogeographic research revealed that a few reef fishes had been able to migrate toward higher diversities. It became practical to distinguish between hard and soft (semipermeable) biogeographic barriers; the latter proved to be important for the stimulation of parapatric or sympatric speciation. Accommodation was proposed as a theory to explain the acceptance of invasive species by native species that occupied the appropriate habitat. A re-evaluation of existing provinces, description of new provinces, and world maps illustrating all the marine regions and provinces were published (Briggs and Bowen 2012).

As the various provinces became better known, it became apparent that speciation, resulting in the development of high diversity, was not taking place evenly throughout each province, but was concentrated in smaller areas, called centers of origin, within some of the large provinces. In the case of the Coral Triangle (CT), a small part of the huge Indo-Polynesian Province, its diversity concentration had been known for many years. Diverse opinions had been expressed about the origin of the CT. Did it represent an
accumulation of species formed elsewhere, an overlap of Indian Ocean and Pacific biotas, or a center of evolutionary innovation and distribution? Recent research appears to have solved the problem. The CT has apparently passed through three developmental stages: (i) origination via migration from the Tethys Sea to the East Indies, (ii) speciation in place, and (iii) outward dispersal during the past 10 million years. There is also a “feedback” mechanism by which species in outlying provinces can occasionally penetrate and add to the diversity of the CT, as well as to the Caribbean center (Bowen et al. 2013).

In the Caribbean Province the highest diversity among the invertebrates occurs from Cuba along the Antilles arc to Colombia and Venezuela. This may be true for the fishes as well. In the Eastern Tropical Pacific, shore fish diversity peaks along the mainland coast of Costa Rica and Panama as well as at the tip of the Baja Peninsula. In the North Pacific, there are two centers of origin, one on each side of the Bering Sea.

The world’s greatest diversity of marine organisms, at least within the corals, molluscs, fishes, and mangroves, occurs within the CT. The location of world’s highest diversity of reef fishes, at least 1426 species, exists in the vicinity of the Bird’s Head region of Indonesia at the extreme western end of New Guinea. In their book, Reef Fishes of the East Indies, Allen and Erdman (2012) identified Cenderawasih Bay, West Papua, as a living laboratory of evolution due to its numerous short-range endemics. It has become clear that the CT does not comprise a single center of origin but contains multiple centers. A general characteristic of centers of origin is high species diversity, indicating an enhanced level of competition which produces dominant species that can spread into less diverse areas. As such species become accommodated in peripheral habitats they increase community biodiversity, stability, and productivity. At the same time, speciation has continued to take place in other parts of the world ocean resulting in a general buildup of biodiversity that has been apparent since the early Pleistocene. Although many marine species have small populations due to overfishing and habitat destruction, there have been very few extinctions. Therefore, despite speculations to the contrary, biodiversity loss in the sea has yet to occur and there is still opportunity to rescue threatened populations through prompt application of conservation measures.

The deep ocean

Below the continental shelf, the benthic deep sea consists of the continental slope (200–4500 m), abyssal plain (4500–6000 m), and the hadal zone of the trenches (6000–11000 m). The pelagic parts of the deep sea are often called bathyl or bathypelagic. The distribution patterns of organisms in these environments are poorly known, so that it has not often been possible to positively identify biogeographic relationships. About 84% of the ocean floor exceeds a depth of 2000 m. The enormous size of the deep sea, and the difficulty of adequately sampling its fauna, has prevented an overall characterization of biogeographic regions and provinces. Although generalizations remain elusive, many taxa appear to be broadly distributed across the deep-sea floor.

Broad distributions are apparent not only among soft-bottom taxa across the abyssal plain, but also in highly patchy environments such as hydrothermal vents and seamounts. Species in methane seeps and large food-fall (whale carcass) communities may have more restricted ranges but undersampling is a problem. At the generic level, evidence indicates high levels of
cosmopolitanism across all habitats. Many taxa display an amazing ability for larval dispersal, which may be augmented by extended larval development in cold deep waters. Dispersal apparently increases with depth but there are barriers consisting of currents with contrasting temperature and salinity, land masses, and other topographic structures. These barriers might define general biogeographic patterns, although many of them are semipermeable for numerous species.

Some distributional patterns bear the signature of historical events as evidenced by multiple points of evolutionary origin and the apparent role of deep-water oxygen concentrations. All current evidence points to a deep-sea fauna comprised of taxa, neither entirely old nor entirely young, filtered through many climatic fluctuations. Far less than 1% of the deep sea has been sampled, which is the primary impediment to the discernment of biogeographic patterns. Furthermore, the sampling of the deep-sea floor done so far has been concentrated in the Northern Hemisphere in proximity to American and European oceanographic institutions, preventing widespread biogeographic syntheses. Rare species, especially those that are narrowly distributed, are difficult to sample in the deep sea. This may lead to an overestimation of the contribution of broadly distributed species to biodiversity.

Future deep-sea research needs to concentrate on sampling over broader geographic areas, on phylogeography in order to clarify timing and points of origin for deep-sea invasions, and on species identifications via systematic and molecular studies than can characterize each deep-sea habitat. This kind of research, compared to that in shallow water locations, is relatively expensive and time-consuming but necessary in order to obtain an adequate knowledge about an environment that extends over 66% of the Earth’s surface.

That the ocean flows, and not just from the immediate effect of the local wind, has probably been recognized ever since humans have lived near coasts with tides. The Ancient Greeks were aware of strong currents in the Atlantic, beyond the Strait of Gibraltar, over 2500 years ago, while Polynesian seafarers implicitly understood the interactions between winds, waves, and currents, enabling them to navigate across open stretches of the Pacific for thousands of years. However, it wasn’t until the Age of Discovery that knowledge of surface ocean currents began to be compiled in a systematic way, and not until William Dampier’s 12-year circumnavigation of the globe (1679–1691) that the principal features of surface ocean circulation were first mapped. With Benjamin Franklin’s investigations of the Gulf Stream in the eighteenth century, Matthew Maury’s wind and current charts of the second half of the nineteenth century, and finally the global Challenger Expedition of 1872–1876, oceanography came of age. Developing understanding of the theory of ocean circulation has occurred ever since, and the World Ocean Circulation Experiment (1990–1998; Ganachaud and Wunsch 2000) produced a global perspective of ocean properties and currents to act as a baseline for interpreting the influence of climate change into the future. Nevertheless, discoveries continue being made, particularly in the polar seas and of the thermohaline circulation in the deep ocean, so this entry is a snapshot of our knowledge of current oceanic circulation.

Surface circulation

The surface oceanic circulation is largely forced by a mixture of surface winds and atmosphere–ocean exchange of heat and freshwater. The effects of tides are largely ignored here (but see the thermohaline section) as they lead to minor consequences for much open ocean circulation. The physical stress of the wind on the surface of the ocean – the wind stress – is the most obvious direct atmospheric forcing; however, it does not lead to direct acceleration of oceanic currents. Wind-driven currents actually come about due to a combination of forces in the ocean. The first of these is the direct effect of the wind on the surface waters. During Fridtjof Nansen’s expedition into the Arctic during 1892–1895 he noticed that the sea ice in which his ship, the Fram, was trapped moved 20–45° to the right of the wind direction. Ten years later, Vagn Walfrid Ekman, a Swedish oceanographer, developed what is now known as Ekman theory to explain this observation through a surface force balance between the wind, the Coriolis force, due to the Earth’s rotation, and friction. However, the frictional effect is transmitted layer by layer down through the upper 100 m or so of the ocean – the Ekman layer – leading to a spiralling velocity with depth. The mean flow in this layer is due to the overall balance between the wind stress and the Coriolis force accumulated with depth, leading to the Ekman transport, a net flow in this layer 90° to the right of the surface wind direction in the Northern
Hemisphere and to the left in the Southern Hemisphere. Ekman transport is a fundamental process affecting flow, and sea level, within the upper ocean (Figure 1). It underlies the reason for the existence of circulatory features of the ocean circulation – the oceanic gyres – shown in Figure 2, as well as the extensive zones of coastally upwelled water found along the eastern boundaries of the subtropical gyres.

However, in producing divergence and convergence of water and sea level slopes, pressure gradients are set up in the ocean that tend to add an additional force in the upper ocean. The final force balance from wind, Coriolis force, and wind-induced pressure gradients leads, on the large scale, to net upper ocean flow slightly to the right of the wind in the Northern Hemisphere. It also results in the main features of the global surface ocean circulation (Figure 2). Thus subtropical gyres are maintained in each ocean basin through this force combination by the overlying atmospheric circulation. Similarly, in the more poleward latitude band of 50–70°, oppositely rotating subpolar ocean gyres, always strongly geographically controlled by basin coastline shape, are driven by a constant succession of traveling low pressure systems. In the Southern Hemisphere, because all the ocean basins are linked by the Southern Ocean, with strong westerly winds above, a global-scale pressure gradient is set up between the high sea levels of the subtropics and the low sea level towards Antarctica. The latter is due to a combination of Ekman transport northwards and the dense, cold waters in the subpolar regions. This global-scale pressure gradient leads to a strong eastward flow called the Antarctic Circumpolar Current (ACC) encircling the Earth between approximately 50 and 60° S and extending 2000–2500 m below the surface. It is one of the strongest ocean currents on the planet, with a mean flux of approximately 130–140 Sv (1 Sverdrup = 1 Sv = 10⁶ m³s⁻¹).

The ACC meanders in places, due to interaction with seafloor topography and the narrowing of the flow as it passes through Drake Passage; it plays a significant role in the thermohaline circulation.

In the tropics, the south-north transition from westward-flowing South Equatorial Current through eastward-flowing Equatorial Countercurrent back to westward-flowing North Equatorial Current is also driven by the combination of meridional variation in wind stress and the sea level pressure gradient, modulated by seasonal shifts in the Intertropical Convergence Zone. Along the equator, the absence of the Coriolis force leads to a strong, equatorially
confined current approximately 100–200 m below the surface, along the thermocline, called the Equatorial Undercurrent, predominantly maintained by the balance of the westward wind stress and the eastward pressure gradient set up within the ocean by a resulting sea level slope. In the Indian Ocean, because of the dramatic seasonal wind reversal associated with the monsoon, this is only a boreal winter feature.

The subtropical oceanic gyres have an additional characteristic, namely that the poleward flow on their western side is largely confined to a narrow (≈100 km), deep (≈1000 m), and strong (≈2.5 ms$^{-1}$) boundary current. In the North Atlantic this is well known as the Gulf Stream, extending past the Florida Keys along the United States’ East Coast, separating from the shore near Cape Hatteras (≈40°N) before crossing the Atlantic towards northern Europe. However, each subtropical gyre possesses a similar feature. These western boundary currents occur because of the additional constraint that the water in a gyre needs to conserve angular momentum, in terms of a quantity better known in oceanography as potential vorticity, as both the Coriolis force and the rotation of the gyre change as water travels around the gyre. Where western boundary currents leave the coast and move into the ocean proper there are key locations for smaller scale (up to a few hundred kilometer) eddy formation and current meanders, supported by baroclinic instability along the strong horizontal temperature gradients typically found here. These features are major mechanisms by which water of different temperature and salinity properties is mixed horizontally, often accompanied by pronounced changes in marine biological productivity.

The pressure gradient forces set up by wind-driven sea level changes are further modified by the impact of heat, precipitation, and evaporation on the upper ocean density. Warming
the ocean or adding freshwater through rainfall or river inflows will lower ocean density, and allow the sea level to rise. Cooling the ocean or evaporation will raise ocean density, leading to a lowering of sea level. These changes will further modify the observed upper ocean circulation, and we will see their fundamental importance for driving the global thermohaline circulation in the next section.

Thermohaline circulation

The thermohaline circulation, often known as the Meridional Overturning Circulation, is the main oceanic circulation by which water is transported on a global scale. Components link all the ocean basins, allowing water to be mixed horizontally and vertically to such an extent that no part of the ocean contains water that was last exposed to the surface more than about 1500 years ago. The thermohaline circulation can also be thought of as the way by which the surface ocean circulation, which we have seen is predominantly driven by winds, connects to the deep ocean circulation, largely driven by density differences, through processes that transform the temperature and salinity properties of the water between extremes. The principal driving force of the thermohaline circulation is therefore the densification of surface water, allowing it to sink to a deeper surface of neutral buoyancy. This densification can occur in several ways. Heat can be extracted from seawater to the atmosphere by either latent or sensible heat transfer, cooling, and densifying, the water. Water can be evaporated from the ocean surface, leaving saltier, and hence denser, water behind. Finally, during the formation of sea ice at the ocean surface, a significant proportion of the salt from the freezing seawater is expelled into the water remaining, increasing salinity, and hence, density.

If each of these mechanisms is sustained, the upper ocean water will be made dense enough to convect to a deeper level of neutral buoyancy. When deep water is formed by this mechanism the convection does not occur spontaneously over the whole of a region where the particular process acts, but in preconditioned plumes, and concentrated in small (≈1 km) chimneys. These lead to mixing with the surrounding water and the effective transfer of properties from the surface to depth (Marshall and Schott 1999).

These regions of convection tend to be regional rather than basin-scale in extent, as much of the near-surface ocean is stratified all or most of the time. The deepest waters are formed where salinity is the driver of convection. At locations around the Antarctic continental shelf, but particularly in the Weddell and Ross Seas, sea ice formation leads to both cooling and salinification of water during the autumn and winter. This dense water sinks, and cascades off the shelf into the abyssal ocean. It then spreads north at depth, as cold, relatively salty, Antarctic Bottom Water (AABW). This is particularly noteworthy in the Atlantic, where deep water properties suggest some AABW penetrates into the mid-latitude North Atlantic from an original production of approximately 27 Sv. Cooling and salinification by sea ice formation also occurs on the Eurasian continental shelf of the Arctic, leading to the deepest waters of the Arctic Ocean, and a component exiting at depth through the Fram Strait into the Greenland-Norwegian Sea. Raised salinity is also crucial to deep water formation in the Mediterranean and Red Seas, but because of evaporation. The Mediterranean has a background salinity more than 10% greater than that of the Atlantic, so winter cooling by strong northerly winds leads to deep water formation in all its three main basins. About 1 Sv of this water leaves the Mediterranean through
the deeper parts of the Strait of Gibraltar, supplying a layer of relatively warm and salty water at mid-depths (≈1000–1500 m) in the central North Atlantic. Through winter mixing in the Atlantic this can help precondition the already salty upper ocean waters of the Atlantic for later convection in the basin’s northern seas. In contrast, the Red Sea water is made dense by intense summer evaporation, leading to warm salty water crossing the shallow sill into the North Indian Ocean, and spreading out, also at depths of around 1000–1500 m.

Cooling of surface waters is the dominant producer of deep and intermediate water in other regions of the globe. In the North Atlantic, principally in the Greenland, Irminger, and Labrador Seas, winter cooling of the relatively salty water of the Atlantic leads to deep water formation to a depth of up to several thousand meters, depending on the year and location. This, with an admixture of Arctic water, becomes North Atlantic Deep Water (NADW). About 20 Sv of this water is created, although the flux south at the only long-term monitoring transect of 26°N varies strongly seasonally and interannually (Srokosz et al. 2012). NADW spreads south in the Atlantic, with a stronger western boundary current at depth, eventually entering the Southern Ocean and mixing with water of other origins to form Circumpolar Deep Water, and hence entering the Indian and Pacific Oceans.

Other regions where large-scale intermediate depth water formation occurs are in the Southern Ocean, in the Antarctic Polar Front Zone between 50 and 60°N, where Antarctic Intermediate Water is formed, and in the North Pacific, north of the Kuroshio Current, where North Pacific Intermediate Water forms. Both of these water masses form due to winter cooling of relatively fresh seawater, beneath mid-latitude storm belts, and spread equatorward at depths of approximately 1000 m.

The deep waters of the global ocean described above eventually mix back to the surface ocean, to be drawn into the surface return flow of the thermohaline circulation. This mixing proceeds in a number of ways. There is a weak upward diffusion of water over the global oceans, but this is at an order of magnitude too small to explain the 1500-year residence time of water in the thermohaline circulation. However, much stronger mixing is concentrated in a number of geographically confined regions to compensate for the weak background mixing. A substantial amount of this stronger mixing is forced from the surface by the strong winds blowing over the weakly stratified Southern Ocean, but leading to mixing through eddies to considerable depths (Marshall and Speer 2012). Another substantial component of localized mixing occurs in the deep ocean, in regions of rough topography. A range of interactions between the ocean flow and this topography leads to enhanced mixing: tidal amplification through deep passages and shallower seas, eddy shedding, and the generation of internal waves. Note that while the oldest water in the global ocean is in the North Pacific, the processes leading to upwelling of the deep component of the thermohaline circulation occur throughout deep water flow, with especial concentration in the Southern Ocean.

The return flow of the thermohaline circulation acts to link the upper ocean circulation of the three main basins of the Pacific, Indian, and Atlantic Oceans. From the Pacific there is significant flux of water both westward into the Indian Ocean between the Indonesian islands, and eastward as part of the ACC, through Drake Passage into the South Atlantic. The former, called the Indonesian Throughflow, varies significantly from year to year (≈7–15 Sv), and supplies warm and fresh water to the Indian Ocean. The latter moves cold water between the Pacific and Atlantic. Most of this remains in the
OCEANIC CIRCULATION

ACC, but it is believed that approximately 6 Sv of this cold, fresh water from the Pacific enters the South Atlantic circulation as part of the East Falklands Current (Speich, Blanke, and Madec 2001).

The Indonesian Throughflow feeds into the Equatorial Currents of the Indian Ocean, helping fuel the western boundary current of the South Indian Ocean—the Agulhas Current—that flows southward along the southeastern coast of Africa. Most of the water in this current forms part of the South Indian Ocean subtropical gyre and so retroreflects towards the east, to the south of Africa. However, a component, perhaps 11 Sv, is entrained in the stream of warm core eddies that are shed from the tip of South Africa during this process (Speich, Blanke, and Madec 2001). These move northwestward, and are entrained in the equatorward arm of South Atlantic subtropical gyre circulation. This episodic process therefore acts as a warm water route by which surface waters re-enter the Atlantic following upwelling from the deep ocean further afield.

Once surface waters return to the Atlantic, a pathway exists whereby some of the water can be transported north, first in the South Atlantic subtropical gyre, then westward across the Atlantic in the Equatorial Current system, and finally northward into the Caribbean to be entrained into the beginning of the Gulf Stream off southern Florida. The Gulf Stream, and then the North Atlantic Drift crossing the Atlantic further north, returns water to the main North Atlantic convection regions, allowing the thermohaline cycle to be repeated. As a southerly component of the North Atlantic Drift, the Azores Current allows approximately 1 Sv of this water to enter the Mediterranean at the surface, also providing water to the Mediterranean arm of the thermohaline circulation.

The future of the study of the oceanic circulation

Much, although not all, of the description of the oceanic circulation given here has relied on the burgeoning of observational studies of the ocean over the last few decades. This is continuing apace. Over the last decade the Argo float program has led to an unprecedented knowledge of the seasonal and interannual variation of temperature, salinity, and currents in the top 2000 m of the ocean, and this looks likely to be maintained in the long term. Satellites have provided global measurements of sea surface temperature, sea level, and sea ice cover, amongst other variables, over the past few decades. Since 2011 it has also become possible to measure surface salinity from space. There are also a number of long-term programs to measure key fluxes in the global oceanic circulation. However, numerical, mathematical models of the ocean circulation have also become an important tool for studying the ocean, since their first development in the 1960s. Ocean models provide the opportunity to understand flows where observational data are not readily available, and to simulate interannual variability, which is still poorly observed in most locations. Ocean, and climate, models also permit study of how oceanic circulation is likely to respond to current and future changes in greenhouse warming. For example, for some years, and reaffirmed by the most recent model results from the 2014 Intergovernmental Panel for Climate Change Working Group 1 Scientific Report, climate models have been predicting a steady decline in the strength of the thermohaline circulation over the next century, which would have significant effects on the rate of climatic change, particularly over the North Atlantic and western Europe, but also further afield. It is known from study of paleoclimate and paleoceanographic records that the ocean circulation has changed abruptly on
occasion in the past; models allow the possibility of advance warning of such abrupt climate change. The World Ocean Circulation Experiment provided a snapshot of oceanic circulation in the 1990s, but environmental change means oceanic circulation will continue to evolve into the future.

Ocean basins

The World Ocean occupies about 71% of the Earth’s surface (Figure 1). Geographically, the World Ocean is divided into four individual ocean basins by continents. In descending order by area, they are the Pacific, Atlantic, Indian, and Arctic Oceans. The first three include their corresponding Southern Ocean region. While each basin has its own geographic distinction, all basins own some common features. They are the continental shelf (a shallow ledge next to the edge of the continent), the continental slope (a slope extending from the shelf toward the deep sea), the continental rise (a gentle slope at the foot of the continental slope), and the abyssal plain (ocean floor of the deep sea). Approximately 76.7% (in volume) of the World Ocean is occupied by the abyssal plain, 7.4% by continental shelf, and 15.9% by continental slope and rise. The abyssal plains are also filled with ridges and trenches. The deepest trench is the Mariana trench in the western Pacific, which is about 11 km deep.

The Pacific Ocean is the largest of all. It spans a zonal distance of approximately 20 000 km from the Strait of Malacca to Panama in the tropics, and a meridional extent of over 15 000 km from the Bering Strait to Antarctica. With all its adjacent seas (a sea is a division of an ocean or a large body of salt water partially enclosed by land) it covers \(178 \times 10^6\) km\(^2\) and represents 40% of the World Ocean surface, equivalent to the area of all continents. Without its southern ocean part the Pacific occupies \(147 \times 10^6\) km\(^2\), about twice the area of the Indian Ocean. This vast ocean facilitates strong air–sea interaction, and is the home for the ocean–atmosphere coupled climate phenomenon: the El Niño Southern Oscillation (ENSO).

The Atlantic Ocean differs from the Pacific in that it has a full meridional extent, from the Arctic Ocean to the Antarctic continent. In comparison, its zonal extent is small, with the largest distance approximately 8300 km between the Gulf of Mexico and the coast of northwest Africa. The full north-south extent exposes the ocean to the cold and dry air in the northern North Atlantic during winter, which cools the ocean and results in sea ice formation. Since the freezing point of saline seawater is \(-2^\circ\)C and that of fresh water is 0°C, fresh water freezes up first, leaving the ocean more saline after sea ice forms. The colder and more saline surface water increases surface density, which induces wintertime oceanic convection when heavier surface water sinks down and forms deep water. This comprises the sinking branch of the Atlantic and global thermohaline circulation (Figure 1). The Atlantic has the largest number of adjacent seas. The Mediterranean Sea produces Mediterranean water mass. Including all adjacent seas, the Atlantic Ocean covers \(106 \times 10^6\) km\(^2\). Variability of the thermohaline circulation can have a large influence on global climate (see “Ocean circulation,” below).

The Indian Ocean is small in comparison with the Pacific and the Atlantic. Different from the other two oceans, the Indian Ocean is bounded by the Asian landmass to the north, and its
northern boundary is located in the tropics. One consequence of this geographic location is that the Indian Ocean is subject to the strong influence of the monsoon, a seasonal reversing wind accompanied by changes in precipitation due to an uneven heating rate between land and ocean. Its meridional extent is 9600 km, from the Antarctic to the inner Bay of Bengal, and its zonal extent is 7800 km, from South Africa to West Australia. Including the southern ocean region, it covers $74 \times 10^6$ km$^2$.

The Arctic Ocean covers the Arctic north polar region. It is the smallest among the four and covers an area of about $14 \times 10^6$ km$^2$. Much of the ocean is covered by sea ice. The sea ice covered area varies with season, with maximum sea ice extent occurring during fall and winter. The Arctic Ocean is connected to the North Atlantic through the Denmark Strait between Greenland and Iceland, via the opening between Iceland and Europe, and to a lesser degree through the Canadian Archipelago. It is also connected to the Pacific through the narrow and shallow Bering Strait (45 m deep and 85 km wide). On the annual mean, seawater from the North Pacific flows into the Arctic, and subsequently exits the Arctic into the North Atlantic. The Arctic Ocean also exports sea ice into the Atlantic Ocean.

The three major oceans are also interconnected. The Pacific is linked to the Indian
Ocean via the Indonesian Throughflow near the Indonesian Archipelago, where fresher and warmer upper-ocean water from the Pacific enters the South Indian Ocean, flows westward, and part of it enters the Atlantic around the southern tip of Africa. The Indonesian Throughflow is an integral part and a choke point of the global ocean conveyor circulation (Figure 1).

Temperature

Temperature of the ocean varies at a wide range, from nearly freezing point at the poles to above 32°C in some regions of the tropical oceans, such as the Indo-Pacific warm pool of the tropical east Indian and west Pacific Oceans (Figure 2). Various instruments have been used to measure the temperature of the surface and subsurface ocean. They include bathythermograph (old method), expendable bathythermograph (XBT), CTD (conductivity, temperature, and depth), and protected/unprotected reversing mercury thermometer on board ships; thermistors on moored buoys, drifting buoys, and profiling floats (e.g., Argo floats). The sea surface temperature (SST) is the temperature close to the ocean surface. The SST values measured by in situ instruments usually represent bulk temperatures at a depth near the surface within the surface mixed layer, where seawater is fairly mixed by wind and turbulence and its density varies little with depth. Depending on the instrument type, the measurement depth of SST can vary from less than 1 m to approximately 20 m. Generally, temperature is high at the ocean surface and decreases with the increase of depth. In the subsurface ocean below the mixed layer there is a layer of water in which temperature decreases more rapidly with depth than it does in the layers above or below. This layer is known as the thermocline.

In recent decades, satellite-derived SST data have become available, including the SST dataset from the Advanced Very High Resolution Radiometer (AVHRR) on board the National Oceanic and Atmospheric Administration (NOAA) satellite since the 1980s, and the SSTs from the National Aeronautics and Space Administration (NASA) Tropical Rainfall Measuring Mission (TRMM)-Microwave Imager (TMI) since 1997. The AVHRR cannot look through clouds, while TMI can penetrate clouds but the data can be contaminated by strong precipitation. Generally, the satellite-observed and in situ measured SSTs agree; however, there are systematic discrepancies, because the satellites detect “ocean skin” temperatures within approximately the top 1 mm, whereas in situ measurements observe bulk temperature below the surface. Very few in situ measurements of the surface skin temperature are made on a regular basis, so the satellite SST data have been calibrated primarily by the bulk SST of in situ observations.

The SST is an important ocean variable that directly affects atmospheric convection (cloud, precipitation) and wind. It is therefore important for climate variability and change. For this reason, the dominant SST pattern and temporal variations are often used to identify natural climate variability modes on various timescales. For example, ENSO, which is an interannual climate mode of the tropical Pacific with a period of 2–7 years, Indian Ocean Dipole (IOD), and Atlantic Multidecadal Oscillation are all characterized by distinct spatial patterns of SST anomalies with temporal variations. They have large impacts on regional and global climate and can cause devastating floods and droughts in various regions around the globe.

Wide-ranging observational evidence shows that the World Ocean has been warming in the past few decades. Earth receives more energy
from the sun than that exits the top of the atmosphere and thus it has gained substantial energy, with most of the energy gain entering the ocean. The global upper ocean (0–700 m) has warmed and thus the upper ocean heat content has increased between 1971 and 2010. It is likely that the upper ocean has also warmed between the 1870s and 1971. The global total ocean (full depth) has stored about 93% of the warming, and the upper 0–700 m ocean has accounted for about 64% (IPCC 2013, section 3.2). The increased concentrations of human-induced greenhouse gases are shown to cause more than half of the observed increase in global average surface temperature from 1951 to 2010. The ocean warming can have various climatic, environmental, and social consequences, such as increased intensity of storm surges in certain coastal areas, sea level rise, coral bleaching, and increased drought or floods in some land areas owing to atmospheric circulation change induced by the ocean warming.

**Salinity**

A primary difference between seawater and pure water is the oceanic salinity. Salinity is defined as the number of grams of dissolved matter in one kilogram of seawater. Ocean temperature and salinity, together with pressure, determine seawater density. Due to the presence of salinity, the freezing point of seawater is lower (\(-2 \degree C\)) than that of fresh water. The oldest method for measuring salinity is to evaporate seawater with known weight and then weigh its residual. Later, the laboratory classical Knudsen method was used to determine the amount of chlorine, bromine, and iodine to give “chlorinity,” and then relate salinity to chlorinity by the equation: salinity = 1.80655 × chlorinity. This method was used until the International Geophysical Year in 1957. More recent methods determine salinity by measuring conductivity of seawater, such as salinity obtained by CTD. Salinity computed through conductivity is more closely related to
the actual dissolved constituents than chlorinity is, and is more independent of salt composition. Because the measurement is based on conductivity rather than mass, the Practical Salinity Scale (unitless) was introduced in 1978. In 2010, the Thermodynamic Equation of Seawater 2010 (TEOS-10) was introduced, which uses absolute salinity $S_A$ (mass fraction of salt in seawater, expressed in g/kg) as opposed to Practical Salinity. As SST, sea surface salinity measured by in situ instruments is the salinity close to the ocean surface. In June 2011, NASA’s Aquarius instrument aboard the Argentine SAC-D satellite was launched. It provided weekly global maps for ocean surface salinity, the skin salinity of the top approximately 1 cm depth, from August 2011 to June 2015.

Sea surface salinity is often referred to as nature’s rain gauge for detecting the global water cycle. In the open ocean, its value generally ranges from 32 to 37. In coastal oceans, salinity can be much lower adjacent to river mouths or melting land ice areas, and much higher near a concentration basin such as the Red Sea, the Persian Gulf, or the Mediterranean Sea. In tropical and subtropical open ocean basins, salinity is generally low in regions where precipitation is strong and exceeds evaporation, such as the Intertropical Convergence Zone (ITCZ), and high where precipitation is low and smaller than evaporation, such as the subtropical Atlantic, the subtropical Pacific, and the Arabian Sea of the Indian Ocean (Figure 3). As a result, changes in precipitation, evaporation, river discharge, and melting of land-based ice can all alter sea surface salinity. In addition, changes in ocean circulation can also affect salinity distribution via advection process.

Recent observational studies indicate that globally, sea surface salinity has increased over the past few decades in regions where evaporation exceeds precipitation and decreased in regions of excess precipitation. This spatial pattern of sea surface salinity changes is consistent with the notion that saltier regions get saltier and fresher regions get fresher under global warming. The surface freshening at mid-to-high latitudes extends downward and equatorward to intermediate depths, primarily through subduction of the fresher surface water into the thermocline, and subsequent advection of salinity anomalies by the mean current within the thermocline (e.g., Durack and Wijffels 2010). The observed salinity changes cannot be explained by natural variability, either internal to the climate system or from external forcing by variations in solar output and volcanic eruptions (e.g., Pierce et al. 2012); rather, they are consistent with the changes expected due to anthropogenic greenhouse gas-induced warming and the resultant amplification of the global hydrological cycle.

### Sea level

The local sea level is defined as the height of the sea with respect to a land benchmark. The local mean sea level (LMSL) is the sea level averaged over a period of time that is sufficiently long (such as a month or a year) to smooth out the fluctuations caused by waves and tides. Sea level variability and change can have direct impacts on coastal and island communities, economy, and natural environment such as marine ecosystems.

On a global mean, sea level variations can be induced by two causes: variation in the ocean basin shapes and change in the volume of ocean water. The variation of the ocean basins can result from vertical land movements, which occur because of isostatic adjustment of the mantle to the melting of continental ice sheets at the end of the last ice age and/or plate tectonics such as earthquakes. The isostatic adjustment happens because the weight of the continental
ice sheets depresses the underlying land, and when the ice sheets melt away the land slowly rebounds. The volume change of ocean water can result from a change in water density or a change in the mass of the ocean. Changes in water volume, and thus sea level, due to changes in density, which in turn result from thermal expansion (water volume expands as ocean water warms) and salinity variations, are referred to as steric change. For the global mean, changes in water density are primarily caused by thermal expansion, while salinity variations are also important in local and regional sea level variations. Changes in ocean mass are determined by water exchange with the continents. Melting of continental ice in a warming climate will increase the ocean mass and volume.

Regionally, changes in atmospheric pressure, ocean currents, and ocean temperature and salinity, which are closely linked to climate variability and change, can affect the LMSL as well. For instance, ocean circulation driven by
the anomalous winds associated with ENSO can cause large-amplitude sea level variability in the central and eastern equatorial Pacific and along the coasts of North and South America. ENSO-induced changes in the hydrological cycle can also cause global mean sea level variations (Cazenave et al. 2012).

Over the last century or so, tide gauges have been primarily used for observing sea level variability and change. Tide gauges, usually placed on piers, measure the local sea level relative to a nearby geodetic benchmark. Vertical land movements affect tide gauge measurements. During the past two decades, reliable measurements of global scale sea level from satellite altimetry have become available following the launch of TOPEX/Poseidon in 1992, which was followed by the Jason-1 satellite in 2001 and the Jason-2 satellite in 2008. The ocean surface elevation variations are mapped using measurements of sea surface height relative to Earth’s geoid by these satellites. The geoid is the shape that the ocean surface would take under the influence of Earth’s gravitation and rotation alone without other influences such as ocean circulation and tides. On the geoid surface, all points have the same gravitational potential energy. The geoid and the Earth’s pole may readjust with the changes in ground-based ice volume, which can affect local and regional sea level. Corrections are often made to tide gauge data to remove the vertical land movement effect, in order to obtain sea level signals that result from climate variability and change.

Tide gauge and satellite observations show that the global mean sea level is rising, and this rising sea level is likely caused by thermal expansion and land ice melt associated with global climate change. Over the twentieth century, the global average sea level rise is estimated to be \(1.7 \pm 0.2 \text{ mm year}^{-1}\), and this rate has increased to \(3.2 \pm 0.4 \text{ mm year}^{-1}\) since the early 1990s (IPCC 2013, section 3.7). Spatial patterns of global-scale sea level change have been detected since October 1992, when high-quality satellite altimetry measurements became available. In the western tropical Pacific, the rate of sea level rise since the early 1990s has been much faster than that of the global mean. This rapid sea level rise results from the combined effect of decadal climate mode – the Interdecadal Pacific Oscillation – and warming of the tropical Indian and Atlantic Oceans (e.g., Han et al. 2014; England et al. 2014).

Except for nonclimatic events like tsunamis, extreme sea level events (e.g., coastal flooding, high water events, storm surges, etc.) are often caused by storms, particularly when they occur with high tides. The IPCC (2013) report has projected that the global mean sea level will continue to rise throughout the twenty-first century. Sea level rise due to human-induced global warming has been suggested to be a major threat to low-lying coastal areas and island countries around the globe, because they might be facing increased risks of inundation, coastal erosions, and in some regions increased intensity of extreme sea level events (Church et al. 2010; IPCC 2013, Chapter 3). As such, understanding, monitoring, and predicting global and regional sea level variability and change are important tasks for adaptation. Sustained in situ and satellite observations are essential for carrying out these tasks.

Ocean circulation

The ocean is not static; rather, it is in constant motion. An ocean current is a continuous, directed movement of seawater generated by the forces acting upon the ocean. For instance, tidal currents are driven by gravitational pull of the moon. Horizontal current speeds have
a wide range, from approximately 200 cm/s in the swift western boundary currents (Gulf Stream, Kuroshio, Somali Current, etc.), through 10–100 cm/s in the equatorial currents, to a fraction of 1 cm/s in much of the surface layer and in the deep ocean. Vertical speeds are much less, in the order of $10^{-5}$ cm/s. Due to its slow speed, vertical current is difficult to measure within the levels of an instrument’s accuracy. Both direct and indirect methods are used to estimate horizontal currents. Surface drifters, subsurface floats, current meters, and acoustic Doppler current profilers are all used to directly measure ocean currents. “Geostrophic method” is also used to infer ocean current, based on the fact that large-scale ocean circulation generally obeys geostrophic balance. Due to the Earth’s rotation, currents are deflected to the right in the Northern Hemisphere and to the left in the Southern Hemisphere. This effect is known as the “Coriolis force.” The deflection causes highs and lows of pressure directly proportional to the speed of the currents, referred to as “geostrophic currents” due to the balance between the Coriolis force and the pressure gradient force – referred to as “geostrophic balance.” Based on geostrophy, the global sea surface heights derived from satellite altimetry (see “Sea level,” above) are often used to infer global surface ocean circulation.

Ocean circulation is referred to as the large-scale movement of waters in the ocean basins. There are two types of basin- and global-scale ocean circulations: wind-driven ocean circulation and thermohaline circulation. For wind-driven ocean circulation, the most prominent features are the “subtropical gyres,” which prevail at the upper approximately 500 m of the subtropical oceans, and their deep parts can reach 1–2 km near the western boundary region, together with the equatorial current systems, subpolar gyres, and Antarctic circumpolar current. The wind-driven surface currents consist of two parts: a directly wind-forced component (Ekman drift) and a geostrophic current associated with the gradient of sea surface height. Surface wind also forces shallow meridional overturning circulations in the upper approximately 700 m tropical and subtropical oceans, known as the subtropical cells. They transport heat from the upper equatorial ocean to the subtropics, where the water gets cooled and subducted into the thermocline due to wind-driven, surface mass convergence. The colder, thermocline water subsequently flows back into the tropics, where it upwells to the ocean surface and completes the shallow overturning cells.

By contrast, thermohaline circulation is a large-scale, deep circulation depending on variations of temperature (thermo) and salinity (haline). It transforms low-density upper ocean waters from the tropics to higher-density intermediate and deep waters in high latitude, such as the northern North Atlantic away from the pole, where surface water gets cooled and may also get salty due to sea ice formation. Both lead to increased surface density and thus deep-water formation. While the conversion to dense waters of the thermohaline circulation occurs in restricted regions at high latitudes, the return to the surface involves slow upwelling, mixing, and diffusive processes over much larger geographic regions (Figure 1). The thermohaline circulation is frequently used synonymously with the deep Meridional Overturning Circulation (MOC), even though the MOC also includes a wind-driven component (IPCC 2013, AIII-19, 29).

The ocean can influence climate by storing heat and then gradually releasing it to the atmosphere to drive atmospheric convection and circulation. Meanwhile, variations of ocean circulation can affect climate by transporting large amounts of heat, fresh water, and carbon,
OCEANS AND CLIMATE

and exchanging these properties with the atmosphere. Changes in ocean circulation, therefore, can have direct impacts on regional and global climate. The cold, Younger Dryas event that occurred about 11,500 years ago is thought to be contributed from the shutdown of the Atlantic MOC (AMOC) due to the large quantity of freshwater influx from the melting land-based ice, which reduced sea surface salinity and density, and therefore stopped the deep water formation in the North Atlantic Ocean. The weakened AMOC reduced northward heat transport and thus caused North Atlantic cooling. It is possible that the cold SST of the North Atlantic induced changes in atmospheric circulation, which helped to spread the cooling to a global scale (Rahmstorf 2002). Climate model simulations suggest that the AMOC very likely will weaken over the twenty-first century relative to preindustrial values, due to the surface warming and melting of continental ice (IPCC 2013, section 3.6). Modeling studies suggest that a weakened AMOC can have important implications for regional acceleration of sea level rise along the northeast coast of the United States (Yin, Schlesinger, and Stouffer 2009). Further observational and modeling studies are needed to understand this effect, in order to provide informed decision-making for adaptation to sea level rise.

Ocean acidification

The ocean is a vast reservoir of carbon dioxide (CO₂). The storage of inorganic carbon in the ocean is roughly 50 times that of the atmosphere. As a result, small changes in the ocean CO₂ inventory can have a significant impact on the atmospheric CO₂ concentration. On the other hand, the ocean is also an important sink for CO₂ released by human activities, anthropogenic CO₂, which is the major human-induced greenhouse gas. Since the beginning of the industrial era, atmospheric CO₂ concentrations have increased from approximately 280 ppm to about 401 ppm in June 2014. Currently, roughly 25% of the total human emission of CO₂ to the atmosphere is accumulating in the ocean. While this oceanic absorption reduces atmospheric CO₂ levels and helps to abate global warming and its impacts, increased CO₂ in the ocean has a significant impact on the chemistry of seawater.

Ocean CO₂ uptake causes pH reductions and alterations in fundamental chemical balances for an extended period of time. Together such processes are commonly referred to as ocean acidification (Doney et al. 2009; IPCC 2013, section 3.8). Ocean pH is a measure of ocean acidity or basicity. A decrease in pH value means an increase in acidity and in hydrogen ion (H⁺) concentration. The pH of pure water is very close to 7. A solution with pH less than 7 is acidic and greater than 7 is basic or alkaline. The average pH (total scale) of surface waters ranges between 7.8 and 8.4 in the open ocean, so the ocean remains mildly alkaline at present. The mean pH of ocean surface waters, however, has fallen by about 0.1 units, from about 8.2 to 8.1, since the beginning of the Industrial Revolution. Uptake of anthropogenic CO₂ is shown to be the dominant cause (Doney et al. 2009; IPCC 2013), even though other natural and anthropogenic processes can also cause variations in oceanic total dissolved inorganic carbon and pH.

IPCC estimates of future atmospheric and oceanic CO₂ concentrations indicate that, by the end of this century, the average surface ocean pH could be lower than it has been for more than 50 million years. Ocean acidification can have large impacts on marine ecosystems, particularly on calcifying organisms such as corals, coral reef communities, and planktonic organisms. The increased CO₂ reduces pH and lowers calcium carbonate. The lower calcium carbonate concentration reduces calcification rate and therefore
affects the shell-forming organisms. The potential for marine organisms to adapt to more acidic water and broader impacts of acidification on marine ecosystems are not well understood. They are priority areas of further research.

Oceans and seas: human geography

Philip E. Steinberg
Durham University, UK

Discovering the sea

Although historically few human geographers have identified the ocean as their area of specialty, the ocean has long had an important, if unrecognized, role in the development of human geographic thought. Since the Classical era, political geographers have highlighted the importance of maritime choke points as strategic sites of geopolitical interest. Following in that vein, the oft-cited works of late nineteenth- and early twentieth-century geopolitical thinkers Alfred Thayer Mahan and Sir Halford Mackinder focus on the balance between sea power and land power. Likewise, many early works on common property resources that inform today’s political ecologists focus on regional fisheries management systems and the ocean tenure regimes of coastal communities. Similarly, transport geographers have long noted the importance of maritime trade, an orientation that in turn impacted mid-twentieth-century urban economic geographers who researched the hinterland connections of port cities. And some of the iconic writings of mid-twentieth-century environmentalists, which went on to inspire a generation of environmental geographers, chronicle the causes and impacts of marine pollution.

Notwithstanding this rich history, however, prior to the 1990s the ocean was generally perceived as a secondary arena for geographic study: a space whose surface was used or impacted by society but not a fundamental space of society. That is, the ocean was typically understood and researched as a surface upon which land-based social processes were played out, rather than being studied as a space within which social processes, institutions, and power relations were constituted. Human geography until the last few decades was unapologetically terracentric.

There are likely a number of reasons for human geography’s terrestrial bias. First, despite the critique that geographers have long leveled at the idealization of the state as a naturally occurring, organic entity, geographers (and, more generally, social scientists) still have tended to conceive of the world as a universe of state territories. Because the ocean lies primarily outside state territory, it has tended to fall off the map of many state-centric human geographers. Second, these naive perspectives on territory have been complemented by naive perspectives on place. Humanistic and phenomenological geographers typically have understood place as a point in space at which people (individually or collectively) transform nature and embed social meaning through material and symbolic inscriptions. Because humans are unable to inscribe their presence at discrete points on the ocean’s surface, the ocean is often (if incorrectly) understood as a space within which communities fail to establish “roots.” The ocean thus has frequently been viewed as placeless and therefore uninteresting. A third reason for the historic lack of attention...
given to the ocean by human geographers is a naive separation between notions of “society” and “nature.” As a space without any obvious social boundaries or transformations, the ocean has appeared to many as a space of “nature.” Thus it is often deemed to be of little interest to human geographers, beyond the subset with a specific interest in bridging the nature–society, or physical–human, divide.

Today, all three of these concepts – the foundational nature of state territory, the association of place with rootedness, and the conceptual division between nature and society – are questioned by human geographers, and this has opened up the ocean as a new area for human geographic research. This explosion in ocean research began in the 1990s with a series of special issues of geography journals. These included a special issue of *The Professional Geographer* (Steinberg 1999) focusing on possibilities for integrating human and physical geographic ocean studies, a special issue of *Geographical Review* (Wigen and Harland-Jacobs 1999) that sought to reconceive the world as a series of ocean regions, and a special issue of the *Journal of Historical Geography* (Lambert, Martins, and Ogborn 2006) that sought to document the role of the ocean in historical geography. This has been accompanied by monographs, edited volumes, and review articles. As just one indicator of how the ocean has come of age as a topic of human geographic study, it is useful to compare the “Coastal and Marine Geography” entries in the two *Geography in America* volumes. In the 1989 edition, the discussion of human geographic themes (West 1989) is brief and devoted almost entirely to tourism issues. By contrast, the entry in the 2003 edition (Psuty, Steinberg, and Wright 2003) covers a broad range of human geographic topics including resource, cultural, political, and transport concerns.

Ocean geography as a mirror of human geography

Since its emergence in the 1990s, ocean geography has advanced in step with changing trends and insights in the broader field of human geography. Thus, while the ocean remains, in some senses, marginal to the dominant, land-centered current of human geography, it simultaneously is now deeply integrated with contemporary aspects of human geographic thought, and it is increasingly playing a role in enhancing geographic perspectives.

First-wave ocean geography: understanding globalization

During the 1990s, human geographers from a range of theoretical backgrounds made a sustained effort to interpret the rising tide of globalization, its historic antecedents, and its implications for nation-states, local cultures, and regional production and trade networks. Two of the first works in the blossoming of modern ocean geography, the “Oceans Connect” special issue of *Geographical Review* (Wigen and Harland-Jacobs 1999) and *The Social Construction of the Ocean* (Steinberg 2001), can be understood in this context. On the one hand, these two works take markedly different approaches. “Oceans Connect” attempts to challenge the terracentric division of the world into continents and states by conceiving a world defined by ocean–basin regions. *The Social Construction of the Ocean* adopts a more historicist and structuralist approach, seeking to understand how various phases of Western capitalism both reflected and were reproduced by specific ideologies and practices for incorporating the ocean into the space of society. Notwithstanding these differences, however, both works are rooted
in an attempt at understanding the ocean in an era of globalization and, conversely, both seek to explore how attentiveness to the ocean as an important space of society can aid our understanding of an increasingly “global” world.

In that respect, the first wave of ocean geography, as exemplified by these two works, can best be understood as fundamentally rooted in international political economy as they sought to uncover the unfolding political economy of the post-Cold War world. That said, first-wave works were not blind to complementary perspectives that were arising from further afield. In particular, works from this era engaged the focus that was emerging – in geography, but especially in the field of cultural studies – on the role of the ocean as a liminal space that both facilitates and symbolizes conditions of hybridity and postcolonialism. Key thinkers like Edward Said, Michel Foucault, and Paul Gilroy all, to a greater or lesser degree, highlight the ocean as a space where social practices challenge modernist ideals that link space, state, and society in coherent wholes, and several of the contributors to “Oceans Connect” as well as Steinberg in *The Social Construction of the Ocean* connect their analyses with these literatures. Nonetheless, even as both works engage theoretical insights from cultural studies, and even as they interpret cultural norms, aesthetic encounters with the sea, and (to a lesser extent) transformations of marine nature, the overall orientation of both is that of historical political economy, derived from the insights of development studies, Marxist studies of imperialism, and global history. Insights from cultural studies and cultural geography are secondarily employed, but generally to support arguments that are rooted in political economy.

Second-wave ocean geography: science and the sea

In the 1980s and, especially, the 1990s, structural explanations in human geography that sought to identify the singular political-economic “logics” of various eras were challenged. Feminist and poststructuralist geographers contended that structuralism was theoretically naïve, missing the intricate ways in which power relations were reproduced and challenged through social and discursive practices at a variety of scales, while empiricist historical geographers were critical of any explanatory system that sought to generalize across eras and geographic contexts. While these two critiques – the feminist/poststructuralist and the empiricist/historicist – were largely distinct from each other, they each, in different ways, pointed to the study of *science* as a key means for bringing the study of the ocean into human geographic research. For historical geographers turning to the sea, science was a crucial dimension of the human–ocean encounter because the ocean has been largely known through science (whether Western science or other, indigenous, techniques of assembling knowledge). Additionally, because ocean science, at least in the modern era, has required extensive state effort, its history is particularly intimately interwoven with histories of state formation and imperialist expansion. Historical geographers thus identified the study of ocean science as a fruitful means for gaining insights into the development of scientific knowledge and scientific institutions, and for understanding how these were connected with the rise of modern political institutions, economic relations, and cultural norms. Many of the articles in the special ocean issue of the *Journal of Historical Geography* (Lambert, Martins, and Ogborn 2006) thus focus on marine science or, more broadly, on how knowledge of the sea was supported, produced, and communicated during past eras.
A second force promoting a focus on science in geographic studies of the sea came from feminist and poststructuralist geographers who turned to science as a means for accounting for the agency of the nonhuman world. Drawing on insights from both feminist science studies (e.g., Donna Haraway) and science and technology studies (e.g., Bruno Latour), actor-network theorists and, somewhat later, posthuman and more-than-human theorists emphasized the role of interactions between the human and the nonhuman in ontogenetic assemblages. Some of the pre-eminent theorists in this area of study – including John Law and Gilles Deleuze and Félix Guattari – give important, if fleeting, attention to the ocean as an exemplary relational space where the human and nonhuman engage in mutual co-constitution. Poststructuralist geographers (and, in particular, actor-network theorists) thus turned to the ocean as a fruitful arena for understanding the role of the nonhuman in social relations. The ocean, after all, is a space where the primacy of the human as the dominant species is always precarious due to the marine environment’s hostility toward human habitation or vision. It is also a space in which it is starkly apparent that “nature” can never be relegated to the role of a stable background or a definable set of resources. Indeed, the ocean’s incessant mobility makes it difficult to consider as anything other than an actant, and this theme has been expanded upon by geographers employing actor-network and assemblage-oriented perspectives. For second-wave ocean geographers, the ocean is continually being co-constituted by human and nonhuman elements: ships, states, and sailors, but also waves, water molecules, and biota, and also regulations, navigation devices, and the unwritten as well as written rules of conduct that guide the lives of people as they travel the ocean’s surface, extract its resources, or gaze into its depths.

Third-wave ocean geography: affective encounters

If the first wave in post-1990 human geography of the ocean drew upon political economy and, secondarily, postcolonial perspectives to understand the ocean amid globalization, and the second wave drew upon science and technology studies to understand the ways in which humans simultaneously differentiate themselves from and integrate themselves with the nature around them, then the third wave has focused more specifically on the affective properties of the ocean encounter. From around 2008, geographers have stressed that while encounters between human and nonhuman natures are characterized by scientific rationality and cognitive understanding, they also are laden with affective meanings that emerge through the processes of connection and co-constitution. In such encounters – for example, between individuals or social institutions and the sea – affective atmospheres are created: not simply emotive reactions (fear, awe, etc.) but a joining of elements in unstable fusion in which, at least temporarily, the whole is greater than the sum of its parts. This perspective is evident in many of the chapters in the Water Worlds edited volume (Anderson and Peters 2014), in chapters ranging from the experiences of surfers and kayakers to scuba divers to offshore pirate radio broadcasters.

To be clear, these three waves of ocean geography have not so much contradicted each other as they have built upon the insights of previous inquiries. Thus some of the key “second-wave” works on science and the sea examine ocean science within the “first-wave” context of global trade and domination. Likewise, “third-wave” works on the affective nature of ocean encounters generally begin from a “second-wave” understanding of the ocean as a space where the human and nonhuman meet in a dynamic assemblage.
This, in turn, sets the stage for the fourth wave of ocean geography that is emerging today.

**Fourth-wave ocean geography: vibrancy, verticality, and volume**

If the first wave of ocean geography was associated with the rise of political-economic perspectives, the second with the rise of an interest in the more-than-human, and the third with a focus on affect and emotion, the fourth wave has emerged in the context of a “new materialism” that increasingly is guiding research across a range of human geographic subdisciplines. While avoiding the excesses of environmental determinism, new materialists stress that the material conditions (i.e., the physical environment) within which human relations occur is nonetheless significant. Drawing extensively on understandings of how the geophysical world is known, changed, and experienced, as well as how it limits and enables human actions, new materialists study, for instance, how economies and social institutions are inseparable from the transformation of matter across space and between physical states. Matter is understood as substance made “vibrant” through human encounters.

This turn in geographic theory has important implications for how geographers think of (and with) the ocean. The new materialism suggests a turn away from understanding the environment as static, flat, and surficial. Instead, the material environment is understood as one with depth, constituted by the incessant churn of molecules that produce a variety of social relations as they re-form through space and time. While this dynamic materiality is present everywhere (all landforms shift and re-form over the very long term due to climate variability and tectonic movement), the ocean presents a particularly poignant environment for revealing the Earth’s voluminous dynamism. Within geography, much of the early work in this genre focused on air-space, as a space that progressively has been incorporated into the social fabric through a variety of political and legal constructions: as a space for war, surveillance, and atmospheric geo-engineering. However, recent works have turned to the sea as well for appreciating the import of a planet whose surface – and whose depths – are understood as vibrant, vertical, and voluminous.

The effect of this perspective on ocean geography is to frame the ocean not as an exceptional space (beyond state territory and beyond human habitation) but as a paradigmatic space, integrated with the other spaces that constitute the world. Although all spaces are mobile, mobility in the ocean operates at a quicker speed and with more evident force. Similarly, although all spaces are voluminous, in the ocean there is particularly profound tension as states and shippers seek to render it as a flat surface. And while all spaces are in a constant state of change, this dynamism is particularly apparent in the ocean as it shifts between its paradigmatic liquid form and related forms of solid (ice) and gas (foam, spray). From this perspective, the melting of polar seas due to climate change or the inundation of cities due to sea level rise can be understood as an integral part of human geography, not an external, environmental stimulus but a constituent part of the dynamic Earth which social life is constantly resisting, adapting to, and enlisting as an ally.

**Destabilizing the sea**

A common theme throughout each of these four waves has been a recognition that the ocean’s difference provides opportunities for geographic inquiry. Prior to the 1990s, the ocean’s difference relegated it to the margins of critical human geographic analysis: while the ocean might have been an interesting space for observing the interaction of human (and physical) processes, it was considered too exceptional for providing
insights into how those processes might actually emerge or for facilitating research on their constitutive elements.

Since the 1990s, however, the ocean’s exceptionalism has been seized upon as presenting an opportunity because of the way in which it destabilizes accepted categories. In the first wave, the persistence of the ocean as a fundamentally global space was used to destabilize the seemingly foundational division of the world into ontologically distinct territorial state-societies. In the second wave, the relative dominance of the nonhuman over the human in the ocean was used to destabilize notions of exclusively human subjectivity. In the third wave, the complex dynamics of the ocean encounter were used to destabilize modernist distinctions between object and emotion. And in the fourth wave, the voluminous dynamism of the ocean is being used to destabilize notions of nature (and space) as background and surface. The ocean, long relegated to being a zone for applying geographic knowledge, has emerged as force for generating knowledge of the world.

Oceans and seas are all around us. For starters, 70% of the Earth’s surface consists of bodies of water. Moreover, 96% of trade (on average) is carried by ship across the liquid voids that separate land masses. In effect, that means that the majority of items we own, clothes we wear, and goods we use on a day-to-day basis will have been touched by the seas and oceans that often seem so distanced from us. For those who live close to the sea, its impact is all the more obvious through storm surges, flooding, coastal erosion, and management schemes put in place to dampen the effects of the seas and oceans on the land and its populations. Nonetheless, in spite of the pervasiveness of the oceans and seas to our everyday lives, in obvious and not so obvious ways, geography has been a traditionally land-locked discipline. Scholars studying both human and physical processes have looked inwards to land rather than outwards to sea as a source of inspiration for their research. By and large the core concerns of geographers have focused on grounded and materially solid phenomena from landforms to sediments and on the sociocultural worlds of people living in cities, towns, and countryside locales. Yet the omission of seas and oceans from geographical enquiry has meant that a vast portion of our planet has escaped study. The word “geography,” translates as “Earth-writing.” If “Earth-writing” is taken to refer to writing about the planet as a whole, then two thirds of the narrative is missing if the seas and oceans are not included.

It might well be asked why geographers have failed to study the sea. Physical geographers have, for many years, focused on the processes borne from water – in rivers, lakes, and by the coast – and the changes to the global landscape that can be read through the processes of ice melt, longshore drift, erosion, and deposition. However, the seas and oceans as distinct areas of concern have been on the horizons of studies. For physical geographers, one of the prominent reasons has been the lack of accessibility of the seas and oceans as research sites and the dangers these locations pose. Although it is possible to explore the sea from the coast, such work tends to focus on the influence of the sea on the land (through erosion, deposition, and the creation and transformation of landforms) rather than the processes of the sea itself. Seas and oceans are vast and deep. This has traditionally made research beyond the shoreline difficult, hazardous, and expensive. That is not to say some land areas do not pose risks, but the scale and breadth of oceans make them a unique challenge to researchers.

Likewise, human geographers have had a long preoccupation with water, but less so with the vast liquid spaces of oceans and seas that separate (and also connect) continents. Sociocultural, economic, political, and environmental geographers have explored issues of water flow (or lack thereof) in developing nations, irrigation systems, damming projects, and flooding prevention, to name just a few engagements with what might be called “hydro worlds.” The sea, though, has been somewhere in the background. Again, the issue of access looms large. Human geographers have grappled with how to study...
a space that is beyond the solid physicality of land. But also the question of why comes to the fore. If, for the majority of us, we don’t live there or work there it may be questioned why seas and oceans are relevant as spaces for human geographers to explore. In human geography, this is embedded in contextual understandings of oceans and seas, which have marginalized them as spaces that matter in examining sociocultural, political, and economic life. As Philip Steinberg contends (2001), the industrial and postindustrial Western world has constructed the ocean as a void to be traversed for capital gain. The sea is an empty space that divides and connects spaces of importance on land. As such, the seas and oceans have been rendered inferior and outside of academic attention.

Yet it is no longer possible to say that geographers have not explored watery environments as part of their investigations. Over the past ten to fifteen years, geographers have increasingly paid attention to the large portion of the Earth that has been previously unreachable and omitted from study. Developments in geography have demonstrated the very relevance of seas and oceans both in their own right and in view of landed life. Indeed, broader advances in geographic thought have reconfigured the world not as constituted of discrete, bounded, and neatly defined parcels of space (land, air, sea, and so on), but as fluid, where spaces are connected and where elements meet, mix, and reform. With this vision of the world it becomes impossible to focus only on the land. Accordingly geographers have explored the ways in which the land is forged in relation to the sea (and also air); and likewise how the sea and air relate to the land. This “opening up” of physical and human geography alike to the interconnections between spaces has drawn increased attention to the seas and oceans as particularly salient spaces in the making of the world as we know it. Far from being irrelevant then, they are now appreciated to be wholly significant in better understanding a range of geographic processes, and re-visioning accepted knowledge of the world.

For physical geographers studies of the seas and oceans have centered on two areas – coastal areas and marine areas with the former focusing on the coast and the latter on the open sea. In view of coastal geography, scholars have investigated the morphologies of landscapes – beaches and coastlines – and how these have been changed by the mobilization of sediment and the velocity of waves. Coastal geomorphology has investigated, on various scales, these alterations to the coast from local to regional scales, driven by regular weather or storms, and the impacts wrought from human interactions with physical processes. Marine geography on the other hand has considered the geographies at work beyond the shore and is equated with marine science or oceanography. Here the seas and oceans have been investigated as a way of gaining a better understanding of the Earth system as a whole. Geographers have explored a range of interests under this branch, from the ecologies and ecosystems of oceans, the influence of weather patterns on ocean movement, to the impacts of pollution on water quality (Psuty, Steinberg, and Wright 2003).

Human geographers have, perhaps surprisingly, developed strands of interest that tie their work closely with the concerns of scientists. There has been a recent shift to explore the elemental mediums through which human life is lived: land, air, and sea. It is argued that the varying states of these mediums lead to particular co-compositions with human life. Indeed, if human geography is the study of the relations between people, space, and place, then it makes sense that such relations depend on the natures of those spaces and places. For human geographers, this interest in what is coined the “non” or “more-than-human” world has resulted in
some of the most diverse work concerned with geographies of seas and oceans. Geographers have become particularly interested in the ways that the physical processes of the sea co-join with sociocultural experience. Human geographers have moved away from understandings of the world as socially constructed (prioritizing the role of humans over the role of nature) to instead focus on the ways that human life is both shaping and shaped by the physical world. Such research draws consideration to the ways in which humans interact with oceans and seas, and moreover, the negotiations they face when trying to manage the force of water. Whereas humans have been traditionally understood as “mastering” nature (through the transformation of the landscape), attention to the seas and oceans demonstrates the complexity of such mastery, illustrating how those using the sea can seek to manipulate or harness its natural power but can also be victim to it. Such work that brings together human and physical dimensions in this context has also sought to consider the temporal force of oceans and seas at periodic moments; for example when tides advance and retreat (a result of broader extraterrestrial forces as the moon’s gravitational pull relates to oceanic movement). Here the oceans and seas are both a routinized and predictable feature of our planet; yet simultaneously irregular and volatile in how they combine with the human world.

Scholars have also, more experimentally, explored the shifting material form of our oceans and seas from the state of liquid to solid; salt water to ice. Research on ice confuses how we might typically think about seas and oceans. Such spaces cannot be understood simply as liquid zones between countries and continents; instead they can become part of countries and the continents they meet, as liquid transforms to ice. This has allowed geographers to challenge the uneasy categorizations that partition the world in identifiable “zones” of study. Rather, the oceans and seas permit an understanding of the constantly changing nature of the planet; its fluid shifting form as land becomes sea and sea becomes land. This work has gained attention not only by those geographers co-combining human and physical concerns (as described) but also by political geographers.

Borders, boundaries, and territory at sea are other core concerns of geographers working in this area. The sea is a space over which political control is contested (particularly in view of resources such as oil and activities such as fishing) and a space with a distinct historical narrative over its legal governance (Steinberg 2001). Traditional explorations of geopolitical control and governance over the oceans have been a concern of geographers who have sought to explore the zonation of ocean space and the politics over activities on and also under the ocean (from shipping violations between territorial and extraterritorial sea spaces to seabed rights where resources can often be gained). Yet the governance of the sea is different to the land. Unlike the creation of nation-states, the formation of the sea as an international space of shared stewardship results in differing conflicts in how it (and events on it, under it, and over it) should be policed. It requires a special form of governance, control, and partitioning. Land is territory to be acquired whereas the sea cannot be acquired in quite the same way. The Arctic Sea, for example, is a pivotal space for rethinking geopolitical processes. Where land turns to sea and sea turns to land through processes of ice formation and ice melt, new territory is perpetually formed and dissolved, creating new questions over ownership, political control, and rights over resources.

Moreover, while the sea might be fluid in its states from solid to liquid, in liquid form the sea’s fluid materiality means it is a constantly moving space that presents particular challenges to governance. Although possible to draw a line across a
OCEANS AND SEAS: PHYSICAL GEOGRAPHY

static representation of the sea on a map, drawing a line to demarcate space in reality is far more difficult. The sea moves – it does not stay still. Partitioning it therefore becomes a tricky task. Those studying fishing at sea have explored this tension. The reliability of sustainable fish certification is challenged when we remember that both seas and oceans move, as do fish (Bear and Eden 2008). Areas of ocean may be designated on a map as zones of sustainable fishing; but there is little to stop fish moving in and out of these areas. The seas and oceans therefore have allowed scholars to complicate and extend work in longstanding areas of geographical concern.

And just as the seas and oceans permit a vision of a more fluid world of connection and boundary dissolution, they also permit a vision of the world that moves beyond a horizontal perspective that looks out and across space to what is in front or behind us. The seas and oceans complicate ideas relating to surfaces. When liquid, seas and oceans open up what is called a “vertical ontology” whereby knowledge of the world can be extended through depth. The sea is not ever moved on. People or things (from rafts and canoes to boats and ships) do not traverse on top of the surface of the sea – they always move in it. Even in a buoyant condition, a floating subject or object is moving through the water with part above and part below. Studies of the sea have thus moved beyond traditional spaces of study to explore submerged, subterranean, and underwater worlds and their distinct natures and sociocultural engagement with them (Anderson and Peters 2014).

Engagement with oceans and seas has been a key intervention of geographers exploring planning and environmental management to prevent coast flooding. Yet human geographers have furthermore sought to unpack the embodied, nonrepresentational, and haptic experiences bound up in relations with the water world. It is argued that our sensory experience with the world is radically altered when we engage with seas and oceans as opposed to the land. Anderson’s work on surfing demonstrates the uniqueness of “being” in the water – a space moving, wet and dynamic (see Anderson and Peters 2014). Other work has investigated diving, swimming, sailing, and, in relation to development studies, the special relationship some societies have with oceans and seas as a means of sustaining life. Where a Western conceptualization of seas and oceans often renders them as distant spaces outside of everyday life, for many nonmodern worlds the seas are as familiar as the land and they are spaces of ritual, ceremony, and also of vital connection and resources central to sustaining life. Indeed, the oceans have also been explored as spaces across which mass migrations have occurred, reshaping societies and histories.

Such studies form part of a wider interest for human geographers in how people relate to seas and oceans, and have done so over time. Historical geographers have explored the relations between people and the sea through the lens of imperialism and colonialism, arguing that the seas were a key site of global expansion during this era. Lambert, Martins, and Ogborn (2006) use the sea as a way of reimagining global politics and change. They contend that the sea permits a way of thinking that moves beyond nation-state driven narratives. Such a focus on the oceans and seas as open and borderless allows us to rethink how the world has come into being. In short, many geographical areas of concern – with sediments, movements, fluctuations, change, management, politics, and society – can be decentered and rethought through attention to the oceans and seas, and this work continues to expand as interest in and access to the sea extend and deepen.

Ontology: domain applications

Nancy Wiegand
University of Wisconsin – Madison, USA

Geospatial data are characterized by containing either explicit spatial location information for geographic features or references to a place. Geospatial data may be used in a GIS (geographic information system) as part of viewing, creating, and analyzing maps and geographic features. Geospatial data are fundamental for many applications, including economic development, natural resources management, environmental protection, and emergency response. This entry explores ontology and applications in the geospatial domain and relates the geospatial domain to work in the area of semantics and ontologies.

Semantic technologies are being developed in the effort to create a Semantic Web and also to add a semantic layer to various kinds of applications. The Semantic Web vision includes the existence of formal ontologies as background semantic knowledge bases that can be referenced from webpages to provide context in a domain. Using such ontologies, automatic or semi-automatic methods can resolve semantic heterogeneity across webpages to relate disparate but related pieces of information. That is, intelligent agents would be able to interpret information on the web without human intervention and potentially return answers to complex queries posed over the web instead of returning links to webpages as done currently. Another aspect of the Semantic Web vision is to create linked open data in which similar data items are linked across multiple datasets through the use of common identifiers.

The World Wide Web Consortium (W3C, http://w3c.org) is developing standards to facilitate the creation of a Semantic Web and associated technologies, such as reasoners and rule and query languages. And, the Open Geospatial Consortium (OGC, http://www.opengeospatial.org/) is adding spatial aspects to semantic standards and technologies to create a Geospatial Semantic Web. The W3C and OGC have recently worked together on best practices for spatial data on the web (https://www.w3.org/TR/2016/WD-sdw-bp-20160119/).

Ontologies

Ontologies are integral in the vision for the Semantic Web and semantically enabled applications. An ontology contains concepts, terms, and relationships that describe a domain. An ontology may or may not be populated with instances. Formal ontologies are represented using an ontology language, such as OWL, a W3C standard for a web ontology language (http://www.w3.org/2001/sw/wiki/OWL).

An ontology is often organized into classes and subclasses but differs from a taxonomy in that attributes, relationships, and constraints can also be included. For example, a taxonomy could show that “river” is a type of (subclass of) “water body,” but an OWL ontology further allows specification of attributes (datatype properties) and relationships (object properties). For example, in OWL, it can be modeled that a river has a datatype property that specifies an
average rate of flow. And, an object property for
river called *flows into* could be modeled as being
transitive and having a range of type water body.

Uses for an ontology include:

- formulation of the concepts of a domain, that
  is, creation of a conceptual model;
- specification of terms to use to describe the
  concepts;
- organization of information;
- potential for ontology terms to be used as a
  type of standard for terms, resulting in future
  conformant terminology;
- enhancement of search;
- resolution of heterogeneous terms involved
  in queries and in data integration;
- enhancement of gazetteers;
- enablement of a Semantic Web and a
  Geospatial Semantic Web.

An ontology expressed in a formal ontology lan-
guage, such as OWL, is machine readable. This
allows automated processing by reasoners. A rea-
soner is an inference engine that infers logical
consequences from a set of asserted facts. A com-
mon type of inference is subsumption to find all
the sub or super classes of a class, for example,
all types of water bodies. A Semantic Web rea-
soner understands formalisms underlying Semi-
tic Web standards including the OWL language
and description logics.

Compared to schemas in database management
systems (DBMSs), which have a closed world
assumption, ontologies are part of an open world
assumption. That is, ontologies are meant to
define a domain more broadly than what would
be necessary for a particular database application.
Also, ontologies are meant to be re-usable and
extendible. Modular ontologies, in particular,
facilitate re-use of pieces of ontologies.

Although ontologies are valuable in enabling
the uses outlined above, they are not easily built.

The process of building an ontology is referred
to as ontology engineering. A typical approach
is to gather domain experts together in person
with ontologists who are then able to formally
express constraints on facts and relationships.
The Ordnance Survey in Great Britain did
seminal experimental work on methods to
create ontologies, such as developing tools for
domain experts to easily express facts in a certain
manner that enabled automatic formalization.
A current ontology editor, such as Protégé,
helps in entering and organizing information
and outputs an ontology in a formal language.
Because ontologies are difficult to build, a goal
is to automate building ontologies.

**Ontologies to enhance search**

for geospatial data

Being able to locate spatial data motivated the
development of national spatial data infrastruc-
tures (SDIs) as well as numerous state and local
geospatial portals. The prior US Geospatial
One-Stop (now subsumed under data.gov),
for example, made federal and other datasets
and resources accessible from one location.
Geospatial data are usually described in separate
metadata files using standard metadata formats
such as those from the Federal Geographic Data
Committee (FGDC), International Organiza-
tion for Standardization (ISO), or Dublin Core.
Metadata elements typically include theme key-
word, date, location, provider, and type of data.
Search in SDIs or portals is done over selected
metadata elements, now likely using a catalog
service for the web (CSW). The simplest user
search interface usually provides a method (text
or map based) to determine an area and also
provides a text box in which the user enters a free
form keyword. The search, however, may pro-
duce no results or too many results. Even when
a search system expands the user keyword with associated synonyms, there might not be any results due to a mismatch of terms and concepts between the data provider and the user. That is, user terms may not match stored metadata keywords or synonyms. Alternatively, a search may yield hundreds of results due to imprecision.

Because of the difficulties of searching for geospatial data, researchers have been working on improvements such as ontology-based search. An example is that theme keyword search can be expanded to include sub or super concepts through lookups to ontologies. For example, if an ontology has a pond as being a type of lake, that is, a subclass of lake, a search for lake could also return records referring to pond, as well as the other subclasses of lake. Also, reference to an ontology for a search term could restrict the domain of the term, enabling more precision, such as water in the domain of hydrography instead of water in a GIS city plumbing application. Another projected use of an ontology not fully exploited yet could be the ability to include information from relationships other than sub or super class relationships, such as flows into or part/whole relations. An example search expression in the near future could be “flows into the Mississippi River” to locate data on particular streams.

Work is ongoing in using ontologies and associated software in portals or SDIs to improve search. For example, Esri’s geoportal technology has been enhanced to expand or refine keyword search over metadata and data through access to ontologies. The International Coastal Atlas Network (ICAN, http://ican.science.oregonstate.edu/) provides ontology-enhanced search that includes an ontology browser and Semantic Web service. For example, a search for “coastline” will include a search for “shoreline” using its knowledge base (http://netmar.nersc.no/sites/netmar.nersc.no/files/ICANCookbook_ConnectingYourAtlas_v2.1_20120730.pdf).

The Museum Finland project (http://www.seco.tkk.fi/applications/museumfinland/) created a semantic portal and used ontologies for intelligent information retrieval across cultural collections. The project was part of larger work on semantic technology (http://www.seco.tkk.fi/projects/finnonto/). Ontologies are being used to improve precision and recall in searching for earth science data at the Oak Ridge National Laboratory using the Mercury metadata search engine. Ontology search is also being used in GeoSearch (Gui et al. 2013), in which multiple SDIs are being accessed through the GEOSS clearinghouse and search for data is enhanced using the SWEET ontology (http://sweet.jpl.nasa.gov/). GeoSearch also uses rules and semantic similarity measures to improve ontology-based search. Another example to improve ontology search mines the data itself using latent semantic relations to create an ontology for polar data (Li, Goodchild, and Raskin 2012). INSPIRE, the Infrastructure for Spatial Information in the European Community, also has initiatives to include semantic technology.

Resolution of heterogeneous terms: data integration and querying

Even after finding data, full use of geospatial data remains difficult because of the semantic heterogeneity in basic terms and concepts. Contrary to this, heterogeneity in file formats and coordinate systems for spatial data can be resolved using file and coordinate conversion routines. Also, some attribute names and values can be resolved using ETL (extract, transform, and load) techniques. But the use of different conceptual notions and vocabularies for nonspatial attributes, which comprises semantic heterogeneity, still poses
significant challenges. Semantic heterogeneity is due to each data provider using different descriptions and models. For example, one dataset may have subsets of terms or terms that are similar but not quite the same as terms in other datasets. Semantic heterogeneity prevents interoperability among spatial datasets.

The lack of semantic interoperability is not only a problem within one domain; it prevents needed collaboration across domains. Although spatial information has been referred to as an integrator for data across domains because different kinds of data can be linked through location, the data are limited in further integration due to different concepts, terms, or classifications of terms.

Data

Just as ontologies can be used to enhance search for geospatial data, they can be a solution for data integration. Data integration is the combining of data from different sources into a new unified view. An early study by Fonseca et al. (2002) presented the notion of ontology-driven geographic information systems to help integrate data and classify features across remotely sensed images. They described high-level ontologies as being an integrator over related applications that would each have more detailed ontologies. In their example, a top level ontology could cover multiple communities and have generic land use and land cover categories, such as forest, nonforest, and deforestation. A domain ontology at the next level of detail could then distinguish types of deforestation due to farms or cities. Finally, an application ontology for a specific task could further expand farms to soybeans, cattle, and so on. Combining these levels of ontology together allows relating specific and general land use or land cover codes to each other.

The approach of using upper level ontologies has also been used to integrate data from completely different domains. Upper ontologies, such as DOLCE, which contain abstractions relevant across knowledge domains, help in integrating data by connecting data items through high level concepts.

Aggregating data laterally, that is, across geographic areas or jurisdictions, also often results in needing to resolve semantic heterogeneity. For example, in local areas, such as neighboring counties, different classification systems in land use, zoning, wetlands, and land cover can occur. And data integration across local, regional, state, national, or world datasets will usually have semantic problems due to a lack of standards and also from language, culture, and landscape differences. For example, differences in landforms in various parts of the Earth and also how they are culturally perceived and described was studied by Mark, Turk, and Stea (2012).

Some solutions to semantic heterogeneity have involved developing standards to make all schemas and data compatible. For example, work in the Consortium of Universities for the Advancement of Hydrologic Science (http://www.cuahsi.org/) involved cooperation among data providers to use similar terms. But, in general, it is difficult to create standards and enforce them. The standards approach also does not cover legacy data unless effort is put forth to convert old data to the new standards. Further, setting standard terms may not be effective because such terms may end up at a high level of description, say, agriculture, and lose needed local detail (e.g., orchard) when comparing land use/cover classifications, for example.

Developing ontologies rather than standards helps prescribe terminology for others to use, enabling future data integration. And, ontologies used as a type of standard may be more
comprehensive than other standards and so help solve the issue of local detail being lost.

**Querying**

In addition to helping integrate data, ontologies can help in querying over heterogeneous data by providing a source of global terms and concepts needed to create semantic agreements (e.g., mappings) to local or legacy terms. Such mappings are then used to resolve semantic heterogeneities. For example, in prototype database or information systems that implement a semantic mapping approach, the query interface typically presents ontology terms for the user to choose to pose a query (rather than allowing the user to type in any term). The ontology terms are then looked up. This approach keeps data local and in its own terms yet allows local data to be part of a combined knowledge base. This is contrary to integrating all data by putting it into a unified form and copying it into a data warehouse, for example, in which local updates would keep needing to be propagated.

As mentioned, land use and land cover are example domains needing semantic resolution for querying. Although not the same, land use and land cover are sometimes combined. They are both represented by taxonomies created for local or national purposes without universal standards. These types of codes can be very heterogeneous even across local areas, and they may change through time. Climate change studies are an example use case that requires resolution of world-wide land cover codes as well as resolution of prior classification systems over time. Various methods have been experimented with to study and resolve land use or land cover classification systems including statistical methods, mappings, and merged ontologies (Ahlqvist, Macgill, and Guo 2004; Gahegan *et al.* 2011; Wiegand 2012).

Distributed query systems, such as federated database systems, that process queries over heterogeneous data also have to resolve differences in schemas and terminology. Global As View and Local As View approaches have been tried, for example. Using formal ontologies to resolve differences is a newer approach. Work has been done in the database community to add ontologies to relational DBMSs to support ontology-based querying, such as in Oracle (Das *et al.* 2004). Newer work is now being done on ontology-based data management to have DBMS technology accommodate formal knowledge representation and reasoning.

**Gazetteers**

Gazetteers provide another example application in the geospatial domain for which work is being done to enhance spatial information with ontologies and semantic relationships. Gazetteers contain a place name, type of feature, and location but do not include a place ontology, for example, in which additional information may be available, such as relationships between features. An example of information that is not now available in gazetteers is how administrative units are related especially when they are not completely nested. Another issue is whether spatial information, such as elevation or latitude and longitude, can be used to automatically determine semantic relationships, such as a change in elevation determining the direction of stream flow between lakes, for example.

**Linked data**

One of the visions of the Semantic Web is to have data within and across domains linked together and accessible over the web. The linked
open data (LOD) project (http://linkeddata.org/) builds and connects distributed data across the web. In the LOD diagram (http://lod-cloud.net/), each circle represents a knowledge base of linked data for a particular domain. Further, data are linked across domains. DBpedia is in the center. Initial data focused on the life sciences but more and more types of data are being added, including geospatial linked data. One value of the linked data initiative is to make data more open by putting it in a standard linked format and having it available over the web. An example is linked government data available through data.gov in the United States. A further value of the LOD cloud is the likelihood that new knowledge will be found through extensive linking of data. Although ontologies are not necessarily part of the LOD, formal domain ontologies and mappings would be helpful in data integration and querying for data not published using the same conceptual terms and identifiers.

The resource description framework (RDF) is a W3C standard data representation (http://www.w3.org/TR/rdf11-primer/) used to create linked data. RDF is a triple format consisting of resources organized as a subject, predicate, and object. Examples of triples are the “Mississippi River flows into the Gulf of Mexico” and “river is a type of water body.” If represented in graph form, the subject is a node connected by an arc that describes the relationship from the subject to either a literal value or a node representing another resource. Because the subject of one triple could be the object of other triples, as well as being the subject of more triples, an interconnected graph can be formed.

Each component of a triple (i.e., subject, predicate, or object other than a literal) is identified by an International Resource Identifier (IRI). IRIs are similar to URLs for web pages and uniquely identify a resource. Linkages are formed between triples when identical IRIs have been used for a resource or when IRIs are equated using owl:sameAs. In this manner, linking can be done between many domains and knowledge bases. As more and more data are linked, a larger graph is created enabling further relationships to be explored.

In the color version of the LOD diagram (http://richard.cyganiak.de/2007/10/lod/lod-datasets_2011-09-19_colored.png), geospatial data are yellow and include Census data, GeoWordNet, Linked Geodata, GeoNames, and many more. GeoNames (www.geonames.org), for example, has information on over six million places and geographic features. Because place is a natural integrator, if data providers re-use the identifiers specified in GeoNames, data from various domains can be linked through place, enhancing the overall knowledge gained from the LOD project.

Various projects are creating RDF data related to the geospatial domain. For example, the United States Geological Survey (USGS) has put some of The National Map data into the RDF GeoSPARQL format (Varanka 2012). In the Consortium for Ocean Leadership, metadata was put into RDF to facilitate search over multiple facets having complex concepts, logic, and frameworks. Another project put weather sensor data into RDF and linked places to GeoNames.

### Storing and querying RDF data

RDF data are typically stored in triplestores, such as Allegrograph, Parliament, Jena, Virtuoso, Sesame, or others. RDF data can also be stored in tables in relational DBMSs, although Oracle, for example, also has native support for RDF graphs. Triplestores may provide a graph-based query language, such as SPARQL, the W3C standard RDF query language (http://www.w3.org/TR/rdf-sparql-query/). Further, an endpoint (a service that accepts SPARQL queries and
returns results) may be set up through which RDF data can be queried over the web.

An example SPARQL query to find all state parks is:

```
SELECT ?sp
WHERE
  ?sp a ex:StatePark .
```

Briefly, the variable sp is being stated to be of type state park. All features from the example database (ex) that are of type state park will be returned.

**Querying spatial RDF data:**

**GeoSPARQL**

Because SPARQL does not support spatial operators, a few spatial RDF query languages have been developed. For example, GeoSPARQL was developed as an extension of SPARQL (Battle and Kolas 2012) and is now a standard spatial RDF query language. It was jointly developed by the OGC and the W3C, with OGC providing the spatial expertise. GeoSPARQL’s design has a class SpatialObject that has two subclasses: feature and geometry. Separating the feature from its geometry allows a feature to have multiple geometries. The object property between the feature and geometry classes is called hasGeometry. For example, if an application has a feature type with a spatial representation, such as parks, parks would be modeled as a subclass of GeoSPARQL’s Feature class and would inherit the hasGeometry spatial property. The geometry class accommodates WKT (well-known text) and GML (geography markup language) representations. GeoSPARQL also accommodates topological relations expressed in any of three forms: OGC simple features, Egenhofer’s 9-intersection model, and region connection calculus-8 relations (RCC-8). These relations include spatial operators such as equals, disjoint, intersects, touches, within, contains, overlaps, crosses, and so on. GeoSPARQL also has additional spatial operators, such as distance.

An example GeoSPARQL query to find towers within state parks is:

```
SELECT ?t ?sp
WHERE {
  ?t a ex:Tower ;
  geo:hasGeometry ?tgeo .
  ?sp a ex:StatePark ;
  geo:hasGeometry ?spgeo .
}
```

This query specifies additional variables for the geometries, tgeo and spgeo. Using GeoSPARQL’s **within** operator, the result of the query will only consist of towers that are within state parks along with the state park containing them (i.e., not all state parks).

SPARQL and GeoSPARQL queries can become hard to write. Because of this and to allow more users to participate in a Geospatial Semantic Web, a graphical query interface, built specifically for spatial data and GeoSPARQL queries has been developed (Grove et al. 2014).

**Geospatial Semantic Web**

Initial work on technology for the Semantic Web did not include spatial considerations, although referring to spatial locations, such as to find the closest doctor’s office, was in the original Semantic Web vision. But, initial work on ontologies, linked data, and query languages, for
example, did not provide for spatial operations. Egenhofer (2002) introduced an early description of a Geospatial Semantic Web. He suggested that spatial functions be accommodated to be able to perform true spatial operations over the web.

In 2006, OGC had a Geospatial Semantic Web interoperability experiment (http://www.opengeospatial.org/projects/initiatives/gswie) to integrate Semantic Web technology into OGC web services. In the goal of creating an architecture that would allow automatic web processing of queries, a target query was to find airports in a specified area of the world that could handle a C-5 cargo plane. The solution included developing ontologies and rules to represent an understanding of the various domains that were involved and to resolve semantic heterogeneities. They also implemented interfaces and profiles to extend OGC web services. Their work helped contribute to the vision of a Geospatial Semantic Web.

Now, with spatial RDF query languages, such as GeoSPARQL or stSPARQL, accommodating the execution of spatial operators, a Geospatial Semantic Web is further enabled. Spatial queries can now be posed on the web over RDF data. As the next phase, to fully realize the vision, more data need to be put on the web in the RDF format.

Ontology design patterns (ODPs)

Creating a comprehensive ontology can be a large undertaking. Because of this, but also in their own right, ontology design patterns (ODPs) are being developed. ODPs are smaller ontologies intended to be re-usable that express overview, partial, or repeatable patterns. Patterns may be high level and generalizable across domains. An example use case is a generic route with beginning and end points that can be used to model various applications ranging from bus routes to bird migrations (Hu et al. 2013).

Ontology repositories

To promote semantic integration, ontologies should be re-used. Making existing ontologies available is the goal of the open ontology repository (OOR) initiative. The OOR initiative
ONTOLOGY: DOMAIN APPLICATIONS

aims to provide sharing of ontologies through modular open source software that uses best practices. As part of the OOR initiative, different repository code bases have been written to store and allow access to ontologies. Metadata for ontologies was developed to be used in searching for and browsing ontologies in these code bases. The repositories also provide for finding individual terms within ontologies and the ability to map terms between different ontologies. Further, the repositories provide web services to be able to access contents remotely.

In the OOR initiative, some ontology repositories are based on the BioPortal ontology repository code (http://bioportal.bioontology.org/), which was developed for biomedical ontologies. A few experimental instances of the BioPortal code were implemented by others including one by SOCoP (Spatial Ontology Community of Practice). The purpose of SOCoP's OOR was to collect ontologies related to the geospatial domain. SOCoP's ontologies have since been moved to Ontohub. Example ontology repository efforts that are part of the OOR initiative but that use different code bases are COLORE (http://stl.mie.utoronto.ca/colore/) and Ontohub (https://ontohub.org/).

Ontologies collected that are relevant to the geospatial domain include upper level ontologies such as DOLCE, SUMO, and BFO as well as domain-oriented ontologies such as SWEET (http://sweet.jpl.nasa.gov/), which encompasses the earth science domain. Other examples are GeoNames, Spatial Relations, Land Use and Land Cover Change (LUCC), Semantic Sensor Net, hydrography, ISO standards, and others.

Future

The use of ontologies and semantic technologies is in its beginning stages in general as well as in its beginning stages in the geospatial domain. New technologies are actively being developed, and a few prototype systems have been built. But semantic systems are not yet pervasive. More work is needed to build semantically enabled spatial systems and a Geospatial Semantic Web. And, more ontologies are needed to represent geospatial data and processes so they can be accessed from semantic systems. Also, more data need to be created in, or translated to, the RDF linked format so that more data are available to be queried over the web.

Ontology: theoretical perspectives

Helen Couclelis
University of California, Santa Barbara, USA

Background

“Ontology” is a relatively recent addition to the geographer’s vocabulary. In its traditional meaning as the study of the essence and structure of what exists, it is a branch of metaphysics that goes back at least to Aristotle and continues as an important theme in philosophy to this day. In modern times the term has acquired certain specialized meanings beyond pure philosophy, as in parts of theoretical physics, where the ontology of space–time and that of quantum fields have been active research topics for several decades. More recently ontology was also introduced in computer science and more specifically in information science, where applications-oriented as well as theoretical versions can be found. The informational version of the concept is, however, much less ambitious than the original: according to the most widely accepted definition, an ontology is “a specification of a conceptualization,” to be used for clarifying the meaning of information items in the context of formal knowledge representation. In other words, the purpose of these ontologies is to enable computers to turn the massive volumes of available information into usable, sharable, actionable knowledge (Guarino 1998). To avoid confusion, these two quite different approaches are often referred to as “Big-O” ontology and “small-o” ontology, respectively. Both the traditional philosophical sense of ontology and the recent informational usage are represented in contemporary geography. The plural form “ontologies” is commonly used in connection with the small-o, applications-oriented kind, and more generally, in reference to the many alternative ontological frameworks that have been proposed over the centuries and in our time. In all cases an ontology is, at the very least, a classification of entities, concepts, or terms of interest, although relations (e.g., hierarchical relations) are typically included along with properties and other structural elements.

Ontology in the philosophical sense is represented in the work of several generations of geographers especially in humanistic and critical geography. These have been influenced by the writings of mostly European major philosophers and thinkers such as Kant, Hegel, Husserl, Heidegger, Habermas, Sartre, and, most notably, Marx, but also by contemporary scholars such as the British philosopher of science Bhaskar and more recently also by certain feminist thinkers. Small-o ontology on the other hand was introduced in quantitative geography in the mid- to late 1990s by researchers in geographic information science, following progress on the topic in the related areas of geoinformatics, and in information science and technology more generally. Some early evidence of ontological thinking is found in the Harvard Papers in Geographic Information Systems from the 1970s (Chrisman 1978), when researchers were exploring the nature of geographical space in the context of the nascent field of computer cartography. Clearly Big-O and small-o ontology have played different roles in the different branches of geography in which
they were adopted. The former has inspired new theoretical analyses and discourses, while the latter, originally meant primarily to facilitate the efficient and consistent retrieval and use of information across databases, is also increasingly raising philosophical questions of its own. In both cases geographers have made original contributions to ontology by exploring and foregrounding the role of space and spatiality in spatiotemporal phenomena and processes, whether natural or social. Despite major differences in interpretation and use that are reflective of the discipline’s diversity, the relevance of ontology for geography as a whole lies in its being one of the rare theoretical concepts that are common to the humanistic, critical, and quantitative streams of the discipline, with the potential to bridge disparate traditions.

**Philosophical foundations**

**Ontology and general human geography**

A number of the philosophical issues and debates surrounding ontology matter to geography. This is true of humanistic and critical geography and surprisingly, perhaps even more so of the geoinformatic (computational) sense of the notion as adopted in geographic information science and quantitative geography. In both cases the central issue is the question of representation: what exactly is being represented and how, and what the implications are for ontology development and use of the answer one gives.

Ontologies take on different forms and mean different things depending on their developers’ acknowledged or unacknowledged philosophical stance. For the purposes of this discussion the most relevant contrast is that between realist and nonrealist philosophies and the ontologies these tend to engender. Realism – which is a position, not a distinct philosophy – is based on two premises: (i) that the things and relations in the world really exist (more or less) such as they appear and with the properties that they appear to have; and (ii) that the reality of things and relations is mind-independent, that is, independent of how we observe, conceptualize, or talk about them. Nonrealist philosophies, of which there are many (for example, conceptualism, constructivism, cognitivism, conventionalism, idealism, instrumentalism, nominalism, poststructuralism, rationalism, perspectivism, phenomenology, and pragmatism), contest one or both of these premises, pointing to inconsistencies and other problems. Much of the critique of realism revolves around its inability to properly account for abstract notions not directly related to observable things, for morality and consciousness, for mathematics, for the role of context in assigning meaning to phenomena, and generally, for neglecting the relation between mental and social life on the one hand and conceptions of the world on the other. Strong versions of realism can be quite doctrinaire, a consequence of the belief in a single objective reality, and thus in only one true ontology. Realist philosophies also draw a sharp distinction between ontology and epistemology (what exists versus what we can know about what exists), whereas the distinction is much less clear in nonrealist philosophies to the extent that these emphasize the constitutive role of the mind, of context, and of situational interests in our conceptualizations of the world.

Ontological thinking in critical geography tends to be realist to the extent that it draws on earlier, strongly realist interpretations of Marx’s work, which was often seen as describing the “hard science” of society. The Frankfurt School’s cultural reformulation of Marxism has softened the edges of the original hard realism by refocusing Marxism on individuals and society and on the process of knowledge creation as part of social reproduction. Since the 1970s Bhaskar’s (1997/1975) critical realism has been very
influential as an ontology of the social sciences, and has been adopted in parts of post-Marxist geography and beyond. Feminist geographers have also involved ontology in their writings, largely in the context of their critique and rejection of Cartesian, “masculinist” ontologies of dualism and opposition (e.g., Stanley and Wise 2002). Both realist and nonrealist influences are found in the feminist literature, which is too diverse to pigeonhole. Humanistic conceptions of ontology on the other hand are more likely to be influenced by nonrealist philosophies such as Kant’s transcendental idealism or the phenomenology of Husserl, Heidegger, and Merleau-Ponty. For example, Pickles (1983) presents a strong critique of the physicalist ontology imported into human geography through positivist research and writings, and goes on to show how phenomenology can help uncover the distortions brought about by positivism while also illuminating spatiality as constitutive part of the human world.

This all is in stark contrast to poststructuralist and postmodern discourses, which tend to be explicitly antirealist and leave no room for visions of reality structured around stable ontological cores. More recently, however, the work of the French philosopher Deleuze (e.g., Deleuze and Guattari 2007) has led to a revival of interest in ontology among critical and cultural geographers and in the social sciences more generally, while also providing theoretical support for “nonrepresentational theory” and perhaps other intellectual movements in the discipline such as “actor-network theory,” or ANT. In any case, ontologies in general human geography, where they exist, are conceptual and often sketchy, unlike the elaborate, highly detailed, formal constructions of information science that are topics of rapidly growing interest in geographic information science and parts of quantitative geography.

Geographic information science and knowledge representation

Philosophical questions and debates made their appearance fairly early on in the development of computational versions of ontology (small-o ontology). Ontologies were originally introduced as tools for facilitating the integration of data from different databases (“interoperability”) so as to allow users to formulate queries about some particular topic that may be answered with data gleaned from more than one source. This can be difficult since data and data structures for the same (or same type of) phenomenon may differ significantly depending on when, where, why, how, and by whom the data are collected, organized, and documented. For example, water quality data collected by a water-supply agency over the summer months may be quite different from data collected from the same water source for research purposes at some other time. Likewise, mountains in the United Kingdom, for example, are known to have very different characteristics from mountains in Central Asia and rivers in northern Europe are very different from rivers in southern Europe so that creating a “world mountains” or a “European rivers” general-purpose knowledge structure is not that simple. Very soon it became clear that there were issues in ontology development reaching far beyond technical or definitional discrepancies and questions about interpretations and meanings, about contexts, about user needs and perspectives, about language and cognition, about place and culture, about the proper treatment of space, time, and information, and so on, became pressing. Increasing numbers of geographers are contributing to these debates through the angle of their own subfield, be it spatial modeling, spatial cognition and behavior, cultural linguistics, spatial decision-making and planning, physical geography, or some other substantive interest.
Perhaps most fundamental of all is the question of representation: what does a small-o ontology really represent? And what are the implications of the ontological commitments one makes in adopting this or the other ontology? While philosophy per se is not a common topic of discussion in the information science community, the contrast between realist and nonrealist positions is stark. On the one hand are those who subscribe to ontology in the traditional metaphysical sense – which is the representation of the things and relations that make up the real world – while making allowances for the distortions of context and cognition. The search is for truths that correspond to what “really” is out there, meaning nature, society, the economy, and so on. An interesting form of realism foregrounds cognition as the more tractable, measurable, and ultimately relevant reality on which to base ontology development. Thus several researchers are attracted to an approach from anthropology and cognitive linguistics known as experiential realism, according to which humans, qua embodied beings, can only know reality through “image schemata” deriving from their bodily experiences in the world. These schemata are expressed in a small number of elementary metaphors such as “container,” “path,” “up-down,” or “surface,” which seem to underlie much of our thinking (e.g., “up” is good, “down” is bad, life is a journey, a place is a container, and so on). Experiential realism offers a workable compromise to researchers with milder realist leanings because it implies that the intersubjective, cross-cultural, invariant reality of cognitive schemata can substitute for the reality that cannot directly be apprehended by humans. The obvious spatial nature of these schemata is an additional attraction (Mark and Frank 1996).

Related to experiential realism is cognitive semantics, another popular approach to ontology development that is also rooted in cognitive linguistics but lacks the former’s emphasis on bodily experience. Cognitive semantics relies instead on the notion of the “semantic triangle,” which is meant to represent the relationships between real-world things, their representations as concepts in a person’s mind, and the signs (words, icons, or any other symbols) used to represent these concepts. Being more remote than experiential realism from the physical reality of human bodies, cognitive semantics is compatible with both realist and nonrealist interpretations.

On the clearly nonrealist side, researchers less interested in cognition or philosophy may simply draw on their own training, practical experiences, and intuitive understandings to produce something that works in practice, resolving conceptual problems as they go. This is the classic engineering approach that views the design of artifacts (material or symbolic, the latter including ontologies) as solutions to constraint satisfaction problems. It is consistent with a view of informational ontology as the representation of the things and relations that make up not the real world itself, but the simplified, abstract artificial worlds that researchers and professional create with their quantitative and logical models. Under this interpretation engineering ontologies may be seen as ontologies of “artificial micro-worlds,” not claiming correspondence with the actual world except in limited, specific areas and for particular purposes. The best ontologies are simply the ones that help solve the most problems.

Both this pragmatist position and the realist one represent coherent conceptual or philosophical views and there are strengths and weaknesses to both. The realist position (more specifically, naïve realism – a technical term for the belief that we see reality as it really is) is the default position in the natural and social sciences: young people are attracted to the (empirical) sciences from a desire to “discover how nature (or society) works,” though this is by no means true
of all scientists. Indeed, a number of nonrealist philosophies of science were propounded by theoretical physicists, mathematicians, and others. But, by and large, the realist view of informational ontologies is in better agreement with most of empirical science. On the downside, small-o ontology development is arguably not an empirical science, but the discipline of designing tools to assist empirical scientists in their work with information. Realism in this case risks conflating two distinct levels: that of empirical science modeling and the meta-level of ontology modeling meant to assist empirical science modeling. This compounds the standard problems of realism mentioned earlier. In any case, since informational ontologies are about knowledge representation, they are closer to epistemologies, technically speaking, than to ontologies. As for the “artificial micro-worlds” interpretation, it has the advantage of justifying the “ontology” designation for something that is clearly an insufficient representation of the world as we understand it, while also encouraging more exploratory and creative approaches, not bound by the search for a single kind of truth. On the negative side, many geographers trained as empirical scientists may have trouble accepting a view of ontology that openly claims to not be modeling the real world. Yet it should be fully consistent for someone to be a pragmatist at the tools design level and still be a realist at the empirical level. An enlightening debate among small-o ontology developers of contrasting philosophical persuasions can be found in a special issue of the journal *Applied Ontology* (Smith and Ceusters 2010).

**Theoretical foundations**

Traditional computational ontologies are of two major kinds: foundational or top-level ontologies organize very general concepts that in principle cut across domains, while domain ontologies are adapted to the specialized concepts and requirements of particular applied domains, such as biology, medicine, law, or spatial recognition of ontology as a research theme in geographic information science may be traced to a 1998 workshop on “the Ontology of Fields,” organized by the National Center for Geographic Information and Analysis (NCGIA) in Maine (“fields” here refers to one of two principal ways of representation in GIS, the other one being “objects”). Geographic information science ontologies (geospatial ontologies for short) are strongly influenced by geoinformatics and by developments in computer science more generally. Ontologies addressing spatiotemporal phenomena are often adaptations of more general ones developed in the engineering disciplines, but original contributions are also beginning to appear out of geography. The growing literature on the subject includes several different forms, from conceptual sketches and frameworks and general theories to detailed domain ontologies addressing information needs in particular subfields. The “ontological turn” in quantitative geography has served to bring conceptual and philosophical issues back to the forefront of the discipline after many years of sometimes narrowly conceived technical advances in spatial modeling and GIS. It is yet to be determined whether the promise of increased clarity, relevance, and rigor that is attracting so many geographers and others to geospatial ontology research will be realized in terms of a better articulated, more powerful, more “interoperable” geographic information science.

**Computational ontologies and geographic information science**

Following several years of development in the United States and elsewhere, the official
decision-making (e.g., Spatial Decision Support Consortium 2008). Recently the idea of a third major kind of ontologies, lightweight or micro-ontologies, has been gaining ground (see next section). Well-known foundational ontologies include the Descriptive Ontology for Linguistic and Cognitive Engineering (DOLCE), the Basic Formal Ontology (BFO), the General Formal Ontology (GFO), the Unified Foundation Ontology (UFO), the popular SUMO (Suggested Upper Merged Ontology), and others. Some of these, especially the first two, have been used and in some cases extended by geographers. As may be gathered from its full name, DOLCE is built around concepts in their relation to language and cognition, whereas BFO is a realist ontology naming and organizing the categories of entities thought to exist in the world. Ontologies are axiomatized in some formal language that enables computational modeling and reasoning. Their conceptual structure is often represented graphically in the form of trees, lattices, concept maps, or other kinds of graphs. Most are hierarchically structured, placing the more general concepts or classes at the top, with subsequent levels becoming increasingly specialized (Figure 1).

Major themes

A number of major themes cut across most foundational ontologies. At the very core of the idea of (small-o) ontology is semantics, the notion that linguistic terms and any other kinds of symbols have meanings that associate them with the entities they refer to and with other symbols, and that these meanings may not be fixed. Semantics is of course fundamental to any ontology, but unlike traditional ontologies that may capitalize on the tolerance of natural language for vagueness and ambiguity, the informational kind must specify meanings rigorously enough to be conveyed to computers. Incompatible semantics is indeed one of the main reasons why interoperability among databases is a challenge, and why computational ontologies were developed in the first place. In the geospatial domain Mark (1993) was among the first to point out that meaningful (i.e., semantically aware) standards are necessary for successful data transfer. The purpose of the ontology is to specify these meanings clearly enough so that they may be formalized, thus allowing semantic compatibility to be verified and the meanings to become computationally tractable. Some people use the term “ontologies” for simple concept taxonomies or even for map legends, but these are not true ontologies at least until the “formalization gap” is crossed.

An important distinction that, like ontology itself, has preoccupied philosophers for the past couple of thousand years is that between universals and particulars. Universals are mind-independent entities that are part of reality and typically reflect the essential qualities of particulars (e.g., the “mountain-ness” of mountains and the triangularity of triangles), while particulars (or individuals) are the specific instances of universals. Universals thus characterize realist ontologies, while nonrealist ontologies deal with concepts and their instances, with linguistic terms, or with things as cognized by humans in particular domains or situations. Practically this means that strongly realist ontologies must first specify the immutable properties of universals before particulars can be handled, whereas ontologies that start with less absolute notions of concepts in agents’ minds, language, or individuals as members of classes have an easier time adapting specifications to the requirements of particular contexts of use. In fact, the widely accepted definition of (informational) ontology as “formal, explicit specification of a shared conceptualization,” further clarified as “a description … of the concepts and relationships that can exist
for an agent or a community of agents,” clearly leans on the side of nonrealist interpretations (Gruber 1993).

Of particular interest to geographers and others dealing with geospatial ontologies are of course the concepts of space and time. Few foundational
ontologies model space and time directly, but most include spatial and temporal concepts (e.g., notions of spatial and temporal qualities), or more general concepts such as regions and intervals that can be specified for spatial and temporal domains. This allows forms of treatment of space (and time) similar to those familiar from GIS and quantitative geography, with the already formalized notions of geometry, scale, resolution, and granularity, of fields and objects and their combinations, of discrete and continuous spaces, of time as fourth dimension, and so on, to be easily represented in most ontologies. Recent proposals in geographic information science for elementary building blocks that integrate spatial, temporal, and substantive characteristics can also be accommodated.

Relating to time, many foundational ontologies adopt a high-level conceptual distinction that is quite unlike anything familiar from geography (see Figure 1). Based on a proposal by the major philosopher of science, Whitehead, entities are commonly distinguished into continuants and occurrents (the terms endurants and perdurants are also used, though there are certain semantic differences between the two pairs). Continuants are the entities that remain stable through time (e.g., ordinary objects or most abstract entities), while occurrents are events, processes, and phenomena that unfold through time, albeit with the participation of continuants (e.g., a hurricane, a university education, a war, a life). However, the continuant–occurrent distinction may be relative to scale, context, and perspective. For example, a traffic jam may be described as an occurrent – something that happens in time and then dissolves – but it can also be described as a continuant – a relatively short-lived, slow-moving object composed of many cars. Users can of course decide which representation is more suitable for a given phenomenon of interest, but forcing a choice where both views might coexist is not fully satisfactory.

Generally there is room for improvement in how most foundational ontologies handle spatiotemporal concepts. Kavouras and Kokla (2008) discuss the reasons for that state of affairs, identifying three problem areas: the lack of a widely accepted geospatial knowledge corpus; the lack of clear objectives for geospatial semantic integration; and the fact that the traditional structures and tools of geographic information science were not developed for the requirements of geospatial knowledge systems. Despite major recent progress in the areas in question, problems remain.

Critiques and recent developments

Along with engineering ontologies in general, geospatial ontologies are still very much in flux. This is partly because of the relative novelty of the field, but also because of their close relation to computer science, which is itself undergoing continuous technical and conceptual transformations of momentous significance. The standard foundational ontologies are already considered outdated in some quarters and calls for “lightweight” or (micro-)ontologies are increasingly heard, sometimes from the very developers of the former (Davies 2011). This change of heart reflects both the past experience of trying to work with monolithic structures ill adaptable to changing needs and the future vision of versatile, easily developed tools that can be tailored to specific user purposes and are suitable for mining the disorganized riches of the rapidly expanding Semantic Web. Lightweight ontologies and formal languages are being developed specifically for the Semantic Web, and should greatly facilitate publishing, finding, sharing, using, and collaborating on information that is
“out there,” somewhere on the web, outside of properly structured and documented databases.

Critiques of the state of the art in geospatial ontologies address missing functionality and other shortcomings. To begin with, it may not even in principle be possible to develop an ontology that will satisfy most people most of the time. Basic conceptual, even philosophical, problems (such as that of realism versus nonrealism) linger. Furthermore, it is difficult to adapt any foundational ontology to the changing practical context of applications, even within a given domain; there is very little work as yet on the ontology of networks, a theme of growing importance in a connected world; adequately supporting the specification of complex dynamic phenomena within an ontology remains a challenge; and lightweight ontologies, despite their great promise, are still too young to be very powerful.

Partly in response to such internal critiques the research frontier in ontology development is represented by a number of efforts, theoretical as well as technical. Of great interest to geographers is work seeking to formalize the notion of place. The practical impetus is provided by the growth of location-based services and other aspects of mobile computing, but this search for clarification of a key geographical concept may also help build bridges between thus far separate domains of the discipline. How to account for the role of context in specifying semantics and in identifying the corresponding most appropriate data and how to make ontologies more responsive to specific user purposes and needs are two further research themes of general interest.

On the technical side, the fast-moving research frontier seeks to adapt ontology development to the even faster developments in computational power and data availability and to the expanding variety of types of data sources and range of applications. Two opposing trends are notable. On the one hand, a major national-scale effort is being deployed in the United States and elsewhere aimed at developing a geospatial cyberinfrastructure within which ontology is expected to play a major role (Brodaric, Fox, and McGuinness 2009). As part of this effort the US National Science Foundation also sponsors the “Earth Cube” initiative, which seeks to create an integrated data management infrastructure across the Geosciences. On the other hand, there is a trend toward downsizing – in addition to the lightweight ontologies mentioned earlier, a topic of growing interest is the development of ontology design patterns (Gangemi and Presutti 2010). These are formalizations of common concepts that are used in different domains and can be largely standardized with no loss of generality. Several such patterns have already been developed in geographic information science, for example, for the notions of “Point of Interest,” “Transport,” and “Trajectory” (Hu et al. 2013). Note that “transport” and “trajectory” are actually image schemata (see above), concepts that lend themselves particularly well to treatment as patterns (Kuhn 2007). Further, as part of making ontologies accessible to broader communities of users, user services such as visualization, editing, versioning, documentation, and search and collaborative utilities are also being constantly expanded and improved. Integrated platforms such as Stanford University’s “Protégé” aim to make ontology accessible to a wider professional public. These initiatives rejoin the broader efforts for the democratization of “big data,” also reflected in the development of the Semantic Web, which view ontologies as the premier tools for helping turn information into knowledge.

**Evaluation**

The place of ontology in geography may be evaluated from two different perspectives. On
the one hand, interest in geospatial ontologies is growing rapidly within geographic information science and related areas. On the other hand, in general human geography, the popularity of explicitly anti-ontological philosophies and influences, such as poststructuralism, deconstruction, and postmodernism, has to a large extent pushed aside the earlier humanistic and Marxist engagement with ontology. Post-Marxism continues to count some forms of realist ontology among its tenets, and certain feminist authors also present alternative ontologies, though the feminist emphasis tends to be on epistemologies. But for a while it appeared that traditional Big-O ontologies would no longer be an active theme in the discipline. Recent enthusiasm in parts of critical geography for Deleuze’s (Deleuze and Guattari 2007) innovative metaphysics of dynamic “assemblages” in space and time may presage a revival of general geography’s interest in ontology, with further such intellectual engagements to come.

The postmodern turn away from Big-O ontology that roughly coincided with the development of geospatial ontologies may be the reason why there has been very little critique of the latter coming from the side of critical geography, unlike what had been the case with GIS a couple of decades ago. In fact, Schuurman (2006) presents a cogent defense of ontology research in geographic information science from the perspective of critical GIS. She notes the great progress achieved in GIS in meeting these earlier critiques and considers ontology to be the latest stage in the development of a more conceptually mature and technically rigorous GIS. This is an important point because, one way or another, ontology is here to stay. It can greatly increase geography’s stakes in the information age, but only as long as societal issues are not lost in code. Here humanistic and critical geography can again play a major role, as they did before in the case of GIS, to the discipline’s major and lasting benefit.

Further reading

The Open Geospatial Consortium (OGC) is an international voluntary consensus standards organization founded in 1994. In the OGC, hundreds of commercial, governmental, non-profit, and research organizations worldwide collaborate in an open consensus process to develop and promote the implementation of open standards for geospatial content and services, geographic information system (GIS) data processing, and data sharing.

History and purpose

In the early 1990s, sharing GIS data was very difficult and error prone. Each GIS vendor had proprietary data formats, application silos, and proprietary data conversion tools. Movement of data from one system to another was difficult and required the use of data translators and labor-intensive data conversion tools. Further, GIS procurement language often stated mandatory requirements that the provider must support specific proprietary geospatial data formats. This restricted open competition and increased the potential for users to become “locked in” to a specific proprietary product architecture. The net result was limited user choice, higher costs, and increased difficulty in sharing data in times of need. Perhaps worst of all, the GIS climate of the early 1990s severely restricted the market potential of the technology.

During the same time period, leaders of the open-source GRASS (Geographic Resources Analysis and Support System) community formed a nonprofit organization – the Open GRASS Foundation (OGF) – chartered to stimulate private sector support for GRASS and create a consensus-based membership process for the management of GRASS community affairs. Soon this group began looking at the issue of interoperable geoprocessing. Instead of focusing on open-source software, the group aimed to create an inclusive, open process that might (i) encourage the development of additional commercial as well as noncommercial geoprocessing choices in the marketplace, (ii) act as a sounding board for the user community to articulate its requirements to the developer community, and (iii) speed up procurement by aligning the needs of users with the product plans of vendors. The OpenGIS Project, which preceded the formal launch of the Open GIS Consortium, Inc. (OGC) in 1994, defined a vision of diverse geoprocessing systems communicating directly over networks by means of a set of open interfaces based on the “Open Geodata Interoperability Specification” (OGIS).

In response to the critical industry need for open, freely available standards to enable geospatial (GIS) data sharing, the Open GIS Consortium (OGC) was founded in September 1994 by eight charter members with this vision and mission:

- Vision: Realization of the full societal, economic, and scientific benefits of integrating electronic location resources into commercial and institutional processes worldwide.
OPEN GEOSPATIAL CONSORTIUM STANDARDS

- Mission: To serve as a global forum for the collaboration of developers and users of spatial data products and services, and to advance the development of international standards for geospatial interoperability.

In 2004, the OGC directors voted to change the name of the organization to the Open Geospatial Consortium to reflect a growing scope of activities that involved not only GIS but also imaging, sensors, location services, and more. From 1994 to 2015, OGC membership grew from 20 to more than 500 government, academic, and private sector organizations. GIS vendors are involved along with information technology integrators, data providers, universities, nongovernmental organizations, research organizations, and companies at the cutting edge of location and mobile services. As described below, liaisons with other standards, professional, and educational organizations have been an important part of the value that OGC provides for its members and the public at large.

While the OGC has its roots in North America, it now has more members in Europe than in North and South America together. The OGC was a founding member of, and continues to participate in, the Global Spatial Data Infrastructure Association, and OGC staff and members present on standards topics at conferences around the world.

Standards

The OGC has a set of formal policies and procedures that guide the consensus process for discussing, developing, processing, and maintaining OGC standards. The OGC also supports a rapid engineering and prototyping program called the OGC Interoperability Program (see below). Many new OGC standards, or enhancements to existing standards, are tested, validated, and demonstrated in interoperability initiatives as part of this program.

Most OGC implementation standards are grounded in a set of conceptual models for such topics as geometry (spatial schema), coordinate reference systems, and observations. These conceptual models collectively are known as the OGC Abstract Specification. These are conceptual models that cannot be implemented directly in operational code. OGC implementation standards based on these conceptual models provide the requirements and rules for implementing specific interface, encoding, and protocol instances. For example, the OGC Abstract Specification provides a set of mathematical definitions for geometry (e.g., points, lines, polygons). The Geography Markup Language (GML) provides the Extensible Markup Language (XML) grammar for these geometry types that can then be implemented by developers and used by end-user applications. Abstract models are technology and platform neutral. OGC implementation standards are technology or platform dependent, such as having a requirement to use the Hypertext Transfer Protocol (HTTP). More information on this topic is available at http://www.opengeospatial.org/standards.

Continual evolution of geospatial standards is necessary to address emerging technology as well as consumer trends and requirements. These include not only requirements to address such issues as the growth of mobile computing and RESTful (Representational State Transfer) programming, but also specific spatial communication and processing requirements in application domains such as hydrology, aviation, and emergency response. New requirements are often reviewed in OGC Technical Committee Domain Working Groups. The actual revision and development of OGC standards take
place in OGC Technical Committee Standards Working Groups. There is a growing need for member representatives in these groups to cross-participate in the working groups of other standards organizations whose standards may have a spatial component.

Figure 1 is based on the following documents that capture several years of Spatial Data Infrastructure implementation experience and policy:

- INSPIRE
- ISO 19119 – Services. The taxonomy of services is based on services defined in this ISO standard.
- The New Zealand SDI Cookbook
- The SDI Cookbook, Chapter 10
- W3C/OGC Web Services Model (Find/Bind/Publish)

The OGC standards baseline comprises more than 37 standards (not all of which are shown in the figure), including interface and encoding standards for:

Catalog services:

- CSW – Catalog Service for the Web: access to catalogs of information about services (including data services), symbols, devices, and other catalogs.

Encodings:

- Filter Encoding – XML and KVP (Key-Value-Pair) encoding for expressing projections, selection, and sorting clauses in a query.
- GeoXACML – Geospatial eXtensible Access Control Markup Language.
- GML – Geography Markup Language: XML grammar for modeling and encoding geographical information.
- Observations and Measurements (O&M) – General conceptual model and encoding for observations and measurements.
- Open GeoSMS – How to location-enable Short Messages (SMS).
- SensorML – Sensor Model Language: Conceptual model and XML encoding for describing a sensor.
- Styled Layer Descriptor (SLD) – Rule-based symbology encoding.
- WaterML – XML encoding and exchanging data describing the state and location of water resources, both above and below the ground surface.
- Web Map Context – Defines a structure for communicating information about the server(s) providing layer(s) in a Web Map Service (WMS) query.

Data services:

- GeoPackage – A universal file format for encoding and sharing geodata.
- Simple Features – SQL (SFS) – Standard Structured Query Language (SQL) schema for the storage, retrieval, query, and update of feature collections.
- Sensor Observation Service (SOS) – Requests an observation from a sensor or sensor archive.
- Web Coverage Service (WCS) – Provides access, subsetting, and processing for imagery and other gridded data types.
- Web Feature Service (WFS) – Provides an interface allowing requests for geographical features across the web using platform-independent calls.
Figure 1  A web services framework for OGC standards. Reproduced by permission of the Open Geospatial Consortium.
Portrayal services:

- Keyhole Markup Language (KML) – XML-based language for expressing geographic annotation and visualization on existing (or future) web-based, two-dimensional maps and three-dimensional Earth browsers.
- Symbology Encoding – XML language for styling information that can be applied to digital feature and coverage data.
- Web Map Service (WMS) – A standard protocol for serving georeferenced map images over the Internet that are generated by a map server using data from a GIS database.

Processing services:

- Sensor Planning Service (SPS) – Tasks a sensor.
- Web Coverage Processing Service (WCPS) – Provides a raster query language for ad hoc processing and filtering on imagery and other gridded data types.
- Web Map Tile Service (WMTS) – Provides map image tiles.
- Web Processing Service (WPS) – Facilitates publishing and ease of client access to calculations or models that operate on spatially referenced raster or vector data.

The design of most of these standards was originally built on the HTTP web services paradigm for message-based interactions in web-based systems. The OGC membership strives to keep OGC standards relevant for developers who employ new advances in distributed processing, such as cloud computing and the Internet of Things. At the same time, there is a strong commitment to and much deliberation over issues such as backwards compatibility, minimizing technology risk, maximizing the value of technology investments, and using the standards process to support technology planning.

Organization structure

The OGC has four operational units:

1 Standards Program: In the OGC Standards Program the Technical Committee and Planning Committee work in a formal consensus process to develop and maintain member-approved (or “adopted”) OGC standards. The OGC Technical Committee runs the standards development process with a published set of policies and procedures to carry out its work. Much of the work and discussion that goes into an OGC standard takes place in the Standards Program’s Committees Domain Working Groups and Standards Working Groups.

2 Interoperability Program: The OGC Interoperability Program organizes and executes hands-on engineering initiatives to accelerate the development and acceptance of OGC standards. These include testbeds, pilots, interoperability experiments, interoperability support services, and concept development studies. Some OGC standards originate in the Interoperability Program.

Since 1999, OGC’s Interoperability Program has conducted a multitude of initiatives that build and exercise public–private partnerships designed to accelerate the development of emerging concepts and drive global trends in interoperability through rapid prototyping of new capabilities. Such initiatives:

- reduce technology risk through accelerating development, testing, and acceptance of interoperability standards
OPEN GEOSPATIAL CONSORTIUM STANDARDS

with the refinement of standards and best practices;
- **expand the market and improve choice** by encouraging industry adoption of new standards and best practices, ensuring market availability of interoperable solutions;
- **mobilize new technologies** through providing participants with real-world experience and a platform to innovate while driving early adoption of standards; and
- **provide a cost-effective method** for sponsors and participants to share expertise and development while gaining early marketplace insight and advantage.

3 Compliance Program: The OGC Compliance Program provides the resources, procedures, and policies for improving software implementation compliance with OGC standards. The purpose of the OGC Compliance Program is to increase system interoperability while reducing technology risks. Vendors gain confidence that they are providing a product compliant with OGC standards, which will be easier to integrate and market. Buyers gain confidence that a compliant product will work with

![Diagram](image)

**Figure 2** Where the OGC fits in the standards world. Reproduced by permission of the Open Geospatial Consortium.
another compliant product based on the same OGC standard, regardless of which company developed the product. The OGC Compliance Program provides a free online testing facility, a process for certification of compliant products, and coordination of a community of developers.

4 Communications and Outreach Program: OGC staff, working with members, provide press coverage, media announcements, publications, workshops, seminars, and conferences to help technology developers and users take advantage of the OGC’s open standards. Technical documents, training materials, test suites, reference implementations, and other interoperability resources developed in OGC Interoperability Initiatives are available on the OGC Network.

Collaboration with other associations and standards development organizations

The standards development work of the OGC cannot happen in a geospatial technology standards silo separated from the larger world of information technology (IT). Therefore, the OGC makes significant efforts to collaborate and liaise with other standards development organizations (SDOs). The OGC’s earliest SDO collaboration was with the International Organization for Standardization (ISO). Since 1994, the OGC has maintained a close relationship with ISO/TC 211 (Geographic Information/Geomatics). Standards from the ISO 19100 series comprise significant topics of the OGC Abstract Specification. Further, the OGC standards WMS, GML, WFS, Filter Encoding (FE), O&M, and Simple Features Access (SF) have become ISO standards. OGC’s submission of its standards to ISO in a formal process for ISO adoption helps many organizations meet policy requirements or preference for de jure international standards (see Figure 2).

The OGC has developed a set of formal relationships with other standards organizations, with the details of cooperation often codified in memoranda of understanding. OGC works with other SDOs to help standardize the representation, processing, and exchange of geospatial/location information in a consistent manner throughout the standards stack. The OGC works with a range of national, regional, and international standards bodies including W3C (World Wide Web Consortium), OASIS (Organization for the Advancement of Structured Information Standards), TM Forum, buildingSMART, and the IETF (Internet Engineering Task Force), with more than 50 alliance partnerships listed on the OGC’s Alliance Partners webpage. Some of these are associations that do not develop standards but that provide the OGC with important knowledge about the geospatial needs of particular industry and professional domains. The OGC’s relationships with these standards groups and associations provide their members and those of the OGC with opportunities to resolve interoperability issues and to participate in joint outreach efforts to promote (i) participation in standards development, (ii) vendor implementation of standards, and (iii) market uptake of products that implement standards.

Open innovation

Faïz Gallouj
Faridah Djellal
Lille 1 University, France

Innovation is an old and fundamental problem that concerns all social sciences, including philosophy, sociology, economics, history, and, of course, geography. It is described as a categorical imperative, a condition for the survival of businesses, companies, territories, and nations. The popular concept of “open innovation” (Chesbrough 2003) is used to review a number of key aspects of the innovation issue. The concept of open innovation is a useful metaphor, a mobilizing semantic innovation, rather than a robust theoretical concept. This metaphor is used to report on the major contemporary openings made by experts in “innovation studies,” and in so doing, a number of important concepts in this field are reviewed. The openings in question concern not only the modalities of organization and implementation of innovation as implied by the concept of open innovation, but also the content and forms of innovation as well as the sectors that engage in these activities.

Open innovation: nature and forms

The first question to address is the definition of innovation and its typologies. Although this question is an old one, it is generally believed that Joseph Schumpeter (1934) is the author who provided the most complete answer. It will be shown how he truly helped open up the definition of innovation. Other pathways toward openness that have supplemented this Schumpeterian tradition of openness will then be examined.

The Schumpeterian tradition of openness

In the work of Schumpeter there are many concepts that not only have become “common knowledge,” but have also become part of our everyday language and culture beyond the academic sphere. This is particularly true of the distinction between “invention” and “innovation” and the concepts of “creative destruction” and “Schumpeterian entrepreneur.”

Thus, according to Schumpeter, innovation, also called new productive combination, is distinguished from invention. The former is a discontinuous socioeconomic process, whereas the latter is a continuous noneconomic process. Innovation is thus the result of the socialization process of the invention, that is to say, its meeting with the market. This relatively rare but more frequent meeting in contemporary economies between two disparate worlds, the scientific and technical world and the socioeconomic world, is brought about by an individual with particular psychological characteristics: the entrepreneur. The “Schumpeterian entrepreneur,” as opposed to the manager (the operator), is a risk-taker, motivated as much by the prospect of profit as by hedonistic reasons (pleasure, sense of adventure and challenge, etc.). He or she has a maieutic function and is characterized by the ability to enrol and mobilize networks (partners, investors, etc.). The introduction of innovation by the entrepreneur (and then by research and development (R&D) departments of large enterprises) results in “creative destruction.”
whereby innovative companies prosper while others are doomed to fail. Innovations that cause creative destruction occur in clusters in which a major innovation or breakthrough induces a myriad of other innovations.

These different concepts establish certain boundaries for innovation. Schumpeterian openness lies in the typology of forms of innovation that he suggested. Indeed, while according to the traditional economic view there are only two types of innovation, product innovation and process innovation (with a focus mainly on the latter), the Schumpeterian view identifies five types: new products, new production methods, new markets, new sources of supply, and new forms of organization. The openness obviously arises because more types of innovation are considered, but also reflects the importance given to nontechnological innovations. After all, some of these types of innovation are nontechnological in nature (organizational innovation, new markets), and product and process innovation can also take on both technological and nontechnological features.

Temporal or historical openness

Neo-Schumpeterian analyses (Nelson and Winter 1982; Dosi 1982) opened up the concept of innovation in time or history. Innovation is no longer seen as “manna from heaven,” an artifact set in stone, but as an endogenous problem-solving process for the specific problems of an organization. The journey is as important as the destination (the result) and is part of the essence of innovation that is therefore a cumulative process in which different forms of learning (learning by doing, by using, by trying, by consulting, etc.) play an essential role.

The combination of these two characteristics of specificity and cumulativeness has resulted in a number of important concepts that may have operational or managerial value. The concepts of irreversibility, technological lock-in, and path dependency reflect the reduced technological freedom over time and the difficulty of going backwards once technological choices have been made. Path dependency can be, in some cases, a strategic problem for an organization. An organization that has been successful in its field and is reluctant to experiment with alternatives gets locked into a competency trap and remains on its cognitive and technological trajectory.

The concept of technological trajectory is defined as a possible direction taken by a technological potential based on a technological paradigm, that is to say, a general model of solution of selected technological problems, based on selected scientific principles and on selected technologies (Dosi 1982). Technological trajectories can be characterized in different ways. They can be powerful or weak, localized or general, complementary or competing. There are so-called natural trajectories, that is to say, technological developments that are necessary and seem to be inevitable (mechanization, miniaturization, etc.). This concept of technological trajectory is a key element of Pavitt’s taxonomy (1984) in which the economy is divided into four groups of firms with similar technological behavior (trajectories): supplier-dominated, scale-intensive, specialized suppliers, and science-based.

The openness of institutional definitions of innovation

Building on the theoretical Schumpeterian openness, international statistical institutions, in particular the Organisation for Economic Co-operation and Development (OECD), have worked to develop and improve innovation indicators for measuring and comparing the characteristics of innovation dynamics using national and international surveys. Thus, while
in its initial version the Oslo Manual (of innovation indicators) distinguished two types of innovation, technological product innovation and technological process innovation, the latest version (OECD 2005) adds two other forms: organizational innovation (new or significantly improved knowledge management systems, a major change to the organization of work, new or significant changes in the relations with other firms or public institutions) and marketing innovation (significant changes to the design or packaging of a good or service, new or significantly changed sales or distribution methods).

This revision takes into account some nontechnological forms of innovation in industry and services and is undeniably a breakthrough, but other forms of innovations remain hidden, in particular services and social innovation (see below). The innovation gap remains, particularly in the following fields: nontechnological product innovations (a new insurance contract, a new financial product, or a new field of consultancy expertise, for example), nontechnological process innovations (methodologies and protocols), ad hoc and custom-made innovations, innovation in public services, innovation in complex packages (also called new concepts), and new formulas (e.g. in commerce or the hotel industry).

Beyond economic innovation: social innovation

Another important opening in the understanding of innovation involves what is known as social innovation (Franz, Hochgerner, and Howaldt 2012). In the context of growing concerns about the need for sustainable development, the concept of social innovation is increasingly important. Its success (both operational and theoretical) is explained in particular by the chronic nature of the socio-economic crisis in developed economies since the 1970s, demographic changes (especially population aging in rich countries), the failure of development policies, and growing environmental concerns. However, this does not mean that the definition of social innovation is clear. Despite many efforts to clarify the notion, it still remains particularly vague. It is heterogeneous and eclectic and covers a wide variety of concepts. Social innovation is often defined in terms that describe its shape or nature, its process and its actors, its target and its purposes: it is said to be immaterial, nontechnological, organizational, noneconomic, nonmarket, informal, local, or designed to solve social problems. However valuable these characteristics may be in defining social innovation, they do not provide indisputable technical criteria. It is easy to find exceptions that refute them. They should simply be regarded as a general indication of the social nature of an innovation.

The opening of innovation toward services

The recognition of innovation in services is probably the most important step forward (especially in terms of public policy) made during the past decades. Innovation studies were developed mainly with reference to industry and above all concerned the dynamics of technological innovation. Services long remained unconcerned by innovation issues, as these two fields ignored one another. The recognition of innovation in services is not independent of the various other openings mentioned above. After all, social innovation is often a service innovation and an innovation in services, and it is primarily the innovation gap in services that is reduced by the shifts to a wider definition of innovation, whether theoretical or institutional (incorporated in the revision of innovation indicators).
Attempts to interpret and understand innovation in services have evolved in four different analytical perspectives, reflecting the increasing importance of innovation in services and of services in innovation (Gallouj and Djellal 2010). The technologist or assimilationist perspective views innovation in services in the same terms as industrial innovation, with emphasis on its relationship to technical systems. Insofar as it is concerned primarily with innovations adopted by services from industrial sectors, the assimilationist perspective is a perspective of subordination. The differentiation (or demarcation) perspective focuses on the distinctive characteristics of services and seeks to identify innovation activities that are invisible to traditional (assimilationist) systems. The first in-depth studies favoring a demarcation perspective focused on knowledge-intensive business services (all forms of consulting), as well as financial services (banking and insurance). The inversion perspective breaks with the idea that services are subordinate to industrial innovation, giving knowledge-intensive business services (KIBS) an active role in the innovation of their clients (especially industrial clients), in a cognitive balance of power that can tip in favor of KIBS. In this case, services, to some extent, dominate industry and not the opposite. At the meso- and macroeconomic levels, KIBS are seen as essential components of local, regional, and national innovation systems. Finally, the integration perspective aims to develop an analytical framework that takes into account both goods and services, both technological innovation and nontechnological innovation. This perspective is justified by the converging trend in contemporary economies toward the servitization of goods and the industrialization of services, that is, a blurring of the boundaries between the two.

Open innovation in terms of organization and implementation

Strictly speaking, the concept of open innovation is not a new development; rather, as already pointed out, it is a particularly effective semantic innovation that covers often more robust economic concepts (but also more complex or esoteric ones). Open innovation reflects an “extroverted” and cooperative way of organizing innovation that has many different configurations. This mode of innovation is characterized by a multiplicity of actors and interactions.

The open innovation model contrasts with the traditional linear model. The latter implies a sequential (and specialized) organization of the innovation process that greatly limits interactions and feedback. In management science, this linear model is illustrated by a well-established theoretical tradition that views the production of new goods or new services according to the new product (or new service) development methodology that uses planned and systematic processes.

Open innovation is an “umbrella concept” that covers multiple types of collaborative innovation processes that are more or less sophisticated, more or less long, more or less formalized, and so on. Thus, the evolution (opening) of the model is illustrated not only by the multiplicity of actors and the diversity and density of their interactions, but also by the varying duration of the innovation projects or facilities (short- or long-term projects, transient or permanent facilities) and the varying degree of institutionalization (formalized projects, informal projects, ad hoc projects). Accounting for this diversity is achieved by distinguishing (simplistically and doubtless with a certain abuse of language) two levels of analysis of the opening of the organization mode: the microeconomic level and mesoeconomic (or even macroeconomic) level.
The microeconomic level

At the microeconomic level, the general perspective of open innovation covers various cooperative models that are more or less sophisticated and formalized. Note that some of them are actually intermediate forms or isolated components of reticular or systemic forms mentioned in another level of analysis: the mesoeconomic level described in the next section.

The perspective of open innovation covers a number of nonformalized and unplanned or emerging models that have been seen in services but whose application is broader, such as the rapid application model, the practice-based model, bricolage innovation, and ad hoc innovation. In the rapid application model, planning does not precede production, as it does in the traditional linear model. Once an idea emerges, it is immediately developed as the service in question is being provided. Thus, the process of providing the service and the process of innovation are one and the same. The practice-based model involves identifying changes in service practices and developing and institutionalizing them. The bricolage model describes change and innovation as the consequences of unplanned activities carried out in response to random events and characterized by trial and error and “learning on the job.” Finally, ad hoc innovation can be defined as the process of constructing a (novel) solution to a problem identified by the client company. This interactive process requires the participation of the customer and is described as ad hoc because it is “unplanned” or “emerging,” which means that it is consubstantial with the process of service provision, from which it can be separated only in retrospect. Ad hoc innovation is recognized as such only after the fact.

Open innovation also includes the chain-linked, or interactive, model introduced by Kline and Rosenberg (1986). This well-known model is doubtless a solid theoretical formulation of the idea of open innovation. It challenges the linear (sequential) vision of innovation and instead suggests a model characterized by multiple actors and places of innovation and the key nature of the interactions between them, at different stages of the innovation process. Thus, unlike the linear model, Kline and Rosenberg’s model has several related paths: (i) a central chain of innovation going from the invention (or design) to development, production, and marketing; (ii) short or long feedback loops that link these sequences together; (iii) multiple links between the central innovation chain and knowledge and/or research chains; (iv) a relatively rare direct link between science and invention that leads to radical innovations (e.g., the laser, nuclear energy).

A configuration variously known as the consultant-assisted, or interactional, innovation model is also part of open innovation. This model describes the role of consultants, and more generally KIBS, in their clients’ innovation processes. KIBS are information and knowledge-processing machines that produce information and knowledge in the form of technological solutions, but also organizational, strategic, legal, fiscal, and other solutions. They constitute an external source of knowledge and innovation for their customers. This model is also sometimes called the Schumpeter 3 model in that it supplements the Schumpeter 1 model (innovation generated by the individual entrepreneur) and the Schumpeter 2 model (in which the spirit of enterprise is associated with the R&D departments of large firms).

The opening of innovation to the customer (the user-driven innovation model) is not a new phenomenon. Statistical analyses all show that customers are the main sources of innovation in businesses. However, customers and users are not all on the same level, and the literature identifies “lead users” who are strategic resources in
innovation projects. In modern economies, the involvement of customers or users is increasing as two new situations arise: (i) the promotion of research and innovation by customers or users in some areas and (ii) the strategies of some companies to involve customers, in different ways and to varying degrees, in the innovation process. Examples of this include the crucial role of patient organizations in research and therapeutic innovation, crowdsourcing, or the use of social media in business innovation.

The meso- and macroeconomic level: networks and systems

Innovation networks and the associated concept of innovation systems are opening up innovation even more. These concepts have been undeniably successful for two decades and they will first be defined before exploring the reasons for their success as both theoretical and operational tools.

An innovation network can be considered both as a structure and as an intermediate mode of coordination (between market coordination and hierarchical coordination). As a structure, an innovation network is a mode of organization dedicated to innovation that comprises a certain number of actors and the learning relationships between those actors. This structure can be described in different ways.

1 According to the nature of the actors involved (and the nature of the relationships between them).
2 According to the nature of the innovation – traditional innovation networks are essentially devoted to technological innovation.
3 According to how the structure is formed – a distinction is made between planned networks, which are set up and orchestrated by one agent, and spontaneous networks, which emerge in a self-organized way because of the convergence of the activities of agents confronted with a problem.
4 According to how the structure operates – it can operate in either a top-down or a bottom-up mode. It can also operate in “caretaker” mode (there is a hub actor who acts as systems integrator) or “noncaretaker” mode (responsibilities are shared).
5 According to the life cycle – innovation networks are born, reach maturity, and may die.

An innovation network involves the establishment of relationships based on trust, reputation, and mutual dependence between selected partners. As a mode of coordination between economic agents, it is more effective than hierarchical coordination (integration in the company) that reduces transaction costs, but brings with it the risk of bureaucratization, which may endanger innovation (a risk already mentioned by Schumpeter). It is also more effective than the market since it is difficult to establish explicit contracts for complex and uncertain research and innovation outputs and there is a risk that strategic secrets might be divulged.

Open innovation also covers new specific innovation networks (public–private innovation networks in services, or ServPPINs) that develop in a dominant service economy. These ServPPINs describe the collaboration between public, private, and third-sector service organizations in the field of innovation (Gallouj, Rubalcaba, and Windrum 2013). They differ from traditional innovation networks in several ways. First, relationships between public, private, and third-sector service organizations are pivotal to the arrangement. Next, service providers are the key stakeholders in the process. Lastly (and the corollary of the previous characteristic), nontechnological innovation (service innovation), often neglected in the literature, is also taken into account. Gallouj, Rubalcaba,
and Windrum (2013) provide a long list of ServPPINs case studies in four service sectors: health, knowledge-intensive services, tourism, and transport. These include public–private networks to develop innovation in elderly care, new tourism products, new training programs focused on patient-centered diabetes education, innovative mobility support services to help public transport users in their daily mobility by providing them with information, and so on.

The innovation network concept has been experiencing growing theoretical success for several decades. It is characterized by its simplicity and its flexibility and it has considerable heuristic value. Its theoretical (but also operational) success lies within its ability, on the one hand, to assimilate many other more basic analytical tools and, on the other hand, to incorporate itself into other, broader concepts that have been undeniably successful as well. For example, among others, the following basic concepts play a major role in the constitution and dynamics of innovation networks: learning (in its various forms: learning by doing, by using, by trying, by consulting, by interacting, etc.), absorptive capacity, economies of scale, scope and agglomeration, transaction costs, positive externalities (spillovers), particularly network externalities, proximity (geographical, cognitive, organizational, social, institutional), and so on.

On the other hand, the notion of the innovation network is the basis for all the concepts in the systems tradition, whether they be national, regional, local, or even technological and sectoral innovation systems, innovative milieus, technological districts, clusters, and so on.

Empirical studies devoted to identifying innovation systems and networks and to the analysis of how they function and perform have steadily increased over the past decades. The pioneering theoretical studies on national innovation systems (NIS) always include concrete cases. For example, Nelson (1993) provides a description and analysis of the NIS of 15 countries. The OECD has been the initiator of many studies that map the NIS profiles of member states (and the underlying networks) and compare their effectiveness. There are also a great many empirical studies devoted to regional or local innovation networks and systems. The recent empirical literature emphasizes the notion of a cluster, which is the new emblematic form of local innovation network or system. It makes a distinction between traditional or low-tech clusters (i.e., automotive, textile, chemistry) and high-tech clusters (information and communication technologies, biotechnologies, nanotechnologies, environment, aerospace and defence, multimedia, etc.). The former follow established technological trajectories, which are sources of incremental innovations with a focus on exploitation rather than exploration. Conversely, the latter are characterized by intense R&D efforts and radical innovations and follow new technological trajectories.

Public policy is another domain of success for system- and network-based approaches to innovation. Theoretical approaches to innovation not only provide tools for mapping existing systems and networks and measuring and comparing their performance, but also provide concrete tools for action (e.g. from a benchmarking perspective). Inspired by the various versions of the concept, policymakers have implemented strategies, especially with regard to spatial development and planning, that seek (from a systems perspective, whether geographic or sectoral) to encourage agglomeration – in other words, to strengthen or create innovation networks of varying sizes and degrees of complexity. Thus, while NIS and the corresponding networks form the basis of science and technology policies at both national and European levels, regional innovation systems and networks and clusters
OPEN INNOVATION

(such as the innovative milieus and industrial districts of past decades) are notions that today lie at the heart of local and national policies in many countries, even though they may be known by different names: “skills clusters” in Germany, “knowledge clusters” and “industrial clusters” in Japan, and “competitiveness clusters” in France.

Optical remote sensing

Guofan Shao
Purdue University, USA

There are various definitions of remote sensing but none are universally recognized. According to the Cambridge English Dictionary, the word “remote” means far away in distance and “sensing” means being aware of something. Thus, “remote sensing” can be literally defined as being aware of something from a far distance. The word “optical” means connected with light. A simple definition of optical remote sensing (ORS) would be being aware of something from a far distance with light. This definition can be divided into four parts: “being aware of,” “something,” “a far distance,” and “light.” Here, “being aware of” is to identify, detect, measure, quantify, and so on; “something” includes objects, phenomena, and processes on Earth; “a far distance” ranges from short distances (as long as there is no physical contact) to hundreds or thousands of kilometers; “light” is solar radiation (i.e., sunlight) or human-made radiation. According to energy sources and radiation wavelengths, remote sensing methods can be classified into four remote-sensing fields: optical remote sensing, thermal remote sensing, LiDAR remote sensing, and radar remote sensing (Figure 1).

Sunlight

Sunlight is the energy foundation for ORS (Figure 2). Just as human eyes detect things that reflect sunlight, ORS sensors record light that is reflected from things on Earth.

Properties of sunlight

Sunlight is electromagnetic radiation (EMR), which is characterized by its wavelength and frequency. Each wavelength corresponds to a frequency and vice versa. Radio and TV signals are also EMR. Different channels have distinct frequencies. ORS signals are divided into channels or bands. Instead of frequencies, wavelengths are commonly used to distinguish ORS bands. The full spectrum of sunlight ranges from very short (<0.1 micrometers or μm) to very long (>1 m) wavelengths. Human eyes are sensitive to the band of wavelengths from about 0.4 to about 0.7 μm, which is called visible band in ORS (Figure 3). The visible band consists of three colors: red, green, and blue (RGB). Blue wavelengths are approximately 0.4–0.5 μm, green is 0.5–0.6 μm, and red is 0.6–0.7 μm. The three visible-light bands can be combined into a single band called panchromatic band or separately into blue, green, and red bands, respectively. EMR with wavelengths between 0.7 and 1.3 μm is the near-infrared (NIR) band; EMR with wavelengths between 1.3 and 3.0 μm is the shortwave infrared (SWIR) band (although there are various definitions for NIR and SWIR wavelength ranges). Because the NIR and SWIR bands are strongly reflected from the Earth’s surface, they both are together called the reflected infrared band. Human eyes cannot detect infrared light but ORS sensors can. Both the visible and reflected infrared bands are the most frequently used bands in ORS.

infrared image can provide information beyond the capability of a visible image (Figures 4 and 5).

Sunlight transmission in the atmosphere

Part of the sunlight incident on Earth is absorbed by the atmosphere and part is reflected. In other words, not all the incident sunlight passes through the atmosphere. The bands that are absorbed by the atmosphere are called absorbed bands because EMR in these bands barely reaches the Earth’s surface. The bands that pass through the atmosphere are called transmitted bands and mostly reach the Earth’s surface. Different atmospheric gases absorb different wavelengths of sunlight but the gas density determines the total amount of sunlight absorbed. This phenomenon provides the foundation for detecting gas (such as water vapor) content in the atmosphere: by measuring the magnitude of certain absorption bands on ground, the gas content of the atmosphere may be determined. However, only the transmitted bands are useful for detecting land resources with ORS. There are two distinct but interrelated remote sensing applications: atmospheric remote sensing and land resource remote sensing.

The reflection of sunlight in the atmosphere is multidirectional and so is called scattering (Figure 2). The proportion of scattered sunlight varies with wavelength – shorter wavelengths scatter more. For example, the proportion of blue-light scattering is about 15 times greater than red-light scattering. This explains why the sky (atmosphere) looks blue on a clear day. This also has implications for ORS data quality: a blue-light sensor is much more likely to capture scattered light than a red-light sensor. Scattered light makes images look foggy. Because the infrared band is at a longer wavelength than the visible band, an infrared sensor receives only a
small amount of scattered light, making infrared images look sharp.

**Sunlight reflected from the Earth’s surface**

Sunlight that reaches the Earth’s surface is reflected or absorbed by the surface (Figure 2). The reflected sunlight makes it possible to distinguish things or objects on Earth by eye or with ORS sensors. The amount of reflected sunlight varies for different objects and results in different shades of brightness. For example, fresh snow is bright white because it reflects a lot of sunlight; asphalt is dark because it reflects little...
sunlight. Within the visible band of sunlight, healthy vegetation in the growing season reflects more green light than blue or red light, making healthy vegetation look green. This suggests that the reflection of sunlight is a function of the sunlight that reaches the Earth’s surface, the type of object from which it is reflected, and the wavelength.

ORS data resolution

Radiometric resolution

ORS sensors convert object brightness into digital numbers to represent object brightness values, which range from 0 for extremely dark objects to a large number (e.g., 255) for extremely bright objects. If the range of brightness values is 256 (0–255), the data quantification level or radiometric resolution is eight bits (because $2^8 = 256$); if an ORS sensor provides 12-bit data, the range of the data recorded will be $2^{12} = 4096$ (0–4095). The earliest generation of digital-satellite ORS data was six bits (e.g., Landsat 1-3) whereas the latest satellite ORS data can be as high as 16 bits (e.g., Landsat 8). The higher the radiometric resolution, the greater the reparability power the data have. For example, two objects with brightness values of 25200 and 26000 when a 16-bit ORS sensor is used would have the same value of 25 when a six-bit ORS sensor is used.

Spatial resolution

The digital data collected by ORS sensors consist of frames or scenes. Each frame of data covers a rectangular area and may contain multiple bands.
OPTICAL REMOTE SENSING

Figure 4  Visual comparison between blue-band picture (left) and near-infrared-band picture (right). Broad-leaved trees and coniferous trees are hardly distinguishable on the visible-band picture but broad-leaved trees look much brighter than coniferous trees in the NIR. The two images received the same automatic correction with Microsoft Office Picture Manager. The area of each picture is about 4 ha. Data source: USDA National Agriculture Imagery Program. Image acquired from Tippecanoe County, Indiana, USA, on June 8, 2012. Spatial resolution is 1 m.

Each band of data within a frame is divided into rows and columns. Corresponding to any row and column, there is a picture element called a pixel, which is a square area with a single brightness value. The dimension of the pixels is the same within a frame of data and is called spatial resolution. The smaller the pixels, the higher the spatial resolution, and the more rows and columns for a given area of land covered by a frame. The position of each pixel is labeled with a row number and a column number. The spatial resolution of ORS data ranges from a few centimeters to hundreds of meters, and each frame can cover an area ranging from dozens of hectares to hundreds of thousands of square kilometers. Depending on the purpose of ORS applications, certain spatial resolutions are more preferable than others. An increase in spatial resolution is normally helpful for visual interpretation (Figure 6) but quantitative analysis of high-spatial-resolution data usually requires complicated methods that require high computational power.

Spectral resolution
ORS data vary with the number of bands, which is referred to as the spectral resolution. The typically available ORS data consist of three categories: panchromatic data (1 band), multispectral data (2–tens of bands), and hyperspectral data (hundreds of bands). Panchromatic data combine blue, green, and red wavelengths into one band, and commonly come with multispectral data. Multispectral data normally have at least three bands, including three visible wavelengths or green, red, and one near-infrared wavelength. Four-band ORS data normally contain three visible bands and one near-infrared band. Some satellite ORS data have more than four bands and their bands are continuous in wavelength. Hyperspectral data contain continuous bands with wavelengths ranging from the visible to up to 2.5 μm or greater. In general, the higher the spectral resolution, the more information an ORS dataset contains. However, in ORS data analysis, the number of parameters increases exponentially with the number of bands. This means that larger reference or training datasets are necessary for analyzing ORS data with a greater number of bands. A subset of bands sometimes is optimal for information extraction.

Temporal resolution
The unavailability of ORS data is often a limiting factor for ORS applications. Every corner of the Earth’s surface has been covered by ORS data but some regions have more repeated coverage than others. The frequency or revisit time of the repeatable coverage within a certain time frame is called the temporal resolution, which
Both natural grass (left) and synthetic grass (right) are used for football fields but their images have totally different colors when the near-infrared band is used instead of the red band.

Comparison between a 30-m-resolution Landsat image (left) and a 2–4-m-resolution image (right) of an illegally logged forest landscape in North Korea (Tang et al. 2010).
characterizes the potential availability of ORS data. For example, Landsat TM data repeat the same area every 16 days. Some other satellite ORS sensors have flexible viewing angles and can increase repeatability over the same area with oblique views. Multiple satellites of the same type can be used to increase temporal resolution. The USDA national agriculture imaging program (NAIP) has provided digital orthophotos for the entire United States once a year since 2003. The MODIS sensors have a temporal resolution of 1–2 days and are useful for tracking wildfires. In any case, repeated images over the same area imply permanent time-series records and provide the data foundation for detecting changes that happened in the past. ORS data from multiple seasons can distinguish phenological differences among different plants or vegetation types and are more powerful for vegetation classification than single-season ORS data.

ORS types based on distance

Airborne ORS

The first aerial photographs were taken from balloons in the 1860s. Aerial photographs were later taken from airplanes in World Wars I and II. Black and white, color, visible, and infrared films were used until the 1990s, when digital sensors gradually became more economical and effective. In many parts of Europe and North America, aerial photographs have been available since the late 1930s or early 1940s. Vertical aerial photographs helped the development of various map products, such as topographic maps. The current aerial photographs are almost exclusively in digital format. A typical example is the USDA NAIP. The relatively low altitudes (ranging from tens to thousands of meters) of airplanes cause locational errors for ground objects with different elevations; such a phenomenon is called displacement. Digital orthophotos are a type of data that are a mosaic of aerial photographs following displacement corrections so that they can be used as maps.

Airborne ORS has been rapidly advancing toward higher spatial and spectral resolutions. It is not surprising to see digital aerial photographs with a spatial resolution of a few centimeters. Hyperspectral digital aerial photographs are also available. Airborne ORS becomes even more flexible, safer, and less expensive when unmanned aerial vehicles (UAVs) are used to carry ORS sensors or cameras (Tang and Shao 2015). The USDA Forest Service has made systematic efforts with UAV ORS for wildfire control, forest health monitoring, and forest management (Ambrosia et al. 2011).

Spaceborne ORS

Spaceborne ORS or satellite ORS is commonly done with Earth-orbiting satellites, which have no limitations regarding national borders and makes ORS globally accessible. The orbits of remote-sensing satellites are between 600 and 900 km above the surface of the Earth, which is tens or hundreds of times higher than airplanes. Thus, vertical satellite images are less distorted than aerial photographs and have spatial properties similar to topographic maps. The first generation of ORS used films and was used for military purposes. Since the 1970s, civilian ORS has been developed for imaging Earth’s resources and meteorological purposes by using scanners. The earliest civilian spaceborne remote sensing was the United States’ NASA Landsat 1, which was launched in 1972. Landsat remote sensing has become the longest ORS over the world. Landsat 8 was launched in 2013 and its imagery products have the highest spatial resolution of all the free satellite data from the U.S. government (Table 1).

All the ORS products from the US government are free of charge. While the US

government has continued developing medium- and coarse-spatial-resolution data for weather forecast and global change activities for more than three decades, private firms have made great contributions to the development of high-spatial-resolution ORS systems (Table 2). Each scene of high-spatial-resolution data is much smaller than that of the coarse-spatial-resolution data, but the high-spatial-resolution sensors have flexible lens pointing angles and, thus, can shorten their revisit time. The five satellites from RapidEye contain identical multispectral, equally
calibrated sensors, which makes them capable of covering relatively larger land areas with vertical images. The geostationary operational environmental satellites (GOES) stay continuously over one position on the Earth’s surface and constantly observe the weather.

Ground-based ORS

For the purposes of sensor calibration and in situ applications, ORS can be operated by hands, on vehicles, or on towers as platforms on the ground. Ground-based ORS is not mainstream ORS but is a flexible approach and can be used without temporal restrictions. The imagery of ground-based ORS can be obtained at spatial resolutions of as high as centimeters or millimeters, and its applications are commonly found in intensive agricultural experiments.

ORS data analysis

ORS data consist of numbers, and often a large amount of numbers. It is up to analysts how to present and interpret the numbers. The methods of ORS data interpretation and presentation vary with the purposes of ORS applications. It is essential to display the numbers as images that can be visually interpreted by humans (Figures 4 and 5). Various computer techniques or algorithms have been developed to assist analysts to carry out automated, quantitative analyses of ORS data. Useful information can be extracted through the quantitative analysis and often is presented in map formats, such as land-use maps and weather-forecast maps.

Data display

As computer technology has advanced, the capabilities of remote sensing have continuously been improved. ORS images were displayed only with single-color dots or symbols in the 1970s–1980s but are now available in “visual reality” formats. The current image-display techniques were unimaginable 3–4 decades ago when the first generation of civilian satellite imagery became available. If one band of ORS data is displayed, black-and-white images are formed; if two or three ORS bands are used, color images may be formed. ORS bands can be combined freely to obtain different looks for the images. For example, ORS data with six bands can have 216 ($= 6^3$) combinations of band displays. When blue, green, and red bands are displayed, it is possible to obtain images with natural colors that are familiar to human eyes; all other combinations, 215 (out of 216), result in fake or pseudo colors. In general, the more colors that are shown, the greater is the amount of information in an image. Researchers have developed various techniques to maximize information from a single display of multispectral and hyperspectral ORS data, including band selection and transformation (Landgrebe 2003; Jensen 2005). A typical band-transformation technique is principal component analysis (PCA), which compresses significant information on multispectral ORS data into a smaller number of new bands (Shao and Duncan 2007). One of the most astonishing band transformations is Tasseled Cap (TC) (Jensen 2005), which generates individual bands that have explicit land-surface implications, such as greenness, brightness, and wetness. Image enhancement is also a common practice with ORS data but is used primarily for visual interpretation rather than information extraction.

Information extraction

Information extraction from ORS data is the basis for various ORS applications. No two natural features are identical; neither are two
pixels if radiometric resolution is high enough. Furthermore, the reflected sunlight captured by an ORS sensor is controlled by many factors that vary with time and position (Figure 2). Therefore, there are large variations in pixel brightness and no two images are identical, even for the same type of ground features. That is why many methods or algorithms have been proposed to extract information from ORS data (Landgrebe 2003; Lu and Weng 2007). There are supervised and unsupervised algorithms of information extraction (Jensen 2005), although both actually require input from analysts. Blind ORS-data analysis without ground experience or knowledge is an unreliable and even irresponsible exercise. Following information extraction, the extracted information must be validated with independent sample data that should be 100% accurate (or close to 100% accurate) (Congalton and Green 1999; Foody 2002). ORS data with relatively low accuracy can have unexpected negative impacts on its downstream applications (Shao and Wu 2008). Regardless of pixel size, there are always pixels that cross boundaries of two or more ground features. Mixed pixels are another characteristic of ORS data and represent one of the error sources from information extraction. Fuzzy classification methods have been developed to extract proportional information from mixed pixels (Jensen 2005).

Remote-sensing software

Since the 1960s, many efforts have been made to develop computer programs for ORS data analysis; a computer program called LARSYS was one of the first systems. A number of systems in government laboratories, university research laboratories, and several commercially offered products were the descendants of LARSYS. MultiSpec is its direct descendant and contains advanced research results; it is available to download via the Internet (https://engineering.purdue.edu/~biehl/MultiSpec/).

There are a number of commercially available remote-sensing software systems. They include Erdas Imagine, ENVI, ER Mapper, INDRISI, PCI, TeraVue, and TNTmips. In general, commercial remote-sensing systems have a broad range of geospatial functions for users in different fields and at varied technical levels whereas free-ware, such as MultiSpec, may be specialized for research- and/or education-oriented capabilities.

ORS applications

ORS can be directly used for detecting things on Earth: their position, if they have changed, and so on. In fact, its indirect applications are even broader and deeper, and are playing an active role in sustainable development all over the world.

Day-to-day applications

Topographic maps on various scales were all derived from aerial photographs, which have become broadly available since the 1940s. Through digitalization, paper maps were converted into digital formats under the framework of geographic information systems (GIS). GIS maps are an important part of the navigation function of the global positioning system (GPS), and GPS navigation has now become an important part of daily life.

Google Earth (http://www.google.com/earth/) has a huge collection of ORS images that cover every corner of the Earth’s surface, and it integrates ORS images from other data sources. Thanks to state-of-the-art image computation techniques, ORS images from Google Earth can be freely expanded or contracted on computers that are connected to the Internet. One can also view ORS images in three
dimensions on Google Earth. Historic images on Google Earth are useful for detecting changes on the ground, be they due to natural causes or human activities. Because of their global coverage, ORS images on Google Earth are useful for assessing land use in places where ground access is impossible (Tang et al. 2010).

Specialized applications

Remote sensing is an effective and efficient technique for many land-use- and land-cover-related investigations at scales from landscape to global. The greater the spatial scales, the more advantages remote sensing can have. Any global or continental map products, such as the global tree-cover map (Defries et al. 2000), which is derived from remote sensing data, could not be obtained or would be too costly with ground survey methods. As a conventional remote sensing technique, ORS has been broadly used since the end of World War II. Airborne and spaceborne ORS has made unique contributions to understanding the dynamics of the atmosphere, oceans, and the vegetation cover of the land and has provided new perspectives in the study of the solid Earth (Goetz et al. 1985). Associated with continuous advances in remote sensing, ORS has been applied in many fields, including archaeology, aquatic ecosystems, biodiversity, climatology, forest measurements, global change, habitat detection and conservation, human health, invasive species, land use and land cover, urban morphology, vegetation stress, and wildfire management. In fact, there are too many applications to be listed here.

Considerations

Remote-sensing technology continues to advance on the producers’ side while its applications continue to grow on the users’ side. It is important to improve communications between the producers and users. The producers need to make data products as reliable as possible while the users need to understand the correct ways to use those products. Such considerations can be better explained with two examples: (i) two sets of global land-cover data were created with the same AVHRR imagery by two groups of reputable remote-sensing analysts, but their overall agreement for aggregated vegetation types was only 80.32% (Hansen and Reed 2000); (ii) two sets of national land cover data for the United States were produced with Landsat imagery acquired in 1992 and 2001 by the same group of professional analysts, but they were not directly comparable (Homer et al. 2007). In short, remote sensing is a useful and powerful tool only if used correctly.

Further reading

In the most basic terms, history is a process by which people convey and try to make sense of incidents. This sense-making has characterized diverse cultures’ spoken traditions and narrative arts – speech, aphorism, recitation, song, ballad, folklore, symbols, architecture, and handicrafts among them. Through such means, traditional knowledge and culture have been passed on over generations, and have communicated the exceptional and the quotidian in our lives.

Whether spoken or written, history takes the form of chronicles, narratives, and modes of inquiry to judge how what has passed may affect what is present or expected; that is, history enables one to envision. As a formal discipline history is, among other things, a means to understand (i) the actions of individuals and groups; (ii) the influence of so-called natural and societal processes, structures, systems, and events; and (iii) the implications, meanings, and significances of them. Like other disciplines – geography not least among them – history is also concerned with its own internal workings: the values that inform it and the frameworks by which historians know and act in and on the world at different scales from households to international domains.

Much formal history has been “from above” rather than “from below,” descriptors coined by Lucien Febvre in the 1930s and popularized by E.P. Thompson in the 1960s. The initial focus of history from below was “the people” (and especially the working class) and, in the period since the 1970s, it has been further concerned with studies of subaltern groups, gender, sexuality, race, ethnicity, and so on. Eric Hobsbawm (2011/1997, 205) has noted that “grassroots” history’s source materials are elusive and require prospecting: there “is generally not material until our questions have revealed it.” Oral history is one of the mechanisms to elucidate historical knowledge from below and, while acknowledging that it is useful, Hobsbawm nevertheless questions its links to personal memory. This he views as a medium too unreliable for preserving facts, and one highly dependent on the corroboration of other verifiable and independent sources of information, or on experimentation – including collaboration with psychologists able to shed light on memory, association, and behavior.

Hobsbawm (and others) have expressed concern at the subjectivity of oral history. Assuredly, distinctions have been – and likely need to be – made between oral history as a form of research practice and as a mechanism for community publishing projects (Bornat 1989). Nevertheless, criticisms that oral history is overly subjective are contestable, and practitioners argue that this very characteristic may be among the method’s most important features – that is, its capacity to use conversation to elicit opinions, sensations, perspectives, and memories rather than (or as well as) “facts.”

To gain access to people’s memories of and views about certain experiences – including those related to singular and repetitive events, habits, practices, customs, and so on – the chief tool used in oral history is the recorded conversation. Initially written down, later audio-taped, and now often captured using
multimedia technologies, oral history conversations involve one or more extended engagements with participants to elicit recollections of the past (although contemporary settings and events are not discounted). At the same time, participants may be asked to share other forms of historical ephemera or information – letters, images, reports, artifacts, and so on. This style of conversation is often qualitatively different from interviews used in social science research. Interviews are more likely to be one-off encounters with participants (excluding interactions to set up discussions and later provide for member checking where participants affirm the accuracy of transcriptions). Typically, interviews will also be of limited duration and may, at least in part, be oriented to current and forthcoming or anticipated issues and events.

Oral history, then, is a method of approach to understanding in great depth the views and experiences held by those who possess direct information, knowledge, and insights about subjects that are also of interest to practitioners. Its enactment as a research method has been attributed to Allan Nevins and others at Columbia University’s Oral History Research Office, the purpose of which from 1948 was to record, analyze, and preserve the spoken recollections and reflections of national leaders. Nevins took the interview – a key tool in journalism, in which he first trained – and applied it in new ways to studies of the elite, framing his own analytical narratives around those stories in order to examine larger questions pertaining to political systems, leadership, and social processes.

Through the 1960s, and intensifying from the 1970s, the use of oral history started to influence reappraisals of the merits of learning about and from everyday life. Its application coincided with shifts in the philosophy of history and historiography – including debates on the relative merits of spoken narratives and written archives and – with broader transformations in epistemology, ontology, and axiology – studies of knowledge, being, and value. Part of the reason for this influence and attendant shifts is because practitioners of oral history articulated a defense of everyday narratives as valid evidence in knowledge production. These narratives were also used to prize open and critique the narrowness of history from above, which was understood to be dominated by public, political, white, wealthy, and masculine accounts. In this light, oral history has been construed as a form of consciousness raising that leads to action and transformational change (Thompson 1998).

Equally, oral history’s democratizing impulse and focus on direct access to living individuals have both challenged and augmented the use of statistical aggregation of the lives of ordinary people, humanizing history and other disciplines (Bornat 1989). According to Paul Thompson (1998, 28), a chief merit of oral history is that it exposes multiple realities and standpoints, facilitating nuanced historical understandings and “a much fairer trial,” which has radical potential (and some risks) for subaltern populations. Hence the need to pay attention to the ethical demands of oral history, among them (i) safeguarding participants’ rights to confidentiality where requested by them; (ii) affording them full respect and ensuring they are not reduced to “just” another source or use value; (iii) understanding the effects on participants of recollection and the ways in which remembering may harm as well as support them; and (iv) ensuring that, where analysis and interpretation of narratives are undertaken by researchers, participants are provided with opportunities to contribute to or comment on those processes.

In addition, particular care needs to be taken when working with indigenous and other cultures possessing traditional knowledge – these engagements must protect customary, spiritual,
and intellectual property rights (WIPO 2015). The same applies when conversing with children and young people, with the disabled or frail, or with those in compromised situations such as prisons or other institutional settings. In this regard, both international and national organizations exist to help oral historians and those using oral history methods demonstrate integrity and foster sound practice. Among these organizations are the International Oral History Association (www.iohanet.org), and like bodies in the United Kingdom (www.ohs.org.uk), Canada (www.canoha.ca), the United States (www.oralhistory.org), New Zealand (www.oralhistory.org.nz), and Australia (http://oralhistoryaustraliasant.org.au). Each also offers detailed instructional guidance about the practicalities of oral history.

Several other broad and institutional effects of oral history’s democratizing influence are worth noting. One of these effects is the method’s overlap with others in social research, for example the use of participatory action research by community groups seeking to engage researchers. In other words, it has been not uncommon for the impetus for oral history work to come from participants rather than practitioners. Another effect of oral history’s validation of the quotidian is that practitioners, participants, and audiences tend to reflect on the relationships between direct experience and its larger contexts – social, economic, political, cultural, and spatial. Such reflections have led to a recognition that oral history involves shared authorship, requires conscious decisions about the locus of interpretation of narratives, and warrants attention to the effects of the redistribution of intellectual authority.

In some oral history there may be cause to rethink the idea of authorship entirely, and to reframe the coproduction of knowledge as a form of curating. “Curating,” from the Latin “to take care,” involves keeping and interpreting heritage materials, and both participants and practitioners of oral history may be thought of as engaging in such activities; so, too, can audiences be invited to care for the everyday histories relayed to – and even coproduced by – them. Either way, practitioners must “respect, understand, invoke, and involve the very real authority [participants and] audiences bring” (Frisch 1990, xxii).

This idea of authority is important for at least two other reasons related to conceptions of “truth.” First, oral histories and the narratives they generate are sources of information and insights that inform and enable generalizations through analysis, comparison, conceptualization, modeling, and prediction. These generalizations also function as contingent truths and hold stable (if not durable) certain knowledge claims. Second, when oral histories and narratives are presented without apparent interpretation, they are seen to bypass the dangers implied by acts of analysis or construal – “apparent” insofar as interpretation might have preceded the production of written transcriptions or recordings and may be embedded in the selection of participants, questions, and conversational situations.

It is in this context that consideration is taken of the relationship of experience to memory and of memory to history and interpretation. Significant discussion arises in response to questions about the ways in which experiences are “translated” to memories later recalled and formalized as part of the historical record – hence Hobson’s call for the validation of oral recollections using other sorts of information. In this light, Frisch (1990, 10–11, 16) commends practitioners to remain alert to certain questions:

What happens to experience on the way to becoming memory? What happens to experience on the way to becoming history [or, one might ask, part of the geographical imaginary]? … what is the relationship of memory to historical generalization? … What sort of person is
ORAL HISTORY AND NARRATIVE

speaking? What sort of thing is he or she talking about? What sorts of statements about it are being made? ... At what distance, in what ways, for what reasons, and in what patterns do people generalize, explain, and interpret experience? ... what role [does] knowledge play in our lives?

Knowledge is, of course, created and, in relation to oral history, there are at least three expressions of this process. The first sort of knowledge produced is that derived from unadulterated transcriptions, where participants have opted not to check their narratives or have not been afforded such opportunity. There have been suggestions that these transcriptions are pure and direct, but they may contain errors of omission and commission that could distort understanding. The second sort of knowledge produced is that from transcriptions that are not edited by practitioners but are checked by participants in order to affirm, amend, augment, or remove what has been produced and thus to protect both themselves and third parties – a responsibility jointly held by practitioners and, in some cases, subject to the laws pertaining to slander. This second expression of knowledge production also allows participants to ensure that the knowledge engendered is coherent – that is, lucid and consistent. The third sort of knowledge produced is that derived from the work undertaken by practitioners who engage in substantial editing of transcriptions (which may or may not have been checked by participants for varied reasons such as lack of interest, absence, or death). To be masterful, such editing requires an intimate understanding of a raw transcription in its totality. It may be used to ensure flow; emphasize key insights; and level expression by removing speech disfluencies such as “um” or “er” and by avoiding the written representation of speech affects, sounds, or accents which risks caricature. In this sense, it should be immaterial to the quality of the outcome that oral histories derive from ordinary people’s recollections of everyday life. Rather, just as history from above is guided by various strategies to ensure its quality, mechanisms exist for ensuring the quality, depth, and salience of oral history transcriptions and their interpretations. These mechanisms – checking and editing not least among them – are deemed important if oral history is to remain estimable. Their use also justifies the considerable resources required to secure – in agreed and appropriate repositories, exhibits, and so on – the deposition of original written, sound, or multimedia files and additional interpretive artifacts (such as documentaries, monographs, or research papers).

Oral history has been taken up in human geography on the understanding that, as well as being a technique by which to understand the past and its importance to present and future knowledges, it is a powerful tool by which to understand the shifting terrain of diverse geographical imaginaries and materialities. According to George and Stratford (2010), geography’s chief concern is to understand people’s sociospatial relations in place, as well as the dynamics and scales of change that occur in locales and are mobilized across territories, regions, landscapes, and environments. Human geographers are particularly concerned to contribute to research-based outcomes that advance wellbeing by paying attention to the varied dynamics of sociospatial relations, spatial justice, embodiment, sense of place, and mobility. Their interest in oral history’s emancipatory potential is partly explained by this impulse. For some geographers, such orientations manifest both as philosophical and as political investments in understanding – rather than appropriating – important but hitherto subaltern perspectives. For others it gains expression as ongoing labors intended to understand the different loci and dynamics of power as it appears in hegemonic spaces. Either way, close attention is applied to considering, inter
alia, geographical imaginaries and memories (Lowenthal 1985): sense of place, experience of displacement, cognizance of connection or distance, capacity to move or to linger, or the ability to generate mental maps that anchor memories through the life course (Ostroff 1995).

Thus, in geography examples of the use of oral history and attention to narrative now abound, and here one example illustrates how this work performs multiple important labors. It relates to Hayden Lorimer’s (2003) consideration of the briefly merged lives of two individuals – a 14-year-old Glaswegian schoolgirl, Margaret Jack, and a 34-year-old geography instructor, Robin Murray – and their shared time and different reminiscences of a four-week residential field course at Glenmore Lodge in the National Forest Park below the Cairngorm Mountains in January 1951. Noting the intrinsic worth of their experiences at the lodge, Lorimer gathers written, visual, and material artifacts from Jack and from Murray’s widow, Catriona (who also knew the lodge), and converses with both – some 52 years after the original field course. He weaves through these reminiscences larger narratives about educational reform and the changing pedagogies of geography at mid-century; the democratization of land management in Scotland; the importance of “the region”; and ways to value “the minor figure” and acknowledge grassroots practices and geographical knowledge – including haptic, sonic, and kinaesthetic forms of experience. These juxtapositions Lorimer interprets as demonstrating the overlapping “fullness and diversity of still-lived lives … fragile connections and situated encounters” (2003, 204), rewarding and unsettling salvage operations that produce fluid knowledges. Just one among many, this case exemplifies the power of oral history in geography, and reveals the ways in which “small stories can tell of epistemic shifts on personal and intimate terms” (Lorimer 2003, 214).

Orientalism and Occidentalism are interrelated concepts. “The Orient” and “the Occident” have been historically produced as stable collections of texts, talks, and ideas that are juxtaposed, both representing fields of knowledge and sets of practices supported by often stereotyped ideas of other cultures and civilizations, and of their imaginative geographies. They are also a product of, and a response to, Eurocentric modernity and to its imperial and colonial projections.

Palestinian American cultural theorist Edward Said (1978), who famously proposed the first critical review of the term, defined “Orientalism” in three distinct ways. First, it is a body of scholarly work focused on “the Orient,” and largely implicated in the realization of the cultural and political conditions that have produced the broader colonial project, and also in the form of Oriental studies courses and programs in Western universities and intellectual circles. Second, it is a cultural and aesthetic interest in “the Orient,” manifested in the fine arts, and in painting in particular, starting from the eighteenth century onward, inspired by so-called “Oriental” themes. Third, it is a critical approach to the very idea of “the Orient” endorsed and implemented by European and American cultural authorities. Orientalist thought is here presented as a regime of truth about a specific region and culture imagined as a sort of discrete entity, as a theatrical setting available to Western scholarly inspection. This approach identifies “the Orient” – an object of study for the other two – as a European and American “invention,” which emerged as part of a constellation of power, knowledge, and geography. Drawing on the conceptual vocabulary of Michel Foucault, Said (1978, 6) maintained that Orientalism was not just a European fantasy but also a discourse made of a constellation of “theory and practice in which, for many generations, there has been considerable material investments.” The result of this long-standing and complex process was the production and circulation of imaginative geographies of “the Orient,” widely supported by popular and scientific understandings of “Oriental” culture and civilization.

It is hard to overestimate the impact of Said’s groundbreaking writings on the development of postcolonial studies in the humanities and the social sciences, including human geography. Said’s inquiry has inspired the proliferation of work in the past few decades on the othering of peoples and regions by imperial powers. Orientalist thought was (and remains) the result of ontological and epistemological categories endorsing a racial and unbreakable distinction between “the Orient” and “the rest,” and especially “the West,” a true practice of othering, based on writings, artworks, trade, military action, political statements, and even tourism. In this framework, the “Orientals” and their culture were imagined as objects that may be studied in isolation and whose presumed characteristics can be clearly and unproblematically defined. It is easy to imagine how such a standpoint could be the origin of a set of stereotyped understandings of the people labeled as such, and of their actions,
which often embraced an overall, albeit implicit, racist agenda. Indeed, what can be learned from Said’s 1978 key book, and from the decades of work that followed in the same vein, is that the imaginative geographies fueling the Orientalist discourse had – and in many cases continue to have – enormous practical implications, since they largely represent background knowledge that informs power relations with the presumed “Oriental world.”

Representations of “Oriental” individuals, typically marking them unreliable, irrational, barbaric, mysterious, and driven by a political economy of desire often matched by a latent sense of cultural inferiority, have traveled through the centuries and pervaded endless forms of encounter between “the West” and “the Orient,” largely based on military confrontation and moral judgment. These imaginative geographies of otherness have dramatized the distance and the difference between “the West” and some “Oriental lands” commonly and unproblematically perceived as culturally separate regions and geopolitical settings, as demonstrated on many occasions in past decades by the global media coverage of the wars in the Gulf region and the Middle East.

Departing from Said’s argument that deploying imaginative geographies is a predominantly European and American project, many scholars have responded with conceptions and analyses of self- and internal Orientalism. Instead of passively receiving the outcomes of the Oriental project and Orientalizing processes, “the Orient” has at times initiated and participated in constructing and circulating such imaginative geographies (Yan and Santos 2009). “Internal Orientalism” (Schein 1997) or “nested Orientalism” (Bakic-Hayden 1995) are identified as the attempt by dominant ethnic groups to exoticize (and consequently marginalize) other ethnic minorities within a specific political entity. Along these lines, other work has investigated the production of equally imaginative geographies of “the West” within non-Western cultural contexts, including the Arab and Muslim world. Such discrete visions of “the West” have been sometimes defined as Occidentalism: that is, a calculated and intended construction of “the West” or “the Occident” as a unified entity, described in scholarly debates as an inversion of the Western imaginary (Carrier 1995) or a counterdiscourse to Orientalism. In the first case, Occidentalism exists as a process in which non-Western cultures construct unifying and stereotypical framings and images of “the Occident,” in the the same way as European and American cultures produce and circulate Orientalist imaginative geographies. In the second, Occidentalism is a discursive and material strategy mobilized and deployed by non-Western cultures to offset the negative impacts of Orientalism and of “Western” cultural and political supremacy.

Many critics resist the idea that Orientalism or Occidentalism may be treated as similar processes, because of the significant historical and political differences that characterize their respective impact and reception. According to Said, the success of Orientalism as a political and cultural project was built on the historical depth, geographical scope, and durability of Western imperialism and colonialism. Unless similar projects of domination and dispossession are imposed on Western places by non-Western cultures, “no one is likely to imagine a field symmetrical to Orientalism called Occidentalism” (Said 1978, 50). Acknowledging that the use of Occidentalism as an inverse to Orientalism potentially distracts from the complicity of power-knowledge embedded in the expansive and extensive histories of imperialism that constituted Orientalism, Coronil (1996, 56) argues for Occidentalism to be framed as a condition of
possibility – as “a dark side of a mirror”; however, recognizing the existence of Occidentalist tropes at the same time allows us to engage in critical ways with the meaning of modernity for non-Western cultures and regions, especially those that have been subjected to colonial rule and the effects of imperialism, and to valorize alternative historical interpretations of the presumed East–West global divide.

Said’s approach to Orientalism was also widely resisted in academia. For example, conservative and influential Orientalist historian Bernard Lewis critiqued Said for his presumed historical inaccuracy and selective presentation of the field of Oriental studies. Another critique came from more sympathetic readers in relation to Said’s tendency to somehow essentialize “the Orientals” and their geographies – although in different ways compared to the Orientalist tradition – as if there were some deeper truth to be unveiled about those regions and cultures. However, goes the critique, the “objects” of past Orientalist investigations should not be seen as simply passive subjects unable to engage with the colonized gaze produced by Eurocentric universalist discourses. In fact, colonized subjectivities have engaged in substantial ways with the powerful discourses of Orientalism. Not acknowledging this engagement may indeed constitute new forms of objectification that deny the actual agency of these peoples in dealing with the Orientalist categories that have for so long qualified them with reference to the colonial and postcolonial contexts.

One final important aspect of Orientalism is the fact that its legacies still have multiple and sometimes subtle effects on the categories and the practices that, on an everyday basis, produce the “contact zones” and the related encounters between presumed “Western” and “Oriental” subjects. These effects have emerged on numerous recent occasions: for example, in the media representation of Saddam Hussein as a typical despotic “Oriental” leader, or in the horrific practices of the Abu Ghraib detention center. But they have also emerged as commonplace in discourses about Western culture and imperialism that feed into radical Islamic representations of Europe, or in local residents’ attitudes toward Western tourists traveling outside of Europe. Orientalism and Occidentalism, in the everyday practices. In their most popular accents they still play an important role in how the broader public, for example in Europe, understand the arrival of asylum-seekers and migrants from across the Mediterranean, and also in how politicians present their often populist views on the integration of people coming from different religious and cultural backgrounds.

The way forward for geography and geographers may indeed lie in persevering with the everyday of Orientalism. This approach can include an unrelenting engagement with how cultural, media, and travel imaginaries shape not only our travels abroad but also our everyday practices. The pervasive operation of Orientalism is in part founded on what has been argued as a (still) “colonial present” – a world that has persisted by dominating and dispossessing an “Oriental Other” based on politically constructed notions of “irrationality” and “unreason” in Afghanistan, Palestine, and Iraq (Gregory 2004). Such analysis can also entail an engagement of the “Oriental”/“Occidental” body as a site for the (un)intended deployment of imaginative geographies concerning “the Orient” and “the Occident” and the implications of such imperialist forms of othering. Such geographical inquiries can be located in the acquisition of the correct body for a beach vacation, in national population policies, racial profiling, biometrics and/in border security, and the “war on terror.” Despite more than three decades of critical work on the special effects of Orientalism,
ORIENTALISM/OCIDENTALISM

its practical implications are still very much among us, including the engagement with the mirrored responses of Occidentalist tropes and their powerful political and cultural geographies.

Outsourcing

Ingo Liefner
Justus Liebig University Giessen, Germany

The term outsourcing is used to describe a company’s decision to stop carrying out a certain business activity and to buy it instead. Outsourcing decisions lead to a redistribution of the production of commodities (usually components) and services between firms. Widespread outsourcing has had a profound impact on economic structures by reducing the dominance of vertically integrated and large-scale producers and creating networks of interrelated specialized firms. Outsourcing has also promoted the emergence of many producer-oriented service companies (Mudambi and Venzin 2010).

Through the lens of manufacturing firms, suppliers enjoy certain advantages over final commodity producers, which justify the outsourcing of component manufacturing, certain manufacturing activities such as final assembly, or production-related services (Venkatesan 1992). First, suppliers find it easier to generate economies of scale in production when they can specialize in a certain component or service and sell it to many customers. Second, they can thus achieve a more favorable cost structure; third, they then have the incentive to improve their competence and recognition regarding the component or service in which they specialize. These advantages of suppliers reduce their production costs compared to vertically integrated firms and thus lower the overall production costs of the final product as long as the cost reduction achieved through outsourcing offsets rising costs of coordination and transaction. Outsourcing is thus promoted by the advancement of information, communication and information technologies, and the decrease in their costs.

Outsourcing is the decision to separate business activities that are necessary to produce one product in terms of business organization and production technology. However, the technical separation can easily lead to a spatial separation of production (Quinn and Hilmer 1994). When there is little need for close collaboration between supplier and customer, and labor costs and other costs that vary between business locations are of greater importance, outsourcing can go hand in hand with spatial relocations of production. Hence, outsourcing has led to a loss of millions of manufacturing jobs in the United States and Europe, while it has accelerated the growth of new companies and jobs that help to organize production processes that are spread over many countries.

However, outsourcing does not necessarily imply spatial relocations, and outsourcing decisions can also lead to the emergence of interrelated networks of specialized producers in close spatial proximity, namely clusters or industrial districts. Hence, the term offshoring should be used to characterize the relocation of business activities across national borders, even if they are initially motivated by outsourcing decisions (Manning, Massini, and Lewin 2008).

Outsourcing is sometimes differentiated into material outsourcing and service outsourcing, with service outsourcing receiving broad media attention. Business services, computing, information, and so forth were long regarded as immobile, and offshore outsourcing of these...
activities has raised fears about job losses, not only among poorly qualified service workers but also among specialists (Amiti and Wei 2004).

Hence, outsourcing is a process that underlies the formation of spatial economic structures that are typical of today’s globalized and knowledge-based economy. Outsourcing decisions are behind the “second great unbundling”; that is, the disintegration of production in spatial terms (Baldwin 2006).

According to *Collins English Dictionary* (2000), “overlay” is defined as “to lay or place something over or upon (something else).” In human geography, overlay is a “process of draping layers of map information on top of each other. Such a process exposes how categories of data intersect and can reveal important patterns of convergence and divergence.” In Hoyt’s classic study *The Structure and Growth of Residential Neighborhoods in American Cities* (1939), he overlaid areas of low rent, high percentage of buildings requiring major repairs, older building stock, and high percentage of nonwhite population, suggesting a strong correlation between the variables (Castree, Kitchin, and Rogers 2013). As DeMers states (2005), the process of overlay is to “place the cartographic representation of thematic information of a selected theme over that of another. It is intuitive that the application long preceded the advent of modern electronic geographic information systems (GIS).” The traditional approach of overlay is to compare polygons over a coverage/area/sector/region, or a coverage/area/sector/region over polygons. A very early application of the analog overlay technique dates back to the days of the American Revolution. During the Battle of Yorktown, in 1781, George Washington engaged the services of the French cartographer Louis-Alexandre Berthier, who employed map overlay to examine the relationship between Washington’s troops and those of the British general, Charles Cornwallis (as cited in DeMers 2005). In modern geographic information systems, however, the term overlay has taken on a more complex significance. Overlay is a key and essential function in all GIS packages and is used to reveal spatial overlap and facilitate pattern analysis.

**Overlay operations**

In practice, map overlay consists of several features, including points, lines, and polygons.

**Vector overlay methods**

In point-in-polygon overlays, the input point features are assigned attributes of the surrounding polygons (Figure 1). One example is to investigate the association between wildlife habitats and classes of vegetation in ecological applications. For instance, Point 1 and Point 2 are two points of wildlife location. Type A and Type B refer to different vegetation cover types. The analyst will be interested in the extent of different types of wildlife that fall into different vegetation covers. Other point-like events, such as occurrence of disease, must be compared to the properties of the surrounding environment.

In line-in-polygon overlays, the identical line features appear in the output, but each of them is intersected by the polygon boundaries when the polygon and line overlay each other (Figure 2). Each segment on the output amalgamates attributes from the polygon and the line map (Chang 2004). One example is to identify pavement materials for a designed road. The input map contains a designed road,
Figure 1  Point-in-polygon overlay.

Figure 2  Line-in-polygon overlay.

Figure 3  Polygon-on-polygon overlay.

and the overlap map is a pavement material map. The output shows a designed road divided into segments, with each road segment having a different set of pavement materials from its adjacent segments.

Polygon-on-polygon overlays involve two polygon maps for which the output integrates input polygon boundaries and those from the overlay maps, in order to generate a new set of polygons (Figure 3). Each new polygon contains attributes from both maps, and these attributes are not the same as those of neighboring polygons (Chang 2004). One example is to examine the common area of land parcels and flood zones. Attributes of both feature classes carry through the overlay operation. A single land parcel can be split into two parcels if only one part is inside the floodplain. An attribute will be given to indicate whether land parcels are inside or outside the flood zone.

**Raster overlay methods**

In contrast to vector overlay methods, which include the geometric objects of points, lines, and polygons, raster overlays work on cells and grids. Raster-based map overlay operations can be implemented on fixed cell blocks, whereas the vector operation works on irregular polygon/line boundaries. In other words, the raster operation is computationally more efficient than the vector operation. However, an additional process of resampling is required to synchronize the resolution (cell size) of each map before graphical overlay. Raster data such as remotely sensed data, digital elevation models, digital orthophotos, digital raster graphs, scanned maps, and graphic files are capable of raster map overlay. Usually, numeric values are assigned to each cell (pixel), allowing mathematical manipulation (calculation) of the layers, such as addition, subtraction, multiplication, and division. A new value is assigned to each cell in the output layer.

Figure 4 shows an example of raster overlay by mathematical addition, that is, two input raster maps added together to generate an output raster map with the values of each cell summed.

**GIS software applications**

With the application of state-of-the-art GIS technology, overlay operations can be processed digitally and automatically. For instance, the analysis tools/overlay toolset of the updated commercial GIS software includes “identity,” “intersect,” “symmetrical difference,” and “union” functions.
First, “identity” calculates the geometric intersection of the inputs, and illustrates feature classes and feature layers (ESRI 2009) See Figure 5.

Second, “intersect” calculates the intersection of the input features geometrically. Features or parts of features which overlap in all layers and/or feature classes will be recorded to the output feature class (ESRI 2009) See Figure 6.

Third, “symmetrical difference” calculates a geometric intersection of the input and update features. Features or parts of features in the input and update features which do not overlap will be recorded to the output feature class (ESRI 2009) See Figure 7.

Fourth, “union” calculates a geometric intersection of the input features. All features will be inserted to the output feature class with the corresponding attributes (ESRI 2009) See Figure 8.

Map overlay is the “placing of multiple thematic maps in precise registration, with the same scale, projection, and extent, so as to allow a compound view” (Clarke 2011). Using modern GIS software, a three-dimensional (3-D) view of map overlay can be produced to enable analysis of shadow, sunview, viewshed, perspective view, wind ventilation, and also application in urban planning (Figure 9), for instance, analysis of urban morphology structure.

Another example is 3-D building temperature data overlaid on a thermal image (Nichol and Wong 2004) (Figure 10). The displayed color
OVERLAY, GRAPHICAL

of a pixel is defined according to the calibrated temperature of the thermal image. It shows the temperature difference between the national stadium of Hong Kong, having a cover of artificial turf, and the Hong Kong racecourse, with real grass cover. The building temperatures are also depicted on the facets of 3-D building models, which show the highest facet temperature on the national stadium of Hong Kong, at over 38°C at the time of image acquisition.

Case study

Urban environmental quality in Hong Kong

In a study by Nichol and Wong (2006), the GIS overlay technique was applied to integrate different datasets and derive urban environmental quality (UEQ) maps. The datasets included air temperature, vegetation density, air quality, noise, building density, and building height. The range of values for each parameter was ranked on a scale, such as 1–10 or quantiles. The resulting UEQ values then corresponded to the sum of data layers, at 4 m and 64 m spatial resolutions. The GIS overlay method could more readily accommodate data originating from different resolutions or units of measurement.

A region-based overlay approach at electoral district level was also evaluated in the study. The aggregate score for each district was obtained by summing the ranked scores for each variable. Higher values represented the most desirable environmental quality in the Kowloon peninsula.

Geospatial Information Hub in the Hong Kong Lands Department

Geospatial Information Hub (GIH) is a web-based information platform for searching, displaying, and sharing a large amount of geospatial data through the Hong Kong government intranet. Several geospatial datasets (e.g. digital maps, aerial photographs, land status information, public facilities, and building address) can be overlaid for display on a user interface. The GIH provides graphical overlay, scaling, panning, and query functions, which reduce resource duplication and search time. Up to December 2012, over 83000 officers in 32 government departments had gained access to geospatial data through this platform, thus greatly reducing the need for hardcopy printouts and paper usage (Tsoi 2007).

GIS applications in the Hong Kong Observatory

The Hong Kong Observatory enhances the tropical cyclone track information webpage by overlaying satellite images to depict the pattern and coverage of clouds associated with tropical
cyclones. The pathways of tropical cyclone movement can be illustrated and the accuracy of the forecast track is indicated (Hong Kong Observatory 2013). In addition, the “Regional Weather in Hong Kong” webpage designed within GIS and HTML5 (Hyper Text Markup Language 5) frameworks has been developed and launched. Several types of weather observations (e.g., rainfall, wind, radar image, lightning location) can be visualized on the webpage using graphical overlay techniques. The Hong Kong Observatory fully utilizes the geographic information systems overlay technique, and precise locational positioning techniques, for meteorological modeling, short-term weather forecasting, and long-term climate change studies.

Urban climatic analysis map from the Hong Kong Planning Department

An urban climatic analysis map (UC-AnMap) collates meteorological, planning, land-use, topographical, and vegetation data, and, based on their spatial relationships and their effects on air ventilation capacity and thermal comfort, these are analyzed and evaluated. In the UC-AnMap, layers of information are overlaid and displayed graphically in a geographic information system. These include building volume, topography, green space, ground coverage, natural landscape, proximity to openness, and wind information (Planning Department 2012). The UC-AnMap addresses the planning and design issues related to urban climate in order

Figure 10  3-D model using raster overlay method. Reproduced from Nichol and Wong 2004 © Elsevier.
to formulate urban development strategies in relation to urban morphology.

Conclusion

Overlay is a GIS spatial operation in which different layers of maps, features, and vector and raster data registered in a common coordinate system are superimposed. Overlay is also an operation for determining the spatial coincidence of features. The spatial relationships between features in the same geographical space can be analyzed so as to pinpoint the required information from a set of stacked layers.

The overlay function can work for diverse datasets and types of data (e.g., vector, raster). The vector overlay approach offers point-in-polygon, line-in-polygon, and polygon-on-polygon functions to determine the spatial coincidence of points, lines, and polygons. The raster overlay approach offers a more efficient operation to determine spatial coincidence from cells and pixels. In current GIS operational systems, functions of “identity,” “intersect,” “symmetrical difference,” and “union” are available for graphical overlay, and these are the key functions in spatial data analysis. In recent years, planning and environmental authorities, surveyors, and researchers have been using graphical overlay operations as objective topological procedures in their daily work.

References

A topological overlay is used to combine and manipulate spatial data by the spatial relationship of their geometries. It relates multiple features and joins attribute tables using a quantitative algorithm that operates on their respective topologies. Attribute values from both input and overlay datasets are passed on to the output dataset. In a topological overlay, two or more layers of data are combined according to a specific set of rules. A new output dataset is created with both geometry and attribute data from the input dataset along with updated topological information. It is the most required and common GIS technique in spatial data processing.

A topological overlay is different from a graphical overlay (image overlay), which neither requires attribute updates nor creates a new dataset. Goodchild (2010) highlighted that many mash-ups simply overlay one layer on another in a visual spatial join rather than making a pure topological overlay.

Although overlay works in both vector and raster format, a topological overlay is mainly applied to vector formats because the overlay procedure involves the rebuilding of the topological relationships that make layers work. A topological overlay results in a new layer with attributes of the original input data layers. It also requires the rebuilding of topology for arc, node, and polygon. A new layer is generated to include the updated topological information. Thus, it is computationally expensive, CPU intensive, and often time-consuming. The processing time of a topological overlay is proportion to the number of vertices in the two input datasets.

The logic behind how topological overlay works is based on rules of Boolean logic. Boolean algebra is based on the basics of binary logical operations of the values one and zero. Boolean operations such as AND, OR, XOR, NOT are applied in GIS for the overlay of multiple data layers to check whether a particular condition is true (1) or false (0). The rules of Boolean logic are used to operate on the attributes and spatial properties of geographic features. The AND Boolean operator represents conjunction, where results are true for all areas that meet both the first and the second criterion. The OR Boolean operator is related to disjunction, where results are true for all areas that meet either the first or the second criterion, independent on the areas overlapping or not. The XOR Boolean operator means exclusive disjunction, where results are true for all areas that meet either the first or the second criterion but not both. The NOT Boolean operator corresponds to negation, where results are true for all areas that meet the first criterion but not the second.

A topological overlay allows users to combine two or more feature classes to intersect, erase, modify, or update datasets and results in a new feature layer with the updated attributes of the input and overlay dataset values. Using the topological overlay on feature data requires both an input dataset and an overlay dataset. The input feature class can include points, lines, or polygons, but the overlay feature class can only comprise polygons. Each in the overlay affects how the data from the input feature class and overlay feature class are combined, which affects
both the spatial data and attribute data of the output dataset. Exemplary methods of a topological overlay include erase, identity, intersect, symmetric difference, union, update, and so on.

Erase overlay creates a layer by overlaying the input layer with an erase polygon. It allows users to remove data from the input layer based on overlay polygons. This is based on the NOT Boolean operator. For example, the city generates a flood map for residents to inform which roads are not damaged by flood and are safe to drive on. The urban planner could input roads and use the erase with an overlay of the areas most affected by the flood to remove the segments of roads in areas affected by flooding.

Identity overlay creates a layer by combining the input layer and identity layer to contain features with attributes of both input and identity datasets where they spatially overlap. This method can be used in a situation where neighborhoods and school districts have independent and overlapping boundaries and an analyst would like to map the neighborhoods that constitute the same school district. With the identity overlay, the urban planner can also take into account proximity to libraries. The output dataset contains all of the data from the input dataset, with the addition of the overlay dataset where it overlaps with the input. If the input dataset consisted of polygons of neighborhood boundaries and school district boundaries, the overlay dataset could consist of a two-mile buffer around the library in that area, so the polygons of the output data will contain data about school district, neighborhood, and whether the area is within two miles of the library.

Intersect overlay creates a layer with only values that overlap from both the input layer and the intersect layer. It combines the input layer and overlay layer to produce an output layer that only contains values shared by both the input layer and overlay layer. This is based on the AND Boolean operator. This can be used in a flood risk assessment, where the input map of residential homes is intersected with a buffered-river intersect layer to determine the residential homes that are at risk of flooding. Imagine that after a flood, an urban planner wants to determine which families were most affected by the flood. This planner could intersect an input dataset of parcels associated with homes and families with a dataset of the areas most affected by flooding. The output dataset would only show the parcels highly affected by flooding and the parcels located within that area. Then the urban planner could use the attribute table to identify which families own those parcels that were most affected by the flood.

Symmetrical difference overlay combines two input layers and creates an output layer where any overlapping data is removed and both input datasets are merged to single layer. This method could be useful in calculating crime rates in the area managed by a police precinct compared with crime rates in the area managed by another precinct if the managed areas overlapped. On a very basic level, to remove the bias of the rate of crime in the area managed by both precincts, the symmetrical difference overlay could be used in analysis. It is often used to remove data. In looking at a residential school district, an urban planner is determining if access to only one library is enough to achieve a specific reading standardized test score. Students who have access to two libraries are excluded from this analysis so the urban planner can use the symmetrical difference overlay on a two-mile radius around libraries in the neighborhood. Both areas without any access and areas with access to two or more libraries will be removed from the dataset and only areas with access to one library will remain as a single dataset.

Union overlay combines two input datasets by including all features and attributes. This method
can be used in a situation where neighborhoods and school districts have independent and overlapping boundaries and an analyst would like to have a layer with polygons that include both school district and neighborhood values to obtain statistics from both datasets. This is based on the OR Boolean operator. With the union method, the neighborhood feature can be combined with the school district feature and the urban planner can select areas that contain attribute data indicating which neighborhood and which school district the polygon is associated with.

Update overlay computes a geometric intersection of the input layer and update layer. It replaces overlapping parts of the input layer with features from the update layer. It maintains features of an existing dataset and an updated feature in which the updated features and attributes replace input features. The attributes and geometry of the input features are updated by the update features in the output feature layer.

Some GIS software provides other types of topological overlay such as clip and paste. The resulting topology from clip overlay includes areas that appear in the input topology, except where they are outside the boundary of the clip layer. The input topology is clipped to the outer boundary of clip layer. The resulting topology from paste overlay includes the paste layer topology and any areas of the input topology that extend beyond the boundaries of the paste overlay topology.

Topological overlay among different feature types is possible. A point-in-polygon overlay is applied where input comprises points and the overlay dataset is a polygon. For example, it is illustrated by selecting houses (point) with children below the age of 18 within a school district boundary (polygon). A line-in-polygon overlay is used when the input comprises lines and the overlay dataset is a polygon. As is illustrated in selecting roads (line) from the flood-risk area, output is roads in a county boundary. A polygon-on-polygon overlay is often used when the input and the overlay dataset both comprise polygon, for example, determining which parcels are affected by a flood by combining parcel boundary with polygons of areas affected by the flood.

There are several challenging issues that could complicate topological overlay operations. Implementation of topological overlay may demand large amounts of memory and time to process the operation, depending on the number of vertices in the input datasets. Efficient algorithms for executing topological overlay in RDBMS are needed. Performing topological overlay functions on a road network dataset could be problematic, having topological errors such as connectivity, adjacency, missing segment, and so on. Although the road network can be rebuilt for integrity, it is not easy to fix those topological errors. Floating nodes, dangling arcs, and spurious or sliver polygons can be problematic during topological overlay although tolerance setting may resolve these issues. More details on indeterminate boundary issues by topological overlay, are given in Zhan and Lin (2003). While it is theoretically feasible to overlay multiple (more than 3) data layers at one time, most GIS software do not provide multiple data overlay operations where more than two data layers are involved.

Paleoclimatology

Michael F.J. Pisaric
Brock University, Canada

Climatic change in response to anthropogenic activities during the twentieth and twenty-first centuries has stimulated considerable research into both anthropogenic-forced climate response and natural climate variability. While Earth’s climate is constantly evolving and changing as natural external and internal forcing mechanisms alter the receipt of solar radiation at timescales ranging from seasons to hundreds of thousands of years, the impact of anthropogenic activities on climate has led to much debate. To better understand the contribution of human activities on climate and gain a better understanding of natural climate variability inherent in the global climate system, studies of past climate are warranted. Paleoclimatology is the science that studies these changes throughout the history of Earth.

Paleoclimatology of the early-Earth, or “deep time,” has largely been the focus of geologists, geochemists, and geophysicists. Contributions by geographers are most often focused on the Quaternary period, representing the past 2.6 myr (myr = million years), or so, of Earth’s history. Thus, this entry on paleoclimatology will only briefly examine the paleoclimatology of the early-Earth and draw upon examples and methods to study paleoclimates of the Quaternary period. The Quaternary period is of importance from a paleoclimatological perspective, since this is the period of Earth’s history from which the greatest abundance of physical data remains today on the landscape to examine past changes in climate; it also represents the geologic time period during which the human species evolved and has now emerged as one of the leading drivers of change affecting global ecosystems.

The global climate system at the start of the twenty-first century appears to have entered a new state, as anthropogenic activities have significantly altered the concentrations of greenhouse gases such as carbon dioxide and methane. Understanding the potential impacts of these atmospheric changes requires an examination of climatic conditions during previous periods in the Earth’s history when climates were similar. Paleoclimatology provides a window through time to place current climatic conditions and the rates of recent climatic change in a long-term context. Paleoclimatic records are typically much longer than those afforded by instrumental data records. Thus, paleoclimatology not only provides a glimpse into past climatic conditions but also can assist in predicting how climate may change in the future. It is the ability to look backward in time to inform the future that makes paleoclimatology such a powerful and important tool.

Methods in paleoclimatology

Instrumental records of past climatic conditions (e.g., temperature and precipitation data collected using standard meteorological instruments, satellite-derived data) are relatively short and often overlap entirely with the period of anthropogenic impacts on global climates. Therefore, there is a need to develop longer records of past climatic conditions to place recent climate trends in a long-term perspective.
and to better understand the full range of natural variability inherent in global climate systems. To do this, paleoclimatologists rely on proxy climate data sources. There is a host of tools available to the paleoclimatologist to reconstruct and interpret past climatic conditions. These proxy indicators of past climate come from biotic or abiotic sources and cover a range of timescales, from decades to billions of years. Today, entire research communities are focused on the use of tree ring growth records (dendroclimatology), corals and other banded remains from oceans and caves (sclerochronology and speleothems), lake sediment analysis (paleolimnology), ice cores, and ocean sediment records (paleoceanography) to reconstruct past climatic conditions. While the breadth of paleoclimate methods is too vast to fully review here, several of the more widely utilized methods are discussed.

**Annually banded proxy records**

Instrumental data have the advantage of being collected at high temporal resolution (hourly, daily, monthly) but normally these records do not extend over long timescales. Some proxy data sources, such as tree rings and corals, provide annual proxy data information and, in some instances, subannual resolution, thus potentially allowing the extension of gathering climate data by hundreds to thousands of years.

**Dendrochronology**

Dendrochronology, the science of dating tree ring growth records, is a widely used paleoclimatic technique. Each year trees growing in regions that experience seasonal climate variability produce annual growth rings. While trees in many parts of the world form annual growth rings, dendrochronology is most useful for paleoclimatology in highly stressed environments, such as at the ecological limits of a particular species. For example, white spruce (*Picea glauca*) grows up to treeline across most of northern Canada. At the northern treeline, growth of trees is controlled primarily by temperature during the growing season (i.e., summer months), with warmer summer conditions leading to wider tree rings and cooler conditions leading to the development of narrower growth bands. This is an example of the principle of ecological amplitude, which represents the range of environments in which a tree species may grow and reproduce. Ecological amplitude is important in dendroclimatology because individual trees that are most useful to dendrochronology are often found near the margins of their natural range, whether that is latitudinally, longitudinally, or at higher or lower elevations.

While the principle of ecological amplitude is fundamental in dendroclimatology studies, the use of tree rings for studying past climatic conditions is also predicated on our understanding of several other guiding principles.

- Uniformitarianism, as applied to paleoclimatic studies in general, proposes that the physical and biological processes that link current environmental processes with current patterns of tree growth must have been in operation in the past. Championed by the Scottish geologist James Hutton, uniformitarianism is often linked with the idea that the “present is the key to the past.” This is critical in paleoclimatic studies, including dendroclimatology, where relationships between climate and proxy indicators are used to develop records of past climate. Within the field of dendroclimatology, there is debate about how stable these climate–growth relationships are. The divergence issue that has been identified at treeline sites in northwest North America and Eurasia suggests these relationships are not time-stable and may have been changing.
during recent decades. There is now ample evidence that northern treeline sites, which were previously temperature limited, are now showing evidence of increased drought stress related to warmer summer conditions. These findings raise uncertainty regarding uniformitarianism and dendroclimatology.

- The principle of limiting factors suggests tree growth (or the growth of any biological organism for that matter) can proceed only as fast as allowed by the primary ecological mechanism(s) that restricts growth. Sometimes, more than one mechanism operates to restrict growth but careful study of the current relations between the growth/presence of an organism and their climatic controls is critical in any paleoclimatic study. In the case of the northern treeline, the mechanism restricting tree growth is temperature during the growing season. The principle of limiting factors is important to dendroclimatology because annual growth rings can only be matched between trees (cross-dated) if one or more factors are in limited supply and persist for sufficiently long periods of time and across a wide geographic area to cause tree rings to vary the same way in many trees.

- Site selection is critical in paleoclimatic studies. By careful selection of sample sites, an attempt can be made to find trees sensitive to the environmental variable of most interest. The dendrochronologist must select sites that will maximize the environmental signal being investigated, and thus proper site selection involves an a priori assessment and knowledge for the selection of trees for sampling. Even so, as demonstrated by the divergence issue, there can still be surprises.

Sclerochronology and speleothems

The oceans and other water bodies cover approximately 70% of the Earth’s surface. Monitoring of these vast expanses of the Earth’s surface is temporally and spatially limited compared to terrestrial environments. Similar to dendrochronology, sclerochronology and speleothems make use of annually deposited layers as proxy indicators of past climatic conditions. Sclerochronology involves the use of accretionary bands formed in corals and mollusk shells and other structures such as otoliths (fish ear stones). These banded remains can represent various time steps from daily and subdaily accretions to annual deposits. Analogous to dendroclimatology, paleoclimatologists often make use of physical measurements of the size of the accretions and their chemical composition. Sclerochronology can provide proxy records of past sea surface temperatures, precipitation, and river discharge. The main limitation of coral reefs as proxy climate data sources is their distribution, as they form only in tropical and subtropical regions where mean annual water temperature is >18°C and water is clear. While continuous records of climate from coral sequences are relatively short (spanning the past several hundreds to thousands of years), discontinuous records can be obtained from corals extending back to the Permo-Triassic extinction event (251 myr) and possibly as far back as the Cambrian (540 myr) for some “reef-like” structures (Pandolfi 2011).

Mollusk records provide similar proxy data information as corals but have a greater spatial distribution. Recent efforts to cross-date multiple samples, similar to matching tree ring width chronologies, are leading to the development of robust mollusk chronologies covering the past millennium and more.

On land, cave systems can provide ideal environments to preserve past changes in climate. Speleothems are accumulations of the carbonate mineral calcite (CaCO₃), which is released from rainwater when it percolates through the
PALEOClimatology

Ground and into a cave. Speleothems collectively include stalagmites (accretions on the floor of caves), stalactites (accretions extending from the ceiling), and flowstones (sheet-like deposits that form on cave walls and floors). Paleoclimatologists analyze chemical changes preserved in these deposits, including stable isotopes (e.g., $^{18}$O), or make measurements of the thickness of accretions. Paleoclimatic studies using speleothems can extend back several 100 kyr (kyr = thousand years) (Vaks et al. 2013) but periods of no deposition (hiatus) during dry periods are common. It is important to note that, while some speleothem records are annually resolved, most have decadal to centennial scale resolution.

Ice cores

Our understanding of the paleoclimate of the Earth has been advanced through the analysis of ice cores recovered from ice sheets in Greenland and Antarctica, in particular. Ice core studies have provided detailed information about Quaternary period climate and atmospheric change, with recent ice core drilling projects providing records of atmospheric greenhouse gas composition and climatic change during the past eight glacial/interglacial cycles or 800 kyr (EPICA 2004). Ice cores from Greenland and Antarctica have been recovered through several kilometers of ice by international teams of researchers. Air bubbles trapped in the ice provide a snapshot of atmospheric greenhouse gas composition during the Quaternary period and analysis of isotopes of oxygen provide key insights into changes in climate.

Paleolimnology and paleoceanography

Paleolimnology is the study of lake sediment records to reconstruct past climatic and environmental change from inland water bodies. Similarly, paleoceanography makes use of many of the same techniques but focuses on sediment records collected from the world’s ocean basins. Unlike the proxy sources discussed thus far, lake and marine sediment records are not normally banded and annual in nature. Instead, sediment records from lakes and marine basins are massive and exhibit limited structural components that are discernible to the naked eye (Figure 1a). Thus, chronology development is a critical step in paleolimnological and paleoceanographic studies. Paleolimnology normally makes use of radiometric dating techniques, such as $^{14}$C dating (for sediment deposited >150 years ago and as much as 40–50 kyr ago) and $^{210}$Pb dating for sediment deposited within the last 150 years. Occasionally, the depositional environment may be such that annual laminations (known as varves) occur in lake and marine sediments (Figure 1b). The deposition of varves normally occurs under anoxic conditions and in deep basins where seasonal overturn and mixing does not occur.

The analysis of lake sediment records in paleolimnological studies is based on the study of a variety of biological subfossils preserved in the sediment in addition to the physical, chemical, and mineralogical properties of the sediment. There are many different types of biological remains and chemical signatures preserved in lake sediment records that can provide insights into past climatic conditions, including siliceous algae (diatoms), charcoal, chironomids (nonbiting midges), Cladocera, pollen, pigments, and stomata (Figure 2). New techniques such as biomarkers and environmental DNA have great promise for unlocking new insights into past climatic conditions.

Lake sediment records are collected using a variety of coring equipment that is enabled either by gravity or by physically pushing, driving, or vibrating the coring apparatus into
PALEOCLIMATOLOGY

Figure 1 Example of massive sediment with little stratigraphy and a thin section scan of varved sediments. (a) ITRAX core scanner image of massive lake sediment from Fort McPherson, Northwest Territories, Canada. Sediment profile illustrated is approximately 50 cm in length (photo taken by the author). (b) Thin section scan (rectangle is 5 mm long) of varved sediments from West Lake, Cape Bounty, NU (Courtesy of Dr Jaclyn Cockburn). The couplets represent seasonal deposition with dark layers representing clay caps deposited under ice cover and lighter gray bands being coarser material deposited under higher energy regimes during the short melt season.

Paleolimnology and paleoceanography can provide insights into past climates across a range of timescales, from very recent changes occurring over the past few decades to millions of years in some of the larger inland lake systems and ocean basins. Ocean sediment coring and the climatic information it can provide are discussed in greater detail in the later section on Quaternary paleoclimates.

Paleoclimatology of the early-Earth

With the coalescence of materials remaining after the formation of the sun, the Earth and other planets were formed. The early sun produced far less solar energy than it does at the current time. These conditions had the potential to thrust the early-Earth into a glacial state but instead hyper or near-hyperthermal conditions characterized this period in Earth’s early history. In spite of the lower solar output, temperatures were believed to be much warmer than today during the Archean eon (2.5–4.0 gyrs) because the composition of atmospheric greenhouse gases was much different. Today, our atmosphere is comprised primarily of nitrogen (78%), oxygen (21%), argon (0.93%), and carbon dioxide (0.04%). While greenhouse gases such as carbon dioxide and methane comprise only a small proportion of the atmosphere today, during Earth’s early history volcanic activity likely produced higher concentrations of carbon dioxide and, later, with the emergence of the first primitive forms of life during the Archean eon approximately 3.5 gyr ago, atmospheric methane concentrations likely increased as well via anaerobic decay processes (Kasting 1993). Some estimates suggest carbon dioxide levels may have been 100–1000 times above current levels (Kasting 1987) and methane may have exceeded 1000 parts per million (ppm) (Kasting 2005). Today, methane concentrations in the atmosphere are around 1.8 ppm. With less solar output, an enhanced greenhouse effect due to higher concentrations of carbon dioxide was
the most likely mechanism that prevented the early-Earth from plunging into glacial conditions. This is known as the faint sun paradox.

One constant of climate today and throughout Earth’s history is change. While climate throughout the majority of Earth’s history can be typified as hyperthermal, long periods of glacial conditions have also occurred. In fact, paleoclimatic studies indicate there have been at least three episodes of glacial conditions that have occurred on global to near-global scales and on timescales of millions to tens of millions of years. This includes the earliest evidence of glaciation during the Neoproterozoic and widespread glaciation during the late Carboniferous and early Permian period. The Quaternary represents the most recent period of widespread glaciation, especially in the Northern Hemisphere. These extensive glacial episodes in the Earth’s early-history are thought to have enveloped the globe in ice and,
thus, are termed “snowball Earth.” The drivers of these extensive glacial episodes are difficult to ascertain but hypotheses include increased volcanic activity or a supervolcano eruption, changes in the composition of greenhouse gases in the atmosphere or changes in solar output. Any of these could lead to a decline in global temperatures and subsequent growth of ice sheets. However, the idea of a snowball Earth is still debated.

Quaternary paleoclimates

The Quaternary period or the most recent “ice age” encompasses the past 2.6 myr of Earth’s history. The Quaternary is characterized by numerous alternating glacial and interglacial episodes, commonly divided into the Pleistocene and Holocene epochs (Figure 3), with the Pleistocene epoch representing the glacial periods and the Holocene epoch (about the past 10 000 years) the most recent interglacial period. Using isotopes of oxygen \(^{18}\text{O}/^{16}\text{O}\) preserved in the shells of marine organisms, long sediment records from deep-sea basins record over 100 episodes of cold/warm climate fluctuations during the Quaternary period (Lisiecki and Raymo 2005). These are commonly referred to as marine isotope stages (MIS).

On land, long terrestrial records of climate change during the Quaternary period have come from the continental ice sheets on Greenland and Antarctica. The longest of these ice core records that have been recovered are from the Antarctic ice sheet, where a drilling program led by the European Project for Ice Core Drilling in Antarctica (EPICA) (1996–2006) recovered a 3270 m ice core from Concordia Station at Dome C that captured the past eight glacial/interglacial cycles (EPICA 2004). On Greenland, the Greenland Ice Core Project (GRIP) (1989–1992), Greenland Ice Sheet Project (GISP) (1971–1981), and GISP2 (1988–1993) recovered long records of paleoclimatic conditions from the Greenland ice sheet. While GRIP and GISP drilled through similar depths of ice as EPICA (GRIP penetrated 3028 m in depth; GISP2 reached a depth of 3053 m), the Greenland records span only the past 100–120 kyr (GRIP 1993; Johnsen et al. 1992), which is much shorter than those from the Antarctic continent.

Ice core studies utilize the changing ratios of isotopes of oxygen \(^{18}\text{O}/^{16}\text{O}\) preserved in air bubbles within the ice to study paleoclimate. Traces of these gases can be extracted from the ice cores, the composition of greenhouse gases can be determined, and the ratio of oxygen isotopes can be measured. By analyzing the composition of gases in these air bubbles, scientists have reconstructed not only the composition of the atmosphere in the past but also how climate changed and oscillated between glacial and interglacial conditions.

The Quaternary glacial/interglacial cycles were primarily driven by changes in the orbital geometry of the Earth over long timescales (Figure 4). These variations in the Earth’s orbital geometry are referred to as Milankovitch cycles or Milankovitch theory of climate (Hays, Imbrie, and Shackleton 1976), after the geophysicist and astronomer, Milutin Milanković. Milankovitch cycles define changes in the Earth’s orbital geometry on timescales of about 100, 41, and 21.7 kyr. These orbital changes led to variability in the receipt of solar radiation (Berger and Loutre 1991), which, in turn, led to the waxing and waning of the glacial ice sheets during the Quaternary period.

Orbital eccentricity, or the shape of the Earth’s orbit around the sun, varies from nearly circular (low eccentricity = 0) to somewhat elliptical (high eccentricity = 0.05) with periodicities of around 405 and 100 kyr (Figure 4a). Orbital
Figure 3  CO₂ concentrations (Lüthi et al. 2008) (red) and reconstructed temperature (Jouzel et al. 2007) (black) from the EPICA ice core, Antarctica during the past 800 kyr. Note recent CO₂ concentrations of around 400 ppm far exceed estimated concentrations during the past 800 kyr. Also apparent in the data is the change in magnitude and cycle length from a 41 kyr cycle to a 100 kyr cycle during the past 500 kyr. Numbers above and below time series indicate select MIS. The time frames of the Pleistocene and Holocene are also indicated.

eccentricity has been of interest regarding Quaternary paleoclimates due to the similarity in the timing of changes in eccentricity and glacial/interglacial cycles during the last 500 kyr, when a pronounced 100 kyr glacial cycle has dominated. However, it remains unclear how eccentricity drives the 100 kyr Quaternary glacial cycle since changes in eccentricity lead to only small changes in solar radiation receipt compared to those generated by changes in precession and obliquity (Berger and Loutre 1991). This is known as the 100-ka enigma or 100-kyr problem.

Obliquity, or the tilt of the Earth’s rotational axis, varies from 22.05° to 24.5° with a periodicity approaching 41 kyr (Figure 4b). When the tilt of the Earth’s rotational axis is closer to 24.5°, the difference between winter and summer solar radiation increases. This leads to warmer summer conditions and cooler winters. As the tilt of the Earth’s rotational axis decreases towards 22.05°, the opposite occurs and summer season conditions tend to cool.

The final component of the Milankovitch theory of climate is precession or the change in the orientation of the rotational axis of the Earth (Figure 4c(i)). With a periodicity of about 21.7 kyr, the Earth’s rotational axis wobbles like a spinning top and the direction it points varies.
Figure 4 Changes in the orbital geometry of the Earth based on the Milankovitch theory of climate. It is believed that these orbital variations are the drivers of glacial/interglacial cycles during the Quaternary period. (a) Eccentricity or the change in the Earth’s orbital geometry around the sun that varies with periodicities of around 400 and 105 kyr. (b) Variations in the tilt of the Earth on its axis from about 22° to 24.5° with a periodicity of about 41 kyr. (c) Changes in precession that alter the timing of perihelion and aphelion (i); (ii) represents precession at the current time, with the Earth being nearest the sun (perihelion) during the austral summer; (iii) precession during the late Pleistocene–Holocene transition when perihelion occurred during the Northern Hemisphere summer.

This causes perihelion (when the Earth is nearest the sun) to occur during the austral summer or the Northern Hemisphere winter (Figure 4c(ii)). During the Pleistocene–Holocene transition (around 10 kyr), precession was such that the Northern Hemisphere summer occurred during perihelion (Figure 4c(iii)).

Precessional change of the rotational axis increased insolation during the Pleistocene–Holocene transition, leading to treelines across the circumpolar boreal region migrating poleward. Paleoclimatic evidence from pollen records and radiocarbon-dated macrofossil stumps from North America and Eurasia, suggest that summer temperatures were several degrees warmer than at present and remained so until summer insolation began to decline again during the past 4 kyr or so.

While early to mid-Holocene epoch climate was warmer than present, there is also
paleoclimatic evidence that storm tracks and precipitation regimes changed. At the Pleistocene–Holocene transition, the Sahara desert was wetter than at present and was covered with savanna-like vegetation. As solar insolation declined after 4 kyr, the Sahara gradually became drier. In the American southwest, large lake systems (pluvial lakes) developed in regions that today are semiarid.

The Anthropocene and the Great Acceleration

The Holocene epoch is often described as a period of relatively stable climatic conditions given the lack of wide climatic swings similar to the glacial/interglacial cycles during the Pleistocene epoch. However, the past 10 kyr of Earth’s climate history have been witness to important periods of climate variability, including the Medieval Climate Anomaly and the Little Ice Age. We are now on the doorstep, and have possibly crossed the threshold, of the next period of climatic variability in the Earth’s history. Many believe we now find ourselves in the Anthropocene epoch, the geologic period of Earth’s history where the impact of humans has become one of the primary drivers of climatic and environmental change. While still not formally recognized as a geologic unit, usage of the term has become widely accepted.

Many argue the Anthropocene epoch commenced with the start of the Industrial Revolution in Europe during the latter part of the eighteenth century (Crutzen and Stoermer 2000). Based on evidence obtained from ice cores, it is at this time that human activities began to noticeably alter the chemical composition of the atmosphere. Carbon dioxide increased from about 280 ppm in 1750 to current levels of around 700 ppm and methane from about 700 ppb in 1750 to current levels of around 1700 ppb.

Regardless of how human impacts are defined from a geologic perspective, anthropogenic impacts on recent climate have been significant. Since the mid-to-late twentieth century, climate has warmed at an accelerated pace, driven by changes in the concentration of greenhouse gases in the atmosphere. Since 1950, synchronous changes in socioeconomic and Earth systems trends occur and begin to accelerate in tandem for the first time in Earth’s history. These changes are certain to continue impacting global climate in the future.

Paleoclimate studies have taught us much about how the Earth’s climate system has responded to changes in climate drivers in the past, providing a window to look back in time and better inform us for the future. However, these studies also confirm that global climate systems are now changing at rates that exceed the range of natural variability noted in many paleoclimatic studies. The divergence issue in dendroclimatology is perhaps an emerging example of this. In a rapidly changing Anthropocene world, interpretations of the relationships between climate change and proxy data sources will continue to yield important findings about past climatic conditions, and likely many new surprises as well.

Paleoecology and methods

The study of paleoecology involves reconstructing past interactions between organisms and their environment. Such biogeographical data about the past provides valuable information relevant to understanding modern and future responses of plants and animals to environmental changes, including climate shifts and human impacts on terrestrial landscapes and aquatic ecosystems. Organisms that offer such paleoecological data are those preserved as fossils in suitable geologic settings, such as those buried in the anoxic sediments of lake bottoms and peatlands, and those remains sheltered in caves, particularly in arid environments. These fossils become “paleoecological proxies” of past environments when they are identified to species or genus by comparison to the remains of modern representatives of the same taxa, that is, the “modern analog concept.” For instance, fossil cones and pollen of white spruce can be directly compared to the components of a living white spruce tree to confirm species identification. And then by applying the modern analog concept a paleoecologist can use data about the modern habitat and range of this species today to infer the paleoecology of this taxon in the past. Using the example of white spruce, this species today occupies the boreal forest biome of northern North America and its southernmost limit is dictated by the 18 °C July isotherm, as summer temperature warmer than this curtail seedling growth of this boreal tree (Yansa 2006). Therefore, a paleoecologist who finds white spruce fossils buried at the bottom of lakes in eastern and central North America, south of the boreal forest today, can infer a boreal climate and habitat for that area in the past. Such a subarctic boreal reconstruction for the Late Pleistocene (≈18,000 to 11,600 years ago) vegetation of this area of North America has been made by several scholars, even though the present-day vegetation is deciduous forest or grassland correlative to a warmer climate.

Pollen and plant macrofossils (cones, seeds, leaves, fruits, and other macroscopic plant remains) are common proxies studied in paleoecology in that they reconstruct the species composition of vegetation communities over past millennia that changed in response to shifts in temperature and moisture regimes. Certain plant fossils can also indicate past human impacts on landscapes, particularly the clearing and burning of land for agriculture, by a decrease in forest pollen abundance, increase in the pollen of grass and open vegetation types, and the appearance of fossils of domesticated plants including maize (corn), wheat, rye, beans, and wild rice. Also, such pollen of crop plants is usually associated with high concentrations of charcoal fragments, indicative of fire, and such information is correlative with archaeological records of prehistoric human–environment interactions. Analyses of charcoal records with an eye toward identifying peaks of greater charcoal accumulation can reconstruct local fire histories of the past and intervals of greater fire occurrence, but cannot discern individual fires.
PALEOECOLOGY

These and other fossils can be collected from peatlands and lake bottoms by excavating trenches to provide vertical exposures (if the water table is lower today than in the past) to sample sediments containing fossils. Or, more commonly, existing lakes are sampled using coring equipment (such as a Livingston piston corer) from a boat in open water or from the frozen surface of a lake in winter. The coring device is typically 1 m in length, so it needs to be put down the same hole to repeatedly collect several meters of lake sediment before reaching an impenetrable layer, such as sand or glacial till. Plant macrofossil and/or charcoal from certain sampled levels of cores and trenches can be sent to radiocarbon (\(^{14}\text{C}\)) laboratories for dating, thereby providing chronologies for sites. The limit of \(^{14}\text{C}\) dating is approximately 50,000 years, but the study of pollen and plant macrofossils can go back further in time, however, the chronologies of these are based on other, indirect dating techniques. The majority of plant fossil studies focus on the last 20,000 years for which fossil preservation is best and the results can be directly applied to understanding modern plant distribution patterns and prehistoric human impacts on landscapes. The last 150 years, up to the present day, cannot be dated using \(^{14}\text{C}\) dating, due to half-life limitations of this isotope, however, \(^{210}\text{Pb}\) and \(^{137}\text{Cs}\) are isotopes that cover this period for fossil records.

Plant fossils are isolated from the sediments of lakes and peatlands by two means: (i) sieving 50 to 250 cm\(^3\) of mud for the larger plant macrofossils and charcoal fragments under tap water, and (ii) for pollen and microscopic charcoal, treating 1 cm\(^3\) of sediment in test tubes to a series of chemicals to remove carbonates, silicates, and cellulose. The macroscopic remains are viewed in petri dishes in distilled water under \(40\times\) magnification, whereas the microscopic pollen and charcoal are dispersed in silicon oil, a tiny amount of which spread on a microscopic slide and viewed under \(400\times\) magnification. For both, the fossils are identified and counted to the lowest taxonomic level, species for most plant macrofossils and usually to genus for pollen. The low numbers of seeds and other macroscopic fossils recovered in a lake or peat core permits only displaying the results as counts.

In contrast, the greater abundance of pollen allows for counts of 400 or more pollen grains per sample and hence statistical analysis and modeling can be performed to elucidate on pollen–climate relationships. Specifically, canonical correspondence analysis (CCA), detrended correspondence analysis (DCA), and principal components analysis (PCA) can be done to derive paleoecological transfer functions. These transfer functions are equations based upon variations in the present-day abundance and geographic distribution of pollen taxa relative to modern climate gradients. These types of inverse modeling assume that climate is the only environmental factor limiting the distribution of plants, which is true at the biome level, but not at the local scale where soils, topography, and disturbance also play important roles. Hence, modeling of pollen data is mainly done to understand biome shifts over past millennia. Other proxies, described below, are more climate-dependent and hence provide transfer functions through the analyses of calibration sets, which yield better paleoclimate reconstructions.

Other biotic proxies

Conveniently, the same lake and peatland sediments that contain pollen and plants macrofossils also hold several other plant and animal proxies, with each providing unique data about past environments, including paleoclimates. Diatoms, for instance, are a group of microscopic eukaryotic algae (phytoplankton) found in freshwater and
marine environments, with the focus here being on those from lakes. Most diatoms are unicellular and comprised of valves (theca) that can be identified to species. Given the great taxonomic diversity of these algae ($\approx 100,000$ species worldwide), each species provides very detailed data of the chemistry and temperature range of the water body it once occupied, and thereby offers valuable paleoecological information. Diatoms are comprised of silica (SiO$_2$) and hence are best preserved in cold, soft water lakes of high latitudes and alpine locations where dissolved silica is abundant and are correspondingly poorly preserved in warm alkaline or saline lakes of the low latitudes. The majority of diatoms are either planktonic, being mainly suspended in the water column, or benthic, those attached to plants, stones, and sediment around the margins of lakes. The ratio of planktonic versus benthic species provides meaningful information about water depth changes and inferred precipitation regimes over time.

For each lake where fossil diatoms will be investigated by deep cores, researchers sample all modern diatom habitats using sediment traps to capture and identify living diatoms at the sediment–water interface as well as collect water samples for chemical analysis. These data are then compared to modern climate data. CCA is used to provide an ordination of each living species against a modern environmental variable, such as temperature, water pH, or phosphorus, and through this method diatomists produce a “calibration training set” for each lake (Battarbee et al. 2001). Then the training set is applied to the fossil species data from that lake to reconstruct the paleoecology of the area, again invoking the modern analog concept. Fossils diatoms are collected using the lake sediment coring methods, described above, and a series of chemicals clean the valves so details of cell walls are visible for species-level identification under 750× magnification. Typically, a diatom study involves the investigation of a series of lakes with a focus on a gradient of interest (e.g., salinity, pH, or total phosphorous) within a region. Fossil diatom analyses have provided invaluable information about (i) past and recent climate change from diatom-inferred salinity changes of lakes situated in semiarid environments, and species changes in lakes attributable to (ii) acid rain pollution by fossil fuel burning, and (iii) cultural eutrophication caused by elevated lake phosphorus levels from fertilizer runoff and other anthropogenic sources.

There are several types of animal fossils preserved in and recovered from lake sediments that are studied in paleoecology. One such animal proxy is ostracods (Ostracoda). These are microcrustaceans in the same family as lobster, crab, and shrimp species, but are tiny, about the size of plant seeds, and have clam-like shells formed by two valves of calcite (CaCO$_3$). Each ostracod species is either planktonic (near the water surface), swimming, or benthic (crawling on and into the mud at lake bottoms). Many ostracods eat decaying organic matter and some fish species prey on them. Interestingly, the eggs and adults of some ostracod species are able to tolerate months of desiccation and freezing and they will emerge from dormancy once suitable water conditions occur. Like diatoms, each species of ostracods is correlative to a certain temperature range and to specific gradients for dissolved oxygen, salinity, and other chemicals in lake waters, and hence calibration training sets (based on modern data to interpret fossil data) have to be constructed as well. Being arthropods, ostracods grow by molting and most individuals will molt eight times prior to adulthood, so the adult shells are the ones identified to species based on differences in shell morphology (size, shape, muscle attachment scars, etc.). The growing shell absorbs
different weights (various isotopes) of a chemical depending on the temperature and salinity of the surrounding water. Geochemical analyses of stable oxygen isotopes (the ratio of heavy $\delta^{18}O$ vs. light $\delta^{16}O$) from ostracod shells are commonly performed to determine the relative amount of fresh water in lakes over time, which is used as a proxy for determining moisture sources in the past. For example, such research has reconstructed the relative input of moisture from the Gulf of Mexico air mass versus moisture from the Pacific air mass for the last 12,500 years for central North America and hence can infer the dominant patterns of atmospheric circulation over these millennia (Yu 2000).

Another small animal proxy derived from lakes is chironomids (Chironomidae), commonly referred to as midges or “lake flies,” which are mosquito-like, aquatic insects found in lakes and slow-moving streams. Like ostracods, they are an important food source for fish. The larval head capsules of midges are made of a hard, semi-transparent material (chitin) that become embedded in sediment and morphological variations of these permit species-level identification at 50× magnification. A calibration set, modern data regarding living midge species in association with current water temperature and chemistry data, are also required to interpret the fossil chironomid data, and hence the paleoecology of a site. Such work has been used to reconstruct summer surface water temperature for lakes over past millennia, based on the optimum ranges of cold-water versus warm-water taxa (e.g., Walker 2001).

Another animal made up of chitin is beetles (Coleoptera), which are found in freshwater and terrestrial habitats throughout the world. These insects are important food for fish, reptiles, birds, and small mammals and beetles play critical roles as pollinators and nutrient recyclers. Those Coleoptera buried and preserved in lake, pond, and river sediments are recovered as separate parts, specifically heads, pronota (thoraces), and electra (wing cases), which are identified to species based on morphological variations. One limitation to studying this proxy is that large volumes (several liters) of sediment are required to find enough remains (using a kerosene flotation and sieving) for meaningful paleoecological reconstructions, and hence only trenched excavations can provide enough material.

Where fossil beetles are abundant, they provide excellent paleoecological data as these insects are dependent on temperature for all phases of their life cycle, and each species has its own temperature range and is associated with a particular biome. Calibration sets are also created to derive more precise paleoclimate information from the fossil beetle data, following a methodology similar to that employed for midges and ostracods. For example, paleo-beetle research in central North America reveals that the area south of the Laurentide ice sheet during the last Glacial maximum, 25,000 to 18,000 years ago, had a mean July temperature that was 10–12°C lower than present, so it was essentially an arctic environment (Ashworth 2001). Subsequently, the climate became warmer so that boreal forest-adapted beetles had arrived by 14,700 years ago, which agrees well with the pollen and plant macrofossil data for this area (Yansa 2006). Sometimes conifer bark beetles are also identified which further corroborate paleovegetation reconstructions.

Another excellent paleoclimate proxy is testate amoebae (Rhizopoda), which are unicellular shelled animals (protozoa) that live on the surface of most Sphagnum acidic peat bogs. These protozoa have tests made of smooth secreted material, preformed plates, and/or cemented particles gathered from the surrounding environment and can be identified to species. Certain taxa are known to live above and others below the water
So the coring of peat bogs and analysis of testate amoebae can reconstruct times when bogs were drier and other intervals when moister conditions prevailed, thereby providing records of past water-level fluctuations. For instance, the 3500-year water table depth reconstruction of Minden Bog, Michigan, based on testate amoebae data, is remarkably similar to the water-level curve of nearby Lake Michigan inferred from dated shoreline elevations (Booth 2008). Of all of the paleoecological proxies, testate amoebae is thus the best to reconstruct past hydrological conditions, but unfortunately it is limited to peat bogs, so is largely restricted to the boreal forest and arctic biomes.

The majority of paleoecological proxies and sites that preserve fossils are found in humid environments, such as eastern North America, Europe, and parts of Asia, however, a few proxies are able to survive oxidation inherent to semiarid and arid climates and thereby provide valuable paleoecological information for these data-sparse areas. One such proxy is phytoliths, which are microfossils comprised of silica found in soils. Plants, particularly grasses, uptake silica from the soil and deposit the silica as an amorphous (opal) solution within and between cells in leaves and stems, where the silica hardens and takes on various sizes and shapes dependent on the cellular nature of different plant types. Anyone who has cut his/her hand by pulling grasses has encountered the abrasive phytoliths (“plant stones,” from Greek), which may be an adaptation by plants to reduce grazing by herbivores. After the plants decay, the phytoliths are liberated into the soil in great numbers and most remain in place. Fossil phytoliths are acquired by the trenching and sampling of soils, and heavy liquid separation of the lighter phytoliths from quartz sand in the laboratory. The study of this proxy has been mainly used to reconstruct the composition of grasslands of the past and to delineate past shifts of grassland-forest ecotones (boundaries) in high-latitude, temperate, and tropical environments.

Phytoliths are identified to morphotype and so can distinguish between tribes of grasses, offering greater precision than do pollen analysis that lumps all native grass types together. Phytolith analysis can differentiate between the Festucoids, which are cool-season C₃ grasses (where the product of photosynthesis is a sugar containing three carbon atoms), from the warm-season C₄ grasses (have a sugar containing four carbon atoms). Phytoliths can further distinguish the C₄ grasses into two types, the short-grass Chloridoids found today in the arid western Great Plains, from the Panicoids, a tall-grass prairie type native to the moister eastern Great Plains and in what is now the Corn Belt. Therefore, the study of phytoliths of buried soils can reconstruct approximate temperature conditions for the past by comparing the abundance of C₃ to the C₄ phytolith types and provide estimates for paleoprecipitation by the relative quantity of Chloridoid versus Panicoid morphotypes.

In the arid and semiarid mountainous areas of western North America, packrats (woodrats), species of the genus Neotoma, are known to collect plant material from the surrounding area to form middens (nests) within rock shelters. Over time these middens become cemented by dried urine (amberat), abandoned by the rodents, and the arid climate prevents dissolution, so that these deposits become uncontaminated “time capsules,” which can be analyzed for plant remains and ¹⁴C dating. Such research has elucidated that there was no deserts in the southwest United States during the last Glacial maximum, the peak of the last glaciation at approximately 20,000 years ago (rather an open conifer woodlands existed), and tracks the subsequent development of the desert biome in this region (Betancourt, Van Devender, and Martin 1990).
The packrat midden data are displaced as abundance classes (1–5), as concentrations, or weight percentages per plant species. The key shortcoming of the midden data is that each species of packrats prefers different kinds of plants; most collect twigs and shoots, but only some species collect seeds, fruits, acorns, and/or cacti. So the absence of certain plant species in midden records not necessarily means that these plants were not present in the landscape at the time the nests were constructed. However, the presence of certain plant species in midden records does provide important paleoecological information for a habitat where lake and peatland records are absent due to aridity. For instance, by using the modern analog concept, the macrofossil presence of saguaro cactus means “hot and dry,” pinyon pine (piñon) equates with “cool,” and mesquite indicates “wet.” Such work can also be applied to archaeology. For instance, a packrat study in Chaco Canyon, New Mexico, indicated that the area was pinyon-juniper woodland until an Anasazi occupation deforested the area between 1000 and 800 years ago, and this vegetation failed to regenerate afterwards (Betancourt, Van Devender, and Martin 1990).

The nature of packrats to collect and store food in their middens is a perfect analog for the archiving of paleoecological data, hence Neotoma is the name of a recent amalgamation of separate proxy-specific databases into one under an umbrella website (www.neotomadb.org). This website provides valuable information and some visualization tools that allow the public to become familiar with the various proxies and to learn of the valuable insights these proxies provide about past environments.

The proxy that receives the greatest attention from the public is the remains of ice age megafauna: the behemoth mammoths, mastodons, and giant sloths; the exotic American lion, saber-tooth cat, and giant beaver; and other mammalian oddities that went extinct between approximately 15,000 and 13,000 years ago, at the end of the Pleistocene. Fossil bones and teeth of over 35 genera of extinct animals are found in a range of environments south of where the ice sheets covered the northern and mid-latitudes of North America and Eurasia. Fossils of these large fauna have been recovered from sinkhole lakes, river deposits, and tar pits, the most famous site being the La Brea tar pits of Los Angeles.

No scientific consensus exists as to the cause(s) of this extinction event at the end of the Pleistocene, a time when the majority of large mammal species disappeared in North America, Eurasia, and in several other locations throughout the world. Several hypotheses have been proposed that solely or in combination can explain this event, including: climate and vegetation change; overhunting by humans (Paleoindians); diseases from humans and their dogs; and the controversial idea of an asteroid impact (Holliday and Meltzer 2010). There are several well-dated archaeologist sites that definitely document the first Native Americans having occupied the west coast and Midwest of North America south of the ice sheets by 14,700 years ago, so humans may have played a role in this extinction.

Late Pleistocene refugia and megafauna

The remainder of this section will weave together paleoecological information from the abovementioned proxies into a short summary of the landscape changes that occurred from the peak of the last glaciation to present. The focus will be on North America, but these patterns are similar to those observed in other mid- and high-latitude locations in the Northern Hemisphere. During the last glaciation, the Laurentide ice sheet expanded south from Hudson Bay and
merged with the Cordillerean ice sheet that covered the mountainous areas of western Canada and the northwestern United States. These ice sheets extended south to approximately 38° N latitude, which resulted in plants and animals being confined to a “refugia” south of these glaciers. The environment closest to the ice sheets during the last Glacial maximum (25,000 to 18,000 years ago) was periglacial, with the mean annual temperate being 10–12°C lower than today. A tundra vegetation was able to tolerate the cold winds coming off the ice sheets and low temperatures caused by the high albedo (sunlight reflectivity) of the glaciers. Occupying this frigid, open habitat were wooly mammoth (extinct), two species of muskox (one of which went extinct), and caribou (extant, living today in the arctic).

South of this tundra resided open boreal woodlands that were inhabited by the now extinct giant beaver, stag-moose, mastodon, and Jefferson mammoth and more familiar (extant) deer, elk, and moose. Immediately to the south, a mosaic of plant communities existed, including mixed coniferous-deciduous forest, open deciduous forest, and pine woodlands, which covered the southern half of the eastern United States. Meanwhile, the vegetation of the western United States south of the Cordilleran ice sheet, was drier, but still diverse, comprising a mix of grassland, temperate scrub and woodlands, and open conifer woodlands. Therefore, the vegetation of the refugia (south of the glaciers) at the end of the Pleistocene was more open and had greater habitat diversity than later during the Holocene. The mosaic of different plant communities at the end of the ice age can explain the great diversity and abundance of herbivores, especially in the central and western parts of the United States, many of which are now extinct. These herbivores included species of horses, llamas, camels, Columbian mammoths, and a larger form of bison and thus supported a greater diversity of carnivores, such as the short-faced bears, American lions, American cheetahs, saber-toothed cats, and scimitar cats.

This great mammalian diversity collapsed at the end of the Pleistocene and only a limited number of herbivores and carnivores survived. Vegetation changes can at least partly explain this event. The recession of the Cordilleran and Laurentide ice sheet permitted plants to colonize barren, water-logged glacial sediment and the first vegetation to appear was tundra. Later an extensive spruce parkland/sedge wetland covered the central and eastern portion of this formerly glaciated area which reduced the food variety for herbivores and probably contributed to population decline and the extinction of some of the larger herbivores, with many of the carnivores following suit. The transition from this boreal-like spruce vegetation to deciduous forests and farther west grasslands and deserts resulted in fewer biomes and correspondingly reduced habitat diversity that could support fewer species as compared to the Late Pleistocene mosaic. Such paleoecological information is relevant to us today given the current habitat destruction and species extinctions caused by climate change and human impacts.

In summary, a variety of plant and animal fossils can be used as proxies for reconstructing past climates and habitats and how they changed over time. Certain proxies are better than others to study particular environments and time intervals and the use of multiple proxies in an investigation provides more robust paleoecological reconstructions. Some of this research has focused on interpreting past habitat changes of Pleistocene megafauna to explain, in part, their extinction. And such information about past responses of plants and animals to environmental changes, including range shifts, can provide insights into
how organisms today and into the future will adapt to climate changes this century and beyond.

Paleofloods

Victor R. Baker
University of Arizona, USA

Paleofloods are past or ancient floods that are indicated through natural recording processes. The recordings of paleofloods occur because of direct causal connections of past floods to deposition, erosion, or other markings that can subsequently be documented by knowledgeable investigators. More specifically, paleofloods are defined (Baker 1987) as floods that occurred prior to either (i) systematic measurement of flood flows using modern hydrological procedures (e.g., at stream gages or by surveys conducted after directly observed flood events), or (ii) other observation and recording by human agents (in which case the floods are termed “historical floods”). The natural archives of paleofloods extend information on the phenomenon of flooding well beyond the artificial limitations imposed by the opportunities afforded to humans for the direct observation of floods. This is especially important in regard to the largest and most intense flood phenomena, because (i) these are rare and thus less likely to be observed on human timescales; (ii) they are dangerous for direct measurement and also difficult to approach because of associated damage to infrastructure; and (iii) such floods can be so energetic as to commonly destroy the recording instrumentation at gaging stations.

The scientific study of paleofloods is associated with a long tradition in geology that was classically concerned with field evidence for ancient floods in regard to their shaping of landscapes. This concern remains important as one of the applications for paleoflood data. A scientifically interesting development in this regard is the recognition that especially immense and intense flood phenomena occurred during the terminal phases of the last ice age, that is, the late Pleistocene epoch of the geological timescale. These paleofloods are studied under the general topic of “megaflooding” (Burr et al. 2009). Although the term is somewhat loosely applied to a variety of high-discharge flood flow events, a “megaflood” can be more precisely defined as freshwater flow of 1 million cubic meters per second or greater. There are no well-documented humanly observed flood flows of this magnitude, but some Late Pleistocene outburst paleofloods from glacially dammed lakes achieved peak discharges of 10 million cubic meters per second or greater (Burr et al. 2009).

The geological study of intense flooding was highly stimulated by studies in the 1920s and 1930s of the Channeled Scabland region of the northwestern United States (Baker 2009). Professor J Harlen Bretz of the University of Chicago proposed that the distinctive landscape of this region had been eroded by spectacular megaflooding during the terminal phase of the Pleistocene. It was subsequently recognized that this flooding emanated from an immense ice-dammed lake in western Montana that held approximately 2500 cubic kilometers of water. About 16 000 or 17 000 years ago the failure of this lake, Glacial Lake Missoula, released water that was 600 meters deep at the ice dam location in northern Idaho. As the high-velocity water flows spread over the mostly basalt plateaus of eastern Washington state, they carved huge, irregular channels into the bedrock, deposited

immense bars of gravel and boulders, and created other distinctive features indicative of the past flooding magnitude. These features provide extreme examples of the natural recording process that are so important to the recognition of paleofloods.

In contrast to the megaflooding of the last ice age, the types of flooding associated with present-day hydrometeorological processes are represented in paleofloods that occurred during the last 10,000 years, the Holocene geological epoch. It is these paleofloods that are of particular interest for characterizing the hazards posed by very large, rare floods for which modern hydrological records, or even historical accounts, are inadequate.

A formal scientific approach to the study of ancient floods began to emerge in the mid-twentieth century. The term “paleoflood” first appeared in the scientific literature during the 1970s, and paleoflood hydrology was formally defined as a scientific discipline in 1982 (see Baker 2008; 2014). Paleoflood hydrology is actually a synthesis of two somewhat different scientific approaches to the study of floods. As noted, the geological approach emphasizes the recognition of various signs or traces that can be interpreted by the experienced geological investigator as evidence for past flood processes. Thus, the geological investigator of floods works out a history of past flood events in much the same way that a history of past biological organisms is worked out through geological studies of their fossil forms. This history is used to make discoveries about the nature of the flooding, including its patterns in time and space.

The hydrological approach to flood studies developed out of origins in which hydrology acted as a scientific arm for practical hydraulic engineering. The latter is concerned with the design of hydraulic structures, such as large dams. Since these structures can be at risk from extremely large floods, it is necessary to generate numeric measures of risk that can be used to achieve designs within some level of tolerance. Risk in this context is defined as the peak flood discharge multiplied by the probability for its exceedance or nonexceedance. The necessary probability estimates for risk assessment are achieved through a flood-frequency analysis of the available systematic stream-gage data. Given the lack of information on extremely large, rare floods, the prediction of flood probabilities for risk analysis must entail certain assumptions, including (i) that floods are random in time and space; (ii) that the floods at a specific place, such as at a stream-gaging station, arise from a single probability distribution; and (iii) that the mean and variance for this probability distribution are time-invariant, that is, these statistical moments are stationary in time. Modern hydrological research has shown that all these assumptions are wrong to varying degrees (Baker et al. 2002), though they continue to be applied because of the necessity to make engineering design decisions in the light of what is presumed to be a lack of data on extremely large, rare floods. Of course, this is exactly the kind of data that can be provided through the study of paleofloods.

There are many types of indicators associated with the recognition of paleofloods. For alluvial rivers, in which the beds and banks of the river are composed of the same types of sediment that the river transports, the size of the channel and its stage at overbank levels correspond to relatively low-magnitude paleoflooding that commonly recurs every year or two. This is the regime-based approach to identifying paleofloods that makes use of various empirically derived relationships to estimate the magnitudes of bankfull and other relatively high-frequency paleoflood magnitudes (for a review of this topic see Baker 2014).
More interesting evidence of high-magnitude floods can be found in their effects on trees that grow on floodplains or along valley bottoms. The stages reached by the floods produce scars on the trees that can serve as paleostage indicators (PSIs) for past flooding. Moreover, the sequence of tree rings related to the scarring events can rather precisely determine the year in which flooding occurred. Paleostages can also be inferred from the highest levels eroded by energetic flooding along the margins of channels in canyon and valley bottoms.

The boulders transported by very intense floods can be related to measures of stream competence, usually through expressions of flow velocity, bed shear stress, or stream energy expenditure (power). These can all be related through various hydraulic formulae to measures of flow depth, with the latter indicated by the preserved PSI evidence provided by the paleoflood. Additional parameters also need to be estimated, including the channel geometry, the energy gradient of the stream, and the flow resistance of the channel bed. Though estimating these parameters is subject to many uncertainties, paleocompetence calculations provide general information for approximating the magnitudes of the paleofloods that emplaced various boulder deposits.

A relatively accurate means of characterizing both the magnitudes and frequencies of paleofloods was developed in the latter part of the twentieth century based on the recognition that extreme flooding along bedrock streams conveying sandy sediments will deposit well-preserved sequences of those sediments in appropriate, protected riverine settings. In these environments, during especially intense flooding, sedimentary particles with sufficiently high settling velocities accumulate relatively rapidly from suspension in areas of flow separation and slack water, such as at the mouths of back-flooded tributaries or in bedrock alcoves set into canyon walls. The resulting slackwater deposits (SWDs) commonly comprise thick accumulations (Figure 1), in which individual sandy layers correspond to the causative flood events and layers of nonflood materials or boundaries between the SWD layers correspond to intervals between the flood events. The nature of the preservation sites for the SWDs is such that they are protected from the erosive action of later floods. The well-preserved evidence provided from sequences of slackwater deposits (SWDs) is combined with other paleostage indicators (PSIs) to comprise the mode of investigation that has come to be known as SWD–PSI paleoflood hydrology (Baker 1987).

Several technological developments contribute to the greatly improved accuracy of SWD–PSI studies for estimating both the magnitude and frequency of paleofloods. Frequency estimation requires understanding of the timescales in which flooding occurs, and there are now many new analytical tools for assigning timescales to sequences of paleofloods. The tool that was first applied to SWD–PSI paleoflood hydrology in its initial phases of development was the radiocarbon-dating of organic material intercalated with the flood deposits. This method is applicable to paleofloods that occur throughout the Holocene epoch. Recent developments in tandem accelerator mass spectrometry now allow organic grains with a mass of only a few milligrams to be dated within an error range of several decades.

Of course, many flood deposits do not contain organic material. Recent developments in the geochronological tool of luminescence dating are filling this void by making possible the direct dating of mineral grains of quartz and feldspar that were transported by paleofloods. Another new geochronological tool, terrestrial cosmogenic nuclide dating, makes possible the direct dating of flood-eroded rock surfaces and flood-transported boulders.
PALEOFLOODS

Figure 1 A sequence of sandy paleoflood slackwater deposits (SWDs) exposed in a bedrock alcove developed in cliffs along the margins of the Escalante River, a tributary of the Colorado River in south central Utah. Note the multiple layers indicating deposition by separate flooding events. (Photograph by the author.)

The calculation of paleoflood discharges was originally accomplished using simple hydraulic formulae, such as the Manning equation, which relate the discharge of the paleoflood to its cross-sectional area, flow depth, energy slope, and a measure of flow resistance. Starting in the 1980s, computer flow models began to be employed to perform the hydraulic calculations. The first models performed step-backwater calculations in one dimension, along the thread of the main channel. Multiple cross-sections are used along a channel reach that is long enough to achieve an energy-balanced calculation of multiple water-surface elevations for various potential paleoflood discharges. By matching the flood paleostage evidence to the calculated water-surface profiles, paleodischarges are estimated. More recently, further increases in computational capability have enabled the use of two-dimensional flow models. These are appropriate for the more complex channel geometries that can be accurately represented in the one-dimensional models.

A variant of PSI paleoflood hydrology was developed in the 1990s by the US Bureau of Reclamation for the study of potential risks posed to large dams by very rare, extreme flooding. This methodology identifies the various threshold indicators of paleoflood nonexceedence. It then calculates the paleodischarge values for these thresholds, uses geochronology to determine the timescales over which the nonexceedence thresholds apply, and finally puts the discharge values and their timescales into a flood-frequency analytical scheme that determines the likelihoods of nonexceedance.

In contrast to these applications by the US Bureau of Reclamation, much of the US engineering community has been relatively slow to embrace paleoflood hydrology in its operational approaches to the evaluation of extreme flooding hazards. One reason for this seems to be reliance on engineering rather than scientific approaches to the phenomenon of flooding. Some of the engineering literature continues to repeat criticisms of paleoflood hydrology that were expressed during the early development of that science in the 1970s. As reviewed by Baker, Webb, and House (2002), those 1970s concerns included (i) the impossibility of determining the ages for very ancient floods; (ii) the impossibility of accurately determining the discharges for
ancient floods; (iii) the lack of appropriate statistical procedures for incorporating paleoflood data into risk analyses; and (iv) the presumption that future changes in climate and/or land-use practice will invalidate the incorporation of information on past floods into the statistical analyses that determine the risk of future floods. As noted, concerns (i) and (ii) have been met by new technology for geochronology and for hydraulic modeling. Concern (iii) has been met by developing the appropriate statistical procedures, as exemplified by the US Bureau of Reclamation approach. Finally, concern (iv) is merely a kind of skepticism that applies to all historical information. Its logic would hold that all empirical information about floods, including that derived from stream gages, is invalidated by the reality of the future not being exactly like the past.

Though the modern science of paleoflood hydrology was developed in the United States, some of its more extensive applications have been taken up in foreign countries. SWD–PSI paleoflood hydrology spread to Australia in the 1980s, and to India and Israel in the 1990s. These countries all have many areas that are highly appropriate for the SWD–PSI methodology. Extensive paleoflood investigations in the 1990s and the new millennium have also been conducted in southern Europe, mainly in Spain, France, and Greece; in southern Africa, both in Namibia and in the Republic of South Africa; in South America (Chile and Peru); and in parts of Asia, including China, Japan, and Thailand. A recent survey (Baker 2013) documents 60 paleoflood study areas from 21 US states and 25 other countries. High potential for very accurate applications of SWD–PSI paleoflood hydrology occurs in other parts of Africa (e.g., Algeria, Libya, Somalia), Asia (e.g., Turkey, Iran, Mongolia, Sri Lanka), Europe (e.g., Russia, Romania, Portugal), and South America (e.g., Argentina, Brazil, Venezuela).

Very interesting paleoflood hydrological research is currently being done in China. As a result of war and turmoil in the mid-twentieth century, China did not have the infrastructure of stream gages to provide the data necessary to hydrological design decisions for the large dam projects of recent decades. During the period immediately after World War II China made extensive use of historical accounts of river flooding that were documented over the past 2000 years by the bureaucracies of the various Chinese emperors. These included actual marks and inscriptions on canyon walls showing the stages reached by ancient floods. Moreover, largely independent of the work on paleofloods in the United States and other Western countries, some Chinese investigators in the 1980s were supplementing the historical accounts by field studies of slackwater sediments along major rivers, such as the Huang He (Yellow River) and Chang Jiang (Yangtze River). In more recent years Chinese investigators have fully embraced SWD–PSI methodologies (Baker 1987), using them to study the risks posed by flooding to major dam projects, water-transfer schemes, and the hazards posed to very dense human populations along river bottomlands.

Future global climate change is widely recognized to be a likely consequence of well-documented anthropogenic increases in radiatively active atmospheric gases, particularly carbon dioxide. There are sound physical reasons to expect that the increases in global mean temperature associated with these atmospheric changes will result in more intense flood phenomena. In essence, the increased radiative forcing associated with increased tropospheric carbon dioxide, methane, and other gases should lead to greater surface heating, which will increase air temperatures and evaporation. Much of this effect will occur in the tropics, probably enhancing tropical flood-generating phenomena and
also promoting more atmospheric water transport from the tropics to higher latitudes. This will, in turn, lead to more atmospheric water vapor at those latitudes, which will contribute to areas of more intense precipitation and increased storm intensities. Recent examples of extreme flooding phenomena in parts of the United States have led to concern that this phenomenon may be a consequence of global warming.

Because conventional engineering approaches to flood-risk analysis rely on flood-frequency procedures, the expected changes in flood magnitudes from global climate change pose a major concern for the evaluation of future flood risk. Clearly such changes violate the stationarity assumption noted earlier as underpinning engineering design decisions that are based on mathematical extrapolations from flood-frequency distributions. Thus, it may not be inappropriate to ask whether this entire engineering approach to estimating extreme flooding phenomena is flawed scientifically. As an alternative, it is clear that the largest paleo-floods are very real manifestations of the most extreme kinds of flooding that can be produced by storm systems. Global warming will produce climate change, that is, it will result in shifts of storm patterns. Global warming is not going to create entirely new kinds of meteorological phenomena that have never before occurred on the planet. Evidence for the kinds of extreme floods likely to be associated with the new storm patterns is available from the natural archives of paleo-floods. To ignore these archives of SWD–PSI and other paleo-flood evidence would be the anti-intellectual equivalent of ignoring the lessons of human history when facing the expected uncertainties of future human affairs.

As a final observation, paleo-floods have the potential to play a unique role in regard to the communication of flood risk to the general public. Such use sharply contrasts with prevailing authoritative government pronouncements regarding the so-called hundred-year flood. The latter is a by-product of the engineering flood-frequency approach to flood-risk assessment described earlier in the entry. Unfortunately, the “hundred-year flood” designation is nearly universally misunderstood. It does not refer to an actual flood, and it has nothing to do with real years. Instead, it is the inverse of annual exceedance probabilities derived from mathematical extrapolations that are based on questionable assumptions. In contrast, paleo-flood information derives its authority from the natural recording of ancient (but very real) cataclysmic processes with the obviously documented potential to cause harm. The commonsense recognition that what has actually happened will very likely happen again has much more potential to provoke engaged and wise public response than the invocation of abstract terminology that befuddles rather than informs.

Paleosols

B. Brandon Curry
University of Illinois at Urbana–Champaign, USA

A Paleosol is the evidence of an ancient soil, either at ground surface (a “relict soil”), or buried at depth by sediment (a “buried soil”). Relict soils are evident at places where the surface soil characteristics are incongruous with the prevailing environment, for example, a deeply weathered soil (implying abundant moisture) in an arid climate. An “exhumed soil” is a special case in which sheet erosion brings a buried soil horizon to the surface. Exhumed soils are especially common in semiarid regions. Here, mesas may be capped by thick, resistant carbonate horizons (hardpans, caliches, or calcretes) that originally formed at depth in the past. In areas with episodic sedimentation, such as on floodplains and in glaciated regions, Paleosols constitute marker beds that allow differentiation and correlation of past soil-forming versus sedimentation/burial events.

Most studies of Paleosols require (or prefer) that the age of the soil be known. If it is not known, determining the age of the soil is often a key part of its study. Soil “age” in this context can be defined in a number of different ways. The period of time during which soil actually formed, from its period of inception (commonly called timezero) to its burial, is called a soil-forming interval. Most soil-forming intervals represent times of geomorphic stability when the surface was neither eroding nor getting buried, hence, a soil could form. If the age of the soil-forming interval is known, then the characteristics of the Paleosol can be used to interpret what the environment was like during that period of time. Another key aspect to soils, with respect to age or time, is establishing the date of timezero — exactly when the surface stabilized and the soil started to form. And lastly, one often wants to determine when a buried soil was actually buried. This date (the end of the soil-forming interval) helps define when in the geologic past conditions became unstable, locally or regionally, causing sediment to be deposited on the soil, effectively burying it.

The upper surface of a buried Paleosol is a non-conformity, representing a time when little or no sediment was deposited and the surface was geomorphically stable. However, in many pedogenic environments surface soils are said to be cumulic, that is, the geomorphic surface slowly incorporated new material, gradually grew upward, and thickened as a result. Thus, an important attribute of Paleosols is the time span represented by the nonconformity, that is, the soil-forming interval, or at the very least, the slowdown in sediment accumulation rates. These temporal or chronometric issues may be addressed by various dating techniques, particularly by methods such as radiocarbon or luminescence dating. The stratigraphic and time elements of Paleosols are encapsulated in the fields of pedostratigraphy and allostratigraphy (American Commission on Stratigraphic Nomenclature 2005).

Because Paleosols possess attributes that reflect past climate and environmental changes associated with past climates, they serve as important paleoenvironmental proxies. Indeed, the first field geologists who studied stream cuts and other
outcrops in the upper Midwest of North America used Paleosols to infer that Earth’s recent climate had shifted over time between “glacial” and “interglacial” periods (Leverett 1899).

Paleopedology is the study of Paleosols. It is closely allied with pedology, the study of modern soils. Many paleopedologists have couched their interpretations of Paleosols in the context of modern soil surveys (i.e., Retallack 2001). Soil surveys provide soil maps and descriptions of key soil horizons and other features, using an established classification system. The United States Department of Agriculture’s latest effort, *Keys to Soil Taxonomy* (Soil Survey Staff 2010) classifies soils into 12 orders with diagnostic surficial layers (such as the mollic epipedon, a diagnostic horizon for Mollisols, which are characteristic of the prairies) and subsurface soil horizons (such as the argillic horizon, a diagnostic horizon for Alfisols, which are characteristic of temperate forested ecosystems), as well as other compositional and climatic criteria. The International Union of Soil Sciences system includes additional classes of soils not found in the United States, such as anthropic soils with very high phosphorus content due to centuries of human occupation (IUSS 2006). Key soil horizons, also observed in Paleosols, are rigorously defined in these systems. In general, the morphological features of all soils become coarser with depth, which is a characteristic for identifying a soil profile. This type of depth trend is normally absent from geologic strata.

**Soil-forming factors**

At many scales, Paleosols exhibit predictable variability. The vertical and spatial variability observed in Paleosols is perhaps best interpreted through Jenny’s (1941) state factor concept, in which soil (and Paleosol) characteristics are viewed as a function of five soil-forming factors: climate (cl), organisms (o), relief (r), parent material (p), and time (t). For buried and exhumed Paleosols, one could add the d factor – diagenesis, which includes postburial changes in the physical and chemical characteristics of Paleosols, such as rubification (reddening) of fossil B horizons due to oxidation of iron (typically a bacterially mediated process) (Retallack 2001). Diagenesis includes compaction, which can dramatically affect soil structure (Follmer *et al.* 1979; Follmer 1998). In leaching regimes, diagenesis also commonly includes the recarbonation of buried, acidic Paleosols, as percolating water moving through overlying, calcareous sediment adds carbonates to the buried soil. A theme that quickly emerges is that the state factors are intertwined; one cannot fully assess the impact of one factor on Paleosol development without examining its effects on the others.

**Organisms**

The role of organisms in soil development is complex. Most soils form in equilibrium with the current vegetation of the site, allowing interpretations of soil paleoenvironments from soil morphology and chemistry. For example, Paleosols with thick, dark A horizons likely formed under grass vegetation. Paleofauna impacted Paleosol development in ways that are readily observable (such as burrows of ants, worms, wasps, cicadas, crayfish, and gophers) (Johnson 1989; Follmer 1983; Retallack 2001). In addition, micro-organisms play vital roles in pedogenesis, and they remain active after burial (Driese and Nordt 2013). Most diagenetic reactions are mediated by micro-organisms, primarily bacteria. The once-living components of the soil, such as plant roots or burrowing ants, were affected by the prevailing climate and other factors (such as parent material porosity) which impacted critical conditions such as the depth...
and degree of saturation during the growing season, and depth of frost.

Parent material

Parent material is the sediment in which the soil or Paleosol has developed. Careful studies have revealed that, rather than a static entity, soil parent materials are dynamic through additions of new material of eolian or alluvial origin (or both) that can become mixed into the upper parts of the soil (solum). Consider a soil on a low-lying river terrace that receives increments of fine sediment from floods. In this scenario, thin layers of new sediment may be rapidly incorporated in the soil through mixing agents such as worms or ants. A less obvious example would be a soil which had been undergoing additions of eolian dust to its surface, which eventually become incorporated into the profile. Significant dust sources include outwash surfaces in glaciated areas, dry lake beds, and volcanic ash. The nature of such eolian additions may be revealed through careful textural and chemical analyses, which may show enrichment of certain constituents in the upper solum that may not be present in relatively unaltered material at depth. For example, some Paleosols in the deserts of North America have meters-thick calcrete (Bkkm) horizons, and yet the unaltered parent material may not contain any carbonate. Dust traps installed in such areas have revealed that the primary carbonate source was carbonate-rich eolian dust. In many areas, groundwater is also a source of carbonate. Recent studies have shown that dust literally travels across the globe; North African dust carried on easterly trade winds reaches Florida, Barbados, and Amazonia (Muhs et al. 2007). Incorporation of dust into soils also affects their physical properties, especially if the original parent material is coarse grained. Soil chemistry and fertility are also altered and diversified, because eolian dust contains minerals rich in carbonate, iron, and phosphorus.

Relief

Not only do Paleosols exhibit changes in the vertical (“z”) direction, but they show much variation along former slopes in the x-y (lateral) direction, producing a characteristic pattern of soils across the paleolandscape. This pattern of slope-dependent, physical and chemical variation in a sequence of soils is referred to as a catena, or toposequence. Along catenas, certain types of soil features or profiles tend to develop in certain slope positions (summits, shoulder-, back-, foot-, and toeslopes). For example, cumulic (overthickened A horizons) occur in areas of deposition at the bases of some slopes, for example, footslopes or toeslopes, and erosion is common on steeply sloping shoulder slopes and backslopes. An example of variable Paleosol characteristics along a catena might include those on summit positions that have reddish hues and well-defined soil horizonation, but which transition to poorly drained, gray (gleyed) weathering profiles in the footslope or lower positions (Follmer et al. 1979). The redness versus grayness of the soil in the previous example is related to soil aeration, which is a function of water content. Soil water content, in turn, impacts the soil flora (organisms) that mediate chemical conditions and valence of iron-bearing minerals. Slope-dependent soil moisture characteristics also impact terrestrial vegetation and hence the chemistry of the soil horizons (Follmer 1983; Retallack 2001). Of the five soil-forming factors, paleoslope and paleorelief require the least interpretation. That is, determining past changes in effective moisture, temperature, soil biota, terrestrial vegetation, and its variability over time, for Paleosols, may often be inferential. If one is fortunate, paleorelief may even be fully revealed in outcrop.
Climate

Seasonally effective moisture and temperature are parameters that control rates of leaching and chemical transformations in soils, and also dramatically affect the composition of flora and fauna living in and on the soil. Due to natural climatic variability, interpretation of past climates is more inferential and complex the longer the time span associated with development of the Paleosol. Even under ideal circumstances, specific climatic conditions inferred from Paleosols (such as mean annual temperature or mean annual precipitation) are, at best, generalized estimates (Retallack 2001).

Regionally significant and well-developed Quaternary Paleosols typically have formed over a relatively long period of time, for example, over 5000–75,000-year time spans or more (Follmer 1983). During this time span of soil formation, climatic characteristics may have changed significantly, especially for the longer time spans. A traditional school of thought suggests that most pedogenic chemical work is done under optimal soil-forming intervals (i.e., climatic “optima”), that is, a synergy of moisture regime and temperature resulted in high physical biotic activity (burrowing, homogenizing soil material), biochemical production (organic acids), and physiochemical transformations (mineral weathering) to produce a well-developed soil. Evidence for accelerated soil formation in some areas, however, has been attributed to rapid rates of dust incorporation, rather than to increased weathering rates under an “optimal” climate. Nonoptimal conditions for pedogenesis in the geologic past may have been “too dry,” “too cold,” or “too hot,” resulting in slower rates of soil formation. Conditions that are “too wet” lead to waterlogged conditions or erosion, and little profile development. Another school of thought suggests that overall rates of pedogenesis are more or less steady over time. In this scenario, under changing environmental conditions a waning pedogenic process is replaced by another (Birkeland 1999).

Time

Time (soil age) is of considerable interest in paleopedology, in both applied research and stratigraphic studies (including geoarcheology). For applied studies, the age of tectonically displaced Paleosol horizons may be critical in determining the capability or periodicity of seismic activity of a particular fault or fault zone (McCalpin 2009). The chronologic age of the Paleosol’s parent materials, however, can raise several complex issues, and the paleopedologists must specify the context of the dated fraction. Minimum ages for \( t_{\text{zero}} \) may be provided by radiocarbon ages of in situ tree stumps (rooted in the soil, and subsequently buried by a deposit not related to the soil). Alternatively, optically stimulated luminescence (OSL) ages of eolian material above the soil may help to isolate the date of burial and the end of soil formation. Relative to the stump age, older and less precise ages may be obtained from radiocarbon dating of disseminated organic material (humus) in A and O horizons (organic-rich surficial soil horizons) which reflect the mass balance of additions of “new” organic matter with the oxidation or consumption of “old” organic matter. These ages will conceptually lie between \( t_{\text{zero}} \) of soil formation, which often is equivalent to the age of the parent material, and the soil’s minimum-limiting age (provided, for example, by the stump). Some workers provide ages of the whole soil or organic fractions that are separated either chemically (into organic fulvic and humic acid groups) or thermally into volatile and more stable fractions (Wang et al. 2003). The longer the time span during which the soil formed, the larger the potential error associated with the estimated soil age.
Polygenesis

Polygenesis refers to soils that have developed under more than one set of soil-forming conditions, usually as associated with the five soil-forming factors. In contrast, monogenesis implies soil formation under nearly unwavering soil-forming conditions. Although polygenesis can imply changes in parent material (e.g., through additions of dust) or relief (through erosion), it typically refers to changes in vegetation and/or climate. Normally, polygenesis is complex and involves multiple factors, such as a local erosion event that results in changes in slope, parent material, and possibly organisms. Paleosols are more likely to have become polygenetic if they have formed over long time spans, that is, long enough to involve periods of significant climate or environmental change. For example, the Sangamon Geosol in midwestern North America formed in most places over a period of about 50,000–75,000 years during the last interglaciation (Curry and Follmer 1992). This soil shows morphological evidence of polygenesis, but overall its features indicate development under a temperate, humid climate, similar to today’s climate (Follmer et al. 1979; Follmer 1983). However, coeval pollen and ostracode records from lake deposits in the “type” region of the Sangamon Geosol show that climate was considerably more variable than what is implied by soil morphology (Curry and Baker 2000). The upshot is that the most significant and readily observable features of polygenetic Paleosols are ones that reflect periods when the soil environment was conducive to weathering and biotic activity, namely, warmer, moister intervals. Paleosols with shorter soil-forming intervals typically are best preserved in areas where there has been episodic sedimentation, as revealed by proxy data that have more detailed resolution, such as rhythmic beds of thin A-O horizons separated by thin increments of loess.

As noted above, diagenesis refers to changes to the original soil’s physical and chemical makeup that occur during, but mainly after, burial. The most important diagenetic changes in Paleosols include increased density (through loss of pores via compaction, and decay of roots and other organic masses such as fungi), changes in wetness due most commonly to perched water above the buried soil, and chemical interactions with groundwater. The net effect of diagenesis is that the material in the buried soil slowly loses its original pedogenic character. Commonly, sediment cores will more readily reveal subtle paleostructures and fabrics that have been affected by diagenesis after the material has been allowed to be exposed to air, but not completely dry. Virtually all interpretations of features observed in Paleosols are impacted by equifinality, that is, similar features may have been formed by different processes. Equifinality can imply that two Paleosols that were quite different when they were forming became increasingly alike after burial and diagenesis affected their morphology and chemistry. The effects of diagenesis and equifinality require that paleopedologists constantly entertain alternative hypotheses when interpreting a Paleosol. For example, many features thought to be purely abiotic, such as soil reddening, may be initiated or stimulated by biotic processes, particularly those of bacteria.

In the study of buried soils, the description of “klumpen” has been added to the traditional United States Department of Agriculture methods (Schoeneberger et al. 2012) to focus on hand sample-size features ranging in size from 0.02 to 2.0 mm in diameter (Follmer 1998). The most valuable klumpen features for identifying buried A and E horizons are pores, aggregates, and organic materials, especially charcoal. These features aid in the identification of the upper horizons of buried soils; here, coarser features and organic matter are often lost. In buried soils,
due to diagenesis, the original granularity of surface horizons is usually compressed into a massive aggregate nature that breaks into irregular clumps and granules upon drying (“klumpen”).

Geosols

A buried Paleosol with regionally consistent stratigraphic relationships among its parent materials and its superjacent, younger geologic material may classify as a Geosol. Geosols are the basis of pedostratigraphy, one of several independent stratigraphic systems used to describe and interpret layers of Earth materials. Other related but independent classifications include chronostratigraphy (time stratigraphy) and lithostratigraphy (material stratigraphy) (American Commission on Stratigraphic Nomenclature 2005). Pedostratigraphy is related to allostratigraphy, which is a stratigraphic system based on unconformities (paleosurfaces) and their cross-cutting relationships.

In the context of the Sangamon Geosol, we note the Indian Point and Farmdale Geosols which formed in advance of, or adjacent to, the Lake Michigan Lobe over periods of time ranging from hundreds to about 5000 years.

Figure 1  Poorly drained pedofacies in the Athens Quarry, Athens, Illinois. Moss and wood fragments impart the brown color to the organic-rich Peoria Silt (loess). The Farmdale Geosol is developed in colluviated loess of the Robein Member (Roxana Silt), and the gleyed Sangamon Geosol is developed in the Vandalia Member of the Glasford Formation. (Curry and Follmer 1992; Figures 1 and 2). The parent material for these Geosols is colluviated and locally cryoturbated loess and alluvium. As the colluvial parent material thins away from the source areas (e.g., river valleys), so does the evidence of separate pedostratigraphic entities.

PALEOSOLS

Parallel computing

Shashi Shekhar  
*University of Minnesota, USA*

Daniel Cintra Cugler  
*University of Campinas, Brazil*

Parallel computing is a computational technique in which multiple operations are executed concurrently rather than sequentially. It is a broad area of computer science that encompasses processor technologies and computer communication infrastructures in order to provide high performance and redundancy in high-availability systems. Parallel computing has become essential for managing and processing the massive volumes of data generated or acquired by different technologies, such as smartphones (e.g., location-aware applications), satellites (e.g., remote sensing), sensors (e.g., temperature, humidity, and seismic sensors), and social media platforms (e.g., Twitter). Vast amounts of these data have spatial features that make it inherently challenging to manage. Unlike sequential computing, which relies on one central processing unit (CPU), parallel computing solves complex problems quickly by harnessing the power of multiple CPUs simultaneously. Computations that in the past took days, months, or even years can be done in minutes, seconds, or even milliseconds using parallel computing.

Parallel computing plays an important role in geography (e.g., processing spatial information for weather forecasting and climate change prediction), as well as in many other fields, including astrophysics (e.g., computing galaxy formation), electrical engineering (e.g., electromagnetic field computation), biology (e.g., genome mapping), and physics (e.g., hydrodynamics). Parallel computing that specializes in spatial information is known as parallel GIS (parallel geographic information systems). In order to exploit the full potential of parallel GIS, technologies need to be developed that focus on solving challenges surrounding spatial data, such as methods for parallelizing GIS (Shekhar et al. 1996; 1998). The evolution of parallel computing can be classified into two eras: pre-cloud computing and cloud computing.

**Parallel computing in the pre-cloud era**

Single, multicore, multiprocessor, and special purpose processors

One of the most important parts of a computer is the central processing unit. The CPU, also known as the core, is responsible for performing arithmetic and logical calculations. The main technologies adopted for processors are the single processor, the multicore processor, the multiprocessor, and the special purpose processor. In the past, most computers were equipped with a single processor (with one core), which could perform only one operation at a time (sequential computing). The way to increase processing speed in such processors was to increase their clock frequency. However, the fastest speeds consumed too much power. This problem hampered the creation of computer processors faster than 3 GHz (Hey, Tansley, and Tolle 2009). The cheapest solution adopted by the main computer processor manufacturers was to execute tasks in parallel, by replacing the single-core processor with a multiprocessor. Modern processors have from two to four cores. The clock speed of these processors has reached 4 GHz, and the number of transistors in them has reached hundreds of millions, making them highly versatile and powerful.
PARALLEL COMPUTING

with a collection of processors on the same chip, known as a multicore processor (Asanovic et al. 2009). A multicore processor has two or more cores that enable the parallel execution of computer operations. The performance of such processors is relative to the number of their cores and the clock frequency. Multicore processors are responsible for making parallel computing more popular in the past few years. Figures 1 and 2 illustrate the core of a single processor and a multicore processor.

The computational power provided by multicore processors is limited by the number of cores that could be inserted in one processor. One solution to this problem is to provide computers with two or more processors (multiprocessor). In a multiprocessor computer, computations are performed not only in different processors but also within the different cores of each processor. The evolution of such kinds of processors settled a number of architectural issues in computer science, such as the definition of memory access, for example, shared and distributed (Asanovic et al. 2009). Figure 3 illustrates the processors and their cores in a multiprocessor computer.

Processors can be designed to execute general or specific tasks. General-purpose processors (GPP) are widely used in desktops, laptops, and server computers. They treat a large class of problems but can lack high performance when used to execute specific applications. For these cases there are special-purpose processors (SPP), also known as application-specific processors (ASP). SPPs combine
low cost, low power consumption, and high performance for devices such as smartphones, LCD monitors, digital cameras, and wireless routers. A well-known example of an SPP is the graphics processing unit (GPU), a kind of processor that specializes in efficiently generating graphic displays. Nowadays, some GPUs also enable software developers to add support for GPU acceleration in their own applications. Such kinds of GPUs are called *general-purpose graphics processing units* (GPGPU). GPGPUs provide parallel computing platforms and programming languages (e.g., NVIDIA CUDA) in which software developers develop general purpose applications which are traditionally handled by CPUs.

**Clusters and grids**

Clusters and grids are another kind of technology that use parallelism to provide high-performance computing and redundancy in high-availability systems. A computer cluster is a set of linked computers working together that behave as a large single computer. The machines have similar hardware and are usually connected to each other through a local area network (Kumar et al. 1994). The Titan supercomputer is a well-known example.

A grid is also a set of linked computers working together and behaving as one large computer. Unlike clusters, however, the computer nodes in a grid tend to be heterogeneous and geographically dispersed (e.g., SETI@home project). This means that the grid’s nodes are connected through some kind of wide area network (WAN), such as the Internet. Grids may be made up of machines with very different hardware configurations. Normally, users have little or no knowledge of where the computer nodes are located or which kind of hardware and operational systems have been used (Jacob et al. 2005). A cluster is tightly coupled, whereas a grid is loosely coupled.

Besides providing high-performance computing, clusters and grids also support high-availability computation by providing redundant nodes that can assume computational duties when other computer nodes fail. In the past, grids and clusters were available only to governments and big companies that could afford the high financial cost of their design and upkeep.

**Software aspects**

Parallel computing hardware alone does not guarantee significant gains in computing power. Harnessing the power of different kinds of processors, grids, and clusters requires computer programs that are developed specifically for each parallel environment. Algorithms are needed to divide complex problems into simpler and smaller parts so that they can be solved concurrently. Existing serial computer programs need to be reimplemented in the parallel format. All these processes can be time-consuming, and different tools have been created to support them. Examples of programming languages that support parallel programming are C*, SequenceL, CUDA, OpenCL, Unified Parallel C (UPC), Parallel Fortran, OpenMP, and MPI.

Parallel programming languages have more complex data and control models than serial programming languages. The data model defines how processors communicate with each other. The control model determines how processors are coordinated. Usually programmers do not need to know such features, since high-level programming languages encapsulate this information.

In the pre-cloud computing era, high-performance environments were usually developed to provide a small number of computational
services for a specific domain. Their capacity to provide a broad range of services was limited. With the advent of cloud computing, a broad range of general-purpose computational services has become available to the wider public, for example, Microsoft Office web apps and Google Calendar.

Cloud computing era

Cloud computing, which is intimately linked to parallel computing, enables ubiquitous and on-demand network access to a shared pool of configurable computing resources, such as networks, servers, storage, applications, and services (Mell and Grance 2011). Cloud computing enables groups of users to host, process, and analyze large volumes of multidisciplinary data (Hey, Tansley, and Tolle 2009). Although the cloud approach does not necessarily speed up the computational power provided by parallel computing, it has revolutionized parallel computing, providing access to inexpensive high-performance systems and many new remote services.

According to the American National Institute of Standards and Technology (NIST), these services fall into three main categories. (i) Software as a service (SaaS) is the most widely used kind of cloud computing service. It provides sophisticated applications that are accessed and executed through the Internet, usually using web browsers (Yang et al. 2011). Google apps, Salesforce CRM, GoToMeeting, and Workday are typical examples. (ii) Platform as a service (PaaS) is a cloud-based platform service for the development of new applications. PaaS provides hardware and software infrastructure, thus freeing users from the need to maintain server hardware and operating systems. Software or services developed to run over cloud PaaS can be executed entirely on the Internet. Examples include Google App Engine and Microsoft Azure (Yang et al. 2011). (iii) Infrastructure as a service (IaaS) provides computer infrastructure, such as processing, storage, networks, and other fundamental computing resources as virtualized services (Yang et al. 2011). Users cannot control the cloud infrastructure but they can control the operating systems, storage, and deployed applications (Mell and Grance 2011). A widely known example of IaaS is the Amazon Elastic Compute Cloud (EC2).

According to NIST, all categories of cloud computing services share five essential features: (i) on-demand self-service, where consumers can reserve more computing capability (e.g., server time) without the need for human interaction with the service provider; (ii) broad network access, where services are provided for different kinds of client platforms (e.g., mobile phones and laptops); (iii) pooling of resources, where a variety of resources are provided as a single pooled resource; (iv) rapid elasticity, where capabilities can be rapidly and elastically supplied, making them appear to be unlimited and available for purchase in any quantity, at any time; and (v) measured service, where resource usage can be monitored, controlled, and reported, providing transparency for both the provider and the consumer. These five features distinguish cloud computing from other kinds of parallel paradigms, such as grid computing (Yang et al. 2011).

As cloud computing has become cheaper and more popular over time, access to high-performance environments is no longer limited to large organizations with deep pockets. Pay-as-you-go, in which users pay only for the services they use, is a good example of a pricing model that is used for selling cloud computing services. Moreover, many cloud-based services, such as Google Docs and Dropbox, are provided at no cost to end users. All of these benefits have been made possible thanks to the parallel computing infrastructure provided by multiprocessors.
(with multicores) working in large clusters, as well as by new highly efficient programming models and associated implementations that are able to orchestrate large numbers of parallel tasks within clusters.

MapReduce

MapReduce is a popular programming model used for processing and generating large datasets in cloud environments. Created at Google in 2004, it was inspired by the map and reduce primitives present in Lisp and other functional programming languages. Software for MapReduce platforms is designed to divide a problem into many small parts, each of which may be executed on any node in a cluster. The core of MapReduce is the map and reduce functions, which parallelize computation across large-scale clusters of machines, handle machine failures, and schedule intermachine communication to make efficient use of the network and disks. These features allow programmers with little or no experience with parallel and distributed systems to utilize the resources of a large distributed system and process enormous amounts of data (Dean and Ghemawat 2008).

A popular free and open source implementation of MapReduce is the Apache Hadoop framework. It provides an environment in which programmers do not have to deal with issues of parallelization, remote execution, data distribution, load balancing, or fault tolerance. Hadoop libraries have been created for programming languages such as Java, Perl, Python, and PHP. Apache Hadoop also provides the Hadoop Distributed File System (HDFS), which enables high aggregate bandwidth across the cluster as well as reliable storage of very large files across machines in a large cluster. Both Hadoop MapReduce and HDFS are designed so that node failures are automatically handled by the framework.

Spatial problems such as spatial autoregression (SAR) or spatial graph algorithms (e.g., breadth-first search and shortest path) challenge MapReduce because these algorithms are iterative. Although processing one iteration is parallelizable, the synchronization overhead across iterations for cloud environments may be too large to maintain speedups. Recently, approaches such as Spark (Zaharia et al. 2010) have been proposed to address iterative computations that are popular in spatial problems. Since Spark is memory-based, it may have a cheaper “reduce” step, leading to speedups for iterative spatial problems.

Spatial cloud computing and parallel GIS

Parallel computing specialized to spatial applications is known as parallel GIS. Spatial data have long been recognized as presenting unique challenges (Shekhar et al. 1996; 1998). Today, spatial data volumes are exceeding the capacity of commonly used spatial computing and spatial database technologies to manage and process data with reasonable effort. Such spatial data are known as spatial big data. Current tools supporting the common activities in data-intensive processing are often limited in the face of challenges posed by emerging big spatial datasets, due to the volume (e.g., petabytes), acquisition/search demands (e.g., terabytes per second) and variety (e.g., maps, GPS tracks, sensor measurements). Spatial big data require new advances in GIS.

Spatial cloud computing (SC2) adds parallel GIS services and technologies to cloud computing. Similar to cloud computing, SC2 encompasses the entire cyberinfrastructure, including hardware, software, and networking. Spatial cloud computing can also be optimized with spatiotemporal principles to make efficient use of available distributed computing resources.
There are an increasing number of software tools to manage spatial big data in SC2 platforms. For example, SpatialHadoop is a MapReduce framework, developed at the University of Minnesota, designed especially to work with spatial data. It can be used to analyze large spatial datasets on a cluster of machines. Another example is Google Earth, a virtual globe that uses a large cloud computing infrastructure and the BigTable data structure. BigTable is a data storage system developed by Google which provides compression and high performance for large datasets.

Large spatial data repositories can be accessed using data as a service (DaaS). Spatial DaaS enables spatial data sharing and reuse, and it plays an essential role in spatial cloud computing. Although the term DaaS concept is not defined by NIST, it is commonly used in the literature. Spatial DaaS centralizes spatial data in a repository that can only be accessed through service interfaces, while providing fast and secure access to Earth observations. Data services can perform preprocessing steps (e.g., using validation filters) before effectively saving them in the cloud, making DaaS suitable for improving the quality of spatial data. DaaS enables data sharing, discoverability, accessibility, and usability on the fly to support “science on demand” (Yang et al. 2011).

Spatial cloud services can provide several kinds of functions to compute, for example, Normalized Difference Vegetation Index (NDVI), Earth surface temperature, ocean temperature, thermal anomalies and fire, burned areas, digital land elevation, and other functions that often involve a complex series of geospatial processes. Today there are many different kinds of spatial cloud computing software, such as the ArcGIS implementation in the cloud, GISCloud, CartoDB, Google Timelapse, GeoCommons, MangoMap, OpenGeo Cloud Edition, SpatialStream, and MapBox.

Software development in cloud environments

Developing software to run in cloud or non-cloud parallel environments requires different strategies. In a noncloud environment, software development can use implicit or explicit parallelism. In implicit parallelism, programming language compilers or interpreters translate computer program codes into parallel codes automatically. However, if the codes are created in a sequential (serial) way, parallelism can be lost. In explicit parallelism, programming languages (e.g., C*) provide specific functions to deal with parallelism.

Cloud environments provide their own application program interfaces (API). Therefore, programmers developing software for cloud environments must make use of specific APIs for each environment. For example, Google provides APIs for their cloud computing infrastructure (Google Cloud Platform) in different programming languages, such as Java, Python, and PHP.

Participatory action research

Jeffrey R. Masuda
Queen’s University, Canada

Participatory action research (PAR) refers to a wide range of collaborative principles and practices that aim to increase the relevance and impact of research by positioning communities at the center of inquiry into problems that affect them. PAR has been embraced by researchers who have recognized how traditional expert-driven approaches have often prioritized government and corporate interests to the exclusion of individuals, communities, or populations who are the subjects of research inquiry and are often exploited by it. PAR theorists accuse the dominant research industry of being complicit in a range of injustices that affect these people because of its inability to take on problems linked to patriarchy, racism, sexism, ableism, ageism, and colonialism that both structure various forms of oppression in the world and are deeply embedded in research institutions and practices themselves. In the latter case, feminist PAR has been particularly influential in exposing the unchecked power of research disciplines and institutions to historically privilege some, often white, masculine, heteronormative, ableist, and Eurocentric perspectives over others. PAR directly confronts this epistemological crisis by shifting notions of expertise to include nonacademic, experiential, and indigenous forms of knowledge, and by ensuring that all aspects of research, from design to dissemination, are initiated, vetted, and controlled by those who are affected by its conduct and outcomes. This approach departs from conventional research where academic or professional researchers place themselves in the position of inquirer, and often position individuals, communities, or whole populations as the inquired (or research subject). In this sense, research is seen to be complicit in human oppression insofar as its practice strips people of their agency, whether by quantitatively reducing them to variables of statistical manipulation or, in qualitative approaches, condensing, cleansing, and transforming their insights into “data” and granting them the status of knowledge only after they have been subjected to the interpretation of the researcher.

In contrast, subscribers to PAR prioritize the pursuit of justice in the world by communities as the primary aim of research. They achieve this by offering several specific principles which equip researchers and communities to work in concert to expose the political and economic underpinnings of the oppressive social and environmental conditions in which they live and often suffer. Commonly cited principles include: (i) leveraging the power of collaboration between researchers and communities to provoke a transformation of societal power structures; (ii) treating knowledge production as a democratic process; (iii) widening the scope of research practices in ways that accommodate a more pluralistic notion of expertise; and (iv) promoting collective emancipatory action, either within or outside of existing structures of power, leading to social justice. The idea of community empowerment is often cited as both a means and an end of PAR. However, while the placing of
PARTICIPATORY ACTION RESEARCH

communities in greater decision-making roles over research has proven effective in achieving many local aims, some have sounded a note of caution over how the rhetoric of empowerment is easily co-opted into neoliberal agendas of governmental downloading, a rhetoric of individual responsibility, and “third way” politics more generally (see Jupp 2007 for a discussion of, as well as an empirically substantiated response to, this critique within geography).

In PAR, those affected by a particular health, social, or political problem learn to become investigators into the conditions that affect their own lived experiences. But PAR is not a methodology per se, although methodological preferences often gravitate toward the qualitative and hermeneutic, rather than the quantitative and positivist. PAR may include research that does not involve people at all, as for instance in research problems focused on environmental problems such as pollution monitoring or investigations of housing conditions. There are many examples, including in geography, of quantitative studies that have been undertaken by and with communities to confirm suspected environmental problems as a way to mobilize action. For example, numerous US-based PAR studies of environmental determinants of asthma have deployed epidemiological methods and geographical information science (GIScience) to successfully support community-based policy advocacy and outcomes (see Minkler (2010) for one of many examples). Whatever methods are undertaken, the overarching goal of PAR is to prompt political action that not only addresses the immediate problems but provokes more systemic societal change that corrects the social, environmental, or health injustices that give rise to them.

Many variations of PAR exist (see Kindon, Pain, and Kesby 2007 for a concise review) owing to numerous historical origins around the world and a concomitant plurality of philosophical foundations, terminological traditions, and methodological preferences that coincide with the disciplinary and political climates of their founding practitioners. For brevity, only main lineages will be reviewed here. The so-called Southern School of popular education originated in the seminal work of Brazilian academic activist Paulo Freire who, from the 1940s through the 1990s, elaborated a critical pedagogical approach that aimed to increase the political literacy of peasants toward the conditions of their oppression. Influenced by his own lived experience of poverty and oppression as a child, Freire sought to join together political and functional literacy in the delivery of education to (or rather with) the illiterate poor as a means to restore their humanity as political citizens. Thoroughly Marxist and anticolonialist in its orientation, Pedagogy of the Oppressed (1968; translated into English in 1970) provides a philosophy of inquiry that places human oppression in a relational space between the oppressed and their oppressors; both are required to participate in education if there is to be true liberation, otherwise one form of oppression is merely replaced by another: “the oppressed, instead of striving for liberation, tend themselves to become oppressors” (Freire 2000/1968, 45). At the heart of Freirian pedagogy is a rejection of the “banking approach” to education, which has a dehumanizing effect on recipients who are treated as passive receptacles, to be filled with the very systems of knowledge that oppress them. This approach, which applies equally to research as it does to education, is seen to have a colonizing influence on learners, subjugating them into a relation of domination that reinforces the power of societal elites. Rather, Freire’s popular education involves a radical shift in the concept of education, in which all inquirers, whether oppressor or
PARTICIPATORY ACTION RESEARCH

oppressed, engage in a process of collective political consciousness raising (conscientization) which facilitates a more radical scrutiny of the underlying conditions of oppression that are responsible for an alienation from justice that is shared by all. Often considered revolutionary in nature, popular education has been influential throughout the world in prompting political action among the poor, women, and other politically oppressed groups, particularly in the Global South. Those in the North who draw inspiration from Freire have tended to tone down this revolutionary impetus into more of a philosophical barometer that gauges the level of community engagement and solidarity required by researchers who wish to work within marginalized communities.

The so-called Northern School of PAR, often known as “action research,” is a more conservative version of PAR that originated in the 1940s with philosopher and psychologist Kurt Lewin. Born into a Prussian Jewish family and educated in Germany, Lewin immigrated to the United States before World War II, where he elaborated an approach to research that could be specifically applied to solving social problems. Influenced by Lewin’s theoretical forays into field theory in which group participation is central, both to the accomplishment of tasks and to the functioning of democracy, action research emphasizes a deliberative process of collective discussion as fundamental to personal and organizational change. The role of research in this approach is as an agent of change, responsible for facilitating purposeful collaborative efforts toward group goals. In action research, the artificial distance that is held up in conventional, individually oriented research between knowledge production (of the researcher) and actions to be taken (by the user) is seen as detrimental to the effectiveness of organizations. This distance can be reduced by building a more collaborative approach to inquiry that places research projects within an iterative cycle of planning, action, and evaluation, leading to direct social action as the desired result.

Community-based participatory research (CBPR) is a term that has gained traction since the mid-1990s, in many ways as a compromise response to the radical and conservative orthodoxies of the Northern and Southern Schools respectively. CBPR has come to refer to research arrangements that are based on an allegiance to postpositivist forms of research undertaken in partnership with nonacademic organizations. Studies that have employed CBPR range from modest efforts to evoke the priorities of communities in local affairs that concern them to those that deploy a more radical politics that mobilize communities to expose manifest injustices and to scale up action into national and even international arenas. A term often used by researchers working in the area of health, CBPR-inspired projects tend to harness local activisms surrounding chronic social or environmental deprivations that have affected community health and well-being. Many communities, particularly indigenous ones, are attracted to CBPR not just as an alternative to conventional approaches, but as a way to directly confront the colonizing agenda of research itself, including countless injustices and atrocities that have been invoked on racial minorities and indigenous peoples in the name of research (see Meyer 1981 for the classic example of the Tuskegee syphilis experiment, a study that followed but did not treat over 400 African American men with syphilis; see Mosby 2013 for a recent and explosive example of intentional starvation by Canadian government scientists of over 1000 First Nations children in northern Manitoba and in residential schools during the 1940s and 1950s).
Indigenous PAR has become increasingly influential among anticolonial scholars working in both the Global South and North who are interested in correcting long-standing social and environmental injustices inflicted on indigenous communities. Inspired by Linda Tuhiwai Smith’s influential book *Decolonizing Methodologies* (1999), indigenous PAR implicates research within current and former colonial powers as both part of the problem and the solution in the struggle for indigenous rights. Smith is unrelenting in her evisceration of the colonial agenda underpinning Western forms of inquiry, including its long history of racial oppression under the guise of Enlightenment philosophy and its valorization of the “civilized” society. An indigenous research agenda of self-determination, decolonization, and social justice can be achieved for indigenous people only by research that positions indigenous worldviews centrally. This agenda goes to the core of the research enterprise, indicting the ontological status of knowledge itself as being inseparable from the people whose bodies, histories, and experiences have produced it. It is with this understanding that indigenous research principles such as OCAP (ownership, control, access, possession) have begun to counter the dispossessing legacies of nonindigenous research (Schnarch 2004), in part by ensuring that indigenous knowledge stays in the hands of indigenous peoples.

**Motivations in geography**

Contemporary applications of PAR in geography can be found in all of the aforementioned traditions. Generally speaking, geographers who embrace PAR have been motivated by a search for the root causes of localized spatial inequalities, whether measured in human outcomes, such as socioeconomic status and health and wellbeing, or in the environmental conditions that precede them, such as urban air pollution, housing conditions, or water quality. The PAR field has been receptive to geographers’ conceptual and methodological repertoire, as communities that become engaged in research want to know more about the local context and conditions that directly affect their lives. Investigations of community problems have been enhanced by geographers’ ability to provide and interpret thick descriptions of every life, as well as by their proficiency in mapping, in photography, and in other forms of conceptual and empirical sociospatial visualization. Among these, photography-mediated interviewing has been favored by geographers since the late 1990s (Castleden and Garvin 2008). Most PAR studies in geography point to place-based processes of racialization, class-based economic marginalization, colonialism, or other forms of discrimination as being responsible for observed and experienced inequalities. In tying local conditions to these systemic social structures, PAR provides geographers and their community partners with a mechanism to scale up research insights and impacts into broader political arenas.

A strong uptake of PAR by critical geographers, starting in the 1990s, coincided with a demand for more relevant “public geography” (see Martin 2001), following the discipline’s reorientation away from positivist spatial science in the 1970s as well as the meandering, albeit often critically oriented, postmodern turn of the 1980s. With the ushering in of more culturally substantive modes of inquiry into social and health inequities, and the corresponding elaboration of social theories pertaining to communities, cities, and “place” more broadly, geographers have become acutely aware of
the epistemological tensions implicit in acts of inquiry that take place at a distance from the world, as well as the claims geographers make about the world, including their complicit role in global imperialism since the nineteenth century. Since the 1990s, PAR has given geographers of a more critical orientation a more praxis-focused way to critique the structural forces of capitalism and neoliberalization, following long-standing complaints about the failure of the “armchair” theory of radical geography to offer viable alternatives to the status quo (Pain 2004).

One epistemological objective of PAR-inspired geography is the reassertion of human values connected to place within often abstract and dehumanized governmental, corporate policies and practices. For example, issues of environmental contamination affecting particular communities involve more than the scientific assessment of levels of exposure and resulting health impacts, important as these are. Rather, environmental risk affects wellbeing, disrupting not only people’s physical health but also the ontological security of whole cultures and societies that are tied to universal human values of personal dignity, home, family, and community (Edelstein 1988). Furthermore PAR provides a practical solution to the problem of distrust in environmental science and policy, including the professionalized forms of knowledge inquiry that produce them, which are widely perceived to have been given over to governmental and corporate control and to be serving agendas that are incommensurate with grassroots preferences and priorities connected to place. More recent PAR applications in geography have attempted to reconcile the need for evidence and human values, adopting mixed-methods approaches that engage citizens not just in introspective studies of their own perceptions and experiences but in scientific agenda setting, research processes, and policy-influencing activities, literally working alongside scientists and policymakers in their own highly specialized and professionalized domains. In this vein, public participatory geographical information systems (PPGIS) deserve mention as a burgeoning method of problem and solution mapping made possible by technological advances and increasingly user-friendly GIS software and its uptake in web-based platforms. Finally, in widening the scope of participation in research to marginalized groups, geographers have been particularly adept in engaging with youth. In recent years, youth-led PAR (YPAR) has been developed as a special form of PAR that prioritizes both youth-accessible and -preferred processes (often replacing more rigid, linear, and formalized methods with more flexible and creative, fun, and age-appropriate activities) as well as youth-specific outcomes, particularly in terms of confronting urban spaces (and the policies that produce them) that attempt to “put youth in their place” (see Skinner and Masuda 2013 for a more in-depth account of these priorities).

In summary, the combined effect of the burgeoning literature in PAR has given geographers new inroads in their abiding insistence that place matters in the production of space and spatial inequality. As PAR approaches evolve, they are becoming ever more effective in garnering community involvement in knowledge production, displacing conventional modes of inquiry long favored by academic practitioners with more creative and often arts-based forms of inquiry that are seen to be accessible to a more diverse spectrum of community researchers and more effective in reaching public audiences.

Participatory development

Tony Binns
University of Otago, New Zealand

“Top-down” and “bottom-up” development

Participatory development (PD) aims to engage local people in planning for development interventions which are normally intended to benefit them. PD strategies have become progressively popular since the late 1980s and 1990s, and now represent development orthodoxy, being popular with many nongovernmental organizations (NGOs), as well as with bodies such as the World Bank.

More democratic “bottom-up” PD methodologies are seen as a significant step forward from the somewhat dictatorial “top-down” development planning that was undertaken in the early decades after World War II. A classic example of this was the ill-fated East African (or Tanganyikan) Groundnut Scheme, designed to meet a serious shortfall of vegetable oils in postwar Britain. Launched in 1947, after a superficial nine-week survey, the plan was to clear and plant 1.3 m ha of land with groundnuts, mainly in Tanzania, then the British Protectorate of Tanganyika. Using converted ex-army equipment, 1000 Europeans and 60 000 Africans were engaged in land clearing and planting. Despite expenditure of £49m, crop yields were lamentable and the project was canceled in 1951. This top-down, highly centralized project suffered from inadequate soil and rainfall data in a drought-prone region, and an unrealistic faith in Western technology. Sadly, no one thought to talk with the local Wagogo agropastoralists about environmental conditions (Binns, Dixon, and Nel 2012).

Many postwar development projects followed European-based modernization strategies and showed little awareness of local knowledge among the communities that were supposedly “being developed.” Rural communities in developing countries were often portrayed as being remarkably uniform. Anthropologists such as Polly Hill, working in West Africa in the late 1960s, challenged the idea of an “amorphous peasantry,” and observed that among such communities there were “rural capitalists” who were engaged in adopting new crops, forward planning, and investment in infrastructure development. In criticizing current data collection methods, Hill strongly advocated giving greater attention to “producers” rather than to “production” (Hill 1970).

Early PD methodologies were inspired by the work in the 1960s and 1970s of Brazilian educator and philosopher Paulo Freire. He encouraged teachers to mingle with communities, asking questions and understanding the people in their broader social context. During the 1970s, frustration with brief and superficial “rural development tourism,” and lengthy and costly questionnaire surveys, led to the emergence of Rapid Rural Appraisal (RRA) and a range of new participatory survey methods such as transects, sketch mapping, and semistructured interviews, which would, it was hoped, deliver information that was relevant, timely, accurate, and usable. Agroecosystem analysis in the 1980s contributed further data collection methods.
PARTICIPATORY DEVELOPMENT

The growing popularity of participatory development

Robert Chambers has played a key role in championing PD methodologies. His 1983 book *Rural Development: Putting the Last First* (Chambers 1983) was a landmark in raising awareness about the need for a better understanding of rural communities in poor countries, and paved the way for the wider use of PD methodologies. Chambers argued that, “Outsiders (whether in universities, government departments, research or training institutes, or NGOs) have believed their professional knowledge to be superior, and so have behaved in ways which have almost universally inhibited the expression of local people’s capabilities” (Chambers 1993, 98). Chambers was concerned about issues such as rural people’s knowledge, power and the poor, and the need for change and “reversals” to “put the last first.” He argued, “Reversals require professionals who are explorers and multi-disciplinarians, those who ask, again and again, who will benefit and who will lose from their choices and actions. New professionals who put the last first already exist; the hard question is how they can multiply” (Chambers 1983, 168).

In the late 1980s, lessons from RRA and agroecosystem analysis led to the development of Participatory Rural Appraisal (PRA), and a range of participatory methodologies designed to empower local and often marginalized people, allowing them to express their views, share their knowledge, and engage in action that has meaningful benefits for themselves and their communities. Working within and in close collaboration with communities, PD methodologies involve a range of data collection techniques including: focus group discussions, participatory surveys, transect walks, participatory mapping and modeling, matrix ranking, scoring, and diagramming. These methods

should lead to developing empathy, building up trust with communities, understanding “what makes them tick,” and “handing over the stick” to the participating communities in leading the data collection processes, identifying needs and aspirations, and ultimately playing a greater role in development interventions.

The challenges of participatory development

Many academics and development practitioners working among poor communities would probably agree that PD represents a significant step forward from the “blind surveys” and “top-down” development strategies of the 1950s and 1960s. There now seems to be a genuine concern to work “with,” rather than “on,” communities in shaping development interventions which will hopefully empower and uplift livelihoods (Kyamusugulwa 2013). But often the question is asked as to whether PD is a means to an end, or actually an end in itself. In simple terms, it is probably both, as the process should assist in both identifying and implementing more appropriate development interventions, while also helping to articulate and empower participating communities. But the key test is whether outcomes from PD include tangible benefits for all members of the community.

As PD strategies have become more widely used, the nature of participation has been closely interrogated, since complex issues of power and control are involved. The key parameters seem to be: Who participates? How do they participate? When do they participate? As Cornwall observes, “‘participatory’ processes can serve to deepen the exclusion of particular groups unless explicit efforts are made to include them” (Cornwall 2008, 277). A key challenge for those who are conducting PD methodologies
among communities is to be sure that everyone is involved, that certain groups are not excluded, and that different viewpoints are equally articulated and incorporated into decision-making processes. Inclusion, exclusion, and degrees of involvement in PD methodologies are important considerations, making the implementing of such methodologies a skilful undertaking. Some individuals or groups may exclude themselves, for example, by intentionally not attending public meetings. Incorporating the views of marginalized groups such as the poor, the elderly, the young, and women is a particular challenge. Much concern has been expressed about women’s views being overlooked or marginalized (Gujit and Kaul Shah 1998). For example, in a 1996 survey of urban farming activities in Kano, northern Nigeria, it was apparent that relatively few women were visible in the fields due to strict Hausa Islamic seclusion protocols, so it was necessary to engage a team of women enumerators to go into family compounds to talk with women vegetable growers.

Local power hierarchies need to be fully appreciated in relation to levels of participation and possibilities for delivering tangible outcomes. But fully appreciating such power structures can take time. One of the criticisms of PD is that communities and groups may be perceived as being homogeneous and isolated, while in reality there are complex social networks both within and beyond the community, and development interventions can easily be shaped by pre-existing relationships. While power relations commonly exist among community members, they also exist between development facilitators and possible beneficiaries. A particular concern is the possibility of “elite capture,” or “elite control,” where participatory methodologies are dominated by elite members of the community who have particular objectives which can shape development interventions (Kyamusugulwa 2013). But, in reality, any interest group within a community could control the PD process.

More recently, and drawing on PD methodologies, the “Reality Check Approach” (RCA) was initiated in 2007 by the Swedish Embassy in Bangladesh – supported by the Swedish International Development Cooperation Agency (SIDA). Through a process of “immersion” and living with households, RCA aims to “engage with, listen to, observe and document the voices, opinions and experiences of ‘people living in poverty’ in relation to the policies and interventions that are carried out in their name.” The main purpose of RCA is to understand how specific policies lead to tangible benefits at grassroots level by developing two-way relaxed and informal conversations that can be held without interruption to household duties. Using RCA, strong and trusting relationships have developed through revisiting households each year (SIDA 2012). There is some concern that engaging with communities through PD methodologies can be time-consuming and possibly even stressful, and that “participation fatigue” may lead to self-exclusion by certain individuals and groups.

Despite its attendant difficulties, PD can yield some real benefits for communities and households, and interaction, dialogue, and decision-making among community members and with development teams might be regarded as a valuable expression of citizenship.

Participatory geographies

Kye Askins

University of Glasgow, UK

Participatory geographies do not (only) describe geographic research in which people participate; they are not (only) methodological/a set of methods; neither are they (only) community engagement, or “impact,” or limited to and by “knowledge exchange.” Participatory geographies include yet exceed all of these. And it is necessary to start our definition in such a way, since “participatory geographies” are increasingly being claimed within and beyond the discipline, loosely and out with the epistemological and political framings that we seek to define here.

Participatory geographies are political and politicized; they are activist and aim to resist oppressive structures and hegemonic discourses that serve to socially and spatially marginalize individuals and communities; they explicitly set out to enact progressive change; they are about working together with communities and individuals, ever cognizant and making visible issues of power, inequality, voice, agency, and difference. Participatory approaches destabilize academic-as-expert: they suggest new ways of collecting data, coproducing knowledges and determining outcomes, with more horizontal focus on who steers and benefits from research.

Participatory geographies are closely aligned to participatory action research (PAR): both center around collaborative processes of research, education and action as/toward social change; both are produced through and productive of a range of actors, including academics and nonacademic co-researchers and participants; both involve investigation that leads to action, which leads to reflection and learning, which then feeds back into investigation, in ongoing processes of “verification” of research data and outcomes.

Such approaches have been in resurgence since the early 2000s, with a “participatory turn” across contemporary social and environmental sciences, representing radical, creative, and exciting provocations for/in human geography (Kindon, Pain, and Kesby 2007). Participatory geographies and PAR are often referred to interchangeably; yet recently participatory geographers/geographers orientated to PAR are foregrounding more explicitly the role of geography and emphasizing the more-than-action-research elements: we return to this possible distinction later.

First, we need to acknowledge issues regarding voice here. This is a multi-authored piece, in that its ideas and examples come from a decade of learning, debating, and dialoguing about participatory geographies with a diverse range of academics and publics. Collaborative writing, unfortunately, remains anathema to normalized academic publishing structures, and meaningful collaboration was unfeasible for this entry, due to deadlines and word length. We thus adopt Cook’s use of “et al.” (Cook et al. 2014) to indicate the co-authorship inherent in writing this entry, through which many voices resonate.

Mindful of our privileged position in the (Western) academy, we also highlight the gaps and omissions throughout.
PARTICIPATORY GEOGRAPHIES

Theory and praxis

Participatory geographies are epistemological. Paulo Freire, a South American educator, is often cited as a key inspiration for involving participants directly in research, knowledge production, and its outcomes. In the 1960s, Freire developed an epistemology foregrounding research as social transformation, explicitly connecting with local struggles and knowledges, to enable a process of conscientization (conscientizacao) through which impoverished people increase awareness and understanding of their marginalized positions, and the structural forces involved, to (better) resist such positioning through political and social action. These theoretical underpinnings and political perspectives reverberated across the Global South/majority world throughout the 1960s/1970s, challenging ongoing legacies of colonization and resisting capitalist oppressions and early neoliberal “development” paradigms. Versions of anticolonial approaches to research echoed across India, Africa, and South America and among indigenous people in Global North countries.

Participatory geographies resonate, then, with postcolonial and subaltern geographies: listening carefully and dialoguing, reframing issues, and nudging learning and scholarship in new directions, while always foregrounding power relations and paying serious attention to issues of positionality and subjectivity. Critical race theory also informs such work, unpicking and addressing identity politics and exclusions (material and discursive) within communities as well as across cities, states, and the world. Participatory geographies are described as “enabling” or “facilitating” participation, critically aware of the need to reconceptualize who is enabling whom, in line with postcolonial critiques that argue against such academic orientalism. And also mindful of issues of representation: who is speaking for whom.

Feminist theory is central too: challenging extractive research as normalized within academia, through alternative methods and approaches that work to destabilize any public-academic dualism or “ivory tower” notion (see here commonalities with “public geographies”). Key here is addressing the power inequalities that enable and are reiterated through academic-as-expert. Informed by feminist ethics of reciprocal care in its most profound sense, as a deep respect for relationships and humanity, participatory geographies conceive public–private and global–local as interconnected rather than binary, engaging an analysis of how the intimate and global intertwine, and connecting to critical geopolitical work on social and spatial in/justices as interscaling/interscaled.

Poststructural theory further offers us alternative perspectives on the circulations of power in/through discourse. Paying attention to language, representation, and narrative is vital to foreground relational, fluid, plural subjectivities that emerge and are (re)made through intersubjective engagements in research. Such epistemological approaches in geography and other disciplines, as well as across (some) governmental/nongovernmental policy, have increasingly precipitated a renewed uptake of participatory action research.

Participatory action research

Participatory geographies have been developing from PAR since the early 2000s in response to renewed debates around the “relevance” of the discipline, and also in parallel with and connected to re-emergent focus at that time on more overtly activist ways of doing research, learning, and teaching. It is important
to consider here participatory geographies’ heritage and continuing overlap. PAR itself is embedded in a long trajectory of emancipatory approaches to research and learning across a range of disciplines, including legal studies, education, liberation theology, and social/critical psychology. Kurt Lewin is credited with the phrase “action research” in 1946, to describe the idea of iterative, cyclical rounds of action and reflection in “spiral science.” This approach evolved to become science that is not hierarchical, extractive, imperial; research that critically questions its purpose and relevance, taking seriously the idea that academia embodies, and, often and problematically, reproduces classed, raced, gendered, and other hierarchies.

Both participatory geographies and PAR, then, are engaged with/in everyday realms of struggle, working with communities, identifying issues to challenge and change, and raising consciousness (after Freire) – wary of privileged/ing academic positions and aware of the capacities of people to raise their own conscious understandings of sociospatial exclusions. In PAR, action is central, and emphasis is on research outcomes/actions directed by and of utility to co-researchers/participants. This can be booking university IT labs for community group access to computers for learning; training people in research methods and data analysis; producing policy-relevant publications and/or education/awareness-raising materials, crucially, writing with co-researchers; staging direct action campaigns; and so forth. (For vibrant examples see http://publicscienceproject.org/.)

More narrow approaches to PAR, when limited to methods, have been and should be critiqued for re-paternalizing development approaches in the Global South, and simplifying complex lived realities for managerialist needs: another neoliberal tool disguised as “participation,” tokenism at best. This critique highlights knowledge as a powerful normative construct, produced through social norms and cultural practices, embedded within logics of power relations. “Local knowledge” is thus not some fixed, uncontested commodity held/owned by local communities, which may be appropriated by authority. As such, PAR and participatory geographies must remain alert to these issues to avoid epistemic violence. Certainly, methods are key to deconstructing dominant discourses and social hierarchies (see later), but the wider deployment of ethics, politics, and relationships is crucial to ensure that research progresses through co-ownership, mapping out relationships between social structures and injustice in everyday life experiences (Cahill 2010). Such deployment emphasizes working as/toward equality and justice, rather than simplistic “solutions” that may be completed, precisely because identities and social relations are always becoming and shifting through participatory geographies as process.

Participatory geographies as process

Participatory geographies are “messy” encounters with and across intersectional differences, involving coproduction of knowledges (including but far in excess of academic knowledge) and foregrounding the process of collaborative research (Askins and Pain 2011). Inherent is a commitment to understanding diverse and marginalized experiences in affirmative ways, through an ethics of encounter that remains open, responsive, and supportive. Such iterative and becoming relationships, between academic researchers and co-researchers and between/among co-researchers, are always fragile and at risk and full of transformative potential.

Taking process seriously demands opening out to emergent, innovative, and creative methods
PARTICIPATORY GEOGRAPHIES

that may draw from and surpass one or more of the following:

- art;
- drama/theatre/role playing;
- diagramming;
- mapping;
- storytelling;
- media;
- dialoguing;
- photography;
- video and filmmaking;
- educational camps;
- exchange programs;
- focus groups/interviews/standard qualitative techniques;
- surveying/questionnaires/standard quantitative techniques;
- shared analysis;
- collaborative reporting, presentation, and writing;
- direct political action and advocacy.

More than research methods, we highlight here participatory geographies’ educational potential, both in learning and teaching praxis in formal classrooms, lecture and seminar spaces, and beyond – the list here pertains to participatory pedagogies as well as part of action research. Regarding the latter, participatory video (PV) is well known and developed and shares a politics of bringing forth issues for communities in context to effect change. Co-researchers are trained in all aspects of filmmaking, from choice of topic, through storyboarding, filming, and editing: key is putting people behind as well as in front of the camera. Participatory mapping is also particularly effective, and often emergent through research with indigenous communities, increasingly utilizing GIS and digital media. Indeed, the potential of new social media and technologies is being explored through participatory geographies, with exciting and creative “methods” being developed by co-researchers all the time, emergent in process and the material realities of place.

Emphasizing process raises issues regarding the temporal dimensions to participatory geographies. It is critical to engage in slower ways of working that build trust and reciprocal relationships, to engage reflectively and iteratively with co-researchers through all stages of a project, including analysis and “outputs.” At the same time, there is often an urgency as co-participants suggest outcomes and actions that need to be fast paced to respond to local public policymaking. The long delay of peer review or high level policy report writing, to which co-researchers including academics may aspire, is useless to many projects in the reality of everyday struggles. Thus participatory geographies simultaneously involve long term engagement and commitment and more immediate responses and activities (see activist geographies).

Given the importance of process, and emergent nature of method/activity/outputs, we need to consider more carefully the role of place and space.

The role of place and space

Geography matters. Participatory geographies are embedded in and across the everyday neighborhoods and locales of people’s lives, opening up new spaces for knowledge coproduction and action – spaces that are as much a part of the process, mutually co-constructing identities, relations, and encounters. While PAR certainly pays attention to the place of research, it is on this point that geographers have specific spatial theorizing to bring to bear. We raise three key, interrelated issues here that speak to the theories discussed earlier.
First, a feminist understanding of scale as interconnecting allows us to work closely with the ways in which global hegemonies and dominant structures are not (only) top down but also hierarchically influencing everyday experiences in different locations. Participatory geographies are centered on the ways in which local, embodied, and intimate spaces speak and act back, such that the body, nation, and global are conceived as caught up in similar processes rather than operating as/at different scales. This further destabilizes any separation between public and private spaces, deconstructs the “state” versus the “domestic” scale binary, and demands attention to the complexities and contradictions within individual/community lives caught up in webs of regional, national, and global processes. Carefully conceptualizing across place, space, and scale brings a specifically geographical lens to participatory approaches.

Second, in line with the above and drawing on activist work, participatory geographies may be enacted as “convergence spaces”: engagements that are place-based but not place-bound, centrally concerned with developing a politics of solidarity capable of transferring across space without flattening out contested positions, struggles, and beliefs. For example, the Participatory Geographies Research Group (PyGyRG) is UK-based, but endeavors to research, learn, and write collaboratively and act in solidarity with communities and academics across the world (see PyGyRG 2012). Here too, reflective participatory pedagogies can connect students with struggles outside the university; for example, see Mrs. Kinpaisby’s (2008) notion of “communiversity,” which remakes/redoess university-community as interrelational, connecting research and pedagogy, and engaging with communities as positioned in cross-scale structures of governance. Indeed, participatory geographies offer genuine pedagogic opportunities and respond to problematic, dominant discourses regarding “service learning” provision and “community engagement” practices.

Third, in taking issues of voice, agency, and power seriously, Torre et al. (2008) draw on “contact theory” to understand participatory approaches as “contact zones” within which all involved encounter each other through close negotiation, emergent identities, and contested diversity. In this vein, participatory geographies may work toward creating autonomous spaces as action in itself. Autonomy is explicitly about a prefigurative politics in which a “politics of affinity” examines ways in which multi-issue politics and diverse, contested positions come together to address overlapping oppressions (see Autonomous Geographies Collective 2010). It is precisely the messy negotiation of different bodies within communities and local spaces that often remain masculinized, raced, homophobic, and so forth, to which participatory geographies explicitly attend.

Foregrounding what we might call an ethic of space, participatory geographies incorporate a more-than-action-research agenda. What we mean here is that the material realities and discursive productions of/in local neighborhoods are central to co-making participatory geographies whatever they need to be in that environment: research, action, education, reflection, and other aspects ebb and flow at different stages of any project, depending on context. Critical PAR attends to these issues too, opening out to process without a research component. Our argument here is that participatory geographies involve greater attention to the centrality and understanding of place and space. And such focus is increasingly concerned with participatory approaches as embodied and emotional.
PARTICIPATORY GEOGRAPHIES

Participatory approaches as embodied and emotional

There is a burgeoning literature regarding emotional and embodied geographies, exploring the relationality of bodies, emotions, and affect, and their role in coproducing spaces and knowledges. Being/becoming emotionally involved in/through contact zones and processes, it is not surprising that participatory geographers are paying attention to the ways in which social and spatial relations are produced through and productive of emotions and affect. Furthermore, the approaches and epistemologies outlined above suggest the creation of space for emotion in participatory dialogue and process as central to challenging inequalities within and across communities, paying attention to emotion in all aspects of research, from bid-writing/proposal stage, inclusive of participants thoughts and feelings, through to dissemination and after, cognizant of how “leaving” any project affects researchers and participants and incorporating these issues into the approach/work (e.g., Askins 2009). Such embodiment connects to debates regarding nonrepresentational and actor-network theories, and more-than-human geographies, considering everyday identities and lives as felt, facilitated, and performatively practiced through ontologies of becoming.

Participatory geographies are starting to explore how the materiality of objects, landscapes, environments, and urban fabrics – and how they are mobilized – is co-constructive of identities, emotions, affects, and in/exclusions, crucially maintaining a humanism/responsivity to human agency through engagements that practice ontological politics (Gibson-Graham 2008). Wider calls for methods that attend to more than spoken or textual elements of the world, across a range of senses inherent to embodied experiences, are being taken up through the creative and open approaches to developing more-than-methods outlined above. Indeed, since participatory geographies are a diverse set of praxes, with ongoing, emotional self-reflection, among all co-researchers, working in ways that closely attend to emotions and affect is one of the key future challenges.

Future challenges

Participatory geographies share the complex challenges of the twenty-first century: widening gaps between rich and impoverished in late capitalist “austerity”; multiple climate crises; and ever-rising urban populations. If we ask ourselves who we are as academics, what is our purpose; it seems clear that participatory geographies are increasingly relevant, required, and demanded. Some may identify their particular academic position as an educator, others as scholar, most of us with elements of both, recognizing the broad continuum along which we may sit. Wherever we are, our argument here is that working with students and research participants is central to co-developing democratic, grounded knowledges that may better actively address issues of social, spatial, and environmental injustices.

One concern among radical geographers and other academics is regarding the ways in which neoliberalism suture capital as inevitable, and how capitalist structural compulsions attempt to recoup resistance, at the moment of resistance, by re-appropriating the “marginal” in a post-political or postdemocratic frame. Autonomy, creativity, and fluidity have become buzzwords of contemporary capitalist business organizing. We worry at the start of this entry that “participatory geographies” are increasingly being claimed outside the epistemological and political framings that we seek to define, because “impact” and
engagement activities are being brought into academic audit frameworks across the world, not necessarily in critical ways. Pain, Kesby, and Askins (2012, 120) discuss the ambivalence of participatory geographers here, arguing “for the potential of more participatory praxis to undermine neoliberal structures within the academy precisely through subverting notions of “impact” toward a social justice agenda.”

For participatory geographies to retain an emancipatory politics, they must continue to challenge increasing commodification and competition in academic knowledge production and practices, destabilizing entrenched disadvantage within and beyond the academy. We end, then, with a focus on the opportunities that participatory geographies afford: staying alive to hope, possibility, and the potential of for people to resist oppression and the surprise of collaboration and solidarity such that neoliberal and exclusionary structures and discourses continue to be exceeded.

The case for participatory modeling in environmental decision-making

The decision-making needed for addressing increasingly complex environmental issues requires input from multiple disciplines. But that input, often presented via complex scientific models, can be difficult for many stakeholders to comprehend, leaving many of them excluded from the decision-making process and/or unable to make good use of the knowledge offered to them. Participatory modeling (PM) is one way of addressing these concerns. PM links science and modeling to stakeholder knowledge and experiences, thus supporting and enabling participatory decision-making. PM brings stakeholders’ interpretations, experiences, and know-how together with researchers’ scientific knowledge, and integrates this information via models ranging from conceptual frameworks to computer programs. Scientists are thus seen as only one stakeholder group who learn from and interact with other stakeholders in order to address issues with high complexity and uncertainty. Whereas traditional science emphasizes objectivity, rationality, and expert-driven collection of information and modeling of problems, PM emphasizes collective deliberation, where learning outcomes emerge from ongoing discussions. As such, learning is often linked to practical action, and thus, PM is seen as a means to bridge science with policymaking.

International support for participatory processes came in 1992, when the UN Rio Declaration on environment and development and its local Agenda 21 called for community planning as a vehicle to re-engage people with their community and society. More recently, participatory actions have gained support in Europe, where policies such as the Aarhus Convention on Access to Information, Public Participation in Decision-Making and Access to Justice in Environmental Matters require environmental managers and policymakers to increase the involvement of stakeholders in their decision-making and management work. In addition, the term “government” has frequently been replaced with “governance” in both academic and policy circles to reflect the need to involve citizens, nongovernmental organizations, and social movements directly in the development and implementation of environmental policies (Lane 2005). In addition to policy drivers, public participation in science research has been applied in a number of academic fields ranging from development studies and public health to natural resource management. Citizen-science, which refers to the engagement of nonprofessionals in scientific investigations, has a long tradition within academia. The data, technology, and skills emerging from citizen-science provide multiple examples of how
PARTICIPATORY MODELING

engagement of nonscientists in scientific research can yield fruitful, often innovative outcomes.

There is broad agreement that participation can help with complex social-ecological problems or, as Arnstein (1969, 216) noted: “The idea of citizen participation is a little like eating spinach: no one is against it in principle because it is good for you.” Indeed, the use of participatory procedures has been an increasingly common feature of environmental management, although the approaches employed are wide-ranging and reflect different rationales. First, there is an ethical or normative rationale. Stakeholders have a legitimate right to participate in model-building processes because the outputs and results of the model directly impact them. Participation is an important part of the trend towards democratization of society and is increasingly a statutory requirement. Second, there is a substantive rationale. Local people may be the best source of knowledge about their surroundings, providing comprehensive understanding of historical and current processes of change. Such local knowledge can thus supplement, or be triangulated with, scientific knowledge, potentially resulting in better models that are likely to be more “fit for purpose” and create outcomes that are more likely to be in tune with what is needed and wanted. Third, there is an instrumental rationale, by which engagement is a potential means to build greater trust between scientists and nonscientists. Forth, there is a learning rationale, the hope being that through PM, stakeholders can engage in meaningful dialogue, potentially resulting in innovative solutions and knowledge creation by changing values and mental models. Fifth, there is an empowerment rationale, where PM builds local people’s confidence, skills, and ability to cooperate, thus leading to a sense of community and stewardship as people feel more attached to the environment they interact with.

People often want to be involved in shaping their environment and seem to enjoy the process.

The underlying rationales for stakeholder participation in modeling processes can be regarded as mutually reinforcing, cutting across different levels of involvement. A first level of involvement is simply providing information, that is, “knowledge transfer,” in order to raise awareness of the model’s functionality, capabilities, and practical applications. A second level of involvement is consultation: here the concern is to elicit precise information from stakeholders to inform the model’s development. This form of engagement is a more interactive but structured process where stakeholders fulfil data needs elicited through interviews or workshops. The deepest level of involvement is “collaborative model building.” Here, stakeholders engage in more fundamental aspects of model development. They engage in collective problem framing, priority setting, option formulation, and model evaluation. Models are coproduced in an iterative learning process between modelers and stakeholders.

Evolution of PM approaches

Any form of stakeholder participation in modeling processes, or conversely, the use of modeling to support decision-making processes that involve stakeholders, can be labeled as PM. We review here some of the more influential approaches that have been developed from diverse intellectual sources.

“Group model building” emerged in the 1960s, based on system dynamics applied to industrial systems, and later to urban systems studies (Forrester 1969). In the 1980s, group modeling was pioneered by Royal Dutch Shell for developing business strategies. The approach mainly consisted of involving diverse stakeholder groups to capture and model
their worldviews and help experimentation, cooperation, and learning (Akkermans 1995). In group model building interventions stakeholders contribute with partial views of the system, but they are affected by the system as a whole.

“Adaptive management” is a decision-making process rooted in ecological studies, which emerged in the 1970s to address the twin challenges of learning and management of complex ecological systems and human–environment interactions (Holling 1978). Grounded in systems thinking, “adaptive modeling” confronts the complexity and uncertainty of natural resource management by integrating modeling within a cyclical learning process. Recently, the adaptive management literature has moved more in the direction of “collaborative learning,” which focuses on actively engaging stakeholders throughout a given learning cycle. Indeed, many PM approaches have begun adopting a collaborative learning approach grounded in soft-system methodology (Checkland and Scholes 1990).

Participatory “integrated assessment modeling” (IAM) emerged in the mid-1990s (Van Asselt Marjolein and Rijkens-Klomp 2002). Integrated assessment was a modeling approach applied to human–environment phenomena such as climate change or land change that sought to transcend disciplinary and policy boundaries and single policy arenas. Expressly participatory integrated models advocated reflections on the management of uncertainty and engagement of multiple perspectives, including those of lay people, often under the aegis of ecological economics as “mediated modeling” or “collaborative modeling,” which emerged in the 2000s as a variation of group model building. Mediated modeling broadens the participation of stakeholders to increase the shared understanding of a system’s dynamics through consensus building over complex environmental challenges (Van den Belt 2004). Other methods to support participatory decision-making processes, such as scenario development and multicriteria evaluation, have been used in combination with integrated modeling, especially in integrated water resources management.

“Companion modeling” (ComMod) (Etienne 2014), which is rooted in complex system thinking and participatory action research, was developed by researchers from the Centre de Coopération Internationale en Recherche Agronomique pour le Développement (CIRAD; French Agricultural Research Centre for International Development) in the mid-1990s. Despite the diversity of applications of ComMod, their common basis resides in an underlying constructivist approach and the combination of diverse modeling tools inspired by social psychology (e.g., conceptual modeling, agent-based models, role-playing games, and spatially explicit models) to help stakeholders confront some of the implications of their own perceptions, beliefs, and behaviors. Stakeholders interact within a virtual, computerized world, to resolve conflicts or manage natural resources.

“Participatory mapping and geographical information system (GIS),” broadly defined as using participation-based methods for eliciting and modeling spatial data, was developed in geographical information science, in the late 1990s. For instance, the pioneering Varenius initiative investigated how to extend conceptual frameworks for spatial decision support systems to help groups of decision-makers generate tractable solutions to ill-defined spatial problems and to enable them to work together by providing a set of tools that handle tasks such as data exchange, group evaluation, consensus building, and voting. The initiative also guided research on how GIS can be democratized through placing it in the hands of a wider spectrum of society and by considering broader
PARTICIPATORY MODELING

ethical and legal implications. Since then, participatory GIS (and other variants, such as Critical GIS, GISocial, and participatory geomatics) has gained followers from urban planning, development research, community development, and landscape ecology, as well as from environmental and natural resources research.

Differences and commonalities of PM approaches

Current approaches in participatory modeling share a number of commonalities but differ with regards to goals, elements of the process, the level of stakeholder engagement, and models used or developed during the process. The key commonality among PM approaches is the emphasis on bringing nonscientists and modelers together to inform model development. Here we also highlight some additional commonalities and differences.

Aims and principles

PM approaches can differ with regards to the following aims:

- to gain insights on specific decision problems and complex interactions between socioeconomic and ecological dynamics of systems,
- to gain clarity on the impacts of decisions,
- to increase the legitimacy of the process,
- to facilitate social learning and consensus building.

Though their focus and application may vary with regards to aims, PM approaches tend to be guided by common principles. These include the following.

- Emphasis on iterative learning. The models emerging from PM approaches are less about prediction, and more about helping stakeholders learn and think through uncertainties in complex environments and potential implications of their values, preferences, and choices.

- The traditional role of scientists is questioned. PM approaches value the insights of nonscientists, seeing their inputs as complementary to their own.

- Emphasis on the process. Given the complexity of environmental issues, PM focuses less on certain one-time changes but emphasizes what kinds of knowledge gets created, how behaviors, perceptions, and institutions change and adapt, and in what ways innovative thinking and learning can be improved.

Types of stakeholders’ engagement

Classifications for PM may differ with regards to: (i) the timing of stakeholder engagement in different modeling stages; (ii) roles stakeholders take on during the process; (iii) the level and mode of participation; and (iv) direction of information flow between researchers and stakeholders. Depending on the modeling approach adopted, stakeholders may be involved individually or in groups. Their level of involvement can range from being asked to be informed and being informants at discrete points in time, to iteratively interacting and steering from the beginning and throughout the modeling stages.

Moreover, scientists assume new roles, such as scientific knowledge providers, process facilitators, and mediators. They differentially interact with stakeholders through techniques taken from participatory research and communication. At earlier stages of the modeling process, scientists may adopt a broad range of methods from social sciences and participatory action research to collect primary and secondary
data, share knowledge, or identify actors and resources. Other approaches are necessary during model conceptualization and design, including developing the modeled system’s ontology, the model boundary, and the user requirements. Stakeholders may be asked to choose analytical tools and, in some case, to help create prototypes. During model construction, scientists may build in participatory workshops, jointly with stakeholders, the operative simulation model. Then, at the stage of model calibration, verification, and validation, stakeholders may be involved through workshops or questionnaires to elicit feedback on content, the model’s validity and usefulness, and their evaluation of the learning process. Finally, the use of models by stakeholders may be direct or mediated by scientists.

Differences in models

There are two main categories of models being built during a participatory modeling process: (i) qualitative or conceptual models, which explain the system on the basis of multiple knowledge sources and mental maps; and (ii) quantitative, computational models of the system. Conceptual models have been used to point the way toward future research and can help stakeholders to articulate hypotheses to be tested. Many proponents of this methodology, especially those from sociological, anthropological, and development studies traditions, stop at the stage of a diagrammatic conceptual model. Others argue that although all models are simplifications, using mathematics to create different simulations of the future is necessary for exploring the consequences of what is assumed at the conceptual modeling stage.

Quantitative models applied to natural resource management have been developed by different research groups and they span a range of methods, including dynamic system models, multi-agent models, Bayesian networks, and mixed models adopted in integrated assessment. Dynamic system models usually represent social and ecological systems in a causal loop model, where stocks are connected by flows. Multi-agent systems (MAS) are intended as simplified, virtual metaphors of reality (social, biological, and physical) via creation of artificial worlds composed by agents with some degree of autonomy that interact with other agents and with the environment. Frequently microworlds and games are adopted, including role-playing games, which generate new knowledge by creating common understanding of shared situations (and at the same time allowing to reflect on divergences among agents), via learning-by-experimenting within the model, and by establishing the rules and goals of negotiation processes. Bayesian networks provide a probabilistic representation of the relationships between input parameters and their dependent variables. They integrate different knowledge sources and can include expressions of stakeholder perceptions of uncertainty. Overall, natural resource management has mixed and matched quantitative and qualitative modeling tools, such as coupled socioeconomic and ecological models in combination with storylines and all integrated within a PM approach.

Outlook, critical issues, and barriers to implementation

In traditional science-intensive environmental decision-making processes, the science is more or less separated from policy processes. Given the increasing frustration with the outcomes and shortcomings of traditional approaches to model building, alternative processes have been developed to facilitate the interactions between scientists and other stakeholders. But new forms of knowledge production may lead to an institutional split of science into an academic and a

Public policy branch (Haag and Kaupenjohann 2001) with potentially quite different characteristics, processes, and outcomes (see Table 1).

Not all decisions and decision contexts are equally suited for PM, thus the analyst has to make choices and consider tradeoffs with regards to purpose of the modeling exercise, model type and method, and the participation mode. There is a need to better match the choice of participation level and processes to the problem it attempts to solve.

These challenges hint at the fact that in spite of advances, the combined application of participatory processes and computer models to support environmental decision-making raises a number of theoretical and practical issues. The difficulties in filling the philosophical gap underlying qualitative and quantitative research and operationalizing their integration remain widely unexplored. Research is needed to close the gap between natural science models that simulate change and stakeholders’ experiences...
and perceptions of change. Moreover, the use of computer models may lead to a risk of developing fixed paradigms of the future through unified conceptual or computational models with generalized knowledge, and this counteracts one of the original aims of participatory processes of including a variety of knowledge types and backgrounds (Crane 2010). The integration of knowledge in PM exercises carries the danger of discouraging less accepted and more tacit forms of knowledge, which points towards the problem of managing and facilitating power within such processes. More generally, having the real power needed to affect the outcome of the process and translate findings into actions is often listed as a key impediment to PM. But this criticism might arise mainly from a focus on formal and relative power rather than an evaluation of outcomes from deliberative processes.

Moreover, environmental problems are the result of aggregate actions of numerous actors rather than a single decision-maker, a fact that also adds credence to the importance of the deliberative and social learning aspects of PM (Lane 2005). But these processes take time and can be fairly complex and thus are often not well managed because facilitators and participants are not aware that knowledge and practices have developed over time. This problem is often amplified by unrealistic expectations about what environmental stakeholder processes ought to be, and what they can achieve, resulting in ineffective use of resources and time. Stakeholders frequently struggle to balance requirements of their day-to-day job with their participation in deliberative processes. Similarly, scientists and modelers are also pulled in different directions when confronted with producing scientific outputs versus the needs of the process. The exploration and inclusion of local assumptions and knowledge as main inputs of the recursive PM process can frustrate researchers and modelers who might feel that this kind of process is not rigorous and robust enough. In addition, the modeler is cast into an arena that can be very different from the usual modeling environment, where he or she must contend with stakeholders’ agendas and the need to translate model outputs in ways that all stakeholders can understand. Models also tend to ignore the emotive side of decision-making, even though emotions play a very important role, especially when resource conflicts are involved. PM can provide a framework in which these conflicts can play out by simulating implications of choices in a safe environment, by organizing knowledge and contributing to the integration of scientific and nonscientific knowledge, and by catalyzing mutual learning processes.

Participatory video

Sara Kindon
Victoria University of Wellington, New Zealand

Participatory video, in both community development and academic research, has been growing exponentially since the late 1960s. It can be thought of as a field “coming of age” (Mitchell, Milne, and de Lange 2012, 10). Its diverse forms involve groups or communities in the production of videos that tell their stories, explore their concerns, and/or enable them to mobilize and take collective action. It is also sometimes known as process video, community video, or video-as-dialog and is used within participatory processes to raise awareness, share meanings, and facilitate discussion, often with distant stakeholders.

Participatory video processes may result in the production of documentary films, but participatory video differs from most forms of documentary filmmaking in three main ways. First, it emphasizes the ethics of access by placing the means of production into the hands of subject-communities, rather than filmmakers/experts. Second, it attends to the ethics of representation enabling people to self-represent according to their own aesthetic and cultural conventions, and, third, it foregrounds the ethical responsibilities of audiences by seeking to affect them, as a vehicle to effect change. Its origins and uses are entwined with participatory (action) research, participatory development, and indigenous media and research practices, although the latter remains generally unacknowledged in mainstream accounts.

The Fogo Method is frequently attributed as the formal origin of participatory video processes. Carried out by Colin Low and Fred Earle within the isolated fishing communities of Newfoundland in 1967, the process was innovative in many ways. Funded by the Canadian Film Board through a program called Challenge for Change, Low produced a number of short single-person “vertical” films as opposed to a longer, more wide-ranging “horizontal” documentary involving the intercutting of opposing perspectives. He enabled community members’ input into the focus, shooting, editing, and final content of the films produced, and emphasized the closing of the subject-feedback loop, screening the films produced to different island communities, as well as to distant academic and policy-oriented stakeholders, to generate discussion and dialogue. Such an orientation reflected earlier innovations in documentary filmmaking by American Robert Flaherty (Nanook of the North, 1922), British filmmakers involved in the 1935 documentary Housing Problems, the work of film-maker Raymond Garceau in New Brunswick and Gaspésie, Canada, in 1965, and the influence of British documentary filmmaker John Grierson within the Canadian Film Board at the time. However, the Fogo Method differed in its outcomes. The screenings of the films produced resulted in new filmic responses as interrelated stakeholders chose to use the medium to “talk to each other” across geographic distances, and to mobilize for local change.

The Fogo Method is credited with giving its participants a “voice” facilitating their empowerment. Over the next two decades, it influenced filmmaking processes across the world. Its spread was aided by the reduction in size, weight, and...
PARTICIPATORY VIDEO

costs of the recording and editing technology needed, and as video began to replace 16 mm film as the main medium of production, it became easier for nonexperts to transport and use. It was also supported by wider human and environmental rights movements across the world advocating for greater democracy and participation. In New York, Martha Stuart established the Village Video Network in 1984. She traveled to India to work with the Self-Employed Women’s Association (SEWA). Members of SEWA have gone on to produce more than 400 videos and have used them to advocate for women’s and labor rights.

Elsewhere, what has become loosely defined as participatory video emerged from diverse sources. In Tanzania, one influence was the approach of Soviet propagandist filmmaker Aleksandr Medvedkin, who in 1932 created and ran a film-train consisting of three railway cars carrying a film crew, production equipment, projection room, laboratory, and film-printing machinery. It was a self-contained film studio that could stay on location for months at a time reaching remote communities to produce critical films on their conditions. These films were shown locally to stimulate discussion and development initiatives. Also in East Africa in the mid-1930s, the Bantu Kinema Educational Experiment attempted to create a cinema produced by and for the local people. Medvedkin’s work inspired others, including French avant-garde filmmaker Jean-Luc Godard, who lent his 16 mm film camera to workers in a factory in Lyon in the 1960s. His practices were then taken up by video activists in the community television movement in the United States and Canada in the 1970s.

Further south, in Latin America, uses of video were informed by the critical pedagogy of Paulo Freire to enable people to document and take action against the oppressive aspects of their lives during civil war or dictatorship.

Throughout this period, equipment was still cumbersome despite the emergence of more mobile synchronous sound 16 mm film cameras like those used by Godard. It was not until the 1960s when portable video cameras were developed with an immediate playback function that participatory aspects of production became a more frequent possibility within project-based applications and academic research.

During the late 1960s and early 1970s, academics in various disciplines, particularly anthropology, began experimenting with participant-led forms of visual ethnography and data generation. Such initiatives embraced a more inclusive ethics of access and sought to understand the worlds of others through the generation of their own representations. At first they sought to capture “the native’s view” as somehow more authentic and “real” than that of the outside filmmaker – as a transparent window into a different reality. However, over time, scholars such as Jean Rouch, David and Judith MacDougall, and Eric Michaels embraced a more reflexive or intersubjective orientation to their work.

Rouch used the camera as an agent of investigation and to initiate ethnographic encounters. He advocated the practice of “feedback” whereby the first rushes of a film were shown to the people who were represented in it to invite their comments and ideas. This “audiovisual countergift,” as he termed it, acted as a stimulant for mutual understanding and participant dignity. He also envisioned a “shared anthropology” where the camera was placed in the hands of those usually in front of it. The MacDougalls developed a practice of “participatory cinema” in which they sought to make the filmic encounter – the process of production – visible to audiences by including discussions with participants about the making of their films and shots of the equipment being used. In Australia, Michaels used video with Aboriginal Walpiri peoples to
enable them to tell their own audiovisual stories via television. These practices called attention to the role of the researcher or filmmaker and to the politics of cultural production associated with the technology itself in shaping the products and representations produced (Pink 2007).

In the 1980s and 1990s, feminist, postcolonial, and indigenous critiques, coupled with the uptake of participatory and social learning methodologies, foregrounded the “participatory” dimensions of participatory video practice more prominently in both development and research applications. As mentioned above, advances in the technology also enabled greater participation in filming by nonexperts. As examples of successful practice around the world were shared, claims about participatory video’s ability to empower others and give them a voice led to the construction of a dominant discourse that was celebratory, romanticizing, and largely uncritical (White 2003).

Alongside these developments, the indigenization of visual media by people dominated by white eurocolonial settler populations such as in the United States, Canada, Australia, and Aotearoa, New Zealand, represents a different but related form of participatory practice. As a particular form of cultural activism, it has involved a political dynamic or intercultural negotiation implicated in a politics of identity and broader movements for cultural autonomy and political self-determination. One of the earliest and most striking examples of indigenous media use was by the Kayapo Indians in Brazil, who used video to document historical encounters with Brazilian state power and internal political events. In Mexico, the Chiapas Media Project/Promedios enabled indigenous communities to use video to draw attention to their plight and to challenge dominant media representations of themselves and their struggle. The international dissemination of their videos produced worldwide solidarity and political pressure on the Mexican government.

Through these uses of video, the ethical responsibilities of the audience emerged as a key, if undertheorized, element of various approaches to participatory and advocacy video (Corneil 2012). They also highlighted a key tension in participatory video practice: that of the promotion of a more objectified or fixed notion of social reality in order to communicate across or between cultures, while giving people more control over that process of objectification.

Since the late 1990s, visual and participatory research methodologies have become more mainstreamed within the social sciences and geography. The rise of digital technologies and online connectivity have sustained this trend and brought new logistical and ethical challenges. Two main strands of current scholarship are evident: first, the use of participatory video in discrete citizens’ media projects drawing on participatory development and/or critical pedagogy to facilitate the expression of participant agency and self-representation through video; second, participatory video as a research method, which can epistemologically challenge extractive social science approaches, and generate rich qualitative data for collaborative analysis. In some cases, academic engagements with participatory video bridge both project and research orientations.

Parallel to, and feeding into, both of these trends has been the growth of UK-based organization InsightShare as the most prominent provider of participatory video training around the world. Not only have they secured major contracts with international organizations like the World Bank and national governments such as Myanmar to integrate participatory video into their ongoing development programs, they have also partnered with British academics through the establishment of PV-Net since 2007. Funded by the Economic and Social Research
Council to bring researchers together to develop their capacity to integrate participatory video into academic research, InsightShare’s form of participatory video is now proliferating via PV-Net activities and within academic research in similar ways to the adoption of participatory rural appraisal techniques in the 1990s. For example, the majority of British-based geographers deploying participatory video since 2008 have been trained through InsightShare.

Throughout these developments, critical questions about the relationships between participation, video, and audience remain relatively undertheorized. Scholars rarely make explicit what they mean by participation, agency, voice, or representation, despite their contested meanings. Studies frequently imply that participation is evidence of agency and that expressions of agency demonstrate personal or social empowerment or transformation, “as if telling one’s story necessarily means taking charge of, or making changes to, one’s like and community or acting in the wider public sphere” (Low et al. 2012, 55). Yet the histories and politics of representation complicate understandings of the relationships between participation and the use of video.

In addition, there is increasing recognition that processes of filming, screening, and discussing video products simultaneously express and produce subjectivities, and that having subject-community or indigenous members operating the technology does not necessarily make the representations produced more authentic, respectful, or politically powerful. That said, many authors argue for the value in continuing to have so-called marginalized peoples carve out a discursive space for their own understandings and uses of audiovisual media, and that within this space, indigenous media is a specific kind of representational project.

These more recent developments in the field suggest encouraging efforts to better understand the relationships between affect and effect, aesthetic, artistic, and political expression, and how they are informed by the means of cultural production being facilitated. They also recognize that handing over the camera to participants and an ethics of access is only one part of a complex process. Researchers are starting to explore how the media logic of the technologies in use shape, limit, and fix what can be represented. The recent critical reappraisal of participation as tyranny has fueled a re-examination of the processes of facilitation and group work at the heart of participatory video (Kindon 2012). There is also much to be learned from indigenous media discourse where more explicit attention and acknowledgement has been paid to the highly charged intercultural dynamics and colonial continuities associated with the politics of seeing, researching, and representing (Deger 2006).

Questions are beginning to be asked about how we can document and theorize the intangible and/or affective aspects of people’s engagements with video, such as pleasure, fun, and frustration. In addition, there is growing awareness that not everything can be rendered visible, nor is there a clear and consistent relationship between the realization of a particular vision and the performance of agency or voice. In this respect, the work of long-time participatory video practitioner and academic Jackie Shaw (2012) is significant in its attempt to theorize the gaps between participatory video’s ideals and realities with respect to empowerment. And as the dissemination of participatory video products into distant spaces and online environments increases, there is much work needed to inform more appropriate ethical practices associated with consent and ownership. There is also a need to better understand the diverse audiences being both targeted and reached by participatory video products.
Out of this greater focus on praxis across different stages and spaces of interventions there emerges no singular “participatory video” nor a solution to its enduring tensions, only a call to remain vigilant to the contextual interplay of people, power, and audiovisual technologies. Making sense of how participatory video is continually remade in different places provides opportunities for further geographic inquiry.

Human dominance has been established for thousands of years and human activities have been changing the world prodigiously. Forests are cut down to make fuels and build houses; artificial rivers are dug to facilitate irrigation and transportation; interstate highways are constructed, breaking up vast fields, to make our lives more convenient. However, various environmental crises have arisen due to such human-induced changes. The forest may never grow back; tons of topsoil are lost; imported plants take up large area and original local species start to die out, and so on. By drastically disturbing natural habitats, human beings have greatly disturbed the ecosystem. The decrease in biodiversity and the emergence of different environmental problems have pushed humans, especially resource managers and scientists, to search for ways to better manage the environment.

The relationship between spatial patterns and ecological processes forms the overarching question in the science of landscape ecology. Under the premise that the change of landscape patterns interferes with critical ecological processes, scholars have put much effort into quantifying landscape patterns, which is essential before the pattern–process relationship can be understood. The landscape is composed of various elements, such as mountains, rivers, vegetation, buildings, and so on. According to the phenomenon being considered, these elements form homogeneous areas, that is, patches, which collectively make up a distinct pattern or structure of the landscape. Over the past three decades, landscape metrics have been developed and have become one of the most popular methods to quantify landscape patterns at different scales. In the beginning, indices from traditional community ecology were adapted to quantify the composition (what and how many patches). Since then, a number of new metrics have been proposed to add a new dimension of information: spatial configuration (position and arrangement of the patches) of the landscape. Specifically, the metrics computed for each patch are defined as patch metrics. Additionally, a set of metrics can be derived for all patches belonging to the same class, or for the entire landscape. Correspondingly, they are referred to as class metrics and landscape metrics, respectively, and thus are not included here.

McGarigal, Cushman, and Ene (2012) summarized most of the prevalent patch metrics according to which aspect of landscape pattern is measured. As such, patch metrics are put into five different categories.

1. **Area and edge metrics**: for example, patch area, patch parameter, radius of gyration (extent of the patch). Metrics in this category provide important measures of the edge effect.
2. **Shape metrics**: for example, perimeter–area ratio, shape index, contiguity index. The effects of the patch shape are also related to edge effects. For example, patch shape has been found to affect inter-patch processes, for example, animal migration.
3. **Core area metrics**: for example, core area. The core area is the area of a patch excluding a
certain buffer from the edge. Therefore, core area is a metric that takes patch size, patch shape, and edge effect distance into consideration simultaneously.

4 **Contrast metrics:** for example, edge contrast index. This describes how different the patch is from the adjacent patches with regard to one or more attributes.

5 **Aggregation metrics:** for example, Euclidean nearest neighbor distance, proximity index, similarity index. These metrics describe how dispersed (dispersion), fragmented (subdivision), or isolated (isolation) the patches are. Furthermore, by comparing a certain patch measure (e.g., area, shape) to the mean value within the class and the landscape, the deviation and percentile of one patch from the class and the landscape also form a set of important patch metrics to identify patches with extreme values.

Often, patch metrics are defined on the basis of thematic maps. Depending on the definition of thematic classes, different landscape patterns and structures may be derived. For example, if deforestation is the underlying topic, all of the tree areas will be defined as the same patch type, “forest,” whereas if the topic switches to bird habitats, it may be desirable to separate yellow birch and white ash as two different patch types. Nevertheless, when studying the problem of fish habitats, it is not necessary to define the ocean as patches. In summary, it is important to correctly define classes according to the question being addressed before patch metrics can be calculated.

Habitat or biodiversity conservation has been the top concern that patch metrics strive to address (Wu 2013). In this regard, studies have been carried out on all kinds of species, including mammals, birds, plants, fishes, insects, and so on. Specifically, patch metrics are usually factored in the ecological models as predicting variables to assess the effects of environmental change on biodiversity. Two examples that illustrate the implications of patch metrics are: (i) the increasing fragmentation of habitats, which has been found to be a major threat to biodiversity all over the world; (ii) the different responses of native and invasive plant species to the same landscape pattern, for which patch metrics are helpful in predicting the distribution of invasive species.

Land-use/land-cover (LULC) changes benefit from patch metrics study. Urbanization, deforestation, and cultivation are three main processes of human interference that are taking place in the environment. With comparison of the patch metrics for the initial and the changed LULC landscape, the change of landscape patterns is quantified – for example, how much land has been taken over by new buildings or constructions, how much forest has disappeared, and how much land has become new farmland. Besides the questions of “how much,” patch metrics facilitate the explanation of more important issues. For example, they can address the questions of whether urban areas are expanding by merging with neighbors in all directions or by growing in one direction; which scenario, cutting trees from the outer boundary of woods or fragmenting the forest by cutting trees, suffers worse deforestation; or what LULC type is more likely to be replaced by farmlands. To sum up, patch metrics provide more in-depth information than pure comparison of two LULC maps. Alternatively, prediction models are also engaged to predict future trends of LULC change. In the model-based approach, patch metrics are utilized as one set of predicting variables for models such as cellular automata and Markov chain.

Landscape regulation with the help of patch metrics received considerable attention recently.
Studies have revealed that different environmental components are influenced by various aspects of the landscape, which can be characterized by patch metrics. For instance, water quality is more related to landscape composition than to spatial configuration; the spreading of fire is well explained by fragmentation metrics and the severity of fire depends more on the composition of the forest; after a forest fire, a more fragmented landscape pattern is usually created; soil erosion is affected by watershed landscape patterns, and so on. Therefore, regulation issues regarding water quality control, fire risk reduction, and soil preservation benefit much from the utilization of patch metrics. Additionally, researchers started to understand microclimate (e.g., urban heat islands) using patch metrics as predictors. The findings have led scientists to believe that patch metrics are promising in helping to analyze the relationship between larger-scale (e.g., national, global) climate change and ecosystem functioning (Uuemaa and Mander 2013).

The potential to facilitate so many environmental research topics attracted researchers to create a variety of patch metrics. By the end of the twentieth century, a number of patch metrics had already been developed and convenient software packages produced. Despite the development of these metrics, three limiting factors still exist. As a result, a major question now concerns how to effectively relate the values of patch metrics to corresponding ecological processes without developing new measures.

First, scale of view is a widely discussed issue on landscape patterns and metrics. With the rapid development of remote sensing, the availability of global data at different spatial resolutions reveals the problem of scale. “Scale” here has two different meanings: grain and extent. Grain, or resolution, refers to the smallest spatial size of the data to be studied. Different patterns will appear at different grain sizes and the metrics will also change. Taking the edge effect as an example, when the grain size decreases, more details become visible and the straight edges may become sharpened. Therefore, comparing edge effect at different scales will not be very informative. Extent, as the name implies, refers to the area of study. Compared to changing the grain size, the effect of changing extent on patch metrics is rather more random. It’s often infeasible to deal with the scale problem by interpolation or extrapolation. To use the patch metrics wisely, for instance, to link the pattern to certain processes, or to compare the patterns at different times, it’s important to keep the scale at the same level.

Second, although the number of available patch metrics is huge, they are not mutually independent. Great redundancy exists between different metrics. Some metrics are inherently correlated by design. For example, the perimeter–area ratio is the ratio of patch perimeter and patch area. Hence, these three metrics are completely correlated. However, all of these correlated metrics are maintained because each of them can be more convenient to represent the landscape, depending on what aspect is to be emphasized. On the other hand, some metrics may be empirically dependent under certain landscape conditions, such as scale, dominant patch size, number of classes, and so on. When selecting metrics, it’s better to avoid using the highly correlated metrics simultaneously. Techniques such as principal component analysis and factor analysis are often applied to reduce the redundancy in the set of metrics used.

Last, patch metrics themselves stop at being a quantitative description of the landscape pattern at a certain time point. To be more useful, the metrics should be applied to compare landscape pattern at different times or in different scenarios. The application in LULC change is one example of utilizing the metrics. However, usually only a few discrete time periods are
chosen to study the change and the majority of temporal dynamics are still omitted. Patch metrics can also serve to predict variables in modeling. However, the relationship between the metric value and a certain pattern may not be one-to-one. The pattern represented by patch metrics, the pattern that causes certain processes, and the pattern that is seen by humans can all be different from one another. Therefore, further exploration is still needed of how to better relate patch metrics to the function of patterns.

Path dependence

Jinn-Yuh Hsu
Yu-Kai Liao
National Taiwan University

The concept of “path dependence” emphasizes that the set of decisions one can make is influenced by the decisions one has made in the past. More specifically, it argues that certain historic events would disproportionately cause later conditions. One of the most well-known examples, offered by economist Paul David, is the adoption of QWERTY keyboard. Although the layout of QWERTY keyboard is not the most efficient one in comparison to many other keyboard models that have existed in history, it has become the industrial standard (David 1985). Paul David explained that this is because in the initial stage of the development of typewriters, most typists were trained to learn and memorize the arrangement of the keys in the QWERTY layout. And, as it is difficult to change typists’ habit, more and more typewriter manufacturers adopted the QWERTY keyboard. As a result, the less efficient keyboard model became the mainstream. In short, path dependence emphasizes that economic configurations cannot be explained solely by some timeless logics such as cost or benefit; history matters in the shaping of economic structures.

Since its introduction in the late 1980s, the concept of path dependence has undergone several rounds of elaboration and modification. One important contribution was made by economist William Brian Arthur, who, in Increasing Returns and Path Dependence in the Economy (1994), proposed four concepts – large initial fixed set-up costs, dynamic learning effects, coordination effects, and self-reinforcing expectations – to further elaborate on the relationship between history and the economy. “Large initial fixed set-up costs” refers to the fixed capital that a company has to expend prior to the production of a particular product. To cover this cost, most companies, in the initial stage of the production at least, will focus on increasing production outputs, thus bringing inertia to changes that may make the production process more efficient. “Dynamic learning effects” emphasizes the importance of learning by doing and learning by interacting, which would increase human capital. “Coordination effects” argues that cooperation between firms confer advantages to going along with other firms taking similar actions. Lastly, “self-reinforcing expectations” refers to the situation where increased prevalence of a particular product, technology, or production practice enhances beliefs of further prevalence. As a result, more suppliers and consumers would invest in the common standard, and products will fulfill the expectation and reduce the risk of investing.

David’s work on the economics of technology (the adoption of the QWERTY keyboard being his most famous example) and Arthur’s thesis about increasing returns together inspired a generation of economists to investigate how economic structures are shaped by historical accidents and contingencies. This strand of scholarship is often referred to in literature as evolutionary economics (EE). It is also worth noting that in economics insights from path dependence theory encouraged some scholars to bring geography into the study of the

PATH DEPENDENCE

economy. In *Geography and Trade*, for example, Paul Krugman (1991) points out that increasing returns is one of the determining factors behind trade. This approach to trade is in sharp contrast

**Box 1**

The case that Krugman examined was the formation of the Rust Belt in the United States. He developed a simple model that shows that the interaction of increasing returns, transportation costs, and demand can give rise to the spatial concentration of the manufacturing sector. In the early history of the United States, where manufacturing was marked by few economies of scale and where transportation was costly, no strong geographical concentration could occur. As the country began its industrial transition, manufacturing grew in areas that contained most of the agricultural population outside the South. As this economy of scale increased, transportation costs fell, and the share of the population in nonagricultural occupations rose. As a result, the initial advantage of the manufacturing belt was locked in.

to Ricardo’s notion of comparative advantage, upon which mainstream economics has been based on. In economics, literature works by Paul Krugman and his followers are often referred to as *new economic geography*.

The influence of path dependency theory on other social sciences disciplines – human geography, sociology, and political sciences in particular – has been no less significant than it has been on economics. In human geography, the introduction of the path dependence theory is closely associated with the emergence of the literature of *evolutionary economic geography* (EEG), which is our primary interest here.

**Evolutionary economic geography**

Evolutionary economic geography concerns the evolution of economic landscape, or the transformation of the spatial organization of production, distribution, and consumption. Two lines of inquiry characterize this body of research. The first is the study of the evolution of economic landscape in a given location. For example, in his study about the coal and steel industrial complex in Rhur, Grabher (1993) identified three types of “lock-in” – functional (based on hierarchical relations between firm), cognitive (consisting of a common world-view), and political (a thick and dense institutional structure that hampers restructuring) – to explain why the region become inflexible, unable to absorb new ideas, and ultimately unable to respond to competition.

The second is the study of the novelty of economic landscape across locations. Here, the scholar’s primary interest is in the spatial logic of the emergence of new industries. Boschma (1997), for example, argues that the requirements of newly emerging industries are often discontinuous with the environment of pre-existing industries. This is because previous local context does not necessarily provide an advantage to stimulate for the development of new industries. The implication of this proposition is that regions that are lagging behind are often more attractive to new industries. The case that Boschma used to develop this argument is the transformation of industries in Belgium since the nineteenth century. He carefully examined the locational patterns of five industries: coal-based iron making, cotton, electronic engineering, automobile, and microelectronics. He found that the development of electrical engineering and automobile industries (often referred to as the “second industrial revolution”) require specific technological knowledge, skill, and capital.
These requirements are very different from those of coal-based iron making (which required proximity to the coal and ore mines) and the cotton industry (which required a pool of experienced labor and skilled entrepreneurs). As a result, the electrical engineering and automobile industries preferred to locate in particularly old industrial regions or lagging regions that could provide the specific technology knowledge, skill, and capital.

Without doubt, prior to Boschma’s research, economic geographers had investigated the issue of industrial locations. In *The Capitalist Imperative*, Michael Storper and Richard Walker (1989), for example, proposed the concept of “windows of locational opportunity” to bring political economy into industrial location theory. They pointed out that the geography of capitalism is uneven and inconstant. Through technical innovations, organizational changes, and labor intensification, capital is able to escape from the past and creates a new industrial landscape. This means that new industries would not necessarily develop in established industrial regions. What is new about Boschma’s research, however, is that it points out that every place has its history, and the history leads to different regional capacity and possibility. An analysis of the spatial logic of the emergence of new industries thus has to consider historical contingency.

Between EE and EEG, there is thus a clear difference in terms of research agenda. Evolutionary economic geographers investigate how place dependence (as a form of path dependence) shapes the trajectory of economic development, an issue that is largely absent in the scholarship of evolutionary economics. Such a unique research focus reflects an important theoretical stance that has been widely accepted among human geographers: that space and place are not just stages upon which activities and events occur, but also (and more of) driving forces that bring about social, economic, political, and cultural transformations.

Within geography, EEG is often seen as a critic to *institutional economic geography* (IEG), which also studies the spatial logic of industry. Researchers regarded institutions as carriers of geographical–historical context and sociocultural product. Ash Amin and Nigel Thrift (1995), for example, use the concept of “institutional thickness” to emphasize the importance of institutional decisions, such as strong institutional arrangements, high level of interaction among institutions, well-defined structure on institution, collective mobilization, and the spatial organization of industries.

For them, the transformation of industrial landscape cannot be understood without attention to instructional transformations. EEG criticizes the concept of institutional thickness for lacking a clear definition and being difficult to measure. In general, there are two main
differences between the two approaches. First, while EEG is concerned about the dynamics of the changing economic landscape during a particular period of time, IEG is less concerned with the issue of change. Second, while EEG emphasizes the importance of the routines of firms (which are shaped by past experiences and learning by doing), IEG argues that communities and territories produce a macro-context, which influences on the routine of firms and guides the firms to work.

Without doubt, attention to history, or inquiries about spatial transformation through time, existed in human geography long before the introduction of path dependence theory. The Marxist turn in human geography during the 1970s had drawn many scholars to the approach of geographical–historical materialism, which views space as the product of historical processes. In the broadest sense, Marxist geographers see an existing spatial structure (e.g., uneven development between the developed world and the developing world) not as a state of equilibrium brought about by some abstract economic laws (e.g., the invisible hands of supply and demand) but as the product of the dynamics of capitalism. David Harvey (1982) and Neil Smith (1984), for example, emphasize uneven development as an inevitable condition under capitalism. To solve the inherent problem of overaccumulation, capitalists have to constantly create profitable terrains for surplus production. This can be achieved through, for example, induced unemployment, technological innovation, immigration, or exporting capital. If all these methods failed, capital accumulation is blocked and capital can be devalued or physically destroyed. The spatial implication of this dynamic is that development in one place is often interconnected with underdevelopment in another place. Yesterday’s boomtown may thus become a ghost town tomorrow (as in the case of Detroit), and previously deprived regions may become new centers of production (as in the case of post-Mao China) or speculation. Along a similar line, Doreen Massey, whose research focuses on the restructuring of industries in postwar Britain, drew attention to the spatial division of labor (Massey 1984). Her main argument was that the economic landscape inherits the legacies of its past development and that these legacies exert an influence on its present and future development.

There exists, however, one profound difference between the ways in which Marxist geographers and evolutionary economic geographers treat history. While Marxist geographers’ concern is the meta-narrative of political economy, many evolutionary economic geographers, as Martin and Sunley (2010) pointed out, build their research upon universal Darwinism, complexity theory, or panarchy theory (Boschma and Frenken 2006; Martin and Sunley 2006). In other words, not all the evolutionary economic geographers are concerned with the political economy.

**Geography’s contribution to path dependence theory**

The relationship between human geography and path dependence theory is not unilateral. While path dependence theory inspires geographers to ask new research questions, geographers have also, in turn, helped shape the contour of the theory. One good example is Martin and Sunley’s (2006, 2010) critique and modification of the basic path dependence model.

The initial path dependence model developed by Paul David and William Arthur was composed of four difference phases: pre-formation, path creation, path lock-in, and path dissolution (Figure 1). The pre-formation phase, also often called multiple equilibria, refers to the situation in which a lot of choices and possibilities are available
Box 3

Within institutionalism, there are also discussions about incremental changes. In *Explaining Institutional Change: Ambiguity, Agency, and Power*, James Mahoney and Kathleen Thelen (2009) argued that significance of gradual evolution of institutions should be considered and the endogenous forces are also the driving force. Mahoney and Thelen viewed institutions as distributional instruments that raise tensions between different groups. Different actors will compete or ally with others to create, maintain, or revise institutions according to their interests. Actors change institutions through four modes of institutional change – displacement, layering, drift, and conversion. The occurrence of these four modes of institutional change is dependent on political context and institution form not only directly induces institutions to change but also shapes the emergence of the type of dominant change-agent and the strategies which the agent adopted.

(or could be discovered). The path creation phase refers to the situation in which a certain path is formed as the result of random events or historical accidents, and along the path new technologies, organizations and institutions are developed. The path lock-in phase refers to a rather stable condition (as the result of network externalities and increasing returns) in which a certain economic system reproduces (or being locked in) the conditions of the chosen path. Lastly, the path dissolution phase refers to the destabilization of the lock-in and the decline of the path as the result of some “external shocks,” such as innovation.

![Figure 1](image-url) The basic path dependence model developed by Paul David and William Arthur. Source: Martin and Sunley (2010).
of technology, competition, or institutional change.

Martin and Sunley criticized the basic path dependence model for being, first of all, not evolutionary enough. They pointed out that, in the basic model, history matters only in the initial stage. The model implies that there would be a state of equilibrium once an economy is locked in certain practices. Martin and Sunley insisted that the evolution of an economy should be seen as a continuous process rather than a series of states of equilibrium. Second, they questioned the presumption that there exists a phase of development that is free of pre-existing conditions (as how the phase of pre-formation was described). Martin and Sunley emphasized that economic structures are always shaped by pre-existing technological structures, knowledge, and competence. Lastly, they criticized the emphasis on the influence of “external shocks,” which, according to the basic model, would result in the decline of a certain path. Martin and Sunley pointed out that the concept of “external shock,” on the one hand, denies the possibility that endogenous forces can also lead to significant changes while, on the other hand, it fails to take into account incremental changes and modifications (which can be endogenous or exogenous).

The alternative model that Martin proposed emphasizes that the environment for the emergence of new technologies and industries can

Figure 2  Regional path dependence model developed by Martin. Source: Martin (2010).
be either constraining or enabling (Figure 2). A constraining environment would often lead to a “static state,” where selected technologies and existing structures and knowledge of the firms tend to last and reproduce themselves until there comes an internal or external shock. An enabling environment, in contrast, would make a selected path more dynamic. Here, Martin elaborated how layering, conversion, and recombination effects would lead to incremental, path dependent evolution and the renewal of industries or technology. The layering effect refers to the addition of new rules to an existing institution, which allows the institution to change incrementally. The “conversion effect” refers to the addition of new rules (or the abolition of the old) that would convert an institution’s original logic of operation. Lastly, the “recombination effect” argues that “any particular existing social-political-economic structure is a system of resources and properties that actors can recombine and redefine to produce a new structure” (Martin 2010, 15).

Martin used the case of the development of the high-tech cluster in Cambridge, UK, to further elaborate the proposition that economic evolution is a process instead of a series of states of equilibrium. In the early 1960s, the Cambridge consultant proposed to recruit academic staff from the University of Cambridge to industry. The result of this action was the development of a high-tech cluster in the region, which includes computing and science instrument, software, and bio-tech companies. The formation of this cluster greatly contributed to the region’s economic growth. Based on this case, Martin argues that path creation frequently emerges from existing industrial regions, which allows innovation to happen. Innovation thus is place-specific and locally contingent rather than accidental or random.

PATH DEPENDENCE

Broadly defined, patriarchy refers to social structures governed by hierarchical power relations that privilege masculinity over femininity, and permit the domination, oppression, and exploitation of women by men (Walby 1990). Derived from the Greek words patria (family) and archy (rule), patriarchy initially referred to the autocratic rule of male heads of household and older men in government. Western, radical, second-wave feminists deployed the concept of patriarchy in critically and politically strategic ways to reveal the universality of a distinct social system that disadvantages all women irrespective of other forms of social stratification. Second-wave Marxist and socialist feminists theorized patriarchy as a product of the overarching social structures of capitalism that govern class and gender relations; while liberal feminists drew attention to the “small-scale” deprivations women experience (e.g., in employment and domestic division of labor) (Walby 1990). Such theorizations of patriarchy, however, have been criticized, not least by women of color, for producing totalizing and tautological effects that presuppose what patriarchy defines, as well as for producing ahistorical and acultural generalizations that overlook nuances and variations in power relations (Kandiyoti 1988). As a consequence, overt use of the term has waned and some of its meaning is now conveyed with terms (such as “male domination,” “sexual inequality,” and “gender asymmetry”) that carry less essentialist conceptual baggage.

In the 1990s anti-essentialist poststructural and postmodern approaches to feminism complicated singular concepts of gender and the dichotomization of gendered individuals into women and men. Critiquing the neglect of differential power relations between women and men, and patriarchy’s inherent heterosexism, these studies also foregrounded the forms of agency women employ to resist systems of male power and to “bargain with patriarchy” (Kandiyoti 1988). The local specificity of such bargaining strategies reveals the way in which patriarchy is entangled with the historical, transterritorial, and transnational processes and particularities of capitalism and colonialism.

Extending out of debates in Antipode initiated by Foord and Gregson (1986), feminist geographical scholarship examines the ways in which patriarchy operates across a range of spatial scales from the body to the nation-state: from the construction of an abstract modern liberal subjectivity to gender inequality in law, as well as constructions of ethnic and national identities. A state can be interpreted as patriarchal in that it is neither hegemonic nor monolithic, but rather a mediator of many powers that shape women’s lives. Within the context of Western liberal nations, secularism emerges as a crucial component of patriarchal state sovereignty by serving as a pretext for the marginalization of communities based on religious background, ethnicity, and race. In Turkey, for example, Arik (2015) reveals how secularist national security discourses work to control the public representation of Muslim women through regulations about “contentious” religious embodiment (e.g.,
Patriarchy

headscarf) and practice (e.g., gender segregation). For feminist geographers, the body remains a significant spatial scale of intersectional analysis that permits an intricate understanding of the insidious ways in which patriarchy continues to operate through the political, social, cultural, and economic institutions of society.

Patterned ground (PG) refers to a collective set of surficial geometric landforms associated with periglacial environments located in polar, subpolar, and alpine tundra locations. Permafrost is not a requirement for PG; however, it may be present at the site. The landforms are classified into five shapes: circles, polygons, nets, steps, and stripes. Typical classification of PG is based on visual inspection rather than determination of formation processes, allowing both relict and active landforms to be categorized and compared. The surface of the landform may be flat or raised above the surrounding surface, either along the edges or in the center—or middle in the case of stripes—of the landform; however, a landform with an elevated center is not automatically PG, as other landforms have raised centers, including frost boils, mima mounds, and hummocks or thufur (see Goudie 2004). PG is categorized into sorted or nonsorted features, with sorted landforms exhibiting a surficial appearance of a progression from the smallest to largest material sorted by size from the center outward, with the inside containing sediment or a combination of small pieces of gravel and sediment, and the outer edges of the landform (sometimes referred to as the “gutter”) containing the largest clasts. Nonsorted features do not exhibit any size organization, with different sizes of clasts and sediment mixed together. The geometric appearance of PG is influenced by the slope of the surface, with a general positive relationship existing between landform shape and its slope: as slope increases, PG features become more elongated in appearance. Circles are located on the flattest slopes, whereas polygons, nets, steps, and stripes will be found, in the order listed, on slopes of increasing inclines. Washburn (1980) noted that nonsorted features may not follow this progression as predictably as sorted features. One of the most well-known examples of PG is in Spitsbergen, an island in the Svalbard archipelago, Norway (78°45′ N 16°00′ E), where sorted circles with raised edges measure 3–5 m in diameter (Hallet and Prestrud 1986). These distinctive large sorted circles were featured on the cover of Science in conjunction with an article on computer modeling PG formation by Kessler and Werner (2003).

Washburn’s (1956, 1980) series of works produced the seminal classification scheme for periglacial PG based on visual inspection of landforms. Washburn’s (1956) goal in creating the original classification scheme was to eliminate duplicate terms and to consolidate the terminology of PG features. He later added further categorization by noting that the features can be classified as “small patterned ground” when smaller than 1 m (Washburn 1980). In the years following Washburn (1980), “miniature patterned ground” was added to further distinguish geometric features measuring smaller than 20 cm. The evolution of this category began appearing in the literature in the 1980s, with Wilson and Clark (1991, 369) finally outlining quantitative parameters defining miniature patterned ground, specifying that landforms have a “mesh diameter or stripe width not exceeding ca. 20 cm.” These parameters are still in use.
today by both alpine and polar researchers to classify the smallest forms of PG, resulting in a three-prong classification scheme to describe PG: (i) shape: circles, polygons, nets, steps, or stripes; (ii) organization: sorted or unsorted; and (iii) size: large, small, miniature.

In a periglacial environment, types of PG encompass a majority of the landforms but are not the only landforms present, as pingos, palsas, and blockfields or felsenmeer are also found in alpine and polar and subpolar regions (Washburn 1956). Geometric landforms found outside of periglacial environments may or may not be considered PG, depending on the researcher. Goudie’s (2004) definition of PG included gilgai (a landform whose process is attributed to the shrink–swell properties of clay), polygons on playas (formed from salt deposits or shrinkage from water evaporation), and brousse tigrée or tiger brush (alternating light and dark bands of vegetation that give the impression of stripes on the surface) all within the suite of PG landforms.

Processes responsible for and that maintain PG are associated with frost action, a general phrase referring to processes experiencing water freezing in the subsurface in response to cold temperatures, including freeze–thaw cycles, needle ice formation, frost weathering, and frost heaving. Freeze–thaw cycles and other processes encompassing the freezing of water are the result of a phase transition of liquid (water) to a solid (ice) with the force of that process driven by the expansion of the water when frozen (to approximately 8–9% greater volume than its liquid state). Frost action is consistently cited in studies involving currently active PG in polar and alpine regions. However, no single process is known to start the initial formation of PG, nor does a single process control all continued appearance of PG. In addition, processes responsible for the formation of PG may not be the same process actively modifying active PG (Washburn 1980).

Consequently, determining why PG initially formed at a location is difficult, as is the length of time PG was present prior to discovery. Washburn (1956) identified 19 possible mechanisms or processes responsible for PG formation; he did not associate a particular type of PG (e.g., sorted circles) with a mechanism. The list included processes associated with the freezing of water (e.g., seasonal frost, frost heaving, primary frost sorting), salt (salt heaving), and water (rillwork). Washburn (1980) elucidated on his original list by categorizing the mechanisms into two basic processes: essential surface cracking and nonessential surface cracking, both of which are linked to sorted and nonsorted PG landforms (Table 1). Surface cracking is caused by the contraction and expansion of the ground in relation to active processes, which may not necessarily be frost-related (e.g., the expansion and contraction of clay). Desiccation cracking is the result of soil drying and contracting, and is associated with small and miniature PG, both sorted and nonsorted features, containing silt and clay (Washburn 1980); however, the amount of either silt or clay needed for activity has not been specified. Seasonal frost cracking has also been associated with sorted and nonsorted landforms (Washburn 1980). Unlike desiccation cracking, silt and clay do not need to be present; however, moisture is required. Frost cracking begins each fall, and on the ground thawing in the spring the cracks may disappear (Washburn 1980), making confirmation of the process difficult.

Freeze–thaw cycles, cryoturbation, and frost heaving have typically been attributed to active nonsorted PG, with only frost heaving specifically mentioned by Washburn (1980) as part of his 19 mechanisms. These three processes are similar to each other as they all involve freezing temperatures, with cryoturbation attributing the churning of sediment or soil, as is seen in cryosols, to nonsorted PG movement. (1980) listed eight processes where surficial cracking was not essential, including frost heaving (Table 1). Within that list, he created subcategories of differential and nondifferential, thereby noting that some processes may occur at unequal rates. Differential frost heaving, where the ground heaves in unequal amounts across a surface on freezing, can explain the uneven heaving of measurement tools such as nail and wooden dowels placed in PG. Additionally, differential frost heaving may be responsible for surficial clasts moving, turning, and becoming buried as the surface expands at different rates, causing sediment on the edges of the expansion to fall to the side or be buried by other sediment.

Processes responsible for PG formation studied by other researchers since 1980 include convective cell movement, self-organized criticality (SOC), and chaos theory. For example, Kessler and Werner (2003) developed a computer model based on SOC to study the hypothesis that sorted circle formation can occur through convective cell movement. Kessler’s and Werner’s (2003) study did not provide the seminal answer to PG formation, nor did it eliminate any of Washburn’s proposed mechanisms; however, the study illuminated a continued central quandary in PG research: the lack of a single formation mechanism.

The study of PG continues today and should be considered a topic with great research potential. For example, the daily, seasonal, or annual rate of movement within PG features is not well documented in periglacial environments, but it should be, considering that the change in the amount of activity of PG in response to climate change cannot be made without knowing current movement rates and condition. In addition, as resolutions of remote sensing platforms increase, the ability to study PG in remote polar and alpine regions over greater temporal scales continues to increase, opening up several avenues of research of PG. The use of remote sensing, specifically multiseasonal imagery, would be a great help to many researchers, as field access to many sites, particularly high alpine locations, is limited during the winter months. The study of PG tends to focus on processes for movement or the amount of activity in PG; however, one key research topic of the future will be the interaction between vegetation and active PG. The interrelationship between active PG and vegetation growth, and establishment is currently understudied, as a majority of PG research occurs in polar and subpolar regions whereas interaction between vegetation and PG is most notable in the alpine tundra, where treeline may advance with climate. Past studies have shown that the movement of
material in sorted and nonsorted PG prevents seedling establishment at the alpine treeline in the western United States. As climate changes, PG in the alpine regions should be observed for the effect its movement has on the treeline, and vice versa (Resler, Butler, and Malanson 2005).

Peace

Sara Koopman
York University, Canada

Peace is all too often understood as being simply not war. It is also,ironically,widely used to justify violence and oppression. Peace for some means pacification through military victory. For others it means free reign for corporations. Yet even if it is defined only as a lack of direct political violence between states, peace is never clearly distinct from war. It is widely argued that, in effect, war is inside peace, shaping everyday political life, institutions, and sociospatial order. But the norms of armed conflict have also changed, and war no longer has a clear beginning or end in time or space, and the lines between civilian and combatant are also increasingly blurred.

Peace, then, is not a separate end point to achieve in time or space. Peace also happens inside war, not only in peace zone enclaves, but in everyday peace building by all sorts of actors. But, whether or not it is made in the midst of armed conflict, peace is always precarious and must be constantly remade.

The hegemonic understanding of peace among elites is of a liberal peace, although the liberal descriptor is rarely used by those who believe that (neo)liberal democracies will not go to war against one another. This belief is closely linked to the idea that (capitalist) development will bring peace. Paradoxically, though, rushed liberalization can be deeply destabilizing.

The growing belief in the “West” after World War II in a liberal peace led to the establishment of peace studies as an academic field. There are now encyclopedias of the field that cover various sorts of peace. The distinction most widely used in peace studies is between positive and negative peace. In a letter from a Birmingham jail in 1963, Martin Luther King Jr defined negative peace as “the absence of tension” and positive peace as “the presence of justice” (King 1991). In peace studies these terms are widely associated with Johan Galtung, who in 1958 founded one of the first and the most well-known peace institutes, the Peace Research Institute of Oslo (PRIO). In 1964 Galtung argued that negative peace was the absence of direct violence, that is, bodily harm, and that positive peace was the absence of structural violence, that is, social structures with life-shortening consequences. Thirty years later Galtung (1996) added a third type of violence, cultural violence, which he defined as the ideas used to legitimize both direct and structural violence. In Galtung’s triangle, structural violence leads to cultural violence, which in turn leads to direct violence. Negative peace is the absence of direct violence (although not the absence of all conflict). Positive peace, Galtung now argues, is the absence of both structural and cultural violence. Ironically, though, even in Galtung’s definition of positive peace, it is defined by what it is not rather than by, as King defined it, the presence of justice or of life-affirming values and structures.

Ideas of a positive peace can even be used to promote a liberal peace and hide an economic liberalization agenda. In 1997 Dietrich and Sützl, working at the Burg Peace Centre in Austria, put forward “A Call for Many Peaces,” in which they argued that the vision of the “one peace” has long been tied to an understanding of development born of the civilizing mission. They write...
that, without being based in “concrete places,” peace is simply an abstraction, and to argue for one peace is an act of intellectual violence that can lead to other violences (Dietrich and Sützl 1997; emphasis added). They imply that peace can be conceived and achieved only on a small scale.

Place and Scale are the classic remit of geographers, and it would seem that such a call would inspire a turn by peace studies to geography. That has been slow to come, but perhaps this is because, until recently, there was not much work in geography that explicitly used the term. Yet geographers are increasingly turning to the study of peace, and making similar calls to understand peace as varied across place, space, and scale, and as shaped in and through the spaces and times through which they are made, as they too shape those spaces.

Even in one place, for one group of people, peace is not a static end point but, rather, is always changing and must be made anew daily. Geographers now write widely of peace as a process rather than a steady state, and of peace as having different meanings across time and place, as Loyd (2012) argues in her useful overview of work in the field. (For an earlier and also essential genealogy of work by geographers on and for peace see Mamadouh 2005.)

Peace is always situated. It is made in some way but also somewhere for some people. Haraway (1992) argues that it is because knowledge is always situated that we need to enter into noninnocent conversations that open us to understanding and alliances with others. Likewise, it is because peace(s) are situated that it is important to draw connections between them to build more just peace(s). Geographers are well placed to connect, as Williams and McConnell put it, situated knowledges of peace. They call for geographers to research more “sites and scales to show how peace is differentially constructed, materialized and interpreted through space and time” (Williams and McConnell 2011, 930).

Does this work actually have to use the word “peace”? Williams and McConnell “propose a more expansive and critical focus around “peace-full” concepts such as tolerance, friendship, hope, reconciliation, justice, humanitarianism, cosmopolitanism, resistance, solidarity, hospitality, care and empathy” (2011, 930). The notion of peace is so contested that other terms are often used instead. Peace is understood not only in an entangled relation to war, but also in relation to the (also contested) concepts of development, security, and human rights.

If peace is broad enough to encompass all of this, it might be questioned whether the term is useful. The danger is that, if the term is left undefined, it is too often assumed as a universal across time and place, and sentimentally idealized as either simply not-war or as all that is good. But the benefit, as Williams and McConnell have argued, is that using a “richer theorisation of peace” as both messier than and more than not-war can, as they put it, “intersect and engage” with research agendas across geography. Loyd (2012), for example, makes a strong argument for geographers of peace to learn from the ways these broad connections are made by the antiviolence movement, and in particular the work being done on and against racial state violence within the United States and Canada.

Framing research in terms of peace allows for a different engagement with scale. Security is traditionally understood to be kept at the national scale, while human security is measured at the individual scale but generally understood to be kept by nations, intergovernmental organizations (IGOs), and nongovernmental organizations (NGOs). Peace, meanwhile, can be experienced as both intimate and global. Peace can be created
at an individual, family, neighborhood, community, and other scales, and use of the term can foster seeing these scales as intertwined.

It may seem odd to turn to geography for peace, for geographers have long offered advice to the prince and justification to the great powers for their colonial exploits. Ó Tuathail (2011) argues that war made geography, and gives a history of how war has spurred the academic institutionalization of geography since the Franco-Prussian War of 1870–1871.

Even so, Ó Tuathail argues that the discipline of geography is not “beholden to battlefields,” even though it has been shaped by them (2011, 478). Many geographers today are resistant to and critical of the discipline’s military ties, but those ties continue to be strong. These have come under greater scrutiny after the Bowman expeditions were accused by research subjects in Oaxaca, Mexico, of not divulging their US military financing, yet the board of the American Association of Geographers (AAG) has voted not to investigate that issue or to form a commission to discuss the relationship between geographers and the military.

Given that the discipline of geography has long been a tool used for violence and domination, it may seem odd to turn to it as a way to study and build peace(s). Yet geography is well placed to study and build peace precisely because war and peace are entangled, and both are inherently spatial. Geography itself can also be enriched by a focus on peace, for if war and peace are intertwined we cannot fully understand the making of space if we focus only on how war shapes space.

After a series of edited collections on war and peace which focused much more on war than on peace, and tended to leave peace undefined, the most recent collection is entitled simply Geographies of Peace (Megoran, McConnell, and Williams 2014), and takes great care to problematize the term.

Geographies of peace can take many forms, but a traditional global map of peace is problematic. Dan Smith (2003) has attempted to map peace over the years in several iterations of his Atlas of War and Peace, which has various versions of maps of war and conflict, overlaid with things like poverty, rights, and political systems – but only two maps of “peace,” limited to negotiated peace processes and militarized peacekeeping. In 2007 the organization Vision of Humanity developed an annual Global Peace Index. It includes an interactive online map that now has 23 indicators, which have changed over the years. Yet both what is tracked, and how, are contentious. Colombia, which ranked 146 out of 162 ranked countries in 2015, exemplifies many of these issues. The number of dead and disappeared in Colombia overall, as well as which to attribute to the conflict, are heavily disputed. It is often not safe to report deaths. The index does not track violence against women, unionists, journalists, or any other targeted violence, such as by sexuality or race. But, then again, even if it did track these, numbers would vary wildly depending on systems for reporting and the safety of doing so. These and other issues with the data are also a concern with arguments that violence has declined globally.

The Global Peace Index has been focused on a negative peace, but did begin to include positive peace in its report in 2015, although this is not yet included on its map. For this purpose, it uses eight indices, including a sound business environment and levels of corruption. It does not track access to food, health, or education. Yet, even if it did, it would be mapping one peace, imposing one definition of peace equally across time and space. These concerns were raised at the 2015 AAG meeting, during two panel sessions discussing the possibility of a future atlas of peace. Creative proposals were presented, including crowdsourcing
online maps that would show various peaces as ongoing processes.

Maps of peace may work best at a small scale, but peace is not necessarily only to be found in the local, nor must it be global. Peace is built both everyday by all of us in all of our interactions, and in high-level international peace negotiations. Peace means different things at different scales, and different groups, and at different times and places. Peace is not the same everywhere any more than war is. When peace is portrayed as a mythical singular, it can become so abstract as to be seen as unobtainable. Or it can become so unspecified that it can be attached to violent pacification. Instead, geographers see peace as a located and spatial process – and, as such, as necessarily plural.

Peacekeeping is a conflict management strategy whereby nonaligned soldiers and civilian personnel are deployed to a postconflict country in order to provide security and, in some cases, humanitarian assistance. On a global scale, peacekeeping is largely, although not exclusively, carried out by forces operating under the auspices of the United Nations, wearing the anti-camouflage blue helmets or berets that signify neutrality. In some ways, peacekeeping is a departure from the original purpose of the United Nations, which was founded in October 1945 under the mandate to prevent wars between states but not necessarily to intercede in civil wars or to engage in nation-building exercises. Peacekeeping operations have been embraced by international powers (especially in Europe, North America, and East Asia) to end hostilities, maintain ceasefires, establish stability, mitigate fallout from regional violence, and distribute humanitarian aid. In several countries in Africa, as well as in Haiti, UN peacekeeping forces have become a semipermanent feature of the military policing landscape. While UN peacekeepers have been instrumental in establishing and maintaining order in several countries, peacekeeping forces nonetheless have come under scrutiny due to accusations of corruption, arbitrary violence, and, in some cases, sex crimes against civilians.

Historically, peacekeeping can be usefully divided into two periods: the Cold War period (1956 to 1991), and the post-Cold War period (1991 to the present).

The Cold War period

The origins of peacekeeping cannot be separated from the great revolutionary movements of decolonization that reconfigured world politics in the 1950s and 1960s. Most peacekeeping missions in the Cold War era were designed to monitor the often violent fallout following colonial withdrawal from newly independent countries. In 1956 the first large-scale UN peacekeeping operation occurred in the aftermath of the Tripartite invasion of Egypt (known in the West as the “Suez Crisis”), where peacekeepers oversaw the withdrawal of Israeli, French, and British forces from the Egyptian Sinai. After the Tripartite Aggression mission UN peacekeepers were immediately deployed in 1960 to the Congo at the request of the first Congolese prime minister, Patrice Lumumba. This large-scale mission monitored the withdrawal of the Belgian colonial forces, and worked to prevent the outbreak of a civil war, in the wake of Lumumba’s murder by Katangan authorities in January 1961. Throughout the 1960s, 1970s, and 1980s, UN peacekeeping forces operated in multiple countries, predominantly in Africa, but also with sizable missions in the Middle East, Central America, and the Caribbean. Compared to the post-Cold War period, United Nations-led peacekeeping operations during the Cold War were occasional and largely focused on preventing interstate conflict. Between 1945 and 1989, 15 peacekeeping operations occurred globally. After 1991 the...
frequency, focus, and conduct of peacekeeping activities changed dramatically; as of December 2014, there were 16 active UN peacekeeping operations worldwide.

**The post-Cold War period**

In the post-Cold War era, peacekeeping operations underwent two distinct phases – conveniently marked by the September 11 terrorist attacks in the United States – in terms of force configuration, the types of institutions involved, and the frequency of operations. As Western capitals celebrated the end of the Cold War and hyped the coming era of economic liberalization and globalization, new interconnected global threats and human insecurities were identified: the rapid movement of rural populations to urban slums; a rise in ethnic cleansing and civil wars; religious extremism; structural poverty; a booming black-market arms and drug trade; organized crime; human trafficking; state instability in the Global South; and the impact of climate change on agriculture and social destabilization (the list is not exhaustive).

In the 1990s novel political concepts were introduced to general publics, like “failed states,” “new wars,” “humanitarian intervention,” and “nation building,” and new industries emerged to tackle global threats, such as nongovernmental organizations (NGOs) and intergovernmental organizations (IGOs) to private security contractors. The geographical imaginaries often employed to conceptualize the post–Cold War “conflict environment” relied on a neo-Orientalist binary, whereby the Global North was framed as an orderly hemisphere of tech-savvy, humanitarian states that could cruise the frictionless processes of globalization to address problems plaguing “failed states” at the frontiers of modern civilization. Despite the neo-Orientalist baggage, peacekeeping was a predominant instrument used in the 1990s by the “international community” to address global instabilities in the Global South. Moreover, peacekeeping became multilateral and “multifunctional” insofar as the remit of peacekeeping moved beyond just monitoring interstate hostilities to integrating “diplomatic, military, and humanitarian activities in an overall political strategy” for intrastate conflicts (Chopra 1996, 355).

Since September 11, the global geopolitical landscape has undergone even more profound transformations, especially in the Middle East, Central Asia, and western, northern, and central Africa – from the acute instability caused by the US–led wars in Afghanistan and Iraq, to the lingering fallout of the 2008 global financial crisis. As Perkins and Neumayer (2008) have shown, not only have the number of the peacekeeping operations increased, but the composition of peacekeeping forces has changed, with the inclusion of intergovernmental organizations, “third-party” missions, and ad hoc “coalitions of the willing” conducting such duties.

The approach to conflict management has also changed with the introduction of new technologies, such as remote sensing and geospatial analysis (Herscher 2014). By allowing operators to analyze conflict conditions at a distance inside humanitarian hubs, advocates claim that such technologies enable more “efficient” peacekeeping and aid operations. Moreover, in recent years, the goals of peacekeeping seem to have moved away from “nation building” toward what the US military calls “stability operations,” which forgo grand schemes buttress central states in the Global South in favor of basic police operations that provide basic security and population control (Hills 2009). In the immediate future, peacekeeping operations will likely continue to rely heavily on
so-called technological solutions, as governments in the Global North continue pursuing austerity measures which affect their ability to put large numbers of peacekeepers on the ground.

Further reading

The term “pedoturbation” refers to processes by which soil is physically mixed or disturbed. Although its chief cause would seem to be biological, in the form of digging animals and falling trees, a diverse range of processes can actually lead to soil mixing, many of which are abiotic. Indeed, soils can be mixed by a wide variety of vectors, such as freeze–thaw and shrink–swell activity, seismic shaking, slope failure, and even exploding bombs. And although, historically, pedoturbation has been associated with profile simplification, it is now viewed as a process that does not always destroy but may sometimes form and maintain genetic soil horizons. Although long underappreciated and only minimally studied, pedoturbation is a measurable process in almost all soils, and has important consequences for soil genesis, properties, and behavior.

Expressions of pedoturbation

In its various forms, pedoturbation is studied either by observing the process (such as termites digging tunnels and, in so doing, moving soil particles) or by examining and interpreting the end products of pedoturbation within the soil itself. Signatures of pedoturbation are primarily expressed as within-profile, morphological imprints and as surface topographic features. Within-soil expressions include slickensides, fecal pellets, microfabric alterations, stone lines, broken and disrupted soil horizons, and open and infilled burrows (krotovinas). Because many forms of pedoturbation cannot effectively move larger fragments upward in soils (with tree uprooting and freeze–thaw activity being the major exceptions), they tend to settle and become concentrated at the lowermost depth of the process, as a stone line or zone. This type of depth distribution of coarse fragments is commonly used to infer long-term pedoturbation in the upper parts of a soil. Surface expressions of pedoturbation occur as microrelief such as gilgai, tree-throw mounds and pits, ant and termite mounds, patterned ground, and depressions associated with caved-in krotovinas.

Agents of pedoturbation

Types of pedoturbation are identified by the vectors that cause them. The list of such vectors, originally compiled by Hole (1961) and expanded on by Johnson et al. (1987), includes faunal- (animals), floral- (plants), gravi- (soil movement under gravity), congeli- or cryo- (freeze–thaw cycles), argilli- (shrinking and swelling of clay minerals), seismi- (earthquakes), aero- (passage of air, wind), aqua- (passage of water through soil), crystal- (rupture by growth of salt and other types of crystals) and impact- (comets and meteorites) turbation. To these, Hupy and Schaetzl (2006) added bombturba- tion. Normally, the term bioturbation is given to mixing by biota, including plants and/or fauna.
Bioturbation has received more attention than perhaps all other forms of pedoturbation combined (Wilkinson, Richards, and Humphreys 2009). Each of these agents/vectors may be prominent in some environments and negligible in others.

In most cases, pedoturbation is associated with increases in soil volume and porosity, and with concomitant reductions in bulk density. Positive feedback can readily be imagined, especially with respect to bioturbation — as habitation opens up the soil, rendering it even more habitable for bioturbators. Synergy of other kinds, between various pedoturbation vectors, may also occur, for example, the combination of high precipitation, steep slopes, deep weathering, and giant trees in the humid tropics results inevitably in isotropy or haploidization — minimal differentiation of the soil profile into recognizable horizons (Hole 1961). The following sections briefly cover some abiotic processes of pedoturbation, eventually focusing on the role of bioturbation, given the prime function of soil as terrestrial habitat for biota. Biotic processes also include past and future human activities, which disturb soil for better or for worse (anthropoturbation).

Abiotic processes

Although bioturbation is the most commonly viewed and studied form of pedoturbation, many other forms also exist, and most of these are abiotic in nature. For example, in graviturbation, soil moves from elevated upland positions to bottomlands by piecemeal erosion or mass movement processes. This movement can be imperceptibly slow (as surface wash and soil creep) or catastrophic (in the form of debris flows and landslides). Any degree of mixing can occur during these processes. The end results of such mixing are evident in the colluvial or alluvial end products near the bottom of slopes. Textural sorting may be evident here, although not easily distinguishable from that of animals. Mass movement can also be triggered by seismic activity, in which case it is considered a type of seismiturbation.

Climate is an important mediator in all forms of pedoturbation, even the abiotic ones. For example, the flow of water on and within soils can mobilize the solid constituents within, causing mixing. Water is an agent of volume change in soils, as enacted by the swelling of wetted clays or the expansion of ice crystals. It is also a generator and concentrator of salts through weathering, leaching, evaporation, and crystallization. Soil mixing caused by the growth of such crystals is called crystalturbation. The pedogenic development of Vertisols is a celebrated example of abiotic pedoturbation by the expansion caused as smectite clays wet up (Jackson 1965; Southard, Driese, and Nordt 2011). In wet dry climates, such soils undergo many cycles of wetting and drying, causing volume changes and churning of the soil profile; this form of pedoturbation is called argilliturbation.

Abiotic influences on pedoturbation are also, in turn, mediated by biota. Rates of infiltration, for example, are affected by faunal burrowing, and by vegetation cover which reduces raindrop impact. Less surface runoff means reduced sheet erosion, but it also makes mass movement more likely because of the increased incidence of saturation.

Biotic factors

Floralturbation (soil mixing by plants) is largely accounted for by the mixing that occurs when trees are uprooted (Hole 1961; Schaetzl et al. 1990; Šamonil, Kral, and Hort 2010). In this case the real agents are wind and gravity, with the tree itself playing a passive role. Trees tear up
soil as they uproot, often forming a pit at the former location of the roots, and an adjacent mound, located where the soil slumps off the roots. Soil materials within the mound can be extremely mixed, although in some cases, they are simply overturned in a more or less intact manner (Schaetzl 1986).

A spectacular example of tree uprooting can be observed where rainforest occurs on bauxite terrain in the interior of Guyana. Here, to a depth of about 2 m, the soil consists of a friable brown earth containing abundant, angular, disoriented fragments of saprolitic bauxite (Figure 1a), below which the saprolite shows an inherited jointing pattern, indicating preservation in situ. When wet, the tree canopy becomes top-heavy and the anchoring substrate loses much of its coherence, needing only a light breeze to topple the trees and tear up deep bauxite fragments. The disorganized morphology of the upper bauxite profile is therefore often attributed to uprooting. Loose surface gravels above hard laterite in the ancient jarrah forest of the Darling Range in Western Australia are possibly due to a similar mechanism, in which the laterite cap is progressively broken up by roots of falling trees (Figure 1b).

In southern Africa, a noteworthy accessory agent of floralturbation by uprooting is the elephant. In pushing trees over while foraging, elephants indirectly create a surface armoring of uprooted gravel in terrain with pedogenic calcrete (Figure 1c). The surface armor forms as the uprooted soil slowly erodes, leaving the coarse fragments at the surface as a lag concentrate. This example shows how flora and fauna may combine to mix soils, as well as illustrating that most soil processes are both biotic and abiotic in nature. The way in which animals interact with the plants on which they forage has many examples, especially among rodents and pigs which burrow for roots, bulbs, and truffles. Some rodents, such as North American gophers and Southern African mole rats, live below-ground in large family groups and have extensive tunnel networks. The constant bioturbation they cause is easy for the casual observer to miss.

**Figure 1** Examples of floralturbation by tree uprooting in contrasting environments. (a) The top 1 m of lateritic bauxite profiles in the Kopinang district of Guyana consists of randomly broken bauxite fragments mixed with a friable, earthy matrix. (b) Roots of fallen giant jarrah trees (*Eucalyptus marginata*) in the Darling Ranges, Western Australia, exhume large fragments of the laterite hardcap. (c) The combined effect of animals and plants near Lake Etosha, Namibia. Thorn trees (*Vachellia* sp.) pushed down by foraging elephants break up the pedogenic calcrete layer, eventually leading to armoring of the soil surface with limestone fragments. (Photos by Martin Fey.) *Continued opposite.*
Figure 1  Continued
Floralturbation is not always passive. The emergence of seedlings and the growth and death of plant roots are examples of active floralturbation processes, even though their scale is small compared to that of tree uprooting.

Faunalturbation (soil mixing by animals) is perhaps the most conspicuous category of soil mixing, with the greatest diversity of expression. Every continent has its own evolved assemblage of small and large animals that either live underground or dig, burrow, and scratch in the soil for various purposes, for example worms, insects, spiders, snakes, frogs, birds, and mammals (Johnson et al., 1987; Fey, Milewski and Mills 2010; Fleming et al. 2014). Quite likely, the largest overall amount of faunalturbation is produced by smaller animals, especially earthworms, ants and termites (Figure 2) – an observation that even Charles Darwin (1881) noted. Associated with the activity of these smaller fauna are the burrowing and nutrient-cycling effects of larger animals that prey on them. Their digging is additional to that of animals that forage for vegetable matter and of still others that simply make their home in the soil.

Figure 2  Termite mounds on an open grassy dambo (marshland) in northwestern Zambia (photo reproduced by permission of Tamara Knudsen).
Mima mounds are a famously controversial surface expression of bioturbation. Named for the Mima Prairie in Washington State, United States, Mima mounds are dome-shaped earth mounds, often >2m high and 10–50m in diameter (Figure 3). They are widespread on many grassland landscapes and can cover vast acreages at densities exceeding 100 ha$^{-1}$. Mima mounds occur only on soils shallow to bedrock or a subsurface pan, such as a duripan, or in soils that have high water tables (Horwath Burnham and Johnson 2012). The origin of these features has long been controversial, and many have attributed their formation to abiotic processes. Modes of origin include wind and water erosion of intermound lows, sediment accumulation at the sites of individual plants (shrubs or clumps of grass), trapping eolian or fluvial sediment, and paleoperiglacial origins, like Arctic stone circles, in large part because areas between the mounds were often bare of vegetation and strewn with large rocks. The fossorial rodent hypothesis of Mima mound origin, widely accepted today, was in fact once ridiculed. In this hypothesis, Mima mounds are formed as pocket gophers or similar burrowing rodents, for example moles or tuco-tucos, tunnel outward (not so much downward), pushing soil material behind them and building up a mound. The mounds serve as nesting chambers in the thin or wet soils, providing the increased soil thickness necessary to protect them from predation, winter cold, or high water
tables. Because these animals are so territorial, their mounds come to be located almost in perfect, regular arrangements on the landscape. Where soils are thick, gophers are not restricted in siting their nests; thus, they move from place to place, burrow more deeply, and mounds per se are not formed. Between the mounds one commonly finds a zone where soil is thin and rocks are numerous; the rodents have removed the soil from these areas. The mounds contain small stones only, equal to the size that the rodents can carry upward. Stone lines containing stones too large for gophers to move (>≈6 cm diameter) commonly underlie and ring the mounds. Thus, the mounds are essentially overthickened biomantles formed by point-centered burrowing (Horwath and Johnson 2006).

Mounds similar to Mima mounds are conspicuous over large areas of the African continent. In South Africa they are locally known as _heuweltjies_ (Afrikaans) or _isiduli_ (Zulu), and termite activity seems to be central to their formation (Fey, Milewski and Mills 2010), although, as is the case with Mima mounds, more than a single factor may be involved (McAuliffe et al. 2014).

Bioturbationally mixed parts or layers in soils are referred to as biomantles. Usually, a biomantle represents the upper part of the soil that is or has been thoroughly mixed and disturbed by biota (Johnson, Domier, and Johnson 2005). The idea of the biomantle was perhaps first introduced (but not named as such) by Charles Darwin (Johnson 2002). Johnson, Domier, and Johnson (2005) have argued that the role of animals in soil formation has until quite recently been underestimated because of the agricultural orientation of soil science. Especially useful is their honing of the concepts of proisotropic and proanisotropic pedoturbations, giving rise to regressive and progressive expressions of soil development, and resulting in soil profiles becoming either haploid (simple) or differentiated (horizonated), respectively.

It is appropriate to include all types of human activities in the category of faunal turburbation. Human actions include the ploughing and draining of farmland, diverse urban excavations and cut and fill operations, mining and reclaiming of mined lands, and various land-use practices that accelerate soil erosion. Some of these activities can fall under the rubric of pedoturbation. Anthrosols and Technosols are two groups of soils defined in the World Reference Base for Soil Resources (FAO 1998), that accommodate soils with properties markedly affected by human activity, some of which would involve mixing or anthropoturbation. The human factor may also have operated negatively with respect to bioturbation, because much human activity has led to a decline in the number and species of animals, that is bioturbators, in most environments.

### Consequences of pedoturbation

Of all the effects which soil mixing and disturbance produce, perhaps the most important involves soil structure and, more specifically, its corollary, soil porosity. Soil without pores would be lifeless. Porosity, pore size distribution, and the connectivity of pores all contribute to life-sustaining functions of soils such as the infiltration, storage, and discharge of air and water, including both nutrients and gases that may be either necessary or harmful. Furthermore, the penetrability of soil by roots and burrowing animals is mediated by porosity, which imparts a softer, more friable consistence to soils, especially finer-textured soils. Some clay soils such as Oxisols are highly porous. Others, such as Vertisols, are dense, compact, and deficient in functionally useful pores, except for either extremely fine ones that inhibit water
uptake by plant roots, or wide transmission cracks that allow rapid water infiltration into dry soil but close up soon after wetting. In Oxisols, porosity generated by the deep burrowing and construction activity of small fauna, especially termites and ants (Reatto et al. 2009), is preserved through a combination of soil climate and clay mineralogy which results in minimal shrinkage and swelling, and negligible clay dispersion. In Vertisols and related clayey soils, mixing by swelling and clay dispersion (argilliturbation) likely combine to destroy larger soil pores not long after they have been generated via bioturbation. Shrink–swell cycles also create ephemeral porosity in the form of spaces between peds, which are most evident when the soils are dry.

A number of other, secondary consequences of soil mixing also stem from the development of soil porosity. Many of these take the form of feedback loops, through which pathways of development, having crossed a pedogenic threshold, become increasingly divergent. The clay minerals that characterize the Oxisol–Vertisol catena derived from mafic rocks in tropical landscapes are promoted by the flushing of silica and bases from the Oxisol and the accumulation of these solutes in the Vertisol (Jackson 1965). In considering the chemistry of such pedogenic divergence, it might be interesting to assess the contribution made by pore-initiating soil biota.

Pedoturbation has other interesting consequences. In agriculture, there is increasing awareness of the fuel-saving and soil structure-preserving benefits that may accrue from minimal tillage or no-till farming. In reality, soil tillage does not cease with no-till farming; it continues, but in the form of biotillage, driven by bioturbators and fueled by crop residues. Worms and other soil fauna do the work of tractor and plow. In repairing landscapes disturbed by mining, the long-term stability of restored vegetation hinges on the extent to which a new ecosystem can be established, including soil organisms, especially burrowers that can counter the effects of human-induced soil compaction. Water yields from catchments are affected by faunal pedoturbation, including preferential subsurface flow through krotovinas. The ways in which bioturbation affects land use and ecosystem function are reviewed by Wilkinson, Richards, and Humphreys (2009). The development of subsurface stone lines below a biomantle, as is so common in many landscapes (Nye 1954; Johnson et al. 1987; Figure 4), is of special interest to archaeology because human artifacts are often included in these stone lines.

Other consequences of pedoturbation in its broader sense are those of an engineering nature. Landslides produce characteristic soil morphology that can serve as a warning to builders. Slickensides, cracks, self-mulching, and gilgai microrelief are all indications that the site may be unsuitable for construction due to argilliturbation. And the presence of cryoturbation (frost heave) may sometimes also be revealed by characteristic spatial patterning (Johnson et al. 1987).

Theoretical considerations regarding pedoturbation

For decades, soil science has focused on how pedologic order (anisotropy, soil horizonation) can evolve from sediments that were initially disordered, isotropic parent materials such as loess or dune sand, or ordered, anisotropic ones such as stratified alluvium. Parallel to this, the notion that pedoturbation is a regressive soil process – one that blurs soil horizons or prevents them from forming – has also been historically
Figure 4  Stone lines marking the boundary between the fine earth-textured, humus-rich biomantle above, and underlying B horizon containing weathered saprolite. The soils shown here are both derived from gabbro on the Nolangeni Mountain near Kokstad, South Africa. Buried artifacts, originally left on the surface by paleo-peoples, are lowered by bioturbation and thus are commonly encountered in such stone lines. (Photos by Martin Fey.)
PEDOTURBATION

dominant. Few studies prior to 1960 concluded that pedoturbation can actually create, or even preserve, the anisotropy that often directly results from pedogenesis. Thus, pedoturbation has traditionally been viewed as a process that destroys horizons or that acts to slow or reverse horizon-forming processes.

Current research has found, however, that pedoturbation can also form horizons, or at least be neutral with regard to horizonation processes. Thus, Hole (1961) and Johnson et al. (1987) classified pedoturbation into one of two categories: proisotropic or proanisotropic. The former term implies a condition tending toward (pro) isotropy or disorder, while proanisotropic pedoturbation means a tendency toward layering and order. Proisotropic pedoturbation disrupts, blends, or destroys soil horizons and geologic layers, or impedes their formation. When this type of pedoturbation dominates a soil, a morphologically simplified profile evolves from a more ordered one. Proanisotropic pedoturbation forms or maintains soil horizons and geologic layers, usually causing an overall increase in profile order.

Seldom are pedoturbation processes entirely proisotropic or entirely proanisotropic. Instead, they usually have elements of both, with one form of pedoturbation often being more strongly expressed than the other. Most soils have components of each of these two sets of interacting processes. The balance between the two ultimately determines the morphological makeup of the soil. For example, earthworms may mix organic litter into the A horizon, and in so doing blur the two horizons – a proisotropic phenomenon. But, by doing this, the worms thicken the A horizon at the expense of the litter layer above, thereby promoting horizonation – a form of anisotropic mixing. The expression of this suite of processes is a soil with a slightly thicker A horizon.

Conclusions

Soils are constantly in a state of flux. The flux can be turbulent and catastrophic, but for most of the time and in most places it is barely perceptible, permitting stable anchorage for the growth of plants, shelter of animals, evolution of ecosystems, and the emergence of prosperous agricultural communities. And yet, in such settings, pedoturbation of various sorts may be ongoing almost continually, although usually unseen, below the surface, and in the background. In other landscapes, such as those grasslands where Vertisols dominate, or the tundra where evidence of frost churning is everywhere, the importance of pedoturbation is clear, omnipresent, and less likely to be underestimated.

Normally, pedoturbation rejuvenates and refreshes the soil. Only rarely does it constitute a hazard. Future research could profitably explore the extent to which the soils we study owe some of their attributes to pedoturbation. These attributes may disappear if the flux is not maintained or may have done so already because pedoturbation has ceased. On the other hand, traditional soil tillage may be seen as a substitute for natural pedoturbation but it may in the long run be insufficient to maintain the soil porosity needed for profitable agriculture.

Periglacial processes and landforms

Forrest D. Wilkerson and Ginger L. Schmid
Minnesota State University, USA

The term “periglacial” was first used to describe a variety of landforms that existed in cold climates within the Carpathian Mountains of central Europe (Lozinski 1909). The term refers to landforms that develop near or surrounding glacial environments and originally concerned landforms thought to be influenced and created by glacial climates. It was quickly realized that periglacial landforms can and do develop in numerous localities that are not necessarily located anywhere near glaciers or permanent ice fields. The formation mechanisms that create periglacial landforms are complex, multi-faceted, and to a large degree still poorly understood. The one unifying factor is the requirement of cold temperatures combined with a warmer summer season that allows for numerous freeze-thaw cycles. The majority of periglacial landforms are located in arctic, subarctic, and cold alpine areas where conditions are wet enough for the formation of ground ice, but dry enough to preclude the formation of glacial ice. There are of course exceptions where patterned ground has been documented as forming beneath glacial ice and exposed only as the glacier retreated (Washburn 1956).

As research concerning these landforms began to grow, it was realized that there are numerous landforms that develop in cold temperatures and that the processes that lead to the development of these landforms is complex and often poorly understood to this day. In addition, a variety of researchers began to name these landforms in terms that made sense to their particular language and research background. The nomenclature became so complex and convoluted that it became a serious burden to geomorphologists and other Earth science researchers. The first attempt to streamline the confusing nomenclature occurred in 1933 and this effort was followed by Troll’s (1944) excellent synthesis of the geographic variations, distribution, and variety of formation mechanisms for periglacial landforms. However, it was not until Washburn’s seminal paper was published (1956) that the confusing nomenclature was formalized into a classification system that is still widely used today. Washburn’s paper reduced the confusion and standardized the terminology used for each of the numerous landforms he described (56 landforms). In addition, the processes that lead to the development of these landforms were also described and discussed (19 processes). Only the most significant landforms and processes described by Washburn are discussed in this entry.

Modern investigations understand the complex nature of periglacial landform development, including the concept that the landforms are polygenetic. This term refers to the creation of similar looking landforms being developed by different processes as well as different looking landforms developing through similar processes. The type, number, and activity level of each individual landform is highly dependent upon the presence or absence of water, number of freeze-thaw cycles and depth of freeze penetration, the presence or absence of permafrost, and the depth of the active layer. In the Northern

The International Encyclopedia of Geography.
DOI: 10.1002/9781118786352.wbieg0480
Hemisphere, periglacial landforms are more likely to be found on slopes with a north to northeast facing aspect, within soils containing enough fines (primarily silts and clays) to hold moisture for longer periods, sufficient precipitation, and enough freeze–thaw cycles to allow for the sorting and development of landforms.

The presence of permafrost, ground that is frozen for at least two summers and the intervening winter, is also very common in periglacial landscapes that are presently active. Patterns are also more likely to develop in depressions and shallow ponds that tend to pool water and are wet when the winter freezing front penetrates to depth. It is generally understood that the 9% expansion of water as it changes phase from liquid to ice is the driving force for the inception, development, and maintenance of periglacial landforms.

The majority of periglacial landform formation processes that lead to the inception and development of periglacial landforms have been reviewed (e.g., Washburn 1956; Kessler and Werner 2003; Hallet, Sletten, and Whilden 2011). A useful example can be found in the development of sorted patterned circles. Water in liquid form can migrate through soils by capillary action toward a freezing plane. The freezing plane is usually the base of a stone or boulder that lies within a nonfrozen soil matrix. The stone is denser and will freeze before the soil due to insulating pockets of air contained within the soil. The capillary movement is driven by vapor pressure gradients and can actually occur in soils whose temperature is as much as \(-2^\circ\)C. The liquid water freezes instantly upon contact with the already frozen boulder and begins building an ice lens. As the lens expands and grows through time, the boulder is heaved from the ground and the sorting process begins. The freezing and 9% expansion of water stands out as the primary mechanism for the implementation and development of landforms, but many other factors influence the final landform type and many of these processes appear to be present but as of yet have not been proven. For example, sorted circles appear to be created by convective currents that develop within the soil profile. However, true convection has yet to be proven and others claim that, rather than convection, freezing segregates the larger clasts and forces them to the sides of the pattern. Once all of the larger clasts are separated, the freeze–thaw process no longer sorts any material and the landform is considered to be fully developed.

Even in extremely cold environments, periglacial landforms do not develop everywhere. Stable surfaces are necessary to accommodate the slowly developing landforms. Snowfall is also a significant factor, where too much snow, particularly at the beginning of winter, will insulate the ground and prevent deep freezing, and too little results in inadequate moisture for sorting to occur. Late season snowfall also can help to insulate the frozen ground and preserve the landforms rather than allowing the summer thaw to penetrate deeply enough to melt the permafrost. Coarse soils also have difficulty maintaining enough water to allow sufficient ice expansion when winter freezing occurs. Pockets of fine materials often lead to sporadic landform development and remarkably different rates of activity over very short distances (Wilkerson 1995). In most landscapes containing periglacial landforms, subtle differences in microclimate lead to the development of classic landforms in one area and the complete lack of landforms in adjoining locations (Washburn 1980).

The complexity of periglacial landforms is demonstrated by the diversity of landform distribution and location. Most periglacial landforms are located in the cold dry climates of the Arctic, particularly in northern North America, Europe, and Asia. However, numerous mountain ranges...
in the mid latitudes also have the same types of climate as the High Arctic and contain a number of similar landforms. Landforms can also be found at sea level in high latitude environments, but are also found on the equator in high alpine environments. Troll (1944) provides an excellent and thorough description of the landscapes where patterned ground develops and the types of landforms that develop in each area. The concept of macro-patterns, those greater than 2 m in diameter, and micro-patterns, with diameters less than 1 m in diameter, were defined and described. Activity rates within these macro- and micro-scale landforms vary within landforms in certain mountain environments, with macro landforms being relict and micro landforms nested within the larger landforms showing high rates of activity (Wilkerson 1995).

Washburn’s (1956) classification included 56 distinct periglacial landforms. Only a few of these can be specifically addressed here. In general, these periglacial landforms can be separated into two broad categories of sorted and nonsorted patterns. Nonsorted patterned ground includes symmetrical circles, polygons, nets, and stripes, as well as, ice, sand, and soil wedges that are fairly common in arctic environments. The majority of nonsorted patterns are bordered by slightly raised or depressed soil ridges and not by sorted stones. Different types or amounts of vegetation also often define the borders of nonsorted patterns, which give the pattern its characteristic shape. Solifluction lobes and nonsorted circles, polygons, nets, and stripes are often created by freeze-thaw segregation which allows either a raised or depressed border that can contain denser vegetation, or often different species of vegetation, that form the pattern border. Interestingly, nonsorted patterns usually develop within a soil matrix that contains a variety of different sized material, but boundaries are created by contraction, expansion, and soil mounding rather than by sorting (Washburn 1956). As an example of the complexity with periglacial landform development, ice, soil, and sand wedges are known to rarely exhibit signs of sorting; however, sorted stones have been noted within the borders of some of these landforms.

Sorted patterned ground requires the presence of a soil matrix that contains at least two different sizes of material. Sorting involves the separation of larger and smaller particles and the segregation of larger particles usually to the outsides of the pattern. On flat ground, this sorting produces sorted circles that can be remarkably beautiful and uniform (Hallet and Prestrud-Anderson 1986). As slope angles increase, the circles are stretched into polygons and nets, and if slopes are steep enough, sorted stripes are the result (Figure 1).

As with many periglacial landforms, there are exceptions. For example, stone pits form as opposite or mirror image landforms where the larger stones are forced into a center area or pit and the finer materials surround the central pit. The sorting process and the resulting formation of sorted patterns has been excellently modeled by Kessler and Werner (2003), who eloquently describe the number and property of freeze-thaw cycles that are needed to produce identifiable landforms.

Pattern development, or self-organization, is common in many areas that are considered periglacial environments. In the formation of periglacial patterned ground landforms, self-organization is produced by the repeated freezing and thawing of the soil matrix. This physical process sorts the larger stones by heaving them from the ground and forcing them to the sides of the landform. The heaving is driven by the expansion of ice lenses as water freezes and is spatially differential in nature due to the ability of finer sediments to hold more water within their soil matrix. This heaving process produces
Periglacial sorted circles and polygons formed on a low angle surface (foreground) and stretched into nets and stripes on steeper angles (background) in the White Mountains of California (photo by author).

Sorting and results in a pattern where larger stones define the borders and the interior of the pattern consists of finer material, primarily small gravels, silts, and sand.

Ice, sand, and soil wedge polygons develop in very cold climates where winter temperatures often reach lows approaching or exceeding $-40\,^\circ\text{C}$. As the ground freezes, it contracts to the point where a split or crack develops along a failure plane. Thawing at the surface allows liquid water to flow into the crack and freeze against the still frozen deeper layers, which forces the wedge to widen and grow by accretion. In drier climates, sand or soil will often drift into the crack and fill the void. The crack continues to widen through subsequent winters and continuing deep freezing cycles. In uniform soils, cracks will often develop at $120^\circ$ angles and will through time develop into distinct polygonal patterns. Eventually, the cracks can grow to be a meter wide or larger at the surface and taper down until they pinch out right at or just above the permafrost layer. These often intricate and beautiful landforms are common along arctic coastal plains in the Northern Hemisphere and are usually found in poorly drained marshy environments.

Solifluction is the slow downhill movement of saturated soils due to gravity. Solifluction occurs in soils underlain by seasonally frozen ground,
while gelifluction is a specific type of solifluction that forms over permafrost layers. These landforms develop on shallow slopes and move at rates measured in millimeters to centimeters per year. They are usually nonsorted, but can occasionally develop stone banked lobes along the front of the landform. Solifluction lobes are relatively common in both arctic and high alpine environments and relict landforms often leave behind a series of distinct terraces. In certain environments, sorted patterns develop on the treads of the lobes and the risers contain stripes due to their steeper topography.

The pingo is an unusual ice-cored landform that is found primarily in arctic environments. Liquid water migrates through capillary action to the freezing core of the pingo. The core grows through the accretion of ice and forms a mound or small hill as it develops. The soil on top of the ice core acts as an insulating layer and prevents the ice core from melting. If the pingo grows to the point where it ruptures the overlying layer of insulating soil, warmer conditions often penetrate into the ice and melt the core, which leads to the demise of the landform. Pingos require the presence of permafrost to keep liquid water near the surface and provide a source for the continued growth of the core.

Pingos can be open or closed. Open-system pingos develop where water drains from an elevated source and feeds the growth of the pingo through gravity. Closed-system pingos primarily develop in drained marsh or pond areas where water lying on top of the permafrost layer is added to the pingo through hydrostatic pressure. The palsa is a landform that is somewhat similar to a pingo, though usually much smaller and more often associated with peat bogs rather than drained lakes or gravity-fed soil water. Ice lens development forces the peat upward, forming a distinct mound. The pingo is a distinct landform and similar looking landforms have been noted on the surface of Mars. This suggests that similar mechanisms, whether open or closed, are occurring there.

Climate change and periglacial processes

Climate change, particularly warming, has already had a noticeable impact on permafrost and periglacial landforms in low elevation environments of the Arctic. The permafrost layer of the Arctic is melting noticeably, which has a direct impact on future climate change and periglacial activity. As the permafrost melts, large amounts of methane are released, which produces a negative feedback for continued warming. Melting permafrost also removes the ability of the ground ice to keep liquid water near the surface during the early winter freeze-up. Freezing and ice expansion are the driving mechanisms for the majority of periglacial landforms. Well-drained soils tend to be moisture poor and therefore do not allow the added expansion of ice during re-freeze. If enough warming occurs, the number and depth of freeze-thaw cycles will be compromised and landforms will cease to be active. In certain alpine environments water seems to be more significant than temperatures, as long as freeze-thaw cycles are maintained. If climate change reduces precipitation or significantly impacts the water balance of a periglacial environment, the lack of sufficient water during re-freeze will have a direct impact on the rates of activity and in some cases will lead to periglacial landforms becoming inactive or relict. If climate warms enough to significantly reduce the number of freeze-thaw cycles and the depth of freeze penetration, then all periglacial activity will cease in that particular environment.
PERIGLACIAL PROCESSES AND LANDFORMS

The next frontier: extraterrestrial periglacial environments

With the advent of advanced satellite-based remote sensing, periglacial landscapes can now be monitored in one location and compared with other cryosphere environments. Comparisons can now be made between Earth and the surface of Mars, where it is now known that there are numerous landforms that resemble many of the patterned landforms found on Earth (e.g., Soare, Conway, and Dohm 2014). A number of researchers have documented landforms that resemble ice wedge polygons, pingo fields, collapsed pingos, and possibly even patterned ground. The presence of periglacial landforms on Mars suggests that similar processes are occurring on the surface of that planet as well. These processes are either physically similar to earth-based processes or mimic those found on Earth. It also suggests that freeze-thaw processes, most likely occurring with water but potentially occurring in other substances such as carbon dioxide, are also continuing to impact the surface of Mars.

History

The first mention of permanently frozen ground comes from Siberia, Russia. The first written text dates back to 1598 and the first report documenting its occurrence comes from Yakutia by Tatishchev in 1725. M. Lomonosov in 1757 gave its first scientific description. In 1837 a 116.5 m deep shaft was excavated in a permafrost layer in Yakutsk. The temperature measured there showed the thermal regime of the frozen ground for the first time. The first mammoth body, preserved in the frozen sediments of the Lena River, was discovered in 1799 and caused a sensation on being brought to St Petersburg. Work of M.I. Sumgin, published in 1927, is considered to be the first synthetic description of permafrost. Leonard Jaczewski was the first to establish the southern boundary of permafrost in Siberia and differentiate it into mountain and Arctic permafrost in 1889.

Definition

Permafrost is a thermophysical condition of the lithosphere (rock or soil), the temperature of which is equal to or lower than 0°C for a period of at least two subsequent years, along with the summer season dividing them. In terms of the encompassed area it is the most important component of the Earth cryosphere.

Permafrost is defined on the basis of the substratum temperature and its duration. This means that it is not an object or an Earth surface form, but physical state (Figure 1). As such, it is a direct subject of geophysical research, since the only direct measurement to be applied to permafrost is the measurement of temperature. It is expressed in Celsius due to the important role of water, which usually accompanies the occurrence of permafrost; the solid/liquid phase changes in the water generate a series of geological and geomorphological processes. These processes and the accompanying relief forms are the subject of research both for Earth and other celestial bodies. The geosciences refer to permafrost with the term “phenomenon,” which reflects its essence very well as a subject of research that does not have a material form and is only a geophysical feature. This is why it is probably the only phenomenon in geosciences that remains invisible for the observer.

Characteristics

Permafrost is a geological phenomenon. It is formed as a result of climatic impact, in conditions where cooling causes the seasonal accumulation of “cold” to be greater than the seasonal accumulation of “heat”: the depth of ground that freezes in winter is greater than the depth that thaws in summer. The notions of “cold” and “heat” are colloquial references for <0°C and >0°C, respectively; they facilitate the description of the process of formation and
PERMAFROST: DEFINITION AND EXTENT

Figure 1 Thermophysical model of permafrost of a periglacial environment (bold lines) and associated terms used to describe the ground temperature relative to 0°C.

Freezing takes place in the temperature range of ≤0°C.

The most conducive climates for permafrost are freezing and dry climates, specifically continental ones, whereas cold and humid climates with a large amount of precipitation in solid form are appropriate for glaciation.
Permafrost layer

Permafrost occurs in the form of a geophysical layer in the lithosphere inside which the temperature is constantly equal to or lower than 0°C. Its upper limit is usually the surface of 0°C-permafrost table, that is, the bottom of the seasonally thawing active layer. When the permafrost is of relict nature, not connected with the current climate, both from the top and from the bottom it is limited by a 0°C surface, beyond which the temperature is always positive. Since permafrost is not a sediment in geological terms, there is no sedimentological variability in it. It may be referred to as a “climatic deposit;” however, the stratigraphy of this “deposit” comes down to variability in temperature in its entire thickness. This is its primary feature. Secondary features may be the properties of the material encompassed by permafrost: rock type and the presence of various forms of water and/or ice, which influence changes in the solidity of the ground, for example, by water freezing-cementation.

Cryotic state, presence of water/ice

Permafrost that is developing in unconsolidated sediments may contain ice depending on the type of material. Fine-grained materials can contain water and, thus, are referred to as frost-susceptible. Drainage is better in coarse-grained materials and not all pore spaces are filled with water. Freezing causes ground ice to be the major component of permafrost in both fine and coarse grained materials. Its most important types are: pore ice, segregation ice, vein ice, and intrusive ice. As a decrease in temperature to below 0°C does not have to cause, and usually does not cause, full freezing of all water present in the ground, water occurs both in liquid and frozen form within permafrost. Mineralization, water pressure, capillarity, and surface adsorption in the material encompassed by permafrost cause the freezing point to drop below 0°C; this is the so-called freezing-point depression. In soils and loose sedimentary rocks the freezing point can even be several dozen degrees below 0°C. A rock or soil in which the temperature is ≤0°C without freezing occurring for at least two consecutive years is referred to as remaining in cryotic state. Cryotic ground is a synonym of permafrost. Gradual freezing causes cryosuction, causing water to migrate towards the freezing front, where it freezes, forming lenses of segregational ice. Obviously, the presence of water in the form of ice is much more common in permafrost. The ice in permafrost can be:

- a component of the frozen ground, with homogeneous or heterogeneous nature;
- the medium where permafrost occurs.

In permafrost of the periglacial environment, the accompanying ice can be of different genesis and in various volumes. Permafrost contains mainly pore ice, that is, ice formed in the water freezing process. The terms accompanying permafrost cover over 20 different types of ice. The descriptions include types of ice connected with the particular relief forms, such as pingo ice or ice wedges, as well as types formed as a result of the influence of various processes inside the permafrost layer. Its formation process is usually described in geological categories. Formation of pingo ice is similar to magma intrusion into the sedimentary material. The pressurized water may be derived from groundwater flow beneath the permafrost layer or from the expulsion of water from pores ahead of a penetrating freezing front in saturated unconsolidated sediments. A crystalline laccolith of the intrusive ice is formed in this way: pingo ice is referred to as hydrolaccolith. The ice formation connected with the permafrost environment, as specified
above, is homogeneous. Ice formed in a different environment and then transported to the permafrost environment is heterogeneous. It is usually a fragment of glacier: dead, buried ice. It can also be buried river or sea ice. Melting of ice in nonconsolidated sediments during permafrost degradation can be accompanied by ground subsidence. The irregular relief formed this way is referred to as thermokarst.

**Subsea permafrost**

Subsea or offshore permafrost refers to geological materials that have remained ≤0°C for two or more years and that occur on the seashore at or below sea level. It is formed as a result of sea water flooding of a shore encompassed by permafrost or as an effect of the influence of water on the sea bottom. Most commonly it is of Pleistocene origin and was formed when the lowering of water level during glaciation uncovered a shallow continental shelf and allowed it to freeze. Similarly as on the land, the subsea permafrost also does not have to be frozen due to the lowering of the water freezing point below 0°C resulting from the presence of salt or capillary effects in the fine-grained material. Narrow zones of coastal permafrost are present along most arctic coasts, particularly in the East Siberian Sea, Laptev Sea, and Beaufort Sea. Subsea permafrost can extend up to 100 km from the shore. Sea-bottom temperatures on the Arctic shelves reach a temperature of −1.8°C and salinity up to 34 psu.

**Caves permafrost**

The karst forms, caves, can also be encompassed by the occurrence of permafrost. Its presence and development is related to the specific type of air circulation, called chimney effect or Balch circulation, which is based on the inflow of colder, heavier air that sinks to the lowest point and allows the cold winter air to remain during summer. The diversified relief of mountain areas is particularly conducive to this phenomenon. This allows not only for ground freezing to develop for many years but also for the accumulation of underground ice, the genesis of which is sometimes very similar to accumulation of the glacial ice. These are cases that can be referred to as underground glaciation. Such caves can occur in areas where the average yearly temperature reaches even +7°C, but where it is frosty in winter. This circulation type is also noted in sufficiently high mountainous scree slopes.

**Glacial permafrost**

Until the mid-1970s, glaciers and ice sheets were included into the scope of permafrost. Later, the occurrence of permafrost was excluded a priori from the glacial environment. It is obvious that glaciers are encompassed by permafrost. Firstly, their temperature is never higher than 0°C and, secondly, ice is a mineral – and in greater amount, rock – therefore, it belongs to the lithosphere (Dobinski 2011).

Glacial permafrost occurs in the form of the thermal structure of glaciers where “cold ice” and “temperate ice” can be found (Figure 2). Treating “cold glacial ice” as permafrost is obvious, since it has been frozen for many years. “Temperate ice” also meets the requirements of the definition, as its temperature is always ≤0°C. However, as it is at the pressure melting point, it also contains water in the cryotic state. Since the cryotic state is a synonym for permafrost, each ice sheet, ice cap, and glacier is always and fully encompassed by permafrost. This implies that permafrost occurs also under the glaciers.

The volume of ice in permafrost can be very diversified: from almost 0% in freezing magmatic rocks to 100% in buried glacier ice.
or glacial permafrost. In this context the term “dry permafrost” is also applied; this refers to the perennially frozen rocks that do not contain H₂O. Since the ice, by definition, is dry, the term dry permafrost should cover such a state where all the water within the permafrost is...
PERMAFROST: DEFINITION AND EXTENT

frozen. The notion “wet permafrost” could be justified in relation to the cryotic ground both in glacial and periglacial permafrost.

Active layer

Above the permafrost layer there is a surface layer in direct contact with the atmosphere; it is called the suprapermafrost layer. The part where the temperature increases seasonally above 0°C is called the active layer. This can cover the suprapermafrost layer fully when the permafrost is in direct connect with the current climate. When it is relict and located below the layer that freezes seasonally, there is a nonfrozen ground between the active layer and the permafrost – the talik. The active layer is not a part of the permafrost but is a place where the highest number and complexity of geomorphological processes that accompany the occurrence of permafrost take place, especially when the process of transition through 0°C is accompanied with the presence of water. The active layer has an important role in the cold regions of the world, as the geomorphological processes are most often connected with the seasonal freezing and thawing of the active layer and water present in it. In the case of active permafrost or partially-active permafrost, the active layer is simultaneously the top of the permafrost – the permafrost table. In the case of relict, inactive permafrost which is usually located deeper, the active layer is not in contact with the permafrost table. The temperature in the active layer can change within a great range of positive and negative temperatures, since it reacts to seasonal weather changes. Therefore, its thickness can vary every year. It depends on multiple factors, including the ground surface temperature, surface thermal properties and its cover, soil moisture, snow coverage period, altitude above sea level, slope aspect, topographic conditions, chimney effect, terrain depression, and others.

The thickness of the active layer in peat is very small owing to the very good insulation properties of peat. In the subarctic region the thickness of the active layer in such a material reaches 60–80 cm, whereas in the clastic material in the same region it is 1.5–2 m. Where the thick clastic material is abundant, the thickness of the active layer may reach even several meters. Nicholson and Thom (1973) state that at the Timmins 4 permafrost experimental site in Labrador (55°N, 700 m above sea level (a.s.l.)) the active layer reaches up to 12.3 m deep. The thickness of the active layer changes along with geographical latitude and altitude above sea level. In the northernmost part of Arctic it reaches only about 15 cm and becomes thicker in the subarctic regions. The characteristics of Earth lighting as well as lack of seasonal climate change at the very low latitudes causes the daily nature of the variability of freezing and thawing of the active layer. In equatorial areas at an altitude exceeding 5000 m a.s.l. this process covers only several centimeters of the ground or, in shady places, it does not occur at all, and the perennially frozen ground begins from the surface, thus sometimes the active layer is not present at all. A similar situation can be found only in the central part of the Greenland and Antarctic ice sheet.

Permafrost processes, active permafrost

Since permafrost is a thermal state of the ground that depends on the interaction between the atmosphere and lithosphere, a change in the permafrost temperature is a derivative of the change of atmospheric temperature at its ground layer. There are only two processes acting here: aggradation and degradation. Aggradation is a process reflecting the cooling of the climate,
PERMAFROST: DEFINITION AND EXTENT

consisting of a lowering of the permafrost temperature, usually accompanied by an increase of permafrost thickness, whereas degradation is the reverse process, connected with climatic warming. In both cases the phase transition of water, freezing, can take place if permafrost contains it. The seasonal variability of permafrost temperature can cover its upper part, up to the depth of zero annual amplitude (ZAA) if it is of great thickness, or its entirety when it is appropriately thin. ZAA is then below the permafrost layer. It may be referred to as, correspondingly, partially active or active. This is in respect of the permafrost influenced by the contemporary climate. The relict permafrost, located at a greater depth, is not affected by the current climate, thus it can be referred to as inactive. Its temperature remains constant. The process of aggradation and degradation has influence not only on the thickness of permafrost, but also on its temperature.

**Thickness**

The thickness of permafrost depends on the degree of cooling influencing the ground surface, its length, and the thermal properties of the ground, including water content. A two-year-old permafrost can be an unperceivable centimeter-thick frozen or nonfrozen layer in the ground. In areas of volcanic activity, such as Kamchatka or Iceland, the permafrost thickness is not substantial despite the conducive climate. In the latter, it reaches to 5–30 m. In Canada, in its continental climate, at the southern border of occurrence where the mean annual air temperature (MAAT) is close to 0°C, the permafrost thickness reaches 15 m; in the north of the continent it reaches 60–360 m and on the islands of the northern archipelago it reaches 400–530 m. The estimated thickness reaches up to 1000 m in the Paleozoic rocks quartz sandstones. In Spitsbergen, the thickness of permafrost reaches several dozen meters in valleys, while in mountainous regions it reaches 400–500 m. In the mountains of mean latitudes permafrost thickness reaches from several to several hundred meters. On Monte Rosa in the Alps (4500 m a.s.l.) the thickness can even exceed 1000 m. The thickest permafrost in the world has been measured in western Yakutia, near the Arctic Circle (111°E, 66°N), where the depth reaches 1500 m. The maximum possible depth on Earth is estimated to be about 2600–3000 m in Antarctica.

**Age**

Determination of permafrost age by absolute dating, for example, with isotope methods, is very difficult, as it is a state not a material object. It is an attempt to determine the “age of temperature.” Indirectly, it is possible to date permafrost, bearing in mind that its minimal age is the time needed for its formation with the given thickness. When the temperature at the surface is too low, the penetration of “cold” in the ground is slow and formation of a thick layer of permafrost takes a long time. The age of a layer of permafrost several hundred meters thick is usually estimated to be between several dozen and several hundred thousand years. Most of the Earth’s permafrost dates back to the Pleistocene age. The Siberian permafrost is estimated to be over 1 Ma. The oldest permafrost, located in the Dry Valleys region in Antarctica, is estimated to be over 2 Ma. If the glacial permafrost of Antarctica is taken into consideration, the age of the oldest permafrost on Earth can be estimated at 20 Ma.
PERMAFROST: DEFINITION AND EXTENT

Occurrence

As geosciences are applicable outside the Earth as well, permafrost also commonly occurs in space due to its low temperature: about 3K. This affects planets, moons, and other celestial bodies of the solar system. The surface of Mars, besides the presence of two circumpolar ice sheets, is most probably fully encompassed by permafrost. Many other celestial bodies of the Solar System have an icy lithosphere. These include the planets Uranus and Neptune, as well as the so-called icy satellites: Europa, Ganymede, Callisto, and Io. Their icy lithosphere is encompassed entirely by glacial permafrost.

The main problem regarding the scope of permafrost occurrence on Earth is its presence in glaciers and ice sheets. During the last almost 70 years from the development of its commonly assumed definition, glaciers are taken into account or not in the global area of permafrost occurrence. The solution of this problem is significant, as it concerns approximately 15 × 10^6 km^2 of the Earth’s surface, that is, mainly the ice sheets of the Antarctica and Greenland. Another important factor influencing the determination of permafrost occurrence in the world is the issue of relict permafrost. Its presence has been found in Western Siberia and, recently, also in the Polish lowlands. Research regarding this matter has only just begun in America.

The dominant permafrost is the zonal permafrost, also referred to as the Arctic or latitudinal permafrost, as it is related to the climatic zones of Earth. It occurs from 84° N in Greenland, covers vast areas in Russia (Siberia), the United States (Alaska), China (Tibet), Canada, and Mongolia. Due to the uneven location of lands on Earth, it covers especially the continents on the Northern Hemisphere, Arctic, and polar regions, especially in the continental climates where large annual temperature amplitudes are conducive to deep frost penetration in the lithosphere. Usually, the temperature limit allowing for formation of permafrost is specified as −1°C, mean annual air temperature.

With increasing altitude or latitude, first the isolated patches zone occurs (0–10% ground underlain by permafrost), which then becomes the sporadic permafrost zone (10–50%), then discontinuous permafrost (50–90%) and, finally, the continuous presence of permafrost (90–100%) (Zhang et al. 1999).

When climatic cooling is connected with temperature drop along with the increase of altitude above sea level, altitudinal or Alpine permafrost is formed. These conditions allow for the occurrence of permafrost at all latitudes on Earth; however, only in the Northern Hemisphere can latitudinal permafrost overlap altitudinal permafrost: for example, the Ural Mountains, Scandes (Scandinavian Mountains), and Rocky Mountains. The border between them has been assumed as the altitude of 500 m a.s.l. The highest point is 8848 m (Mount Everest, the Himalayas). In the southern Himalayas it reaches 26° N. In the Southern Hemisphere it reaches a maximum of 6962 m a.s.l. (Aconcagua), in Africa near the equator (03°04′) it reaches 5895 m a.s.l (Kilimanjaro), and in New Guinea (04°04′) it reaches 4884 m a.s.l. (Carstensz).

According to Brown and Haggerty (1998), the land surface of the Northern Hemisphere, together with the ice sheet, is 100.407 × 10^6 km^2. Of this, 25.5 × 10^6 km^2 is encompassed by permafrost, which accounts for 25.4% of the Northern Hemisphere’s surface (Table 1). In the Southern Hemisphere, permafrost occurs at all latitudes. It covers the entire Antarctic: (i) as glacial permafrost, (ii) as subglacial permafrost partly in the cryotic state, and (iii) as the traditionally understood permafrost encompassing the nonglaciated area of this continent. Mountain permafrost encompasses mainly the great

mountain range of the Andes and the mountains in New Zealand.

French (2007) states the permafrost area for the Northern Hemisphere to be $22.7 \times 10^6$ km$^2$, whereas for Southern Hemisphere it is $13.5 \times 10^6$ km$^2$, which encompasses the Antarctica. The total of these values, that is, $36.2$ million km$^2$ (out of $149 \times 10^6$ km$^2$ entire land surface of the Earth), is 24–26% of all land area.

According to Gruber (2012), the global surface covered with permafrost, along with the Antarctic and subsea permafrost, is estimated to be $16–21 \times 10^6$ km$^2$. This accounts for 9–14% of the land surface on Earth. The author claims that the maximal expectation for the occurrence of permafrost is the area of $25 \times 10^6$ km$^2$ (ca. 17%).

Such a great discrepancy in the estimation of the extent of permafrost results from the doubts regarding the ice sheet or the bedrock of the Antarctic.

Petrocapitalism

Matthew T. Huber
Syracuse University, USA

It has become a truism that oil is the foundation of modern capitalist economies. It is the basis of entire states’ budget revenues. It drives global transport networks from North American suburban sprawl to air-based logistics. It is the number one traded global commodity. Its importance is not only because of its strategic importance as an energy source, but also because of its material qualities – its liquid propensity to flow makes it very cheap to transport over land and sea. In one sense, oil is the only energy commodity that circulates so widely (there are serious material and economic constraints to transporting coal, gas, and, for obvious reasons, “renewable” energies like hydro, solar, and wind power). Oil is also said to be a central object of “geopolitical” conflict – oil wars and imperial power rest on who has control over its flow.

Given oil’s centrality to modern industrial life, it is no surprise that geographers – particularly those with interests in political economy – have attempted to theorize the precise relations between petroleum and capitalism itself. As concerns around peak oil, the war in Iraq, climate change, and the resource curse began to proliferate in the early 2000s, geographers began to theorize a specific form of “petrocapitalism.” At first, this concept was used to understand a very specific constellation of forces wrapped up in petroleum extraction or production (particularly in the developing world) – violence, state power, money, local environmental degradation, and, of course, resistance (Sawyer 2001; Watts 2004). As concern with oil’s embeddedness in the reproduction of industrial societies intensified some geographers, and others, began to think about the wider relations between capitalism and oil consumption. While geography of extractive petrocapitalism is focused on specific points in space – what Gavin Bridge (2010, 1) calls the geographies of “the hole” – consumptive petrocapitalism is dispersed and virtually includes the entirety of capitalism itself. Such a wide view of petrocapitalism had led scholars to link oil with some of the foundational values of capitalist liberal economies – from democracy to freedom.

Extractive petrocapitalism: violence, money, and power

In its initial usage, petrocapitalism referred to specific forms of accumulation tied up with the extraction of oil. In his study of Nigeria, Watts (2004, 199) examined how, “petro-capitalism operates through a particular sort of ‘oil complex’ (a configuration of firm, state and community) that is territorially constituted through oil concessions.” This “oil complex” represents both the set of institutions meant to facilitate the extraction of petroleum wealth (multinational private companies, state companies, and state officials), and the local communities who often suffer the environmental and human rights abuses that follow. While the geography of oil extraction might mirror many other forms of extractive mineral economies, what distinguishes petrocapitalism is the tremendous wealth generated from this critical commodity. Often encompassing over 90% of state revenues in oil
exporting countries, oil becomes a “magical” commodity that promises “instant wealth” and dreams of national development (Coronil 1997). As Polish journalist Rizard Kapucinski remarked of oil-rich Iran, “Oil creates the illusion of a completely changed life, life without work, life for free” (quoted in Watts 2004, 213).

Perhaps the most important “institution” within the oil complex is the “petro-state.” In most areas of petroleum extraction (except the United States where private subsurface rights exist), all subsurface minerals are the property of the state. As Coronil (1997) discussed in relation to Venezuela, this means the state acts as the landowner – or the “landlord state” – that grants “concessions” to private oil companies – increasingly in conjunction with a state owned oil company – to explore for and extract oil wealth. The companies then pay the landlord state “rent” in the form of royalties, taxes, and other payments. Even in the most spectacular instances of geopolitical conflict and “oil imperialism” – like the invasion of Iraq in 2003 – the institutional power of the state as “landlord” retains considerable power to act as a “barrier” to forms of capital investment (see Labban 2008).

As Watts suggests, these “concessions” are territorially constituted in the specific locations in which the extraction happens. On the other hand, the wealth generated through this extraction is often funneled elsewhere. Watts (2004, 212) describes the accumulation of money in the petro-state “fiscal centralization.” As many in political science suggest (e.g., Ross 2012), this “oil curse” creates the phenomenon of the “rentier state” where massive windfalls of oil money create state corruption and lack of accountability to domestic populations. For example, while most Nigerians suffer incredible levels of poverty (per capita income is about US$290 per year) the Nigerian government spends lavishly and sizable funds have simply gone missing (Watts 2004, 201). Despite the tendency to pathologize the governments in this literature, it is also worth pointing out that in the context of increasing neoliberalization of oil policy the vast majority of the wealth generated is captured by private transnational corporations. For example, Sawyer (2001, 163) estimates that Texaco generated an astounding $23 billion between 1972 and 1991 – extraction that became even more profitable because the company did not invest in basic environmental safeguards (e.g., the lining of waste pits).

Given that oil extraction can be extremely damaging to both public health and the natural environment, local communities are often forced to bear the brunt of the costs of extraction while the wealth flows elsewhere. Watts (2004, 208) describes the Niger Delta as an “ecological disaster” where “76 percent of natural gas in the oil producing areas is flared.” This lead a visiting journalist to remark that, “some children have never known a dark night even though they have no electricity.” The water – so critical for fishing livelihoods in the Delta – has been decimated by an estimated “300 spills per year” leading to hydrocarbon levels an estimated “360 and 680 times the European Community permissible levels” (Watts 2004, 208).

Bridge (2004, 226) identifies a “scalar mismatch” between the local environmental and human consequences of all forms of mineral extraction and the national–global flows of benefits. This mismatch often leads to substantial forms of political unrest, resistance, and violence. In Ecuador, local indigenous tribes are still attempting to force Chevron (formerly Texaco) to clean up the toxic legacy of their nearly 20 years of operations. In Nigeria, there has been both violent and nonviolent forms of political mobilization – both of which have been brutally repressed by the Nigerian government with thousands killed, including famous nonviolent
environmental activist Ken Saro-Wiwa. Violence almost always accompanies “clearing” the site for extractive activities with displacement of local populations. In Sudan, oil concessions were advertised to investors as unoccupied land – “land, that is, which paramilitaries have first systematically rendered uninhabited by driving off the residents” (Ferguson 2005, 378–379). The sites of extraction themselves become heavily securitized “enclave economies” where companies often make use of state security forces and hired private mercenaries to effectively militarize extractive operations (Ferguson 2005, 378–379).

In its initial usage, petrocapitalism was a particular geography of accumulation centered upon the extraction of oil in the relatively few spots on the Earth where it is profitable to do so. Ultimately the wealth flowing to all the actors within the “oil complex” – corporations, petro-states, private security firms – hinges upon that particular moment and place of extraction. Yet, the travels of oil itself do not end in these sites of extraction. In fact, crude oil by itself is a relatively useless substance (a few oil-rich countries might burn it for electricity but 99% of crude oil is not used in its crude state). It must travel by pipeline and/or ocean tanker to a refinery where it is transformed into a multiplicity of “use-values” that then flow into countless channels of consumer markets – most notably transportation fuel like gasoline and diesel. If, as Mitchell (2011) suggests, we “follow” this dispersed geography of oil consumption, how does our vision of “petrocapitalism” change?

Consumptive petrocapitalism: flowing through daily life

In order to understand oil consumption as a form of “petrocapitalism” it is first necessary to avoid the many platitudes that exist around ideas of “oil addiction.” First, it is increasingly common to recognize that petroleum products have become absolutely central in the reproduction of industrial lifestyles. Most notably this includes gasoline fired automobility, but also the countless petroleum products that saturate daily life from chemicals, pharmaceutical products, plastics, and even food. Often taken for granted, oil appears to be the commodity that holds life together. Second, especially among critical political economists, this “addiction” to oil is often explained as the result of narrow corporate conspiracy among oil and automobile companies. The most notable example of this is the case of “National City Lines” (a conglomerate of auto, oil, and tire companies) who conspired to destroy much of the United States electric streetcar public transit system and replaced them with oil-fired buses.

An understanding of oil-based petrocapitalism requires a wider analysis. It is not enough to recognize oil’s centrality to social reproduction; the real question is how oil emerged historically as such a central commodity in the reproduction of labor power in capitalist societies. Again, oil is not consumed in its raw state, but as particular petroleum products that only become use values in relation to other commodities like the internal combustion engine. The story is also broader than an elite conspiracy. To understand mass oil consumption in the United States you first need to understand the historical process of suburbanization (especially in the post-World War II era) and its relation to wider regimes of capital accumulation. Specifically, the crisis of capitalism during the 1930s and state-led restructuring of capitalism led to a set of institutions – labor regulations, housing reforms, infrastructure development – that created the material conditions for Fordist mass consumption.

Essentially, the state empowered certain privileged sectors of the American working class to
PETROCAPITALISM

gain access to a new widely generalized form of space and energy-intensive life. While it may be true that this form of life is “wasteful” and environmentally disastrous, it served to save capitalism both economically and ideologically at a moment when its historical survival was very much in question. Only in this wider social context where masses of the population actually had the wages and government supports to purchase and use cars, single-family homes, and countless other petroleum-based commodities, does the centrality of oil to social reproduction take hold. Moreover, this form of life also became linked to wider ideologies of “The American Dream” – ideas of leisure, family, freedom, and space – that created ideological legitimacy for oil-based life in the postwar era (legitimacy that did not require a corporate plot).

Of course, this story is not confined to the United States. Essentially the world economy in post–World War II was constructed on the basis of increasing oil consumption. The United States not only ensured the development of Middle Eastern oil fields (e.g., most notably in Saudi Arabia and Iran) by Western capital – sometimes by force, as in the 1953 CIA-organized coup of the popular socialist leader Mohammad Mosaddegh in Iran. The United States also helped “rebuild” the European and Japanese economies to become more oil dependent. For example, the Marshall Plan included massive amounts of refinery construction in Europe to process new oil flowing from the Middle East (Painter 1984). While European states tax gasoline at much higher levels than the United States – reinforcing public commitments to public transit and “compact” cities – most nations remain almost entirely dependent upon “foreign” sources of oil mainly from Russia and the Middle East.

It is also critical to not singularize oil’s importance to postwar capitalism. The postwar economy was created upon the basis of a multiplicity of petroleum products. The “petrochemical” revolution of the post–World War II era was itself a product of the massive mobilization of all industry toward the war effort in the 1940s. Specifically, the government investment in catalytic cracking refinery capacity – to aid the mass production of high octane aviation fuel – created a massive expansion in the production of “olefins” like propylene and ethylene that became the basis of the postwar petrochemical industry based on plastics and other consumer chemical products. Other advances include the use of natural gas as the preferred feedstock in ammonia synthesis (as opposed to coal) which laid the basis for the massive expansion of synthetic nitrogen fertilizer production in the postwar era and the so-called green revolution in crop yields. By 1978 our food system had become so reliant on hydrocarbons – from diesel fired tractors to petrochemical pesticides – a prominent scientist claimed, “Modern agriculture is the use of land to convert petroleum into food” (Bartlett 1978, 880).

The embeddedness of oil in everyday social reproduction has increasingly led geographers and social theorists to attempt to grapple with the ways in which oil-based cultural practices prefigure wider political and ideological discourses. Urry (2013) calls for a “sociology of energy” that confronts the centrality of oil (and other fossil fuel energy) to the relational ties that constitute what we think of as “society” itself. Mitchell (2011) argues that carbon based fuels – and the various forms of movements and contestations over their flow – underlie the political forces we often equate with “democracy” (even as the sites of “extractive” petrocapitalism discussed above are often pathologized as “undemocratic”). Huber (2013) argues oil helped power and provision ideas of freedom
and “entrepreneurial life” that animated sub-
urban right-wing politics as America became
“neoliberal.”

All these insights combine to present a much
more dispersed understanding of petrocapital-
ism. While a focus on extraction has led to
insights into the politics of oil – as a specific object
extracted in a specific point in space – we are
now thinking about oil and energy as ways to
think about the ecology of politics more broadly.

Conclusion: beyond petrocapitalism?

Moving beyond petrocapitalism is relatively
straightforward in technical terms – the goal is to
find an alternative energy source in the transporta-
tion sector (which, for example, consumes 70% of
every barrel in the United States). While there
are a number of alternatives with varying degrees
of feasibility (e.g., hydrogen fuel cells, agrofuels),
the most promising recent developments have
been centered on the electrification of the transport
sector – that is, running cars (and maybe some
day trucks and airplanes) with rechargeable bat-
teries. Of course, as it stands today, the electric
power sector is fueled by a combination of fossil
fuels, nuclear, and some marginal “renewable”
sources (most notably hydropower, but increas-
ingly the green beacons of hope, solar, and wind
power). Thus, in order for electrification to
become a truly “green” alternative, the electric
power sector itself must be weaned off fossil fuels
and dangerous nuclear power.

Yet, it is critical to point out that the real
barriers to transcending petrocapitalism are polit-
ical. First and foremost, there are concentrated
and powerful institutions – from multinational
oil corporations (i.e., “Big Oil”) to petro-states
and their associated government-owned oil
companies (e.g., Saudi Aramco) – who have
much to lose from any decrease in our economic
dependence on oil. Their powerful control
over many countries’ “energy policy” (or lack
thereof) is substantial and entrenched. Yet, from
a more Gramscian political perspective, we must
also recognize that oil “hegemony” is rooted
in much broader political forces than simply
the control of “Big Oil” and the petro-states.
Again, the embeddedness of oil-based practice
with “consent” bound up in everyday notions
of freedom, home, and individuality are much
more formidable political challenges to over-
come. This is clearly the case in the United States
where even the prospect of a marginal increase in
the gasoline tax is met with widespread populist
refusal and outrage. Ultimately, if we insist on
coupling oil with the mode of production “cap-
talism,” it must be self-evident that efforts to
move beyond oil might require moving beyond
capitalism itself – specifically its requirements
for growth and accumulation over questions
of social and environmental benefit. Thus, a
move beyond petrocapitalism needs to be less
understood as a struggle over “technology” and
more a struggle over the political and economic
organization of society as a whole.

Phenology

Mark D. Schwartz
University of Wisconsin–Milwaukee, USA

Phenology “refers to recurring plant and animal life cycle stages” and is also the scientific “study of these recurring plant and animal life cycle stages, especially their timing and relationships with weather and climate” (USA-NPN 2015a). Examples would include the opening of leaf buds on a shrub, the beginning of autumn leaf color on a tree, or the first appearance of a migratory bird species in spring. The timings of many of these phenomena can be quite sensitive to small changes in environmental conditions, such as air or soil temperature. Thus, phenological data provide an important independent measure of the impacts of climate change on the biosphere, which can be assessed at scales ranging from the individual plant to entire biomes.

History

Phenology before the dawn of history

Observing changes in the timing of plant and animal life cycle stages in the natural world has likely always been a part of the human experience. Early nomadic humans would have looked for signs to help pinpoint the migration timing and presence of animals, as well as any information to help them locate and take advantage of fruits, nuts, and other vegetative sources of food. The relevance of phenology must have increased considerably once humans started establishing permanent settlements and practicing agriculture, horticulture, and animal husbandry. Being at the same location over multiple years, and eventually over multiple generations, early farmers would realize that phenological changes in the plants and animals around them could be used as a generalized natural calendar to help direct their planting, care, harvest, and other management activities, especially in temperate regions with pronounced seasonal transitions. Ancient Chinese references, stories with phenological themes in both the Old and New Testaments of the Christian Bible, and other sources offer abundant evidence of the long understanding and utilization of phenology as an integral part of human agricultural practices over many millennia (Schwartz 2003, 3). However, such knowledge would have been highly localized, and much more useful in average than extreme years.

Relatively recent scientific study and terminology

While the practical utilization of general phenological principles in association with agriculture is ancient, the emergence of phenology as a distinct area of scientific inquiry is quite recent. The father of modern scientific phenology was the Swedish botanist Carolus Linnaeus, who outlined methods for developing annual plant calendars, and suggested that these botanical data when combined with climatological observations could be used to show how areas were different (Lieth 1974, 25). However, it was another hundred years before the term “phenology” was coined by Belgian botanist Charles Morren in 1853 (Lieth 1974, 25). Even so, the term and its definition are somewhat
PHENOLOGY

problematic. Phenology is derived from the Greek word *phaino* (which means to show or to appear). While practically speaking the study of things that “show or appear” could mean just about anything, originally the focus was almost exclusively on plants (especially woody plants and wild flowers), with just a few exceptions such as birds, until around the 1950s when more biological organisms began to be considered (Lieth 1974). In recent decades the definition has been generalized even further to include changes in remotely sensed reflectance values (which change in relation to vegetation growth stages) as well as nonbiological events driven by seasonal changes in climate, for example spring ice thaw on fresh water lakes.

Published comprehensive volumes

Schnelle’s book (1955) *Pflanzen-Phänologie* (Plant Phenology) appears to be the first comprehensive volume devoted to phenology as a distinct area of scientific inquiry. He noted the multidisciplinary nature of phenological science and its traditional place as a supporting science within numerous fields (botany, phytopathology, agronomy, agricultural meteorology, climatology, and geography) that explore environmental influences on plant development. However, Schnelle asserted that phenological studies are a holistic way to use plant development as integrative tools that provide a critical focus for evaluating the simultaneous interactions of multiple environmental measurements. This book stimulated increased interest in phenological observations and studies in Europe (including development of an International Phenological Garden Network); however, its worldwide impact has been reduced due to being written in German, and never translated into English.

Lieth’s book (1974, 3) *Phenology and Seasonality Modeling* was a direct result of the International Biological Program (IBP) and work of the United States’ IBP Phenology Committee. This seminal volume clearly established a broader scope for phenological studies as encompassing not only plants but also animals, whole ecosystems, and newly emerging remotely sensed measurements available from sensors on board satellites. Lieth and his colleagues introduced numerous perspectives through which phenological analyses could enhance ecological studies, as well as new modeling and graphical presentation techniques.

Without question, rising recognition in the late 1990s that phenological observations could serve as an additional independent measure of the impacts of global climate change on the biosphere, led to exponential growth of the scientific community’s interest in phenology. The need for an updated volume to summarize the current state of research was realized with the publication of *Phenology: An Integrative Environmental Science* (Schwartz 2003). This book documented the continued broadening of phenological studies to continents beyond Europe and North America, bioclimatic zones outside of temperate moist forests, and additionally to life forms other than plants. Updated synopses of analyses techniques included plant and animal life cycle modeling, new developments using satellite remote sensing-derived measures, and emerging applications in global change studies and ecosystem assessment through carbon/energy flux measurements. The recently published second edition of *Phenology: An Integrative Environmental Science* (Schwartz 2013) provides an overall update on progress in phenological research over the past decade, while highlighting newly emerging approaches such as the use of near-surface cameras as a source for remotely sensed observations of seasonal vegetation changes, and examples of developments in field-based college- and university-level
Phenological education which take advantage of the latest technology.

**Techniques**

**Types of information**

Phenological observations of *higher plants* have traditionally included the timing of visibly distinguishable stages of growth and development, as well as senescence, which occur during seasonal progressions over the course of a year. So for woody perennial plants this would start with the swelling and opening of leaf and flower buds in spring, progress to full leaf and flower development in early summer, in some cases continue through fruiting in mid- to late summer, and end with leaf coloring and fall in autumn. In annual *grasses*, *herbs*, and for *fungi*, observations are generally more restricted to initial appearance, flowering, and in some cases fruiting and senescence over a shorter time period.

*Animal* phenological observations for organisms are generally much simpler than those recorded for plants. Often for warm-blooded animals this can be arrival dates for migratory species such as birds, or appearance dates for those that undergo hibernation, for example various rodents. Other typical life cycle events recorded for warm-blooded animals would including behaviors related to reproduction (nesting, mating, egg-laying, birth and development of young). Cold-blooded species observations are more diverse, depending on the life form types. Observations of reptiles tend to be similar to those for warm-blooded creatures, while those for insects would typically include growth and development stages (egg, larva, pupae, and adult) that would parallel approaches used for plant observations.

Traditionally, (as in the definitions above) phenological observations have been reserved for use solely with organisms. However, recently, no doubt in part due to the exceptionally broad nature of “to show or to appear,” coupled with the renewed visibility of phenological science, publications have appeared applying the term phenology to studies of *nonbiological natural processes* that are also driven by seasonally modulating environmental factors. Some of the best examples of these come from hydrological science, such as timings of winter ice cover and spring thawing in freshwater lakes and rivers, as well as timings of peak and low water flow in rivers. So while it appears likely that the “biological only” definition of phenology will remain dominant, it is important to recognize that a wide range of nonbiological seasonal phenomena are now considered by some to be included in phenological studies as well.

**Types of observations**

For *ground-based visual phenological observations* to be most scientifically valuable they need to be recorded according to a clearly defined and reproducible procedure, typically referred to as an “observation protocol.” First, a couple of terms need to be defined which are crucial to the structural development and subsequent understanding of phenological protocols: “phenophases” and “phenological events.” A *phenophase* is “an observable stage or phase in the annual life cycle of a plant or animal that can be defined by a start and end point.” Phenophases usually last from a few days to several weeks (USA-NPN 2015a). Further, a *phenological event* is “a precisely defined point in the life cycle of a plant or animal, typically expressing the start or end point of a phenophase.” The occurrence of a phenological event can at least theoretically be tied to a specific date and time (USA-NPN 2015a).

Thus, protocols are generally constructed so as to allow multiple observers at a single site, as well...
PHENOLOGY

as different observers at multiple sites, to consistently and precisely identify a specific point in the life cycle of a plant or animal using features that are clearly visible. The most successful protocols are those that define phenological events that are easily recognized visually and then comprehensively described using both a written description and an image. The complexity of a protocol (in terms of the number of events and their detail) is generally related to requirements of the proposed objectives of the studies for which they are designed. Due to the time and effort involved in taking visual phenological observations, most protocols are designed with a small number of events, so as to maximize the likelihood that the majority will be recorded in all years and sites where it is utilized.

Phenological observations are traditionally recorded as the calendar date on which they occur. Thus, one day is the smallest difference that can be measured between two individual phenological events. Further, in order to make comparisons between observations taken in different years and at different locations, calendar dates are often translated into a day-of-the-year format, most commonly with January 1 equal to day number 1. Several limitations of this approach to recording phenological observations have been noted. First, during periods when no events are occurring, no information is recorded. This imposes a certain temporal resolution on the sequence of phenological information being recorded; meaning that unless the protocol includes many events and details, large periods of development may not be well represented. Lastly, there is essentially no information available to assess the error of the observation itself. While some approaches to overcome this problem have been suggested, such as requiring the observer to simultaneously record an image of what they observe (largely impractical in the past, but becoming more feasible as data storage technology improves), the supervising authority responsible for data collection can do little more than hope that the observer followed the protocol faithfully.

For plant phenology, a number of growth processes proceed in continuous fashion, such as leaf development in spring and leaf senescence in autumn. Thus, when monitoring these processes, it is possible and desirable for protocols to be established such that whenever an observation is taken, a level of development is able to be recorded. The advantage in this approach is that it allows phenological information to be recorded at up to the highest temporal resolution possible (every day).

Status monitoring is a different approach to recording phenological observations which addresses some of the limitations inherent in the traditional event date-recording technique. Observers employing status monitoring still regularly check the phenological status of specific individuals from plant and animal species at selected locations. However, phenological information is reported as answers to “a series of yes/no questions.” “This approach ensures the capture of negative data (when the phenophase is not occurring), repeat events …” (such as secondary blooming later in the same year), “… and allows for an estimation of the uncertainty around the beginning or end date of a life stage” (USA-NPN 2015b). Specifically, when status monitoring is used, negative data recorded immediately before positive event data would indicate low error/high reliability, and the periods when neither positive nor negative data are recorded can both contribute to overall assessment of measurement uncertainty.

While phenological observations can be (and often are) taken in isolation at individual sites, their value increases considerably when observations using the same protocol are taken at multiple sites. Such phenological networks allow
assessment of the impacts of varying environmental conditions on phenological events at different locations, and in turn that of the collective effects of changing environmental conditions across all sites. Another consideration is scale. Most phenological observation networks are set up to assess differences across regions or nations. Networks designed to span large countries, continents, or climatic zones face difficulties in species selection, as few or no species are present across all portions of such large areas. In some cases phenological networks can be set up at high spatial density in small areas, in order to explore and separate the impacts of environment, genetics, and other factors on phenological responses within a single species.

Satellite-based sensor-derived observations
The advent of sensor systems on board satellites able to capture reflected and emitted radiation in specific portions of the electromagnetic spectrum systematically has been transformative to many areas of science, including plant phenology. Information about the growth stage of vegetation can in theory be assessed using the same methodology over regional to continental scales at regular time intervals. However, there are a number of important issues which must be considered when utilizing these data in specific applications in practice. Among the most universal are: (i) orbital mechanics and cost generally impose an inverse relationship between the spatial resolution of the smallest individual image element (pixel) size and the frequency at which imagery can be obtained; (ii) cloud cover and other atmospheric interference will reduce the amount of usable data obtained; and (iii) comparisons of conventional ground-based visual phenological observations to satellite-derived reflectance measures are often problematic, given the inherent spatial mismatch of these data as well as the different observational approaches. Despite these difficulties, phenological applications of remote sensing data obtained from satellites, especially when merged with surface-based data, remain a fruitful area for future research.

Near-surface sensor-derived observations
A recent and exciting development in remote sensing phenology is the use of sensors deployed from fixed structures, such as towers or buildings, rather than moving (airborne or orbital) platforms. Such “near-surface” remote sensing data collection offers a number of distinct advantages to phenological studies, especially when used to bridge the spatial and technical gap between satellite-derived and conventional ground-based visual phenological observations. Among the most important of these advantages are: (i) providing essentially continuous data with minimal atmospheric interference; and (ii) allowing detailed information about well-defined groups of plants across the entire yearly cycle of vegetative growth and senescence (Richardson, Klosterman, and Toomey 2013, 414–415).

Model output (plants and animals)
Since a fundamental aspect of phenological information is its intimate link with environmental drivers, a large portion of phenological research has been directed toward understanding the nature of these connections. When successful, such analyses can serve as the basis for constructing models of phenological behavior. Phenological models can subsequently provide predictions of phenological responses in places and times where the environmental driver data are available but actual phenological data are lacking. Such models can serve many purposes at multiple scales, such as predicting the flowering
and fruiting of a specific horticultural species within one orchard based on daily air temperatures (from a combination of past data collected and future forecasts) or reconstructing the timing of the start of the growing seasons from daily air temperatures over the period of instrumental records across North America.

Selected applications

Agriculture and horticulture

Given their ancient connections, it is not at all surprising that agriculture and horticulture remain a healthy area for phenological applications (Chmielewski 2013). Traditional areas that continue to be quite useful include defining the growing seasons for various crops at selected locations, assessing an area’s climatological variables for compatibility with new crops, and evaluating the risk of frost damage to crops based on their state of phenological development. In addition to these uses other common areas include the timing of management practices where the growth stage of the plant is important, such as the timing of pesticide or fertilizer application, as well as irrigation schedules. Agricultural modeling of plant development and yield is also highly dependent on phenological information in order to interpret the interactions of microclimate and other site-dependent factors (Chmielewski 2013).

Global change

The Intergovernmental Panel on Climate Change (IPCC) noted that phenology “is perhaps the simplest process in which to track changes in the ecology of species in response to climate change” (IPCC 2007). Further, phenological data (together with climatic and remote sensing data) provide a third independent measure of these impacts which can be assessed at scales ranging from the individual plant to entire biomes. Phenological data collection and research will continue to inform global change science as researchers grapple with understanding the processes and impacts, as well as search for adaptation strategies for both managed and natural ecosystems.

Education

The integrative natures of phenological data make them well suited to education applications in both formal and informal settings. For example, when individuals participate in data collection networks as observers, they not only gain an immediate and practical understanding of the life history of the organisms they observe, but often also become sensitized to the variations in environmental drivers. In more formal settings, phenological data can facilitate course assignments designed for almost any age level that span the entire range of scientific endeavors, including field methods, hypotheses formulation, numerical analyses, and graphical display of results.

Phenomenology

Alex Jeffrey
University of Cambridge, UK

Phenomenology, or the study of human consciousness and experience, has a long historical lineage within the study of philosophy. Immanuel Kant used the term *phenomena* in the eighteenth century to refer to events and categories that could be apprehended by the physical senses. This approach was later challenged by Hegel who sought to explore how human consciousness of the external world was formed. Consequently, Hegel’s work focused on the challenge of comprehending an external reality, in doing so encouraging reflection on the ways in which objects external to human consciousness are constructed in terms available to the human mind. Such questions of consciousness and human experience were later taken up by Edmund Husserl, Martin Heidegger, and Maurice Merleau-Ponty (among many others), where phenomenological reflection was directed at foundational philosophical questions relating to the objectivism of science, the ability to establish stable truths about the world, and the separation between humans and other animals and objects.

Phenomenology has a shorter history within the study of human geography. As critiques of positivism emerged in the late 1960s and early 1970s questions of existence and being, previously felt to be secondary to concerns of distribution and location, came to the fore. Humanistic geography sought to encourage a more “anthropocentric” (human centered) understanding of the world, and drew on phenomenology — alongside other humanist philosophies such as existentialism — as part of its philosophical toolkit. We must be clear that this was not always a case of wholesale rejection of science: many scholars felt that spatial science was adequate for *describing* geographical processes but they simultaneously felt less confident that they could use scientific approaches to *understand* the meanings behind human choices, distributions, and inequalities. Early humanistic geography was concerned that the models and quantification of spatial science had “de-humanized” geography inquiry, where the complexity of human decision-making was reduced to rational economic choices, pointing in particular to the reliance of modelers on price mechanisms and other market forces to predict human behavior. We must be careful not to characterize the sophistication of quantitative work in summarizing these critiques, but on a philosophical level the production of models was seen by humanistic geographers as focusing on the general rather than the particular, thinking of humans as populations as opposed to individuals. But this was not simply a philosophical reflection: by emphasizing variation and, therefore, inequality, humanistic perspectives could also focus on the ways in which social processes of marginalization or exclusion operate in spatial terms.

A number of traits can be identified that characterize phenomenology’s influence on geographical scholarship. The first is an interest in human subjectivity: phenomenologists are concerned with how humans experience their environment in unique ways. The second is a preoccupation with the construction of knowledge: phenomenologists focus on how individu-
PHENOMENOLOGY

give meaning to their objects of consciousness. The third and perhaps most contentious is the search for shared categories: the goal of such study is the identification of elements in individual consciousness that control the allocation of meaning, what sometimes are referred to as “essences.” But while this three-part division gives a sense of some of the thematic concerns of geographical phenomenologists, it is perhaps more appropriate to think of phenomenology as a methodological approach than a body of theory. For example, uses of phenomenology in geography often draw on the work of Edmund Husserl, who was interested in developing a philosophical method that would allow the scholar to go “back to things themselves” (Entrikin 1976, 617). At heart, then, phenomenology has been concerned with challenging abstraction and thinking about the lived experience of human existence. In terms of scholarly practice, this approach advocates qualitative empirical inquiry and the importance of the humans at the center of this process. But in getting “back to things themselves” Husserl was also advocating setting aside all preconceptions of the nature of human experience and, instead, examining the world afresh.

We can interpret this move to phenomenological reflection in two ways: it seems to reflect a return to a more tangible sense of human experience while also posing a radical empiricist challenge to the production of scientific categories. In Husserl’s view, phenomenologists rejected preconceptions and traced instead a science of beginnings, where the very origins of particular understandings of the world are examined. In many ways, and this is a point that John Pickles (1985) makes across his analysis of phenomenology in geography, the phenomenological challenge to objective science pre-empts many of the more recent genealogical investigations of the production of scientific institutions and expertise (after Michel Foucault, among others) or the wider field of the sociology of scientific knowledge. It is the case that phenomenological studies have explored how subjective elements of human consciousness shape science, in doing so exploring how the influences of history, life, and bodily cognition influence scientific knowledge. But this was not in order to argue for untrammeled subjectivity, an unmooring of knowledge from any exterior reality, but rather to explore how particular themes, categories, and abstractions are produced in specific social and scientific conditions.

Perhaps the most tangible expression of this tension between objective and subjective knowledge production in geography comes in the distinction between space and place. While space has often been presented as an objective category, a plane or volume that expands over a particular physical extent, place is often understood as its antithesis, the subjective experience of space, constructed from human physical sense, emotions, and memories. Of course, this distinction is challenged in thought and practice, not least since the idea of a stable, detached, and abstract image of space shared between all human subjects is itself open to intellectual and political challenge. But place has been a key theme of phenomenological work in geography, a means of capturing and conveying the subjective experience of particular sites. A key proponent of this school was Edward Relph (1976, 43) who emphasized the phenomenological method of centering on human experience:

The basic meaning of place, its essence, does not therefore come from locations, nor from the trivial functions that places serve, nor from the community that occupies it, nor from superficial or mundane experiences … The essence of place lies in the largely unconscious intentionality that defines places as profound centers of human experience.
By drawing on Husserl’s philosophical approaches, phenomenologists have attempted to study human consciousness and in so doing discern shared cognitive categories that underpin experiences both across space and time. An example of the ambition of this style of scholarship can be found in Yi-Fu Tuan’s (1974) *Topophilia* a text that sought to connect sentiment with place. What strikes the reader most forcibly in Tuan’s account is the wide diversity of examples marshaled to explore how motivations, values, and emotions shape human interactions with the environment. Tuan argues for the supposed *universality* of certain forms of cognition (e.g., five senses and stereoscopic vision) in contrast to the *variability* of other factors (e.g., culture and biography). The copious material, from an eclectic array of sites and epochs, aims to discern the individual from the transcendental aspects of place interpretation. This may seem rather subjective and almost playful, but Tuan directs such analysis toward political and environmental ends:

The themes taken up here – perception, attitude and value – prepare us, first of all, to understand ourselves. Without self-understanding we cannot hope for enduring solutions to environmental problems, which are fundamentally human problems. And human problems, whether they be economic, political or social, hinge on the psychological pole of motivation, on the values and attitudes that direct energies to goals.

In this excerpt Tuan sets out two principles of a phenomenological approach that have been discussed: an interest in subjectivity (“understanding ourselves”) and the construction of knowledge (“values and attitudes”). These seem consistent with a question for the variability in human values of place. But Tuan (1974, 2) also alludes to universality, and in particular the search for *essences* of human values concerning place:

What can be the common ground between a detailed analysis of the shopping behavior of housewives in Ames, Iowa and a grand survey of the Christian doctrine of nature? Or between the study of color symbolism as a universal trait and the history of landscape painting? A possible reply is that somehow they all bear on the way human beings respond to their physical setting – their perception of it and the value they put on it.

There are numerous criticisms of phenomenological perspectives: on the basis of its potential blindness to questions of gender, sexuality, and race; for its lack of attention to political and economic structures, and for its underlying humanist philosophy. Reflecting wider critiques of geography in the 1980s and early 1990s, feminist scholars criticized the rather uniform imagination of human subjectivity promoted in some phenomenological work, a subject unmarked by gender difference. This critique exposes a troubling essentialism that underpinned some phenomenology: that it was seeking to uncover general transcendental essences that were shared among all humans. But in doing so, forms of inequality and oppression that mark human experience may be underplayed or ignored. By emphasizing issues of positionality and embodiment feminist geographers have been at the forefront of inserting cultural, bodily, and historical contexts into debates concerning the marginalization and oppression of women. Reflecting a wider feminist critique of the masculinist nature of human geography, “gender blindness” was anything but blind; it led to studies focusing on male-dominated spaces and lifestyles but imagined as universal human experience. In this sense, a gender critique is not necessarily a philosophical challenge to the tenets of phenomenology, but rather a challenge to a sense of an undifferentiated human consciousness.

Reflecting this challenge to the unmarked human subject, critics of phenomenological and humanistic approaches also questioned the
PHENOMENOLOGY

extent to which such studies engaged with the different structural and material factors that shape life choices. As Gregory (1981, 16) states “the materiality of social life is weakly developed in modern humanism, and as a result it inevitably encounters severe difficulties in comprehending objective societal forces.” This lack of attention to structural factors, in particular questions of class, was only amplified by the parallel development of humanistic and Marxist perspectives in human geography over the 1970s. This dual intellectual flowering can be crudely seen as two sides of the structure–agency debate, an ongoing discussion between those who see human actions as determined by external forces (structure) and those who sought to foreground the significance of human decision-making and free will (agency). In neither Marxist nor humanistic cases would proponents see their work as fitting an image of human action as either determined by overbearing economic structures or the product of free-floating and voluntarist human consciousness. But, nevertheless, the focus on human subjectivity is often interpreted as phenomenology’s overemphasis on agency, where – in the words of Entrikin and Tepple (2006, 31) – “experiences, attitudes, and beliefs, as well as moral and aesthetic judgment” inform perceptions of the environment.

The question of human agency is also central to a third line of critique emerging from posthuman (or antihuman) philosophical approaches. This field is diverse and evolving, but at its root is a desire to challenge the centrality of human reason and experience as the center of philosophical and social inquiry. As Braun (2004) notes, the flourishing of deconstruction as a form of geographical research method has challenged the centrality of the human subject, as critical scrutiny turned to the form and effects of language, the relational nature of identity, and the instability of essential truths. Rather than focusing on the operation of human consciousness and experience, this turn to deconstruction has involved exploring instead how the “figure of the human” is formed as an identity separate from other objects or beings. This point flows into a more general philosophical perspective that seeks to examine the world as more-than-human, widening the scope of geographical and philosophical inquiry to include objects, animals, and atmospheres. Such approaches use theoretical frameworks derived from Latour’s actor-network theory or Deleuze’s concept of assemblages (among others) to grasp the spatial complexity of the social world. Of course, scholars have challenged the extent to which this move constitutes a genuine shift from the pre-occupations of phenomenologists, interested as they were in the relational and the material aspects of the world. In particular, Simonsen (2013) encourages a re-reading of phenomenological literature, particularly that of Merleau-Ponty, to examine how this perspective can encourage an understanding of experience that fosters an openness to (human and nonhuman) others: one that does not reduce them to being the same, but does not preclude mutual understandings.

It is in this final point that we can see the emergence of what has been termed a “critical phenomenology,” challenging a sense of the rational human subject but retaining an interest in (diversely experienced) human subjectivity. This perspective retains what is perhaps at the core of phenomenology’s contribution to human geography: the phenomenological method. Rather than an overarching philosophical message, this method involves understanding engagements with place within the terms and categories of everyday life and individual human subjects. It is interested in the generative nature of consciousness, that terms and objects do not preexist the dialogic (that is, two-way
and relational) processes through which they are comprehended and understood. And they unfold in distinct embodied situations, as sensitive to questions of gender, class, race, and sexuality (among other lines of difference) as any other critical account of human geography.

Photogrammetry is defined by the American Society for Photogrammetry and Remote Sensing as “the art, science, and technology of obtaining reliable information about physical objects and the environment through the processes of recording, measuring, and interpreting photographic images and patterns of recorded radiant electromagnetic energy and other phenomena.” Simply, photogrammetry allows 3-D measurements (e.g., position, orientation, shape, and size) of objects from photographs.

Photogrammetry is as old as modern photography and can be dated to the mid-nineteenth century (Konecny 1985). Over the past 80 years, the principal application of photogrammetry has been in the compilation of maps from aerial photographs. In recent decades, the development of high-resolution satellite imaging and close-range techniques have facilitated the application of photogrammetry to many other fields, such as Earth observation, environmental monitoring, smart cities, architecture, industrial inspection, robotics, and so on.

This entry provides a brief review of the historical development of photogrammetry and presents the fundamental techniques for deriving 3-D information from imagery via photogrammetry. Some observations and considerations about the future development of photogrammetry are also presented.

Historical development of photogrammetry

Photogrammetry began soon after the invention of photography in 1839. In 1849, Aimé Laussedat was the first person to use terrestrial photographs for the compilation of a topographic map and is now referred to as the “father of photogrammetry” (Birdseye 1940). In 1893, Albrecht Meydenbauer was the first person to use the term photogrammetry. He also designed the first wide-angle lens for topographical mapping and architectural surveying (Meyer 1987). The 1900s were pioneering years in the development of photogrammetry, with achievements including the generation of topographic maps based on techniques such as a “photographic plane table” using terrestrial photography or aerial photography supported by kites or balloons (Konecny 1985).

With the Wright brothers’ invention of the airplane in 1903, the development of photogrammetry entered a prosperous era due to the better camera platform. Since then, the development of photogrammetry has followed three development stages: analog, analytical, and digital photogrammetry.

Analog photogrammetry

The theory of stereoscopic vision widely used in the 1900s provided the foundations for analog photogrammetry. When looking at an object at a particular distance, our eyes simultaneously focus on and converge upon the object. The angle of convergence is called the parallactic angle. Objects at different distances from the
viewer are perceived through different parallactic angles. Due to the parallactic angle, the image of an object falls on different locations on the retinas of the left and right eyes. Points at different distances from the eyes appear at different relative locations. The difference in the position of the points on images is called parallax, thus changes in the parallactic angle result in parallax. The measurement of parallax offers an accurate method of measuring height or depth from stereo images. Figure 1 illustrates the principle of height determination from stereoscopic vision.

In Figure 1, assuming that two cameras (E_l and E_r) take images of an object at point P, the object’s image will appear as two image points (p_l and p_r) on the left and right images. Their locations in the images along the x direction are x_l and x_r. The parallax is determined as \( p = x_l - x_r \). The height can then be computed from the parallax measurements:

\[
H_p = H - \frac{Bf}{p}
\]

where \( B \) is the baseline length between the two cameras and \( f \) is the focal length of the camera. It can be seen that parallax of any point is inversely proportional to its distance from the camera and that parallax due to height occurs only on the x axis (the direction of flight for aerial images).

If looking at a stereo pair of images, with one eye looking only at the first image and the other looking only at the second image, the scene would appear as a 3-D image. Viewing a stereopair is actually quite difficult without the aid of a mechanical device, the simplest of which is called a stereoscope. A stereoscope set up for viewing a stereopair is shown in Figure 2.

From the beginning of the twentieth century, analog photogrammetry was developed based on the above theory of stereoscopic vision. In 1908, Eduard von Orel invented the first stereoautograph. The development of this plotter was significant because its construction principles made terrestrial photogrammetry practical in mountainous areas by allowing the operator to trace elevation contours directly (Collier 2002). After 50 years of development, this type of instrument reached maturity in the 1960s. As these instruments used an optical or a mechanical projection device, or a combination of them, to simulate the imaging process and to intersect the 3-D positions of the objects in the images, they were called analog photogrammetric instruments. During the evolution of analog photogrammetry, the main focus of development was on expensive stereoscope instruments.
Analytical photogrammetry

Analytical photogrammetry began with the invention of the computer in 1950 (Konecny 1985), which allowed digital projections to replace the physical projections (e.g., the optical or mechanical projections) used in analog photogrammetry. Digital projection uses a computer to calculate the 3-D positions of objects in images in real time, based on the colinearity equation. Fundamental to the colinearity equation is a perspective projection, where a point in the real world, its image point, and the perspective center of the image lie on one straight line. The colinearity equation is described as:

\[
\begin{align*}
    x - x_0 &= -f \frac{m_{11}(X - X_S) + m_{12}(Y - Y_S) + m_{13}(Z - Z_S)}{m_{31}(X - X_S) + m_{32}(Y - Y_S) + m_{33}(Z - Z_S)} \\
    y - y_0 &= -f \frac{m_{21}(X - X_S) + m_{22}(Y - Y_S) + m_{23}(Z - Z_S)}{m_{31}(X - X_S) + m_{32}(Y - Y_S) + m_{33}(Z - Z_S)}
\end{align*}
\]  

\(2\)
This equation represents a direct link between an image point \((x, y)\) and its 3-D position \((X, Y, Z)\) in the object space. \((x_0, y_0)\) is the principal point (the foot of the perpendicular on the image of the perspective center) and \(f\) is the focal length of the camera. \((X_S, Y_S, Z_S)\) are the coordinates of the camera center in the object space and \(m_{ij}\) are the elements of a rotation matrix that is determined by three rotation angles \((\phi, \omega, k)\) of the camera frame with respect to the object space. However, as each equation represents a straight line, the conjugate image points from a stereo pair of images need to be measured to compute the object point’s 3-D position. This process is referred to as space intersection. The colinearity equation provided the theoretical foundation for analytical photogrammetry.

In the early 1950s, Everett Merritt published works on analytical photogrammetry. He developed a series of analytical solutions for camera calibration, space resection, interior and exterior orientation (EO), relative and absolute orientation of stereo pairs, and analytical control extension (Doyle 1964). In 1955, Duane Brown developed new approaches for camera calibration and the mathematical formulation of the bundle adjustment. This was a significant development because it involved the simultaneous solution of the EO parameters of the camera and the coordinates of the survey points, along with the interior orientation (IO) and systematic radial lens distortion. In 1957, Uuno Helava developed the first analytical stereoplotter (Konecny 1985). A computer was used to drive the instrument around the stereomodel and to digitally transform the coordinates between the image and the map. Various types of analytical stereoplotters were developed, reaching a climax in the 1980s due to the technological improvements in large-scale integrated chips, personal computers, and interface technology. Figure 3 shows an example of an analytical photogrammetric system.

Significant technological developments in analytical photogrammetry were also made at this time. For example, the bundle adjustment for large photogrammetric blocks with self-calibration, developed by Duane Brown in

![Figure 3](image-url)  
**Figure 3**  An example of an analytical photogrammetric system.
the 1960s, improved the accuracy and reliability of photogrammetric adjustments. The direct linear transformation method developed by Sam Karara in 1971 enabled photogrammetric applications with non-metric cameras (Wolf 2001). These developments in technologies and instruments led to immense growth in the application of analytical photogrammetry in various fields during the 1980s.

Digital photogrammetry

The previously described analytical methods required an operator to view the photographs and place floating marks in the correct positions to derive the 3-D information. Digital photogrammetry originated from the search for ways of automating the manual work involved in analytical photogrammetry. For example, the task of placing the floating marks on photographs was replaced by image matching, which involves identifying the conjugate points (points representing the same image texture) on a pair of digital images, from which the 3-D coordinates of the point can be computed. Such processes automate and speed up the extraction of 3-D information from a stereo pair of images. Digital photogrammetry also automated other processes, such as image orientations.

Although digital photogrammetry originated in the 1950s, major research activities did not begin until the 1980s, sparked by significant advances in electronics and computing, such as digital cameras, parallel processing, and increased storage capacity (Schenk 1999). In 1957, Gilbert Louis Hobrough first demonstrated the concept of image correlation on a Kelsh plotter. Due to the technology at the time, the correlation process was analog and hardware was used to compare the gray levels of the images (Schenk 1999). In 1967, Hobrough developed the gestalt photo mapper, an automated orthophotographic system that used the correlations between stereo images. The system consisted of a scanner, correlator, computer system, operator console, and input/output device. Uuno Helava also played a central role in the development of digital photogrammetry, helping to develop digital photogrammetric workstations for the Defense Mapping Agency in 1986. Zhizuo Wang of China presented his ideas and solutions for a fully automatic digital photogrammetric system in 1978 and developed the WUDAMS, a fully automatic digital photogrammetric system (Wang 1998). In the 1990s, the WUDAMS was upgraded to a digital photogrammetric workstation, Vitruvzo, and a new generation, DPGrid, was recently developed based on network computing and cluster parallel processing (Zhang et al. 2011). In the early 2000s, Airbus Defence and Space in France released a new generation, fully automatic photogrammetric system named PIXEL FACTORY. Using mass parallel computing technology and native open architecture, PIXEL FACTORY is capable of automatically processing vast numbers of images to produce a wide range of 3-D cartographic end products such as digital surface models (DSMs), digital terrain models (DTMs), and TrueOrtho images.

3-D from imagery via photogrammetry

Deriving 3-D information from imagery via photogrammetry actually involves the reversal of the photographic process. If the position and orientation information of the photography ray when taking the images can be recovered, the reverse process can be achieved so that the 3-D information can be derived from the image. The process of recovering the photographic ray’s position and orientation information is called image orientation.
Image orientation

Image orientation includes interior orientation (IO) and exterior orientation (EO). The former derives the relationship between the image measurement and the image-space coordinate systems, while the latter derives the relationship between the image-space and object-space coordinates. The parameters derived from the image orientation enable the 3-D positions of objects to be calculated from their corresponding image points through the aforementioned colinearity equation.

The interior orientation relates the coordinates measured on the image to those of the object to be measured. To do so, it is necessary to establish the location of the principal point \((x_0, y_0)\) in the image-space coordinate system, as illustrated in Figure 4. The principal point \((x_0, y_0)\) and the camera focal length \(f\) are referred to as the IO parameters in the colinearity equation, as they are the camera’s intrinsic parameters and, thus, do not change when the location and orientation of the camera change.

Taking aerial images as an example, normally there are at least four fiducial marks distributed in the four corners of the image. These marks have known coordinates in the image-coordinate system; these are measured and used as observations. From these observations, a transformation between the observation and image coordinate systems is computed, which can then be used to determine the principal point \((x_0, y_0)\) in the image-space coordinate system and transform other coordinates measured on the image to the image-space coordinate system.

The images taken by cameras may have distortions, as illustrated in Figure 4, that need to be estimated and calibrated for accurate measurement. In the case of film-based images, distortions may occur because of lens distortion and other factors, such as stretching or shrinkage of the film due to handling, processing, or storage. Distortions in digitally recorded images may occur because of lens distortion, dissimilar pixel spacing, or differences in the pixel dimensions of the imaging device. Ultimately, the shape of an object measured on the image must be the same as that of the image when it was recorded. This can be achieved by adding distortion correction parameters to the left side of the colinearity equation in equation 2. The camera distortion parameters also belong to the IO parameters.

The image IO parameters are normally calibrated separately through a special control field with precisely measured targets as ground truth, or through self-calibration approaches.

Figure 4  (a) Image IO parameters \(f\) and \((x_0, y_0)\); (b) image distortions.
that incorporate the IO parameters into a photogrammetric bundle adjustment process so that they can all be solved together and simultaneously with other unknowns.

There are six EO parameters describing the relationship between the image’s and the object’s coordinate systems: the aforementioned three rotation angles ($\phi$, $\omega$, $k$), which describe the angular relationships, and $(X_S, Y_S, Z_S)$, which describe the location of the point of exposure of the image in the object coordinate system. These exterior orientation parameters can be derived in one of three ways:

1. Direct space resection,
2. Relative orientation followed by absolute orientation,
3. Simultaneous orientation by bundle adjustment.

1. **Direct space resection.** Based on the colinearity equation (equation 2), if one point in the object space and its corresponding point in the image space are known (called the control point), they contribute two observations. If three control points are available, the six EO parameters can be solved. In practice, four or more control points are normally used to calculate the EO parameters for improved accuracy, using a least-squares adjustment. This direct space resection method is normally used to determine the EO parameters of single images. For a stereopair or an image block, the exterior orientation parameters are derived by one of the other two methods because they require fewer control points.

2. **Relative orientation and absolute orientation.** Relative orientation is used to establish the relationship between two images without knowing about the object. Relative orientation is based on the coplanarity condition that two image points on a stereopair, the perspective centers of the two images, and the object point lie on the same plane (Figure 5). It assumes that the orientation and position of the left image are fixed, and the relative relationship between the left and right images can be determined by the five relative orientation parameters $b_y$, $b_z$, $\omega$, $\phi$, and $\kappa$ (assuming $b_x = 1$). $\omega$, $\phi$, and $\kappa$ are the rotation angles that are needed to make the right image coordinate system parallel to the left image coordinate system. $b_y$ and $b_z$ are the translations required to correctly position the right image’s perspective center.

   With the coplanarity condition, each pair of conjugate points identified on the stereo images generates one observation. At least five conjugate points are required for a unique solution of the five relative orientation parameters. Normally, six points are used for this process, including the two principal points and four other points distributed on either side of the principal point along the $y$ axis of the images. These are often referred to as von Gruber points. Once the five relative orientation parameters have been obtained, a 3-D model of the imaged scene is established. At this time, however, the 3-D model is not accurately scaled and its coordinates are based on an arbitrary coordinate system.

   Before the 3-D model derived from the relative orientation can be used for measurement, it must be scaled and oriented to the object coordinate system. This procedure is called absolute orientation. Absolute orientation is a 3-D conformal transformation that converts the model coordinates obtained during the relative orientation into correctly oriented mapping coordinates. There are seven parameters in this 3-D conformal transformation, including three rotation angles $R_\omega$, $R_\phi$, and $R_\kappa$, three translation components $T_X$, $T_Y$, and $T_Z$, and a scale factor $s$. At least three control points with known horizontal and vertical positions are necessary to achieve a result. The accuracy of absolute
orientation depends on the quality of the relative orientation and the accuracy of the control points.

The relative and absolute orientations can be performed on an individual stereopair or on complete image blocks covering a large area. In the latter case, the term aerial triangulation is often used to describe the procedure.

3. Simultaneous orientation by bundle adjustment. An alternative to the relative/absolute orientation methods is bundle adjustment. This method is based on the principle that, given a tie point in an image, it is possible to produce an observation based on the aforementioned colinearity equation. This observation represents an optical ray originating from the measured image point that goes through the center of the camera to the ground point. From the conjugate tie points identified on a stereo pair of images or multiple images in a block, a bundle of optical rays defined by the tie points can connect to the images themselves to form an image network and, thus, connect the images and object space. Ideally, the optical rays from the same conjugate tie points on different images should intersect at exactly the same ground point in the object space; however, in reality this may not be the case (Figure 6a) due to various uncertainties and errors. Therefore, bundle adjustment is used to adjust and solve the accurate image orientation parameters so that the corresponding rays intersect correctly (Figure 6b). This process is basically a least-squares adjustment based on the colinearity equation.

Given a few 3-D control points and tie points identified on the images, the image orientation parameters and the object coordinates of tie points can be computed simultaneously through bundle adjustment. This involves a
simultaneous resection and intersection process. The process may be applied either on a stereopair-by-stereopair basis, or on the entire image block. In the latter case, the term block adjustment is often used to describe the procedure. In the stereopair-by-stereopair case, there needs to be at least three 3-D control points in the overlap area of each stereopair. Observation of the image-space coordinates of each control point in the overlap area allows the image orientation parameters to be computed for both images. For an image block, a few 3-D control points and a number of conjugate tie points identified from the images are necessary, and all of the orientation parameters for the images are computed at once. The entire image block is processed in a single homogenous coordinate system.

In the bundle adjustment process, different weights can be assigned to different observations depending on their a priori precisions. The residuals of all parameters can also be computed and used to evaluate the performance of the bundle adjustment, which is an important advantage of this method.

**Figure 6** (a) The optical rays from the conjugate tie points do not intersect at the same ground point due to various uncertainties and errors, and (b) the improved results after bundle adjustment.

**Automatic solutions in digital photogrammetry**

Along with the development of digital photogrammetry since the 1980s, significant advances have been made in digital image processing; these have been applied to almost every aspect of photogrammetry, from image acquisition to image processing. These developments have also facilitated the automation or semi-automation of photogrammetric processing in modern digital photogrammetric workstations. The automation of digital photogrammetry strongly depends on the automation of image matching and the aforementioned IO and EO processes.

**Automatic image matching**

Image matching is the process of finding conjugate image correspondences (points or patterns) in the overlapping regions of two or more digital images. The process is based on either examining and matching the grey levels of small portions (image patches) of both images in a stereopair, or matching an image patch with an
PHOTOGRAMMETRY: 3-D FROM IMAGERY

image template. The matching may be done on a pixel-by-pixel basis (area-based matching) or by examining and matching the individual features of the image patches (feature-based matching). The most important applications of image matching are the automatic IO and EO of images, and the automatic creation of DTMs from multiple images. For the former, only a small number of reliable image correspondences with a favourable distribution are required, whereas for the latter, dense and reliable image correspondences are necessary.

Tremendous work has been done on image matching in the fields of photogrammetry and computer vision. The most straightforward method is normalized cross correlation (NCC), which directly assesses the degree of agreement between two local image windows by cross-correlation of their grey levels (Lhuillie and Quan 2002). An important development in image matching is the scale invariant feature transform (SIFT) method (Lowe 2004). SIFT detects points of interest based on local 3-D extrema in the scaled-space pyramid invariant over a wide set of transformations and matches the points according to descriptors defined by their gradient distributions in the detected local regions. SIFT provides automatic robust matching results even in the presence of scale changes and distortions. However, SIFT only provides sparse matching results. A representative method of area-based matching is semi-global matching (SGM) (Hirschmuller 2008), which combines the concepts of global and local stereo methods for pixel-wise matching. SGM approximates the cost of the global aggregation of matching from a number of 1-D cost paths, which provides accurate dense matching results. A representative method of feature-based matching is self-adaptive triangulation-constrained matching (SATM) (Wu, Zhang, and Zhu 2011), which uses triangulations to constrain the matching of feature points and edges. An important characteristic of SATM is that the triangulations are dynamically updated along with the matching process by inserting the newly matched points and edges into the triangulations. The most distinctive features are always successfully matched first, so that the densification of triangulations automatically self-adapts to the changes in image texture, and provides robust constraints to generate dense and reliable matching results. Figure 7 shows an example of SATM’s results for the automatic matching of Mars ground images acquired by NASA’s Mars Exploration Rover, Opportunity, and the generated DTM. SATM was also used to generate high-precision lunar DTMs for selecting the landing site for the Chinese Chang’E-3 lunar exploration mission (Wu, Hu, and Guo 2014).

Automatic image orientation

IO and EO are the fundamental orientation procedures in analog and analytical photogrammetry. In digital photogrammetry, for example in an interactive setting using digital photogrammetric workstations, the orientation tasks are essentially performed in the same way as on an analytical plotter. This section focuses on automatic orientation procedures, highlights their important differences, and discusses some solutions for digital photogrammetry.

Automatic IO is the starting point of the automation chain. For aerial images from scanning film, automatic measurement of the fiducial marks is the key step in automatic IO. Images from a metric camera contain at least four fiducial marks in the corners. Template matching can be used for this task. This process is driven by the structure description of the template that can be constructed for a fiducial mark, which automatically matches the predefined template with the
Figure 7  (a) A Mars satellite image showing the mapping area; (b) a stereopair of ground images of the area taken by the Mars Rover, with the matching results marked in red; (c) another stereopair showing large perspective changes and the matching results; and (d) the generated DTM from the matching results.

fiducial marks. The autonomous process requires a general and robust solution to accommodate the different types of fiducial marks. Subpixel localization of the fiducial marks should also be emphasized, as the pixel size is likely to be larger than the expected precision of the fiducial centers.

The development of automatic relative orientation has primarily focused on image matching to identify conjugate points. The aforementioned image matching methods can be used to find conjugate points automatically. The existing point-based algorithms developed to determine the orientation parameters in analytical photogrammetry can be used for this purpose. At least five conjugate points are necessary to determine the parameters. In practice, dozens or hundreds of matched conjugate points with a favorable distribution are normally used to identify the relative orientation parameters using least-squares adjustment. To determine the EO parameters of single images through automatic space resection and of stereopairs through automatic absolute orientation, it is critical to automatically establish the relationship between the image and object spaces. Schenk (1999) discussed the theory of using linear (e.g., road boundaries) or surface features (available from existing DTMs or from laser altimetry) as entities in the adjustment procedure, to compute the EO parameters automatically. More recently, Tommaselli and Berveglieri (2014) presented a more practical solution for automatic EO. They used a special camera attached to a GPS receiver to collect panoramic images in nadir view, while simultaneously collecting the 3-D coordinates of control points using the GPS. The panoramic images were then automatically matched with the aerial or satellite images to identify the locations of the control points in the latter to compute the EO parameters.

Future trends in photogrammetry

There is a tremendous worldwide demand for 3-D data, yet the methods for generating 3-D
data from imagery are still not fully automated and remain relatively slow. The development of a more automated photogrammetric process for deriving 3-D data from various types of images is a challenge. High redundancy (e.g., with every ground point visible in about 10 images) may play a major role in the design of fully automatic photogrammetric methods; for example, the UltraCam digital aerial mapping system has eight lenses, providing high imaging redundancy. Multi-image matching with high redundancy ensures reliable matching and enables high-quality 3-D reconstructions to be produced entirely automatically.

Laser scanning has been popular since the 1990s, as it enables much faster delivery of 3-D information than traditional photogrammetric techniques. It has even been argued that laser scanning may replace traditional photogrammetry in the future. However, in the past few years, reliable and automatic image matching has become one of the most active research areas in both the photogrammetric and the computer vision communities. The generation of accurate and dense 3-D information from multi-angled images from multiple sensors with a high level of automation is now a reality. A typical example is the “Building Rome in a Day” project by Microsoft Research. The development of oblique photogrammetry in recent years also offers encouraging solutions for 3-D city data generation and modeling. Photogrammetry and laser scanning have distinct characteristics that render them preferable for certain applications. The respective advantages and disadvantages of the two techniques suggest that their integration would provide better performance than can be achieved by either method alone. Wu, Hu, and Guo (2014) provided an example of integrating lunar imagery and laser altimeter data for consistent and precise lunar topographic mapping.

The timeliness of photogrammetry is currently attracting plenty of attention. In applications such as industrial measurement and real-time monitoring, the timeliness of photogrammetry is the key to success. The development of real-time (or quasi-real-time) photogrammetry has become an urgent task. Compared with traditional photogrammetric techniques, the research and development of real-time photogrammetry needs to overcome certain challenges, such as the full automation of photogrammetric image interpretation, the development of embedded algorithms, chips, and hardware systems for real-time image processing, and the development of new real-time photogrammetric sensors and multisensor collaborative technologies.

In addition, there is a trend of integrating methods developed for computer vision, such as shape-from-shading, shape-from-shadow, and structure-from-motion, into photogrammetry to allow better derivation of 3-D information from images. Regardless of the challenges ahead, photogrammetry remains the most complete, economical, portable, flexible, and widely used approach for deriving 3-D information. With the further developments mentioned here, photogrammetry has a bright future.

Phylogeography and landscape genetics integrate molecular genetics with geography, ecology, and evolutionary biology to provide an understanding of patterns in the spatial distributions of biological diversity. The historical and contemporary processes that underlie the distributions of organisms are inferred from signatures left in spatial patterns of genetic variation. Phylogeography and landscape genetics bring advanced molecular and geospatial tools to bear on issues that are vital to the field of biogeography, including how and where biodiversity arises, how species respond to changing climates, and how and where conservation efforts should be focused. The two disciplines contribute to and integrate with conservation biology, evolutionary biology, paleoecology, geomorphology, and emerging climate and sustainability sciences.

Substantial conceptual and methodological overlap exists between phylogeography and landscape genetics, but the two fields differ in their spatial and temporal scales of study. Phylogeographers investigate impacts of historical geographical conditions on genetic variation within or between species over broad spatial extents, while landscape geneticists focus on contemporary genetic variation within species at the scale of individual landscapes. The spatial and temporal scales investigated using the two approaches can be viewed as a continuum, but individual studies are necessarily limited to discrete time periods and spatial extents. Thus, the appropriate molecular and analytical tools to test a given biogeographical hypothesis may differ with the specific scale(s) under study. Ultimately, however, phylogeography and landscape genetics are highly complementary when used in combination to tell a more complete biogeographical story than either one alone could have done.

Phylogeography arose in 1987 as a synthesis between advancing molecular genetic technology and traditional biogeography. Phylogeographers use both phylogenetic and population genetic methods to investigate evolutionary responses such as speciation, adaptation, and demographic changes (e.g., population expansion or contraction) to broad geographical features (e.g., glaciation, changing climates). The timescales of study range from thousands to millions of years and spatial scales tend to range from continental to global. Phylogeographers sample genetic variation in one or a few closely related species. For example, genetic relationships between modern and ancient (fossil) European red deer indicate that this species persisted in northern refugia during the last glacial period, but that most modern red deer in Europe descend from ancestors that survived in unglaciated areas on the Mediterranean coast (Meiri et al. 2013). Comparative phylogeographers investigate biogeographical histories across distantly related species. Typically, comparative phylogeographic studies compare the responses of different organisms to the same geographical conditions. Rissler and Smith (2010) used genetic information from 37 amphibian species to show a high density of suture zones (areas of overlap between distinct genetic lineages) concentrated at the southern...
end of the Appalachian Mountains, indicating that this region is a hotspot of North American amphibian diversity and an area of special conservation concern.

The field of landscape genetics, which combines population genetics and landscape ecology, was introduced in 2003. Landscape geneticists focus on ecological time periods (the present to hundreds of years) and on finer spatial scales (hundreds of square kilometers). Population genetic methods are used to investigate how ecological processes such as invasive species dynamics and biological responses to human-induced land-cover change are impacted by geographical variation in the matrix (the intervening land cover between habitats) and arrangement of habitats within the matrix. For example, a study in central Germany indicated that both the river Rhine and a nearby highway restrict contemporary genetic connectivity between populations of endangered wildcats (Hartmann et al. 2013).

The evolutionary and ecological processes underlying patterns of genetic variation depend intrinsically on spatial context. As geospatial environmental data have increased in availability, the incorporation of geographical features in phylogeography has shifted from qualitative (e.g., visualization of genetic variation on maps) to quantitative. The burgeoning discipline of landscape genetics has included quantitative geographical analyses since its inception. For example, Mantel tests are commonly used to detect correlations between pairwise genetic and geographical distances. Other geographically quantitative methods in current use include principal components analysis and canonical correlation analysis of genetic covariation with geographical variables.

The use of geographical information science (GIS) to assess spatial patterns of genetic variation is an area of active synthesis in both phylogeography and landscape genetics. One relevant GIS-based method is species distribution modeling (SDM), in which climate maps are used to model historical and future species distributions based on assumptions about ecological niche parameters. For instance, SDMs of European birds, mammals, and plants predicted that diversity will shift broadly northward over the next 70 years under scenarios of climate change (Thuiller et al. 2011). Phylogeographers and landscape geneticists also use GIS methods such as wombling and least-cost path (LCP) analysis. Wombling combines interpolated raster surfaces for genetic and environmental variables to identify spatial locations of boundaries in genetic variation. LCP analysis uses resistance surfaces (hypothetical or, ideally, empirically based spatial quantification of differences in resistance of land cover types to organismal movement) to model likely paths of migration or dispersal. In a comparison of LCP-modeled dispersal routes and estimates of gene flow between bighorn sheep, anthropogenic barriers (e.g., urban areas) explained inconsistencies between observed and predicted dispersal patterns (Epps et al. 2007).

Phylogeography bridges the fields of phylogenetics and population genetics, while landscape genetic analyses are primarily population genetic. Phylogenetic analyses take the form of trees or networks representing relationships within or between species. Population genetic analyses in both fields frequently rely on coalescent theory, which models the path to the most recent common ancestor backwards in time from modern sampling of genetic variation. The coalescent helps to resolve signatures of recent and historical events like range expansion and loss, migration, and population bottlenecks caused by colonization events.

Phylogeographers and landscape geneticists must carefully consider which molecular genetic tools are most appropriate for a given
research question. Phylogeographers use genetic variation, in part, as a powerful complement to the highly incomplete fossil record of spatial distributions of biological diversity. Likewise for landscape geneticists, genetic variation is a surrogate for direct dispersal data (e.g., global positioning system (GPS) tracking or mark recapture data) that may be difficult to obtain. Genetic variation in organisms arises via mutations in deoxyribonucleic acid (DNA) sequences. The variants caused by mutation then change in frequency as a result of processes such as random genetic drift, demographic changes (e.g., in population size), gene flow, and natural selection. Researchers in the two fields focus primarily on sampling neutral genetic variation (i.e., variation not subject to natural selection). Because mutation rates differ for different portions of an organism’s genome, various types of genetic markers capture snapshots of biogeographical processes on different timescales.

The primary genetic markers used in phylogeographical studies have traditionally been uniparentally (often maternally) inherited organelar DNA sequences, including mitochondrial DNA (mtDNA) in animals and chloroplast DNA (cpDNA) in plants. Useful mtDNA markers contain variable regions (informative over thousands to tens of thousands of years), along with regions that are far less variable (informative over millions of years). Because inheritance is exclusively from one parent, analyses using cpDNA or mtDNA sequences may tell a sex-biased story. For instance, comparison of genetic variation in humans between maternally inherited mtDNA and paternally inherited Y chromosome sequences showed evidence of historically higher migration rates in females than in males (Seielstad, Minch, and Cavalli-Sforza 1998). The genetic markers typically used in landscape genetic studies reflect a focus on recent and ongoing processes. The most commonly used markers for landscape genetic studies are microsatellites. These markers change rapidly enough to be informative over tens to hundreds of years. Microsatellites are biparentally inherited nuclear markers that consist of short, repeated sequence fragments of variable length.

Increasingly, both landscape geneticists and phylogeographers combine data from as many molecular markers as possible to provide robust comparisons of biogeographic hypotheses because individual markers tell only a small part of a complex story. A substantial challenge in both fields is the lack of readily available genetic markers for all but a few “model” (extensively studied) organisms. Markers such as amplified fragment length polymorphisms (AFLPs) provide an inexpensive way to sample genetic variation without pre-existing sequence data, but may be less informative. DNA sequences for entire genomes are becoming progressively more attainable for a wide range of organisms. Genomic datasets simplify identification of large numbers of markers, including microsatellites and single nucleotide polymorphisms (SNPs). The use of large SNP datasets allows for easier detection of adaptive genetic variation (i.e., subject to natural selection). Adaptive variation is increasingly being incorporated in phylogeographic and landscape genetic studies.

Physical geography

Antony R. Orme
University of California, Los Angeles, USA

Definition and terminology

In literal terms, physical geography seeks to describe Earth’s natural surface features (Greek geo, Earth; graphos, writing). In practice, it has come to be identified with explaining the nature and distribution of Earth’s landforms and formative processes (geomorphology), weather and climate (climatology, meteorology), water in various states (hydrology, glaciology, oceanography), soil and sediment (pedology, sedimentology), and plants and animals (biogeography, ecology) (Figure 1). Some scholars focus on the more physical themes and treat biogeography (plants, animals, organic soils) separately. In reality, however, no study of Earth’s physical or biological realms can now ignore their interdependence or their interaction with human activity. Physical geography is thus better defined as the geography of the natural world, explained both for its intrinsic interest across space and time, and in its human context.

Scientific progress should always be viewed against its cultural milieu because social mores, religious beliefs, economic wellbeing, political arrangements, and technological assets may promote or restrict new ideas, investigation, and debate. This entry focuses sequentially on the changing nature of physical geography in a human context over time and assesses how present practices predict the field’s future. Not all practitioners would have been called geographers at the time but their work has become the essence of physical geography today (Orme 2013a–f).

Physical geography of the early human world

From earliest human times, people bent on survival learned from experience about weather, potable water, edible plants, and natural hazards. Archaeology reveals much about prehistoric life and livelihood, cave dwellings affording shade and shelter, campsites above flood waters, trackways along rivers and through wetlands, and the use of fire. Early peoples understood the impact of changing seasons on water resources, plant life, and animal and fish migrations. They also fashioned useful tools, weapons, fishing tackle, containers, and boats to serve hunting and gathering needs. They acquired folklore, incidences of which have emerged from archaeological diligence, providing insights to contemporary environments, and gathering momentum among the advancing Paleolithic and Mesolithic cultures of late Pleistocene and early Holocene time.

These early peoples lacked literacy in a modern sense but acquired measures of numeracy and graphicity. Petroglyphs carved on rock reveal an environmental awareness. More dramatic are the cave paintings that survive at Lascaux in France and Altamira in Spain, which with associated materials reveal much about animals hunted and plants eaten. They were also fascinated by the Sun, Moon, and stars beyond. An awareness of the march of the seasons led communities to build structures, such as Stonehenge, which showed a sense of astronomy.

Physical geography among early literate peoples

When folklore was written down, the documentary record began, albeit beguiled by ambiguity, superstition, and mythology. But literacy likely implied some cultural stability, as sedentary peoples fostered by Neolithic farming and animal domestication allowed those not needed for food production time to reflect on and record the world around them. Among these were priests who encouraged literacy in ways appropriate to their beliefs and provided environmental indicators for later cultures (Orme 2013a).

Early scribings contain incidental observations on environments and astronomy, as depicted on Minoan frescoes in Bronze Age Crete, cuneiform scripts on Sumerian and Babylonian clay tablets, and hieroglyphs and pictographs on Egyptian papyrus scrolls. These show an awareness of Sun and sky, rivers and coasts, storms and high seas, plant and animal life, and measurement units. Around 3000 BCE (Before the Common Era), the Sumerians had creative gods for heaven, Earth, air, and water, and lesser gods for mountains and rivers. By 2500 BCE, astronomers in the Nile valley had devised a solar calendar based on a year of 365 days.

For agriculture and settlement to prosper amid the seasonal floods and droughts of the Nile, Tigris, Euphrates, and Indus valleys, these early cultures intuitively grasped the links between climate, hydrology, and food production. Irrigation ditches were being built in Mesopotamia before the date later proposed for Earth’s creation by Judeo-Christian biblical scholars. The success of Egyptian irrigation works, Phoenician aqueducts, Persian qanats, Indian canals, and Chinese flood controls shows an empirical appreciation of water, or conversely drought. Seafarers understood the links between storms and high sea, the perils of shoaling water and lee shores, the tranquility of safe anchorages, and the nature of tides.

Physical geography in the classical Mediterranean Basin

Greek scholars laid the foundations of physical geography in the Mediterranean Basin about 3000 years ago, whence their ideas diffused widely. Although imperfect, their science yielded much that was fundamental to understanding the physical world. Then, as more rational enquiries began probing their habitable world (oikoumene), an ordered semblance of physical geography emerged from philosopher-scientists. Their observations advanced knowledge because they sought explanation, which involved speculation and mathematics. Although most of this work has been lost, partial reconstructions by later scholars reveal their geographies.

Thales of Miletus (ca. 624–546 BCE) was among the first philosophers to explain nature without invoking mythology. Anaximander (ca. 610–547 BCE) pondered water’s origins. Pythagoras (ca. 582–500 BCE) saw a spherical Earth rotating on its own axis, and Aristarchus (ca. 310–250 BCE) favored a heliocentric view of the solar system. Herodotus (484–425 BCE) saw seasonal floods deliver sediment to the coast and equated Nile distributaries with the Greek letter delta (Δ). Aristotle (384–322 BCE) measured Earth’s sphericity, speculated on weather and water, and implied cyclic uplift and subsidence. He followed Hippocrates (ca. 460–370 BCE) in linking climate to human health and behavior! Theophrastus (371–287 BCE) defined the hydrologic cycle and its effect on rivers, and described winds, plants, and animals. Archimedes (288–212 BCE) defined principles for mechanics and hydrostatics. In Geographika, Eratosthenese (ca. 276–194 BCE) discussed Earth’s
PHYSICAL GEOGRAPHY

circumference and its frigid, temperate, and torrid climate zones. Polybius (ca. 200–118 BCE) opined that streams eroded valleys, and navigators, from Pytheas (ca. 325 BCE) and Posidonius (135–51 BCE) in the Atlantic to Seleucus (ca. 150 BCE) in the Indian Ocean, pondered the Earth-Moon-Sun-forcing of tides. Crude maps of the known world improved.

Ancient Rome’s original contributions to science were more practical, although Greek traditions of geography continued. Roman engineers who built aqueducts, highways, and harbors understood many surface processes, exemplified by a surviving text on aqueducts by Sextus Julius Frontinus (40–103 CE (Common Era, equivalent to AD)). Thus, in his 17-volume Geographica, Strabo (63 BCE–24 CE), a Greek scholar flourishing under Roman rule, attributed landforms and ocean changes to earthquakes and volcanic activity, discussed sediment transport, related delta size to drainage-basin erodibility, and bemoaned the effects of forest clearance on denudation. But uncertainties persisted. Astronomer and mapmaker Ptolemy (ca. 100–170 CE) of Alexandria reverted to a geocentric planetary system, with a stationary Earth at its center. Around 540 CE, the Byzantine traveler Cosmas Indicopleustes described a flat Earth on which sailors ventured beyond the horizon at their peril, and explained night and day as a response to the Sun circling a heaven-piercing mountain. While such thoughts may have confused ordinary folk, the torch of scientific progress was relayed to more distant cultures.

Physical geography in early Islamic and Asian cultures

With the decline of classical Mediterranean civilizations, the expansion of Islam from its seventh-century roots absorbed Greek and Roman legacies, while environmental cognition, physics, and mathematics were advanced by Arab, Persian, Indian, and Chinese scholars. Geography flourished under the Abbasid Dynasty, after the caliphate moved in 766 CE from Damascus to Bagdad where Greek science survived in Persian culture. Abu Ma’shar’s ninth-century work defined the astronomical forcing of tides. Astronomers in tenth-century Basra conceived a cycle of erosion and sedimentation that reversed the roles of land and sea over a Great Year of 36,000 years. In Quadrans Habilitatis, Abu Rihan Birunensis (973–1038 CE) described south Asia and east Africa. Al-Idrisi (ca. 1099–1165) and Ibn Batuta (ca. 1304–1369) described features across Eurasia. Ibn Khaldun (1332–1406) identified seven climatic zones, which he dubiously correlated with human traits and behavior. Meanwhile, Persian scholar Avicenna (Ibn Sina, 980–1037) pondered time, rocks, mountains, and denudation in central Asia:

Either [mountains] are the effects of upheavals of the crust of the Earth, such as might occur during a violent earthquake, or they are the effect of water, which, cutting itself a new route, has denuded the valleys, the strata being of different kinds, some soft, some hard … It would require a long period of time for all such changes to be accomplished, during which the mountains themselves might be somewhat diminished in size. (Translation of Avicenna, 1027)

Chinese scholars addressed similar issues. Shen Kuo (1031–1095), noting coastal progradation and sediment-laden rivers, suggested that land is reshaped over time by uplift, erosion, and deposition. He inferred climate change from fossil bamboo found far beyond its present range. The seven voyages of Zheng He (1371–1435) from China to the Indian Ocean (1405–1433) recorded water depths, winds, and currents, while Chinese usage of printing and the magnetic compass were introduced to Europe.
Physical geography in medieval and Renaissance Europe

As the western Roman empire collapsed and its eastern counterpart in Byzantium atrophied before barbarian onslaughts, much of Europe was plunged into intellectual gloom. Even so, amid the uncertainties of these times, glimmers of light persisted as Philoponus (c. 490–570) of Alexandria challenged religious concepts of Earth’s origin. When barbarian leaders became better educated, they encouraged observation, as noted by the Venerable Bede (672–735) in Britain. But many people still thought of a geocentric universe and flat Earth.

Classical learning saw some renaissance under Charlemagne, king of the Franks and Germans from 768 to 814, but this later declined amid dynastic strife. During the Middle Ages, with social contacts mostly local, literacy rare, and religion persuasive, science struggled for debate. Space and time were poorly understood. Maps were few and, following biblical texts, mappae mundi centered on Jerusalem, as shown on the disk map from 1300 now in Hereford Cathedral.

Natural hazards were noted but rarely analyzed: Gerald of Wales (1147–1220) described erosion and Heligolanders measured their island coastline shrinking from 192 km in 800 to 72 km in 1300 (to 5 km by 1900!). Viking documents suggested reduced sea ice around Iceland and expanded cereal cultivation in northern Europe between 900 and 1200, when the climate was warmer than today. Later, as the Little Ice Age approached, glacier advances were noted but scientific studies were limited.

Even the emerging academies of medieval Europe were constrained by faith and rarely excited by nature. Nevertheless, some Europeans were attracted to the geographies of Asia reported by travelers, notably William of Rubruck (Rubruquis, 1220–1293) and Marco Polo (1254–1324) and his kin who traded with China between 1260 and 1295. Stimulated by Arab and Persian studies, enquiring minds began questioning aspects of nature, although the Franciscan friar Roger Bacon (1214–1294) was admonished for advocating experimentation over faith.

Between 1300 and 1600, the bonds of feudalism, religious dogma, and folk tradition on Europeans were loosened by the Renaissance, notably after the socioeconomic catastrophe of the Black Death in the 1340s. Apart from impacts on religion, politics, and art, the Renaissance revived classical mathematics and astronomy, and favored explorations overseas and scientific experiments at home. In France, studies of gravity, acceleration, and momentum by Jean Buridan (ca. 1300–1358) anticipated Newton by more than three centuries. Physical geography revived, based in part on translations of Arabic transcripts of earlier Greek scholarship.

The European age of exploration and discovery

From the late fifteenth century, European maritime explorations yielded much new information for late Renaissance scholars (Table 1). Bartolomeu Dias (1451–1500) and Vasco da Gama (1469–1524) sailed around Africa into the Indian Ocean, aided by local navigators familiar with monsoons. John Cabot (1450–1499), Christopher Columbus (1451–1506), and Amerigo Vespucci (1454–1512) reached Atlantic America, and Ferdinand Magellan (1480–1521) and Francis Drake (1540–1596) passed Cape Horn into the Pacific. Coastal charts or “wagoners” were valuable assets, notably the Spieghel der Zeevaerdt (Mariner’s Mirror, 1584) of Lucas Waghenaer (1533–1606). Military forays by Hernán Cortés (1485–1547) in Mexico
PHYSICAL GEOGRAPHY

(1519–1520) and Francisco Pizarro (1476–1541) in Peru (1531–1533) opened lands for Spanish colonization, even as others were entering the Americas. Not only did these discoveries bring Europeans and their trappings to new lands, but their ships returned with strange plants and animals, accelerating the relentless transfers between continents of alien species that were to transform landscapes far and wide.

Meanwhile, at home, European scholars reaffirmed Greek calculations of Earth’s shape, and new maps began rolling off printing presses from the late fifteenth century. Scale globes became popular and Ptolemy’s mostly forgotten maps reappeared, but, as Greek mapmakers had found, projecting Earth’s curvature onto a flat surface might work locally but was no easy task over larger areas. New facts reached a wider audience through Gerhard Kremer (Mercator, 1512–1594), whose map projection became the basis for sea charts, and Abraham Ortelius (1527–1598) in an atlas of 70 charts of the then known world, Theatrum Orbis Terrarum, in 1570.

The Scientific Revolution in seventeenth-century Europe

By 1600, the intellectual excitement of the Renaissance was waning before the wars of religion and the realignments of emerging nation states. Many cultures were changing—from country folk dependent on nearby field and forest to townspeople for whom outward-looking ports and foreign trade, and thus exposure to new ideas, were becoming influential. Traditional faiths also came into conflict with new ideas. The Scientific Revolution and later Enlightenment responded to the spirit of curiosity and openness spawned by these events (Table 1).

The Scientific Revolution in Europe was favored by Renaissance thought, growing awareness of Islamic and Asian science, overseas discoveries, and printed works that disseminated ideas new and old. Between the birth of Leonardo da Vinci (1452–1519) and the death of Galileo Galilei (1564–1642), major changes occurred in science as metaphysical paradox gave way to measurement and experiment. In 1530, Nicolaus Copernicus (1473–1543) reaffirmed a heliocentric system for the solar system involving Earth’s rotation and precession that, though suppressed by the Roman Catholic Church, gained support from Johannes Kepler (1571–1630) and Galileo’s 1632 work on celestial mechanics. However, as Galileo found at his trial for heresy in 1633, inquisitive scientists could not always rely for support on those more closely linked to the religious and political establishments of their age (Orme 2013a).

When the revolution peaked later in the century, mathematics, astronomy, physics, chemistry, and biology emerged in idioms which, if not modern, are recognizable today. Concepts relevant to physical geography began to appear—momentum and energy conservation from René Descartes (1596–1650) in 1644; air pressure linked to volume by Robert Boyle (1627–1691) in 1662; centrifugal force from Christiaan Huygens (1629–1695) in 1673; kinetic energy from Gottfried Leibniz (1646–1716) in 1686; and laws of motion and calculus from Leibniz and, in 1687, Isaac Newton (1642–1727). Scientific progress also saw better instruments: the optical microscope (ca. 1570), the thermometer (1612) from Santorio Santorre (1561–1636), and the barometer (1643) from Evangelista Torricelli (1608–1647). Even so, the hydrologic cycle was long misconstrued: a popular view offered in 1664 by Athanasius Kircher (1602–1680) showed ocean water suctioned upslope by lunar forces in

subterranean conduits to spill from upland caves into rivers that returned water to the oceans (Figure 2).

Mining heralded interest in Earth’s physical systems while the need to supply water to growing towns advanced hydrology and fluid dynamics. Building on the work of Bernard Palissy (1510–89) and Simon Stevin (1548–1620), Benedetto Castelli (1577–1644) and Torricelli explained streamflows in terms of water and channel properties. A more realistic hydrological cycle appeared when Pierre Perrault (1611–1680), Edmé Mariotte (1620–1684), Domenico Guglielmini (1655–1710), and Edmund Halley (1656–1742) began integrating precipitation, evaporation, and infiltration into models linking atmospheric and soil processes with streamflows (Figure 3).

Climatology began with weather data collected from rain gauges, barometers, and thermometers, notably in London and Paris in the 1660s. Inferences regarding average temperatures and precipitation would later come from these data, adjusted for observer errors, inconsistent instruments, and missing records. William Dampier (1651–1715) described typhoons and George Hadley (1685–1768) explained trade winds in terms of Earth’s rotation.

Biogeography slowly emerged from a curiosity for newly discovered plants and animals. This increased interest in botany and zoology, which in the sixteenth century began diverging from, but never severing, their practical roots.

PHYSICAL GEOGRAPHY

Volumes on Earth’s emerging (mostly physical) geography began to appear. Philip Cluverius (1580–1622) wrote an *Introduction to Universal Geography* published posthumously in 1624, and Nathanael Carpenter (1589–1628) a *Geography Delineated Forth in Two Booke* in 1625. *Geographia Generalis* by Bernard Varenius (1622–1650) came in 1650 and was translated into English as *The Compleat System of General Geography*. Impressed by the works of Copernicus, Kepler, and Galileo, Varenius opined: “Geography is that part of mixed mathematics which explains the state of the Earth and of its parts depending on its quality, namely its figure, place and magnitude.”

Scientific debate was also stimulated by universities expanding beyond their medieval foundations and by new academies, notably the Royal Society of London (1662) and the Académie des Sciences de Paris (1666). In its *Directions for Sea-Men, bound for far Voyages* (1665–1666), the Royal Society urged mariners to record ocean processes and seabed conditions, and to improve navigational aids, sounding gear, and water sampling.

Explanation in physical geography was long confused by questions of Earth time: short time constrains what is possible; longer time offers more flexibility. Certainly, early Greeks had been puzzled by fossils in rocks, Avicenna in 1027 had invoked long time for mountains to be raised and eroded, and Leonardo da Vinci had Po valley sediment accumulating over 200,000 years. However, James Ussher (1581–1656) and others reverted to biblical sources to claim that the six days of creation (Psalm 90, 1 day = 1000 years) implied that Earth was only 6000 years old and that Noah’s Flood began in 2349 BCE. This required Earth’s surface to be shaped and clothed in very short time by divine providence and then changed by frequent catastrophes. A prolonged tussle between persons of faith and observers of the real world ensued, pitting divine revelation against scientific deduction. Carpenter (1625) opined that “Mountaines, Valleyes, and Plaines were created in the Earth from the beginning, and few made by the violence of the Deluge.”

In 1681, Thomas Burnet (1635–1715) ascribed Noah’s Flood to the bursting of a water-filled globe that “at one stroke dissolved the frame of the old world and made us a new one out of its ruins which we now inhabit since the Deluge” (Figure 4). Catastrophism gained support from earthquakes near Port Royal, Jamaica, in 1692, and Lisbon, Portugal, in 1755, and eruptions of Vesuvius. Hooke saw gorges as earthquake rifts. Such time constraints confounded scholarship and were not countered objectively until the advent of radiometric dating in the twentieth century.

The Enlightenment of eighteenth-century Europe

The Enlightenment was a cultural process in which reasoning came from a discerning interest in nature and reality rather than from uncritical acceptance of received texts such as the bible. Studies of the natural world led to conflict with religion and to debates between students challenged to think anew and theologians intent on preserving tradition. The Enlightenment
was led by philosophes such as Montesquieu, Diderot, Voltaire, and Rousseau in France, Kant in Germany, Hume in England, and Franklin and Jefferson in America; some even conducted experiments and offered mathematical solutions for natural relationships. A broader public became engaged in coffee houses and academies, exposure to artists and poets imbued with burgeoning Romanticism, and Grand Tours to civilization’s assumed roots in the Mediterranean and Middle East. The Enlightenment closed with the French Revolution and Napoleonic Wars, from which emerged a very different scientific world, more pragmatic, more aware (Orme 2013a).

Many scientists visited little-known lands in Pacific and polar waters, with navigation aided by improved sextants, marine chronometers, and sea charts. The invention by John Harrison (1693–1776) of a timepiece sufficiently robust for ship travel was a welcome replacement for lunar tables in defining longitude. Notable voyages included those by Vitus Bering (1680–1741), James Cook (1728–1779), George Vancouver (1757–1798), Fabian Bellinghausen (1778–1852), James Weddell (1787–1834), Otto von Kotzebue (1787–1846), and Dumont d’Urville (1790–1842).

English and Dutch trading companies charted Indian Ocean coasts, and Hudson’s Bay Company Canadian Arctic shores. Such charts attracted mapmakers, such as Bourguignon d’Anville (1697–1782) of Paris and the Blunt family of New York. Charts were also made by naval hydrographic agencies such as those founded in France (1720), Spain (1753), and Britain (1794), and the civilian Coast Survey in the United States (1807). While mapmakers still struggled to depict onshore relief, chartmakers were already using contours (isobaths) to link soundings of equal depth to a common datum, notably Luigi Ferdinando di Marsigli (1658–1730) for the Golfe du Lion (1725) and Philippe Buache (1700–1773) for the English Channel (1737). Marsigli also wrote an ambitious *Histoire Physique de la Mer* (1725) (Orme 2013f).

Onshore surveys, hitherto mostly conducted by landowners and military engineers, became systematized under national agencies, such as the Trigonometrical Survey of Great Britain (now the Ordnance Survey) in 1791. Physical geography was further stimulated by geologic mapping and by topographic maps on which hachures were superseded by contours in 1728.

Wisdom spawned by the Scientific Revolution was refined during the Enlightenment. Attempts to explain Earth’s surface features saw biblical Catastrophism and its kin Diluvialism (based on Noah’s Flood) challenged, first by Neptunism and then by Uniformitarianism. Neptunism, proposed by mining geologist Abraham Gottlob Werner (1749–1817), suggested that Earth’s rocks had been precipitated from a universal ocean that had shaped surface features as it receded. In an attempt at reconciliation, naturalist Georges Cuvier (1769–1832) separated the six days of biblical creation with the six catastrophes (révolutions) he found in the fossil record (Figure 5). In various guises, Catastrophism persisted well into the nineteenth century, supported by Benjamin Silliman (1774–1864) in whose journal, the *American Journal of Science*, J.W. Wilson (1821) wrote “is it not the best theory of the Earth, that the Creator, in the beginning, at least at the general deluge, formed it with all its present grand characteristic features?”

In contrast, Uniformitarianism held that the present is the key to the past, that Earth’s surface is mostly shaped by slow but observable processes over a very long time. The concept evolved from Mikhail Lomonosov (1711–1765) in Russia, Giovanni Targioni-Tozzetti (1712–1783) in
Italy, and Jean-Etienne Guettard (1715–1786) and Nicolas Desmarest (1725–1815) in France, who each asserted the then novel idea that valleys are shaped gradually by streams, rather than suddenly by biblical floods and earthquakes.

James Hutton (1726–1797; Figure 6), Scottish physician and farmer, is often hailed as the founder of the Earth sciences in a relatively modern idiom. His writings between 1785 and 1795 include some incisive statements:

But if the succession of worlds is established in the system of nature, it is in vain to look for anything higher in the origin of the Earth. The result, therefore, of our present enquiry, is that we find no vestige of a beginning, – no prospect of an end. (Hutton, *Theory of the Earth, or an investigation of the laws observable in the composition, dissolution, and restoration of land upon the globe* 1788, 304)

The natural operations of this globe, by which the size and shape of our land are changed, are so slow as to be altogether imperceptible to men who are employed in pursuing the various occupations of life and literature. (Hutton, *Theory of the Earth, with Proofs and Illustrations* 1795, II, 563)

Hutton’s ideas were supported in *Illustrations of the Huttonian Theory of the Earth* (1802) by mathematician John Playfair (1747–1819; Figure 7), and in *Hydrogéologie* (1802) by biologist Jean-Baptiste Lamarck (1744–1829). Playfair understood the temporal implications of Hutton’s work in writing “time performs the office of integrating the infinitesimal parts of which this progression is made up.” He defined denudation thus:

“water … in every state from transparent vapour to solid ice, from the smallest rill to the greatest river … attacks whatever has emerged from above the level of the sea and labours incessantly to restore it to the deep. The parts loosened and disengaged by the chemical agents, are carried down by the rains, and, in their descent, rub and grind the superficies of other bodies … [T]he
consequence … is a system of universal decay and degradation, which may be traced over the whole surface of the land, from the mountain top to the sea shore.” (Playfair 1802, 99–100)

In 1830–1833, Charles Lyell (1797–1875; Figure 8) published The Principles of Geology – Being an Attempt to Explain the Former Changes of the Earth’s Surface, by Reference to Causes now in Operation. This extended title had broad implications for questions of time. Hutton’s “succession of worlds” with neither a beginning nor an end, and the slowness of Lyell’s “causes now in operation” denied Catastrophism and encouraged concepts of cyclicity and evolution.

Meanwhile, practical studies of Earth’s surface processes were being made by scientists and engineers across Europe, notably the influential Corps des Ponts et Chaussées (1715) in France. These fostered understanding of processes in ways fundamental to physical geography. Major works included explanations of air and water currents by Daniel Bernoulli (1700–1782), open-channel flow by Antoine de Chézy (1718–1798; Figure 9) and Pierre du Buat (1734–1809), slope stability by Charles Augustin Coulomb (1736–1806; Figure 10), and waves and tidal dynamics by Joseph-Louis Lagrange (1736–1813) and Pierre-Simon Laplace (1749–1827; Figure 11).

Studies of Earth’s atmosphere now acquired a sounder scientific framework. Temperature scales were rationalized in 1724 by Daniel Fahrenheit (1686–1736) and in 1742 by Anders Celsius (1701–1744). Weather data were being collected more consistently in many European locations and from 1730 in Philadelphia. In England, John Dalton (1766–1803) recorded pressure, wind, temperature, and humidity for

PHYSICAL GEOGRAPHY

forecasting purposes. The Mannheim Academy of Meteorology was founded in 1780.

After the Little Ice Age (1500–1850) peaked around 1700, receding glaciers led naturalists to question glacier motion. Johann Scheuchzer (1672–1733) proposed downslope displacement by meltwater freezing in crevasses; Horace-Bénédict de Saussure (1740–1799), viewing striated rock emerge from beneath retreating glaciers, saw basal gravity sliding as the driving mechanism; and Svein Pálsson (1762–1840) in Iceland compared glacier motion to a resin-like viscous fluid. In 1830, Franz Hugi (1791–1855) measured the speed of the Unteraar Glacier.

Biogeography also traces roots to the eighteenth century, notably to the taxonomies of Carl Linnaeus (1707–1778; Figure 12) in his Systema Naturae (1735 on), and to Georges-Louis Leclerc, Comte de Buffon (1707–1788), in his multivolume Histoire naturelle, mostly on animals (1749–1788). Both Linnaeus and Buffon struggled with prevailing Catastrophism. In Des époques de la nature (1778), Buffon suggested from foundry experiments that it would take up to 75,000 years for Earth to cool from a molten state and 3 million years to assemble its sedimentary cover. Links between climate and vegetation were reflected in Carl Wildenow’s (1765–1812) montane zonation in Grundriss der Kräuterkunde (1792). In Zoönomia (1794–1796), Erasmus Darwin (1731–1802) addressed environmental influences on animals, and anticipated evolution, later developed by his grandson Charles. Interest in landscaping, herbaria, and menageries (zoos) generated further impetus.

As the Enlightenment progressed, European scholars saw physical geography as a basis for the broader discipline. These included Anton Büsching (1724–1793) in Neue Erdbe- schreibung (1754); Johann Rheinhold Forster (1729–1798) and son Georg (1754–1794) who sailed on Cook’s second voyage to the Pacific (1772–1775); philosopher Emmanuel Kant (1724–1804); and the versatile Alexander von Humboldt (1769–1859), who measured elevations, climate, and vegetation, and collected specimens across Eurasia and the Americas (Figure 13). These he categorized in terms of natural features (Physiographia), temporal change (Naturgeschichte), and spatial relations (Weltbeschreibung). His five-volume Cosmos (1845–1862) was remarkable for its time.

The agrarian and industrial revolutions of the eighteenth and nineteenth centuries

The seventeenth-century scientific revolution spawned the agrarian and industrial revolutions across much of Europe and eastern North
America over the next two centuries, with a concomitant change from dispersed, mostly self-sufficient, rural farming communities to proliferating urban societies dependent on industry, trade, and services. These changes shaped new landscapes, which provided fresh challenges for physical geography. They also raised questions, notably from political economist Thomas Malthus (1766–1834), who in 1798 pondered how human population, expanding exponentially, could in future be supported by food resources, expanding arithmetically.

The agrarian revolution raised awareness of soil properties, water chemistry, land drainage, and reclamation potential, and encouraged crop rotation and stock improvement, which began changing landscapes far more profoundly than in times past. Recognizing the agricultural potential of wetlands, Dutch engineers initiated bold reclamation schemes from the English Fens to the Baltic. Gerard Boate classified Irish bogs in 1652 and scientists from Scotland to Russia began fertilizing farm crops with peat moss and exploring the industrial uses of peat. Scottish agriculturalist John Morton (1781–1864) linked soil types to parent material, American Amos Eaton (1776–1842) addressed soil fertility, and German chemist Justus von Liebig (1803–1873) enhanced soil productivity with nitrate-rich crops and fertilizers. Water was brought to drylands by British irrigation engineers in India, which from the 1850s inspired American politicians to envisage grand schemes for irrigated agriculture across the American West.

But there were also negative impacts from these changes – loss of open common land and wetland resources, and displacement by enclosure and better tools of country folk, who migrated increasingly to industrial towns in search of work. The diversion of water from rural sources to cities began to pose questions about the use and misuse of this valuable resource.

The furnaces of the industrial revolution, which relied on mineral ores, coal, and fluxes, fed the growth of geology, while needs for better transport and water supplies generated advances in science and engineering. Mining pits and canal cuttings exposed rock strata and fossils to enquiring scientists, such as William Smith (1769–1839) who compiled the first useful geological map of England, Wales, and southern Scotland in 1815. Embankments and cuttings needed for new roads and railways took Coulomb’s principles of slope stability into new arenas. Better transport conveyed more people farther, exposing them to nature as never before. In North America, completion of the first transcontinental railroad in 1869 began opening vast western lands, hitherto lightly explored. Supplying water to growing industrial towns improved understanding of climate, groundwater, and channel flows, exemplified in *Recherches hydrauliques* (1865) by Henry Darcy (1803–1858) and Henri Bazin (1829–1917). Further, while steam engines powered this revolution, their workings also favored thermodynamics through Sadi Carnot (1796–1832), Rudolph Clausius (1822–1888), and Henri-Louis Le Châtelier (1850–1936), whose studies of energy, entropy, and feedback were later invoked to explain natural systems.

The application of industrial technology to steamships encouraged further studies of oceans and distant lands. In his *Physical Geography of the Sea* (1855), Matthew Fontaine Maury (1806–1873; Figure 14) captured much knowledge about the oceans, although his bathymetry of the North Atlantic, with its 1000-fathom contour interval, barely hinted at the Mid-Atlantic Ridge. Oceanography was energized in 1872–1876, when the steam-assisted corvette HMS *Challenger* (Figure 15) carried the first modern oceanographic expedition on a world cruise, directed by Charles Wyville Thomson (1830–1882) and later
John Murray (1841–1914). The ship returned with a vast array of sediment samples, biological specimens, and data on ocean bathymetry, circulation, and chemistry, yielding 50 volumes that set new standards for marine geography. The first *Carte générale bathymétrique des océans* appeared in 1904 (Orme 2013f).

The broader impacts of these revolutions encouraged awareness of how people were changing their environment. *Man and Nature; or, Physical Geography as Modified by Human Action* (1864), by George Perkins Marsh (1801–1882; Figure 16), became a recurring theme. Stirred by Henry David Thoreau (1817–1862), American concern for nature began to differ between preservation (John Muir, 1838–1914) and managed conservation (Gifford Pinchot, 1865–1946).

**Physical geographers of the nineteenth century**

The plethora of new data from expeditions on land and sea was grist to the mill of physical geography during the nineteenth century. Most geographers focused on description, interesting to a civilizing world intrigued by then little-known regions and life forms, but the more discerning sought to explain these new facts, involving such concepts as evolution and cyclicity.

Evolution may be defined as change through time and, in a biological sense, as change in life forms through the survival of the fittest. Charles Darwin (1809–1882) commonly receives the accolade for proposing the concept *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* (1858). In fact he was building on a growing awareness of fossil evidence for changing life forms, extinctions, and mutations addressed earlier by Buffon, Erasmus Darwin, Lamarck, and Cuvier, and by contemporaries such as Lyell and Alfred Russel Wallace (1823–1913). Young Darwin was so impressed with Lyell’s *Principles* that he took the first volume on board his global voyage in HMS *Beagle* (1831–1836). Regardless...
of its precise lineage, evolution profoundly impacted science in the years ahead.

Cyclic thinking was not new but had been revived by Hutton’s “succession of worlds” based on limitless time punctuated by episodic changes in an evolving Earth system. Cyclicity was also espoused over short time by catastrophists, notably in Cuvier’s six “révolutions” in the fossil record. In time the model begat proposals for diverse cycles by which to organize and explain the plethora of information now emerging on the natural world. The cycle mania peaked during the nineteenth century: climate cycles, orogenic cycles, hydrologic cycles, erosion cycles, life cycles, and so on became fodder for physical geography, as the following three examples show.

First, when Swiss paleontologist and impeccable catastrophist Louis Agassiz (1807–1873; Figure 17) lent support to glacial theory Glacial Theory in 1840, scholars began seeking to explain what Karl Schimper (1803–1867) had termed the *Eiszeit* (Ice Age; 1837). Some, such as James Croll (1821–1890; Figure 18), revisited classical sources to ponder the relevance of cyclic changes in Earth–Sun relations to climate oscillations, a theme later expanded by Milutin Milankovitch (1879–1958; Figure 19). Rhythmic bedding in older rocks was also attributed to orbital perturbations, especially the precession of the equinoxes. By the close of the century, the multiple Pleistocene glaciations, found in the American Midwest (Chamberlin, 1883) and the European Alps (*Die Alpen im Eiszeitalter*, Penck and Brückner, 1901–1909), made explanation much more challenging.

Second, in 1847, based on stratigraphic evidence for sedimentary rhythms, James Dwight Dana (1813–1895; Figure 20) proposed that

“epochs” in the geologic record reflected periods of prolonged quiet alternating with pulses of rapid change and mountain building, the latter then explained by Earth’s contraction. Joseph Le Conte (1823–1902; Figure 21) stated cyclicity thus:

Geological history, like all other history, has its periods of comparative quiet, during which the forces of change are gathering strength, and periods of revolution, during which the accumulated forces manifest themselves in conspicuous changes in physical geography and climate, and therefore in rapid movements in the march of evolution of organic forms. (Le Conte, On Critical Periods in the History of the Earth … 1877, 100)

Third, the erosion cycle proposed in the 1880s by Harvard geologist William Morris Davis (1850–1934; Figure 22) reflected the evolutionary dogma of the age, expressed as a “cycle of changes” by Thomas Huxley (1825–1895) in his popular Physiography (1877). Davis’s erosion cycle was initiated by mountain building, followed by prolonged crustal stability during which landscapes were denuded, through stages of youth and maturity to old age, to plains just above sea level. This cycle could be interrupted and reset by renewed orogeny or climate change. Seemingly logical, this model relied heavily on evolutionary thinking and on the bold denudation of the American West described by John Wesley Powell (1834–1902), Grove Karl Gilbert (1845–1918; Figure 23), and Clarence Dutton (1843–1912; Figure 24). Inspired by artist renderings, notably of the Grand Canyon by William Henry Holmes (1846–1933; Figure 25), many adherents to the Davisian cycle were oblivious of its limitations. But, in reality, Davis selected just what he needed to support his model, ignoring the more profound views of Gilbert and Dutton on landform dynamism, crustal instability, and isostasy (Orme 2007; 2013c).

As the nineteenth century progressed, Hutton’s limitless “succession of worlds” was reined in by
those seeking Earth’s age in cooling rates from an initial molten state, sedimentation rates, and ocean salinity. Further, Lyell’s “present as the key to the past” was confounded by evidence for past climate changes, multiple glaciations, fossil ecologies, and sudden events such as glacier outburst floods and earthquakes. Such events, neither catastrophic in a biblical sense nor rigidly uniformitarian in Lyell’s sense, needed to be engaged for Earth’s changing landscapes.

Meanwhile, meteorology and climatology advanced, especially where time series of data were collected from fixed weather stations and ships at sea, initially using kites and balloons to probe the atmosphere. National weather services emerged after the Napoleonic wars and the International Meteorological Organization came in 1873. In 1806, British naval hydrographer Francis Beaufort (1774–1857) codified a scale relating wind force to the amount of sail a frigate could carry. This Beaufort Scale was later calibrated to anemometer data (1850) and sea state (1906). French mathematician Gaspard de Coriolis (1792–1843) analyzed the kinetic energy and rotation of moving bodies relevant to the deflection of air and water currents. In the United States, Elias Loomis (1811–1889) described tornadoes and thunderstorms, William Ferrel (1817–1891) studied cyclonic and anticyclonic circulations, and Lorin Blodget (1823–1901) produced a climate map and base data that became useful for later studies of climate change. Alexander Buchan (1829–1907) recognized weather spells for Scotland. Vasily Dokuchaev (1846–1903; Figure 28) defined the zonal influence of climate and vegetation on pedogenesis in Russian Chernozem (1883). Nikolai Sibirtzev (1860–1899) identified intrazonal and azonal exceptions to the climate forcing of zonal soils, and Konstantin Glinka (1863–1935) studied soils in Asiatic Russia. Russian emphasis on soil profiles influenced pedology in North America where Eugene Hilgard (1833–1916) examined links between Mississippi valley sediment and farm soils.

As the nineteenth century closed, physical geography was being promoted by many eminent scholars, notably in Germany by Ferdinand von Richthofen (1833–1905; Figure 29) in loess studies, Albrecht Penck (1858–1945; Figure 30) in defining multiple Pleistocene glaciations, and Otto Krümmel (1854–1912) in marine geography. Also prominent were Elysée Réclus (1830–1905) and Emmanuel de Martonne

(1873–1955) in France, and Gilbert and Davis in the United States.

**Physical geography in the Electronic Age: the twentieth century and later**

For physical geography, the new century continued, even reinforced, many evolutionary and cyclic paradigms of late nineteenth-century science. Davis's cycle of erosion prospered, except in central Europe where structural explanations of landforms persisted. The concept of plant succession, identified by Henry Cowles (1869–1939) for dune vegetation in 1899, was refined in 1916 by ecologist Frederic Clements (1874–1945; Figure 31). Like Davis's model, Clements's scheme advocated an ideal sequence through time, from pioneer plants to climax vegetation, which could be interrupted and reset by disturbance.

Physical geography in the United States was given impetus in 1904 by the founding, on Davis's initiative, of the Association of American Geographers (AAG). The AAG was dominated early on by geologists (e.g., Gilbert, Fenneman), ecologists (e.g., Cowles, Adams), and soil scientists (e.g., Marbut), who identified with physical geography. Of the 21 papers presented at the inaugural meeting in Philadelphia, all but one were in physical geography. This new forum stressed Davis's model and discouraged views involving crustal instability and surface processes, a selectivity that caused later problems. Eventually, the Davisian model, withering by 1930, crumbled away in the mid-twentieth century under the onslaught of the plate tectonic revolution, resurgent isostasy, radiometric...
PHYSICAL GEOGRAPHY

dating, process studies, and quantitative testing. Clementsian plant succession suffered similarly, notably from analyses by Robert Whittaker (1920–1980).

Notwithstanding this seeming continuum of physical geography across the century divide, change was coming, some revolutionary, most linked to new technology. The agrarian and industrial revolutions had been driven primarily by mechanical processes applied to farming, mining, factories, and transport. In contrast, the twentieth century became an Electronic Age during which electricity and electrons in various guises were increasingly applied to agrarian, industrial, mechanical, and information systems. Powered flight appeared, offering remote views of Earth earlier seen only from the surface (and some balloons). Remote-sensing from airborne, shipborne, and space platforms became a major boost to physical geography. Twelve salient changes that have influenced the field since 1900 are now outlined.

1 Communication, information technology, and digital revolution: The Electronic Age began with experiments on electricity and electromagnetism during the early nineteenth century. The electric telegraph came around 1840, the telephone in the 1870s, wireless radio transmission around 1900, practical television around 1930, the Internet in the 1960s, and electronic mail in 1971. Meanwhile, echo sounding from 1904, and sonar (sound navigation and ranging) from 1906, improved underwater research. Radar (radio detection and ranging) emerged in the 1930s, Doppler radar in the 1940s, synthetic aperture radar in the 1950s, and LiDAR (Light Detection And Ranging) in the 1960s. Since then, satellite altimetry and geophysical surveys have probed changes in air, land, and water bodies with increasing precision. Manned, tethered, and autonomous submersibles have become essential to deep-ocean research, as have aircraft, radiosondes (from 1929), rockets, and drones to atmospheric research. Photography began recording information using sensitive photochemical film from the 1840s and computer-based electronic digital cameras from the 1960s. Over this time frame, computers evolved from mechanical calculators, through the large slow electronic mainframes of the 1960s, to the high-speed miniaturized computers of today, which enable accelerated transmission and processing of large datasets and geographic information systems. These events reflect a digital revolution that, via virtually unconstrained electronic media, has made vast amounts of data available to human and robotic receptors. Electronic publishing, often with few constraints, began augmenting or replacing printed books and journals in the 1990s.

2 Cartography: Cartography progressed rapidly with the aid of the gyrocompass (1906), aerial photography, photogrammetry, radar, lasers, computers, and, from the 1960s, satellite remote sensing and global positioning systems. At sea, closely spaced soundings and bottom sampling preceded laying transoceanic telegraph cables in the 1840s and, as technology improved, deep-sea data proliferated and sonar revolutionized the speed and accuracy of underwater mapping. As the twentieth century progressed, mapping filled many lacunae, notably for polar regions and oceans, while remote sensors began providing detailed information on subtle changes in continental elevation, ocean surface, and bathymetry. Since the mid-twentieth century, spacecraft and satellite landers have
compiled large data banks for mapping planets in the solar system.

3 Radiometric dating: The principles of radioactivity, discovered in 1896, were soon applied to mineral decay and resolutions of Earth time. In 1890, Earth was thought to be 20–400 million years old, depending on the source. By 1911, applying uranium–lead decay methods, Earth was found to be at least 1300 million years old (and approximately 4600 million years old today). Thus, if one accepted the premises of radiometric dating, Hutton’s “no vestige of a beginning – no prospect of an end” became untenable. An extended but not limitless time provides ample opportunity for the many changes in Earth’s geography recorded in rocks and readily accommodates changes over the past few million years most relevant to present geographies. In recent decades, radiometric techniques have resolved the ages of many events over Earth time, although their resolution usually diminishes with increasing time while issues of sample provenance, contamination, and age calibration remain.

4 Climate and environmental change: During the twentieth century, climate change emerged as an important issue for physical geography and society in general. Multiple Pleistocene and older glaciations and changes shown by lengthening weather records demanded explanation. In the 1920s, mathematician Milutin Milankovitch (1879–1958; Figure 19) resurrected James Croll’s orbital forcing of Earth–Sun relations as the principal driver of cyclic climate change, but doubts persisted. Then fossil-rich deep-sea cores began revealing cold-warm cycles reaching far back in Cenozoic time. Advances in coring technology, isotope geochemistry, micropaleontology, paleomagnetism, and radiometric dating now allow comparison with cycles revealed by Greenland and Antarctic ice cores (Figure 32), and from lakes and terrigenous archives, notably loess. These data support degrees of orbital forcing for global climate change, while remote sensing and field studies of glacier retreat confirm inferences on recent warming trends (Figure 33). Even so, variable solar radiation, asteroid impacts, tectonism, volcanism, surface changes,
and human activity are interwoven into climate-change scenarios (Orme 2013b; 2013d; Figure 1).

**Relative sea level change:** It was long unclear whether observed sea level changes were caused by absolute changes in ocean volume (e.g., growth or decay of continental ice sheets) or by changes in ocean-basin capacity and continental freeboard (e.g., tectonism, isostasy, sedimentation) (Orme 2013f). In 1888, Eduard Suess (1831–1914; Figure 34) invoked “eustatische Bewegungen” (eustatic movements) for sea level change, which he attributed to ocean subsidence and sedimentation. Confusingly, the term “eustasy” was then applied to climate forcing of global sea level, a usage that long prevailed until, later in the twentieth century, the issue was revisited in the context of plate tectonics and isostasy. It is now known that many forces influence sea level, depending on the magnitude of change, the spatial context, and the timescale. For example, melting of Antarctic and Greenland ice has contributed 50–80% to recent global sea level rise, which has averaged approximately 1.0–2.4 mm yr\(^{-1}\) since 1850, depending on location. Sea level studies relate to physical geography, not only for the evidence from geomorphology and sedimentology, but for their implications for climatology, hydrology, biogeography, and people.

**Continental mobility:** The growing awareness of Earth’s crustal mobility, culminating in the plate tectonic revolution of 1950–1970, dramatically altered the playing field for physical geography. Mobilist notions were not new, having been invoked earlier to explain fossil biota, but made no headway against prevailing stabilist paradigms wherein deformation was mostly confined to continental margins, mountain building to crustal contraction, and biotic migrations to failed land bridges between fixed continents. When Alfred Wegener (1880–1930; Figure 35) offered a continental drift hypothesis in 1912, expanded in *Die Entstehung der Kontinente und Ozeane in 1915*, his ideas were mostly rejected, even ridiculed. Nevertheless, in *Our Wandering Continents* (1937) Alexander du Toit (1878–1948) felt that “a great and fundamental truth is embodied in [Wegener’s] revolutionary Hypothesis,” and, in 1944, Arthur Holmes (1890–1965) suggested subcrustal convection currents as a possible mechanism for shifting continents. The plate tectonic revolution reset Earth’s stage in ways relevant to explanations of past and present landforms, climates, and biota. Ocean ridges became crustal spreading centers, ocean trenches became subduction zones, and most orogenic belts attributed to collisional tectonics. As early as 1924, Wegener and
his father-in-law, Wladimir Köppen, wrote *Die Klimate der Geologischen Vorzeit*, a study of past climates that became a recurrent theme in later research in paleogeography, notably reinvigorated by the plate tectonic revolution. In recent decades, palinspastic restorations of shifting continents and ocean basins to earlier locations have enhanced understanding of past geographies. Measurements of recent and continuing crustal mobility allow, with appropriate caveats, some prediction of future geographies (Orme 2013b).

7 *Atmospheric dynamics*: Three-dimensional views of the atmosphere began emerging from Scandinavia after 1917, notably from the Bergen School of Meteorology in Norway, a country with a large merchant fleet but whose neutrality in World War I deprived it of weather data from warring nations. This School set an array of weather stations and ships across Scandinavia and nearby seas to study atmospheric dynamics. Vilhelm Bjerknes (1862–1951; Figure 36) studied frontal waves between air masses; his son Jacob Bjerknes (1897–1975; Figure 37) and Halvor Solberg (1895–1974) examined polar-front dynamics and life cycles of depressions, and Tor Bergeron (1891–1977) formulated air-mass analysis. Sverre Petterssen (1898–1974), Erik Palmén (1898–1985), and Carl-Gustav Rossby (1898–1957) added refinements. The School’s work spread widely: Jacob Bjerknes, at UCLA (University of California, Los Angeles) from 1940, studied upper-atmosphere and jet-stream dynamics, and refined studies by Gilbert Walker (1868–1958) on conditions favorable to ENSO (El Niño Southern Oscillation). Rossby, in Chicago from 1940, studied jet streams and planetary waves. Since then,
improved instruments, remote sensing, and modeling have expanded ways for evaluating the processes affecting weather and climate (Figure 38).

8 Advances in soil science: Building on Russian concepts, Curtis Marbut (1863–1935) translated Glinka’s work into The Great Soil Groups of the World and their Development (1927) and refined podsolization, laterization, and calcification in Soils of the United States (1935). In 1938, Charles Kellogg (1902–1980) of the Soil Conservation Service (SCS, US Department of Agriculture) stressed the soil’s organic evolution in stating: “there can be no life without soil and no soil without life; they have evolved together.” Hans Jenny (1899–1992) defined climate, vegetation, relief, parent material, and time as the five Factors of Soil Formation (1941); bioturbation was added later. After 1950, a more quantitative approach began under Guy Smith (1907–1981) at the SCS (now Natural Resources Conservation Service), which led to Soil Taxonomy: A Basic System of Soil Classification for Making and Interpreting Soil Surveys (1975). The resultant hierarchy of soil types and terminology has since been widely applied, limited only by soil complexity.

9 Process studies: Processes of environmental change, whatever their timescale, were long poorly understood. As Leonardo da Vinci opined in 1500: “although nature begins with the cause and ends with the experience, we must follow the opposite course, namely … begin with the experience and by means of it investigate the cause.” This was long a problem for scientists who inferred processes from visible legacies, such as landforms and vegetation. In critiquing the Davisian cycle of erosion, geographer John Leighly (1895–1986) stated: “Davis’s great mistake was the assumption that we knew the processes involved in the development of landforms. We don’t; and until we do we shall be ignorant of the general course of their development. In his eagerness to set up a general system, Davis jumped over the preliminary, necessarily painfully slow study of processes, and so left his system with an inadequate foundation” (Leighly, AAG Symposium, 1940, 225).

This criticism could be applied across physical geography well into the twentieth century. Certainly processes had been studied earlier, mostly by hydraulic engineers and meteorologists, but this work entered mainstream geography but slowly. By the mid-twentieth century, however, scholars were instrumenting field and laboratory studies designed to explain process-response systems across physical geography, notably the hydrogeomorphology of Luna Leopold (1915–2006; Figure 39) and colleagues...
after 1950. Today, we focus on the nature and rate of such processes, such as glacier retreat, sea level change, warming climate, and habitat degradation (Orme 2013d).

10 Quantitative revolution and modeling: The mid-twentieth-century quantitative revolution affected all geography, moving it toward measurement and statistical testing to augment, even replace, what had been a mostly qualitative and descriptive discipline. Even so, reliance on numerical data had long existed in climatology and hydrology, and geometric progressions of arterial and stream systems long recognized. Statistical methods had been advanced before 1900: probability theory by Adolphe Quetelet (1796–1874), regression and correlation by Francis Galton (1822–1911), and multivariate methods and principal components analysis by Karl Pearson (1857–1936) (Amalie Orme 2013). But most geomorphologists and biogeographers had resisted quantification while qualitative methods, deductive reasoning, and conceptual models sufficed. For geomorphology, the revolution began when hydraulic engineer Robert Horton (1875–1945) began quantifying drainage systems in the 1920s; his seminal essay in 1945 introduced a wider audience to numerical measures and statistical tests of physical properties. In 1952, Arthur Strahler (1918–2002; Figure 40) advised geomorphology to “turn to the physical and engineering sciences and mathematics for the vitality which it now lacks.” There followed, from geomorphologists, climatologists, hydrologists, and biogeographers, a suite of quantitative devices by which to improve explanation, including derivation of some spurious “laws.”

Meanwhile, conceptual and scale models spawned into probabilistic and mathematical models to better serve the needs of scientific prediction; new models were devised and old conceptual models, such as Davis’s erosion cycle, were abandoned. Weather forecasting, climate change, river behavior, flood potential, and erosion hazards became attractive avenues for predictive modeling, reliant for success on secure numerical data and time series, informed analysis, and experience, but prone to mathematical sophistry.

11 Nature and People: Building on nature as viewed by Enlightenment philosophies and changed by agrarian and industrial advances, the tenets of Marsh’s Man and Nature (1864) became a rite of passage for geographers. Early disciples of this theme included Russian climatologist Alexander Voeikov (1842–1914), French anarchist Réclus in L’homme et la terre (1905), English geologist Robert Sherlock (1875–1948) in Man as a Geological Agent (1922), and contributors to Man’s Role in Changing the Face of the Earth (1956, edited by W.L. Thomas). Such studies usually bemoaned human impacts on nature but offered few palliatives. The latter often passed unheeded, even by nations keen to advance to the assumed security of a “developed” world suffering from prolonged degradation to their land, water, air, and biota.

Human attitudes to nature have since changed, owing to life in an ever-crowding world, concern for degrading resources and threatened ecosystems, and reassessments of human interactions with nature. Stimulated by the industrial and urban revolutions, Earth’s population grew from 1 billion ($10^9$) in 1800, to 2 billion in 1930, and 7 billion in 2011; absent disaster, it may reach
PHYSICAL GEOGRAPHY

9 billion by 2050. But this growth has been unbalanced: over 1000 people km$^{-2}$ inhabited farmlands of the Ganges-Brahmaputra delta in 2011, and at least 10 megacities, each exceeding 20 million people, are anticipated on Earth by 2025. Overcrowding and the potential for starvation, disease, and conflict focus the mind, as Malthus saw more than 200 years ago. Accordingly, since about 1960, many nations have renewed attempts to conserve the best that nature has bequeathed and to plan for the future, reflected in environmental protection laws, air and water quality controls, and prudent use of resources in managed ecosystems. In the United States, the Environmental Policy Act in 1969 led to creation of the Environmental Protection Agency in 1970. Agencies and scientists from many nations have since exported their experiences, although such advice rarely sits easily with developing societies for whom economic development may take precedence over environmental protection. Modern physical geography, in its literature, curricula, and practices, reflects these challenges.

Environmental planning and management: For physical geographers, a major objective of lessons learned should be their application to environmental planning and management. Planning has a mixed heritage. Many modest plans have been implemented but designing integrated plans is more challenging for large populous regions suffering land degradation, air pollution, foul water, and influxes of alien biota (Orme 2013e). Planning for climate change also poses problems, especially where industrial reorganization and population relocation are resisted. Such challenges are exacerbated by increasing climate variability, including more frequent fires, floods, and droughts that threaten water resources. Ample scope thus exists for physical geographers to design sensitive management plans in a human context (Figure 41).

Ideally environmental planning should lead seamlessly to effective management of plans adopted. The reality is rarely seamless, especially where environmental desiderata are diluted by stakeholders, politicians, and conflict. Despite earlier ventures, effective environmental management only began to crystallize during the twentieth century and is still being refined. This process often pits local interests against regional and national priorities, conservation against development, and new money against old traditions. Most countries now have laws for the protection or conservation of “natural” landscapes and the remediation of degraded areas. But such are the problems confronting the enforcement of environmental laws that the objectives of sound management based on scientific principles may be obscured, sometimes lost. Physical geography is well placed to engage in applying its scientific heritage to the common good.

The future for physical geography

Physical geography is alive and well. Despite unevenness across nations, it is widely taught in primary and secondary schools, and in universities. It is often an integral part of curricula in geography and environmental science, serving to provide students with an introduction to nature in a human context. Portions of the field are also shared by other disciplines, such as geology, biology, engineering, and planning. But physical geography is not merely an academic enterprise; it is a method and a pathway to useful employment in such fields as hazard prediction, weathering forecasting, land

degradation, resource evaluation, urban planning, biotic sustainability, and environmental management. These opportunities may be found across the public sector and in the private sector in agriculture, industry, transport, and finance.

Physical geographers bring to specific tasks a practical awareness of the natural world and, in a human context, an understanding of how environments and people have interacted in the past, how they function today, and their prospects for the future. The time frame for understanding nature varies: it may be very long (e.g., geologic time, tectonic change), variably long (e.g., biological time, climate change),
Physical geography is a discrete but comprehensive study probably peaked in the 100 years between 1870 and 1970. Before 1870, the field was being assembled from knowledge accumulating across the natural sciences. Between 1870 and 1970, geography as a whole became a distinct discipline in secondary and tertiary education, dominated initially by its physical roots. Geography became a part of national high-school curricula and geography departments were formed in many older and most newer universities. After 1970, physical geography began declining within university geography, even as its methods and interdisciplinary strengths were being rediscovered by cognate disciplines. Flagship journals in geography began publishing fewer papers in physical geography, in large measure because the growing body of research by physical geographers was being welcomed in kindred publications. Meanwhile, geography as a whole continued to figure prominently in high-school and university entrance curricula in Europe, Asia, and the British Commonwealth, but not in the United States where, for historic reasons, the discipline had never prospered at these levels (Orme 2013e).

There are several reasons for this change in the context for physical geography at university level. First, a reawakened environmental consciousness led many universities to entertain new curricula that often bypassed existing geography departments. Some of the latter closed; others revised their emphasis. Among the latter, physical geography was sometimes relegated to introductory courses designed to attract students to geography as a whole, although more advanced components, such as geomorphology and climatology, often flourished in the absence of competitive offerings elsewhere on campus. Second, many of the traditions of physical geography were recaptured by the Earth and space sciences (reawakened by plate tectonics and planetary ventures), by life sciences (where ecology and biogeography gained fresh impetus), by engineering (where human impacts were now considered and interdisciplinary practices encouraged), and by planning (where environmental impacts and sustainability became de rigueur). Third, compared with this revived interest in the natural sciences, geography departments pigeon-holed in the social sciences were poorly placed to provide the laboratories, materiel, and initial funds needed for effective research in physical geography. Indeed, programs in the latter were often founded in, or moved to, the natural and engineering sciences. Fourth, from the 1970s onward, flagship journals in geography had to compete with new journals, some devoted to physical geography, others catering to growing cross-disciplinary subfields (geomorphology, climatology, hydrology, biogeography, and environmental science). Meanwhile, established journals and publishers in other fields, such as geology and ecology, welcomed contributions from physical geographers.

In short, physical geography did not die after 1970; it broadened its base by returning to former roots in the natural sciences, which by then were flourishing amid new challenges and aspirations, and by finding fresh applications in the engineering sciences and in urban and regional planning. Physical geography is indeed alive and well, but its practice, content, and emphatic human significance now extend far beyond its base established earlier within the discipline of geography. Herein lies the future of physical geography.

Phytosociology is a branch of vegetation science that deals with current plant assemblages (communities) at a spatial grain size of vegetation stands. Its principal goals are the delimitation and characterization of vegetation types based on the complete floristic (species) composition. Floristically similar concrete stands (phytocoenoses), represented by plot records (so-called relevés), are combined into abstract vegetation types (syntaxa; singular: syntaxon). In analogy to plant taxonomy, phytosociological classification (syntaxonomy) places vegetation units into a hierarchical system based on varying degrees of floristic similarity.

History

The fundamental concepts, methods, and terminology of the discipline were developed by the Swiss-French botanist Josias Braun-Blanquet from the 1920s onwards (Braun-Blanquet 1964). He combined standardized sampling of plant communities on plots, sorting of species-by-plot matrices, delimitation and naming of vegetation types, and their placement into a hierarchical classification. Phytosociology is often called the “Braun-Blanquet approach” (Westhoff and van der Maarel 1973) or, in accordance with the founder’s main places of work, the Zurich-Montpellier school of vegetation science. Methodological developments and the new possibilities of computers have changed phytosociology significantly since the days of Braun-Blanquet, but in essence modern phytosociologists still apply the same ideas that have proven to be so productive.

When plot-based vegetation classification emerged as a scientific task in the first half of the twentieth century, there were several regional “schools” with methodologies different from the Braun-Blanquet approach, the latter prevailing in central and southern Europe (see De Cáceres et al. 2015). Particularly in the Anglo-American scientific realm, the value of a typology of plant communities was fundamentally questioned at that time, based on an individualistic community concept. In retrospect it is evident that only phytosociology managed to create comprehensive and widely applied classifications of vegetation types for larger spatial areas, while all other approaches remained regional or ceased to exist.

Nowadays, phytosociology is the mainstream method throughout Europe and is applied also in northern Asia and various regions of Africa and Latin America. While its application in North America remained limited, relatively recently the US National Vegetation Classification (USNVC; see Peet and Roberts 2013) was launched, which acknowledges the importance of consistent hierarchical classification systems and adopts ideas of the Braun-Blanquet approach in a modified terminology.
PHYTOSOCIOLOGY

Placement and size of plots

While traditional phytosociologists thought that one could represent a whole stand (patch) of vegetation with a single “typical” relevé, current phytosociology is seen as a statistical approach that aims at characterizing vegetation types by the combined information from many different plots. Therefore, it is generally better to sample many smaller rather than fewer larger plots. Sampling strategies normally aim at covering the full variability of vegetation within the defined geographical and ecological extent of a study, while minimizing the within-plot heterogeneity. These two targets can hardly be achieved by a spatially random sampling because this would miss geographically restricted types, which, however, may hold a distinct place in ecological space. As statistical inference across geographic space is usually not the intention of phytosociological sampling, a stratified-random or even a subjective placement of plots is preferable.

Formerly, phytosociologists thought that one could determine a “minimal area” for each vegetation type above which the number of species does not further increase. Sampling vegetation on plots corresponding to or larger than the specific minimal area would yield comparable results, irrespective of different plot sizes. According to modern empirical and theoretical knowledge, however, mean species richness monotonously increases with area and a minimal area is a deception caused by the nonlinear nature of species–area relationships. As most approaches for classification of vegetation are sensitive to different plot sizes, the recommendation is to apply uniform plot sizes within a few structurally delimited formations. In Europe, typically, areas between 4 and 25 m² are used for herbaceous types, and those between 50 and 400 m² for scrublands and forests. In regions without extensive legacy data, a single standard area of 100 m² might be advantageous.

Phytosociological relevés

The data of a single plot are called a relevé (French for “record”); they consist of “header” and species data. The header data comprise plot identification, information on methodology (e.g., date, researcher, plot size), geographic localization (name of the locality, geographic coordinates), environmental data measured/determined on the plot (e.g., altitude, slope and aspect, microrelief, soil parameters, land use), and structural data (i.e., cover and height of the distinguished vegetation layers). The selection of parameters and the precise approach for their measurement will depend on aims and resources of the project in whose context they are sampled, but there are attempts to establish common minimum standards to increase comparability.

The core of a relevé is a list of plant taxa (species and infraspecific taxa, further called species) found on the plot and their attributes. A peculiarity and, at the same time, a major reason for its success is that phytosociology aims at compiling a complete census of species instead of focusing on dominant or woody species only. All visible living vascular plants are included, often also the terricolous bryophytes, lichens, and macro-algae, and sometimes even species growing on substrates other than soil (e.g., epi-phytes). Every species is assigned to a layer (e.g., tree layer, shrub layer, herb layer, cryptogam layer), and species occurring in more than one layer (e.g., young individuals of tree species in the herb layer) are recorded several times. Each observation of a species in a layer is assigned

Phytosociological classification

Classifying vegetation has three fundamental goals (Dengler, Chytrý, and Ewald 2008):

- delimiting and naming parts of the vegetation continuum to enable communication about them
- predicting a multitude of ecosystem attributes (e.g., species composition, site conditions, ecological processes, conservation relevance, appropriate management)
- making multispecies co-occurrence patterns representable by verbal descriptions, tables, diagrams, and maps.

Since vegetation classifications serve many different purposes in fundamental and applied ecology, it is not surprising that no single classification can serve all purposes optimally (Dengler, Chytrý, and Ewald 2008; Peet and Roberts 2013). There is a fundamental tradeoff between having ecologically meaningful and easily recognizable units. Defining temperate European forests according to their dominant tree species, for example, would be easily conceivable even for laymen, but a category “beech forests” would include ecologically dissimilar stands while ecologically similar stands dominated by other trees would be excluded.

Phytosociological classifications stand out from other types of classification in four ways:

- They classify vegetation based on the assemblage of species, making the outcome independent of a priori knowledge of environmental factors and letting the species “tell” what is relevant for them (Peet and Roberts 2013).
- They aim at being suitable for many purposes.
- They aim at being integrated into a single consistent classification system.
- They are hierarchical, allowing for the coding of information effectively at different degrees of floristic and ecological similarity and for the use of different levels depending on specific needs.

All these aspects made phytosociological classifications an efficient system for collecting
and storing information on the vegetation continuum. While in syntaxonomy, as in taxonomy, no two classification systems are identical, the approach is so robust that in regions with phytosociological tradition, syntaxa became the most widely used and understood system for habitat classification, even for non-phytosociologists.

Historically, phytosociological classifications were achieved by manual sorting of species-by-plot matrices, so-called relevés tables. The aim of the sorting was to find groups of floristically similar plots and join them into vegetation units. This was achieved by arranging the discriminating species within the study in “blocks” along the matrix diagonal. Later, algorithms like the still widely used TWINSPAN emulated this sorting approach in a software tool. Nowadays, a wide array of different numerical tools for unsupervised classification are available to phytosociologists, each with specific pros and cons (see Peet and Roberts 2013; De Cáceres et al. 2015; IAVS 2015). However, unsupervised classifications can only use the information contained in the specific dataset. As, for practical and computational reasons, numerical classifications are always carried out for geographically and ecologically restricted datasets, the challenging task is to combine these separate classifications into a single consistent classification system. This latter step still involves much manual work and interpretation, but increasingly tools of supervised or semisupervised classification become available that help with this task (see De Cáceres et al. 2015).

Once a classification is achieved, its units should be validated, both internally (e.g., how well they are separated floristically) and externally (e.g., how well they predict site conditions), and, if necessary, be refined (see De Cáceres et al. 2015). The next step then is the characterization of the distinguished vegetation types (De Cáceres et al. 2015). While the original classification procedure was based on the full species composition, the floristic characterization of a syntaxon aims at highlighting those species that are most important for its recognition. These species are the dominant (those with the highest cover), constant (those with the highest frequency), and diagnostic (those with the highest “fidelity” to that unit) species. The latter can be determined by numerical criteria, such as constancy ratio or total cover ratio, between the target unit and other units or with statistical measures of concentration in the overall dataset, such as the widely applied phi values. Among diagnostic species, one can distinguish character species, discriminating the target unit against all other units of the same rank, and differential species, being diagnostic only within the next-higher syntaxon. Characterization of a vegetation type also includes the determination of its altitudinal and distributional range, frequency, site conditions (through direct measurements in the included plots or inference from the species composition via mean indicator values; see Dengler, Chytrý, and Ewald 2008), disturbance and management regimes, and conservation status.

A specific aspect of phytosociology compared to other schools in vegetation science is that it provides a system for consistent naming of the derived vegetation units that is applicable globally. The naming of formalized units of phytosociological classifications, so-called syntaxa, is regulated by the International Code of Phytosociological Nomenclature (ICPN; Weber, Moravec, and Theurillat 2000). The rules are similar to those that have successfully governed the naming of taxa since the times of Linné. The two basic principles are the priority principle (the oldest valid name must be applied) and the type principle (that attaches each name to a type element). Together they ensure that the system can be built inductively,

that is, bottom-up, before all vegetation types of a region are recorded, and that an inflation of names is avoided when units are joined or split. Phytosociological nomenclature knows four principal ranks, with association being the basic one (Table 2). The names of syntaxa are derived from the scientific names of one or two (or up to three in the case of subassociations) species typical for the type, which are joined with connecting vowels and specific endings. The results are short and easily memorable names, which, despite their conciseness, carry an idea of the character of the unit.

Phytosociological databases

Over 100 years of phytosociological surveys have resulted in several million published and unpublished relevés. Nowadays, they become more and more available in regional, national, and supranational vegetation-plot databases. Presently, the databases registered in the Global Index of Vegetation-Plot Databases (GIVD; www.givd.info; Dengler et al. 2011) alone comprise data from nearly 3 million plots, most of them from phytosociological studies. Combining and harmonizing data from different databases for joint analyses is still a big challenge, given the differences in structure and software of individual databases, different header data fields used, and varying species concepts followed. However, both in Europe (European Vegetation Archive, EVA) and in the Americas (Botanical Information and Ecology Network, BIEN3) initiatives are ongoing to establish continent-wide vegetation-plot archives. The potential of national and supranational databases for fundamental and applied ecology is enormous. Unlike coarse-grain distributional data of individual species as so far used in macroecology and species distribution modeling, vegetation plots contain information on actual species co-occurrence, true absences, species’ relative performance and, in most cases, environmental variables determined at the plot and not just derived from geographic information system maps.

Place

Paul C. Adams
University of Texas at Austin, USA

Place is arguably one of the two or three most important concepts in the discipline of geography. The ways in which geographers address questions of place are inevitably tailored to their particular subdisciplinary interests, but there is a prevalent understanding of place as the coming together of heterogeneous processes. This interest in dynamism and heterogeneity indicates a refusal by geographers to reduce place to location, where things merely happen to come together, or to a container that tidily isolates certain phenomena from the rest of the world. Understanding place as essentially a process of synthesis allows room for the real world’s complexity, with its interplays of space, time, and matter, rather than resorting to an idealized “view from nowhere” in which phenomena are theoretically separated from place. What happens in a place is part and parcel of the place, both materially and conceptually, so the motivation for studying geography can be seen as a full appreciation of “the inter-relationships among the physical environment, the built environment, and the people” (Johnston 1991, 101).

In regard to the various causal chains that operate in the world, place is more than just the end of the line where we can observe the playing-out of effects. Place is also a constant source of causal chains that radiate out into the world. Many places are known for their roles in affecting the world, and some place names serve as coded references to ripples of effects that are still radiating outwards: Seneca Falls (women’s rights in the United States), Maastricht (the European Union), Hiroshima (the era of nuclear weaponry), and so on. Place meaning is a collective production and as such it gives coherence to collective actions such as protecting women’s rights, respecting EU policies, or avoiding a nuclear holocaust. Place identity also contributes to the constitution of personal identity, even as it serves to reflect identity, as in the meaning of being a woman or man, a European or non-European, a supporter or opponent of nuclear armament.

Despite shared, intersubjective strands, place means something different to every person. Pulling the strands together in a coherent fashion poses a major theoretical challenge. Geographical understandings of place are distinct from everyday, vernacular understandings of place, but they engage critically with these vernacular meanings, as well as with the narrowly focused place meanings from other areas of scholarship and creativity. “Place” in the geographer’s lexicon cannot lose touch with place as it is understood in daily life or other branches of scholarship. Daily life is intensely bound up in place so place itself escapes conscious awareness much of the time. Place references pervade everyday communication but the meaning and role of place remain paradoxically indefinite. Academic thought, in contrast, constructs very precise ways of defining place, but only by grossly simplifying place, either to location (in the natural sciences), to social categories and hierarchies (in the social sciences), or to a type of experience (in the humanities). The first of these, scientific knowledge, is often produced in laboratories but it is limited by its dependence
on such places since they lack the messiness of the real-world places where most things happen. In short, ordinary people live place more than they can articulate it, while scientists achieve ontological coherence by walling themselves off in very peculiar places. Either approach obscures place, creating a need for an approach that analyzes the phenomenon of place in general, along with the processes, patterns, and phenomena that are evident in particular places. Geography works in this direction, most explicitly through social science and humanities approaches, but also implicitly, through a shared commitment to maintaining the cohesion of geography itself, since the discipline addresses place in epistemologically diverse ways.

Geographical interest in place stems from an assumption that processes of all sorts (political, economic, cultural, biological, geological, and so forth) happen with places rather than merely in places. This distinction is subtle, but important: for geographers, processes are shaped, affected, reworked, modulated, organized, coordinated, and inflected by places. Place thereby plays an integral role in the world, making things possible and allowing them to emerge and develop in particular ways. Places of geographical interest come in all sizes, from a room to the cosmos, but it is now generally accepted that scale itself is a construct, so that, rather than simply being larger or smaller, places are actively scaled larger or smaller. A room is a place, but a country can also be understood as a place, and even the Earth as a whole is a place, at least when we capture it in images like “spaceship earth,” a blue marble floating against a field of stars (Cosgrove 2003).

The betweenness of place

A formative moment in the evolution of geography’s understanding of place was the Anglo-American geographical debate of the mid-twentieth century between advocates of chorographic versus nomothetic approaches. The chorographic (or chorological) approach built on foundations established by the Greek philosopher and geographer, Strabo, and the seventeenth-century writings of Varenius, but it found its clearest theoretical justification in Immanuel Kant’s eighteenth-century concept of geography as a synthetic discipline. According to him, the geographer’s task is to explore how phenomena come together in space just as historians explore how phenomena come together in time; both strive for disciplined and rigorous descriptions, whether of a particular time or place. Richard Hartshorne developed this idea in the mid-twentieth century, drawing on the German geographers Alexander von Humboldt, Ferdinand von Richthofen, and Carl Ritter to characterize geography as the study of areal differentiation. According to him, places are “element complexes,” combinations of phenomena revealed by the systematic sciences ranging from geology and biology to anthropology and economics. What makes a place significant is the unique coming together of phenomena, so the geographer’s task is ideographic: writing about the particular.

This approach was critiqued as “exceptionalism” by proponents of a nomothetic approach. Under the banner of spatial analysis it was argued that geographers, like other scientists, must search for generalizable relationships and ultimately discover laws governing interactions between and within places. Distance and population would serve as explanatory variables, much like distance and mass do in physics. While the idiographic versus nomothetic debate focused mainly on whether geographers should synthesize the findings of other sciences or develop their own body of theories and laws, it also involved a fundamental disagreement about the
meaning of place. The nomothetic geographers treated place as a location in space while the idiographic approach, identifiable as chorology or chorography, insisted on treating place as a much messier thing, albeit under the rubrics of “region” and “area.”

While spatial analysts continued formulating increasingly complex location-based models into the 1960s and 1970s, a newly emerging approach took a different angle and blended place’s particular and general sides. Humanistic and phenomenological geographers described place experiences in unprecedented depth and detail, borrowing from the social sciences, philosophy, and the humanities, including history. If the ultimate goal of spatial analysis was to predict interactions between multiple locations, and the ultimate goal of chorography was to capture the uniqueness of place, the countervailing goal of humanistic and phenomenological geography was to articulate the universal phenomenon of place experience as revealed by particular people living in particular places.

In contrast to these approaches, several distinct approaches emerged in the 1980s and 1990s that were committed to exposing how places are caught up in, and contribute to, social power relations. These included Marxist/Marxian, feminist, poststructural, postmodernist, and postcolonial methods. While divergent in regard to the power relations exposed by their critiques, these approaches shared the assumption that places are best understood in terms of social power relations. Groups that are at odds with each other almost inevitably divide around the issue of place as they appropriate different places, appropriate the same places in different ways, appropriate different parts of places, scale places differently, or do all of the above. The goal of studying place through power relations is to find out what unites them. These various approaches all seek to intervene in the dynamics that make place a contested terrain.

These three meta-approaches could be parsed as place-as-location, place-as-experience, and place-as-contested-terrain. They pervade the discipline, adding richness but also mutual misunderstanding. Tensions arise between them when divergent goals channel teaching and research efforts. Many geographers attempt to navigate between these extremes, however, and articulate an ideal, albeit difficult to achieve, in which the essence of place is its ability to synthesize multiple characteristics. For Entrikin (1991) such efforts boil down to an exploration of the “betweenness of place,” with place being a lens that combines objective and subjective realities. He argues that the study of place calls for ontological reconciliation between a decentered view from nowhere and multiple views from somewhere, between objective and subjective perspectives.

Agnew and Duncan (1989) conceive of place in terms of a triad: location, locale, and sense of place. This approach incorporates geometrical/physical, social/cultural, and experiential/emotional elements. While location equates place with position in space, locale consists of “the settings for everyday routine social interaction provided in a place,” and sense of place is a form of “identification with a place engendered by living in it” (Agnew and Duncan 1989, 2). Rather than mutually incompatible alternatives, the elements of this triad are offered as complementary dimensions of place and they have been taken up in this spirit by many authors engaging with the topic.

Lynn Staeheli (2008) adds detail, identifying five distinct aspects of place that have been treated in the geographical literature: place as physical location or site, place as a cultural and/or social location, place as context, place as something constructed over time, and place as
process. What produces a place, for Staeheli, is the systematic way in which each facet of that place structures the others. Whether we adopt Entrikin’s notion of betweenness, Agnew and Duncan’s tripartite system, or the five aspects indicated in Staeheli’s review, careful study reveals place as a complex synthesis and interplay of heterogeneous elements. These attempts emerge out of a shared assumption that place is essentially integrative or synthetic. The synthetic quality of place is astonishingly pervasive. Even the planet Mars, out of reach in the nineteenth century, was transformed into a place by the debate among “experts” on its imagined geography (Lane 2011). The social relations between these astronomers imposed competing senses of place time and civilization onto the distant body, although it was barely more than a dot in their telescopes.

A close look at any given place reveals its synthetic quality. This quality does not produce singular outcomes, although it typifies all places. Rather, its multidimensionality permits the creation and evolution of a multitude of distinct places, making place as difficult to analyze as it is important.

Location

Location is primary in some geographical approaches to place. Cartography, remote sensing, and GIS subsume sense of place and locale to locational attributes. Studies of geographical patterns emphasize location, as do efforts in economic geography to quantify and map the global flows of goods, capital, and information, or in political geography to trace flows of bodies, power, and authority. Perhaps the most locationally deterministic approach developed thus far is central place theory which assumes that the relative locations of places (their distances from one another) and their relative masses (populations or economic activities) together determine how places will interact and develop. In the early twentieth century, Walter Christaller theorized that large, medium, and small urban centers would ideally be distributed in hexagonal patterns. The emergence and growth of population centers would be governed by the imperatives of markets, transportation, and administration. In each case settlements would ideally form hexagonal patterns, but the relative frequency of small and large settlements would differ depending on the driving forces in a particular area. It was hoped that once local contingencies were taken into account such patterns could be identified in the distribution of actual urban settlements; however, the patterns predicted by central place theory bore scant resemblance to the actual layout of urban centers. Distance alone did not determine geography, owing to contingencies of site and situation such as terrain, soil, climate, vegetation, water bodies, resource distributions, historical factors (such as the layout of transportation infrastructure), and the choices made by individuals, groups, and governments.

Geographers in the spatial analytic tradition rejected the notion of place as singular, assuming that all relevant characteristics of place could be quantified and their interactions would yield a coherent set of laws. Systematic analysis of the spatial patterns of such thinned-down places appeared to offer a way of rescuing geography from widespread accusations that it lacked scientific rigor, but it became increasingly difficult to defend the relevance of this approach because it lacked predictive power, and in addition it turned people into little more than dots on a map, while avoiding moral and ethical questions. Ultimately, the pared-down notion of place inherent to spatial analysis proved untenable. The reduction of geographical place to location is logically flawed because it separates space from
time and matter, and laws of geometry cannot, on their own, explain the patterns observed in geographic space (Sack 1973). In addition, the key figures in the quantitative revolution were deeply embedded in particular places, such as academic departments and research laboratories, despite their aspirations to transcend the peculiarities of place.

Despite its limitations and contradictions, spatial analysis contributed useful concepts to the study of place. The most important is time–distance. Torsten Hägerstrand initiated time geography, and he and his followers explored the ways in which people’s movements through space are structured by time, authority, and access to various forms of transportation. The options for face-to-face interaction are constrained in multiple ways such that people inhabit invisible prisms demarcating the farthest points they can reach in a given span of time, using a particular mode of transportation and assuming a certain period to be spent at the distant location. Activity occurs not within an unlimited space but within the spatiotemporal constraints imposed by the authority of territorial systems, the physical limitations of one’s own body and vehicles, and the spatiotemporal constraints of one’s social contacts, colleagues, clients, and customers.

Insofar as distance is more often encountered in terms of travel time or communication time than in terms of geodesic distance (as a crow flies), technological changes can be understood as bringing places closer together functionally and experientially, producing time–space convergence. A complementary process of divergence also occurs through various place-based cyclical processes. Donald Janelle argued that time–space convergence leads to centralization (e.g., fewer and larger stores) and specialization (e.g., proliferation of different types of stores), both of which create a demand for improved accessibility. This demand motivates transportation innovation, which may result in further time–space convergence but could also have the unintended consequence of creating divergence; for example, traffic congestion resulting from increased automobile dependency. Related ideas have been advanced, although often with different research objectives, under the name of “time–space compression.” David Harvey argued that time–space compression arises from the acceleration of geographical flows of people, goods, and capital in support of capital’s imperative to conquer space. Time–space compression leads inevitably to tensions between the acceleration of spatial flows and the construction of costly and immobile infrastructure to support those flows. From these various perspectives, innovations in transportation and communication can be seen as radically changing the functional separation between locations, transforming the practical impacts of distance, and thereby creating, transforming, sustaining, and destroying places.

Locale

Throughout the social sciences place is often equated with community but this equation is misleading, since all but the smallest places bring together multiple communities, and there are communities that bind lives across multiple locations. Confusion arises when elements of place are thought to be derived from social relations rather than co-constituted with social relations. A geographical reply points out that a town cannot be reduced to a list of its inhabitants and their social ties any more than it can be reduced to the physical infrastructure at a particular location. A place is the three-way interaction between social relations bound up in one or more mutually interacting communities, varieties of place
Reducing place to community is, in fact, ethically problematic since the idea of community often masks insidious assumptions about who belongs and who does not belong, or in Cresswell’s (1996) terms, who is “in place” and who is “out of place.” Prejudice can lead to an exclusive definition of the community as a group of people that belong in a place, while people not fitting a certain definition are subject to treatments such as expulsion, marginalization, exclusion, and oppression. Shopping malls may expel youth who are just “hanging out” rather than consuming, enforcing an idea of community as consisting of consumers even while evoking nostalgic images of a less materialistic kind of community. Small towns and suburbs may be refuges imbued with purified place images that foster prejudiced ideas of outsiders and stereotypical ways of understanding insiders. In similar fashion a much larger place, the nation, mobilizes racially and ethnically exclusive concepts of identity at borders, ports, airports, and frontiers, where civil servants seek to control the bodies and actions of people moving through. In any place, at any scale, a dynamic tension can be identified between multiple communities in the place, each of which competes to define the place through its communications and actions. Through these processes we see how sense of place interacts with the social dynamics of locale as groups are “denied a place in society through a particular construction of place” (Sibley 1995, 107).

Place’s importance to the formation of collective identity also makes it a lever with which to bring about societal change. A gay pride march, a protest occupation, a flash mob, a work of performance art, or a riot each in its own way uses place to challenge the social order. Their potency derives from the dependency of the social order on place, and specifically on sense of place and locale. Such extraordinary events are essentially performances that “take place” in the dual sense of claiming place and happening. The seizure of public space by groups may be permitted, for example, in the United States under the freedom of assembly clause of the Constitution, but in most cases the actual use of place to challenge collective notions of order and community is tightly controlled and regulated in both space and time. New digital technologies and social media such as Facebook and Twitter have facilitated the strategic occupation of places, allowing protestors to mobilize quickly and to relocate or change tactics in response to police and military intervention. These media have also facilitated the task of gaining the support of distant audiences and using them as a means to put pressure on authorities. Technology’s influence on struggles to seize territories and redefine places can be seen in “developing” and “developed” countries alike. The power of place is therefore reworked by coordinated manipulation of performance in place and technologies that permit people to communicate through space: that is, among scattered protest participants, and also to audiences who live in distant locations and have access to different political resources.

For most people, the place with the most resonance is the home. Adopting a place as one’s home is “the most highly charged commitment one can make in that realm wherein the personal is political, [and] it is also an affirmation to be present in the moment” (YoungBear-Tibbetts 2007, 158). Part of the appeal of home is that, notwithstanding power differentials based on age, sexuality, and gender, one is mostly “in place” there. Home offers a refuge from globalizing processes, but this sense of place can be deceptive insofar as home offers at best a permeable membrane shielding the private world from the economic, political, and physical risks of the public world. The dynamics are complicated and
people may understand their homes as places of refuge or escape even when these homes are colonized by the control mechanisms of a global space of flows. Some people bear the deeply compromised status of “homeless.” The lack of a home is socially (and structurally) imposed on them, since they may “think of themselves as having places to call home even when they were sleeping rough but these places simply do not count in the eyes of those who encounter them” (Cresswell 2004, 117). Locale therefore involves warmth and conviviality but also vicious cycles of exclusion and marginalization.

An interest in locale also directs us to consider how places are colonized by globalizing political and economic forces. While capital is mobile, place’s fixity permits the expansion of capital flows. Globalizing forces relate to places in terms of exploitable resources, incorporating extraction and production facilities as well as infrastructure for shipping and distribution (Harvey 2010). Economic changes can disrupt sense of place through, for example, the leveling of forests, the exhaustion of fisheries, the demolition of inner-city neighborhoods, and the closing of factories. Memories of an earlier time, along with a subsequent sense of loss, can linger and haunt a place. Economic development therefore reworks places, modifying the elements of locale to fit social structures based in larger scales, including national, regional, and global economies. In an ironic twist, not only the resources in a place, but even a sense of place, can be sold to tourists and other outsiders as symbolic carriers of uniqueness, packaged to cater to standardized tastes. Cancun, Mexico, for example, has been reworked to suit the tourist’s gaze and desire for entertainment, and has become what local observers refer to as gringolandia (Torres and Momsen 2005).

In response, place attracts its defenders, those who seek to protect a “space of places” in opposition to capitalism’s “space of flows” (Castells 1989). The symbolism mobilized in such struggles can be progressive. The discovery of common causes and interests among multiple communities can help make a place into a shared home. Such homes can resist the forces of globalization; however, any social order erases certain understandings of a place while promoting others, and when a group defends “our place” they are quite often solidifying one group’s social power and privilege over that of other groups with equally valid claims to that place. Place is therefore deeply ambivalent, providing a scale and focus to movements that resist the expansionary, globalizing forces of capitalism while at the same time fostering conservative and even reactionary politics.

In contrast, there is what Massey (1993) would call a global or progressive sense of place – one that recognizes the many place-making activities that are nonlocal. This view resonates with highly mobile lifestyles incorporating a multitude of communication technologies into place-making. Flows of ideas, information, and emotion enter and leave a place through communications, not only dissolving the boundaries between places but also accentuating the distinctiveness of places as switching points or nodes. Human bodies increasingly occupy transnational spaces, routinely circulating between scattered, rather than clustered, places. The challenge is not just to think carefully about the sending and receiving places of migration, with their push and pull factors, but also to reflect more generally about how “migrant and other mobilities are embodied, embedded and grounded” (Blunt 2007, 691).

While place has traditionally been assumed to require spatial fixity, many people are obliged to develop a sense of place that is not limited to a particular locale; their sense of place incorporates multiple locations or movement itself. Not only refugees, migrant workers, and expat retirees but
also tourists and business travelers “dwell through travel, and vice versa” (Ralph and Staeheli 2011, 519–520). Mobility is nothing new. In many cities of the world there are neighborhoods that have changed hands and identities multiple times as older immigrant populations have given way to newer immigrants. However, over time the “balance between ‘relations of presence’ (local ties) and ‘relations of absence’ (extra-local ties) has moved in the direction of the latter” (Agnew 1989, 24; emphasis original). The proliferation of communication technologies, their permeation of the places of daily life, the acceleration of message transmission, digitization, and media convergence all play roles in this evolution of locale. Claims have been made that new communication technologies will allow people to stay at home or otherwise reduce their mobility, strengthening ties to place. Rather than substituting for travel, however, information and communication technology complements, accompanies, directs, and stimulates travel, migration, and mobility. Even relatively poor immigrants remain in touch with family through interpersonal and social media, as well as by sending remittances, and their sense of place may be split between multiple homes separated by international borders and thousands of miles. At the same time, poverty, political oppression, and lack of education lock some people into comparative immobility, turning place into a kind of trap or prison.

Sense of place

Sense of place builds on the locational and social elements discussed in the previous sections, creating an “organized world of meaning” (Tuan 1977, 179). In a familiar place, every object has a meaning so the places one knows best become “centers of felt value” (Tuan 1977, 4). People attach meanings and emotions to locations and a sense of place develops over time, building up layer on layer. Variations in sense of place indicate the inherently subjective nature of this experiential phenomenon and the challenge of understanding or empathizing with others’ place experiences. A school may be an exciting and fun place to one student and a dull and oppressive place to another; likewise, a home may be experienced as a sanctuary by a man and a prison by his wife, or vice versa. Such variations in sense of place are often deeply politicized as people defend a sense of place rooted in one narrative and dismiss countervailing narratives as distortions and delusions. Nonetheless, a sense of place cannot be mechanistically derived from social structures or dynamics. Locale affects sense of place and vice versa.

If we follow Martin Heidegger in framing the experience of human life as being-in-the-world, then place arises phenomenologically from human intentions and actions, rather than abstractly from categories and measurements. Sense of self and sense of place are formed through a constant interplay. The implication for place scholarship is that deepening one’s understanding of place encourages a critical understanding of oneself and, more generally, of the construction of self-identity and subjectivity. The recent return toward issues of practice and performance under the rubric of “nonrepresentational theory” revitalizes key questions of the phenomenological approach, although the terminology and many of the assumptions have evolved. While Thrift calls for a nonrepresentational “style” of research that would be “a means of valuing and working with everyday practical activities as they occur” (2008, 112), this is remarkably similar to Heidegger’s interest in Dasein (being-in-the-world), which grounds reality in particular purposes and actions, or Husserl’s interest in Akterlebnis (act experience).
The main differences between phenomenology and nonrepresentational theory may be terminological, although the latter advances somewhat more modest claims.

Sense of place includes a range of emotions from profound attachment to dread. The former has been called topophilia (Tuan 1974). The latter may arise from incidences of violence or tragedy, which lead to community responses such as the designation of the site as important to collective memory, the obliteration of lingering signs of the tragic event, rectification of the site by returning it to the status of an ordinary place, or in some cases sanctification of the place as a kind of shrine (Foote 1997). These countervailing notions of topophilia and places of tragedy are ineluctably subjective and interlocked. People migrate to places in pursuit of their own topophilic ideals, but an influx of new residents may cause long-term residents to perceive a deterioration in their place's identity. Here we can see one person's topophilia leading to another's topophobia.

Mediated communication involving books, radio, television, the Internet, and many other media is closely tied to sense of place. Place experiences circulate as generic and particular images in the media: for example, war zones on the nightly television news or beach resorts in advertisements for packaged vacation tours. Such place images interact with collective memories and with each individual's personal experiences, then feed back into first-hand experiences of particular places. Media are encountered in particular places and media represent places, but in addition media also create places, in that they bring together spatially distributed audiences or participants in locales of shared experience. Particular media, texts, and discourses can function much like gathering places when people interact around these media products and their conversations touch base on certain themes, stories, characters, and worldviews. In this regard, mediated place images and media-altered places connect with other trends toward mass production: for example, the proliferation of chain restaurants and stores, international architectural styles, and standardized spaces of travel such as freeways and airports.

In connection with these processes, academic disagreement has revolved around questions of authenticity, and particularly whether there has been a cumulative weakening of place attachment and a progressive loss of local distinctiveness. For some observers, there is a growing homogenization of place. These discussions bring together questions related to sense of place in a way that elicits strong emotions, captured quite often with Relph's term "placelessness" (1976). The term indicates that mobility, tourism, commerce, and other elements of modernity have eroded place-based authenticity. When a place attracts substantial levels of attention from outsiders, for example by catering to tourists, processes are set in motion that rework the landscape to reflect the outsiders' expectations. Relph outlines a range of relationships to place, from existential outsiders at one extreme, in which places are seen in the homogenizing gaze of a visitor who is just passing through, to existential insideness at the other extreme, which entails that "a place is experienced without deliberate and selfconscious reflection yet is full with significances" (1976, 55). Recent work challenges the notion of "authenticity" along with "tradition" and "heritage," since these ideas are often linked to oppressive, exclusionary, and reactionary politics. The sense that place is under siege by globalizing forces that are undermining local distinctiveness can be attributed, in large part, to a more specific concern with Americanization. What passes for "placeless" may in fact be particular place associations that are perceived as alien and invasive because they are redolent of a single country's
iconography, that of the United States. The debate about authenticity has much to do with notions of community; the close ties between locale and sense of place carry normative weight and place images provide neat packages for how things “should be.”

Doreen Massey challenges the assumption that increased mobility and communication erode the foundations of sense of place. Defining place in a way that emphasizes particularity but not separation, her “global sense of place” is one in which places are defined by connections rather than contents, links rather than boundaries, and the people in a place are situated differently with regard to flows of social power. She challenges the assumption that place depends on spatial isolation and stasis, as well as the Marxist concept of place as resistant. Massey argues that “what gives a place its specificity is not some long internalized history but the fact that it is constructed out of a particular constellation of social relations, meeting and weaving together at a particular locus” (1993, 66). By concentrating on places as “moments in networks of social relations and understandings” (Massey 1993, 66), she is able to tell a story about “power-geometry” in which some people control mobility and communication, some move and communicate quite a bit but do not control the processes favoring mobility and communication, and some merely suffer the consequences of living in an increasingly interconnected world.

New directions

Attention across academia to the works of place-sensitive nongeographers such as Michel Foucault, David Morley, Manuel Castells, Saskia Sassen, John Urry, Mimi Sheller, and Judith Butler, among others, indicates a broad “turn” toward place. This turn is also evident in philosophical works like Edward Casey’s Getting Back into Place (1993) and The Fate of Place (2013). There have been particularly earnest turns toward place-based research in anthropology, sociology, and communication theory, as well as in environmental psychology. Scholars in these fields, as well as in architecture, design, and planning, have drawn inspiration from geographical writings of the 1970s and 1980s, including works by Tuan and Relph, as well as the concept of a “place ballet” (Seamon and Nordin 1980). Such place-based social science forays are proliferating, whether signaled by the local as opposed to the global, the symbolic power of home, the economic power of world cities, the consumption of places, or the Deleuzian interest in “topography” as something one lives through rather than merely on.

In geography, the emergent nonrepresentational approach or style of geography revitalizes many long-standing interests of humanistic and phenomenological geography, seeking to understand aspects of place experience. Body language, cooking, dance, everyday life, haunting, play, sports, tool use, and touch are among the topics of interest (Thrift 2008). Embodied passions, emotions, practices, and encounters are now linked to “affective realms,” “encounters,” “events,” “performances,” and “waves of influence” so the details of place experience are in the foreground more than ever. This interest in embodiment, instead of in static patterns and hierarchies, directs attention back to place, suggesting yet another round of conceptual revitalization for this term.

Technological change has also changed how people (including scholars) think of place. The diffusion of the Internet has led to considerable fascination in popular culture with novel ideas of place such as cyberspace and virtuality. In
the mid-1980s, the science fiction novel *Neuromancer* described cyberspace as a “consensual hallucination” consisting of graphic representations of digital information: “Lines of light ranged in the nonspace of the mind, clusters and constellations of data. Like city lights, receding” (Gibson 1984, 69). While the novelty of computer networking has faded considerably and the reality of the Internet has turned out to be somewhat more prosaic, Gibson’s basic insight regarding place is still valid: digital media have altered the relationships between location, locale, and sense of place. The emergence in the early 1990s of graphic user interfaces and online service providers inspired many variations on a theme: for example, online “chat rooms” and “dungeons,” “going online,” “posting” things on one’s “wall,” “pinning” images on one’s “board,” and so on. Such place-based terminology is employed casually but it reveals collective recognition that online experience is related to place: digital code supports interactions in an array of locales, each with its own characteristic sense of place, based on hardware and software rooted in particular locations. All three elements of place are present in and around online interaction, even when bricks and mortar have been left behind.

Geographers are beginning to engage with the idea of virtual place. New technologies call for familiar themes to be revisited, including accessibility, centrality, marginality, privacy, and surveillance. This new research challenge does not prevent critiques of the notion of virtual place or efforts to identify problematic social dynamics in virtual places, but it can potentially reinvigorate earlier discussions of authenticity and placelessness, or “senses of home that are spatially extensible” (Ralph and Staeheli 2011, 520). Insights about how people make a place or even home in complex media like the Internet will help shine light on older transformations in and of place, including those arising from earlier broadcast media, and prior to that the emergence of writing, printing, and literacy. As computing capacity and speed constantly increase, places have become sites for the extraction of “big data.” It is impossible to enter or leave many places without being detected and identified, for example through RFID (radio frequency identification) tags, facial recognition software, and biometric sensors. Where places once offered seclusion and privacy, they now increasingly serve as mechanisms for monitoring and surveillance, which in turn produces a demand for alternative means of carving out privacy, seclusion, and containment of place within the transparent space of digital flows.

PLACE

Further reading

Vegetation influences hydrological fluxes between the atmosphere and the ground surface. The canopy of individual plants acts as a barrier, preventing a proportion of precipitation from reaching the surface and contributing to runoff or groundwater. Precipitation is intercepted by components of the canopy (stems, branches, flowering parts, and foliage), and much of the intercepted water evaporates directly back into the atmosphere (Levia and Frost 2006). Interception ($I$) is calculated as $I = P_g - (T + S)$, where $P_g$ is gross precipitation, $T$ is throughfall, and $S$ is stemflow. All of the variables in this equation are expressed in units of depth equivalent, such as centimeters. Gross precipitation is the quantity of precipitation that falls on the top of the vegetation before it is in contact with the canopy or passes through the canopy. Throughfall is the quantity of precipitation that reaches the ground minus the stemflow. Two pathways of throughfall exist. The first pathway is precipitation falling directly through the canopy during a rainfall event without being intercepted. This quantity of precipitation does not contact vegetative surfaces and falls through canopy gaps. The second pathway is precipitation that drips from the canopy after precipitation splashes on vegetative surfaces. In this pathway, water on vegetative surfaces can coalesce to form large water droplets. Stemflow is the precipitation that reaches the ground after channeling down the branches to the stem of a plant. Because this hydrologic pathway occurs along vegetative surfaces, it is distinguished from the throughfall pathway in which drops of precipitation free-fall to the surface from the canopy.

The most common field method to measure interception is to use precipitation gauges, throughfall collectors, and stemflow collars. For accurate measures of interception, the instruments need to be in close proximity to each other. For this reason, precipitation is best measured from the top of a canopy tower projected above the height of the canopy. Because the construction of a canopy tower is cost prohibitive, the next best solution is to position precipitation gauges in a clearing or large canopy gap in close proximity to the throughfall collectors and stemflow collars. The two most common types of throughfall collectors are precipitation gauges and throughfall troughs positioned under the vegetation canopy. Vegetation canopies create a large variation in size and quantity of gaps. Throughfall collectors positioned under a large canopy gap will potentially measure more throughfall than a throughfall collector positioned under a large branch. As such, the cumulative orifice of throughfall collectors needs to create a large area to represent the heterogeneity of canopy gaps created by the vegetation. To create a large cumulative orifice for throughfall collectors, the number of precipitation gauges collecting throughfall is increased. Throughfall troughs may be better than small throughfall collectors because they may provide a larger area covering a longer swath of canopy gaps and obstructions. Regardless of the type of throughfall collector used, it is best to reposition the throughfall collectors underneath
the canopy on a regular basis to increase the representative area of the canopy. Stemflow collars are constructed of plastic tubing that is cut longitudinally and fastened to the trunk with sealant and small nails to collect the stemflow drainage. Stemflow drainage is channeled into an uncut section of the tubing and into a covered precipitation gauge. Stemflow is calculated as a depth equivalent per unit projected area of canopy. Published research commonly reports that stemflow is only about 1–5% of annual precipitation and is zero in small storms.

Another term related to interception is “canopy storage capacity.” Canopy storage capacity is the amount of water held on the canopy at the end of a rainfall event, after drip has ceased and in the absence of wind. The quantity of canopy storage capacity represents the minimum amount of water that can be stored in the canopy and not the total amount of water that was intercepted by the canopy during a precipitation event. Once the canopy has become saturated, the amount of interception exceeds the canopy storage capacity by whatever is evaporated during the rainfall event. Because the rainfall intensity normally exceeds the evaporation rate by at least an order of magnitude, the canopy will stay wet and evaporate during precipitation events. Direct measurements of canopy storage capacity are labor-intensive and often rely on destructively sampling vegetation. Aston (1979) suspended small trees under a rainfall simulator to demonstrate a mass-balance (gravimetric) approach to the measurement of canopy storage capacity.

Approximately 10–25% of annual precipitation is lost by interception, depending on meteorological and vegetation factors. The meteorological factors that influence interception include rainfall characteristics (e.g., rainfall intensity, precipitation duration, precipitation frequency) and the evaporative potential of the atmosphere. The length of time to achieve canopy storage capacity is reduced with higher rainfall intensity events. Additionally, canopy storage capacity is larger in many broad-leaved species during higher rainfall intensity storms than in lower rainfall intensity storms because of greater amounts of rainsplash on the underside of leaves. The duration of the rainfall event also influences interception. During short duration, low-intensity rainfall events, 100% of precipitation can be intercepted. The evaporative potential of water intercepted by the canopy is influenced by available energy, vapor pressure gradient, and the aerodynamic resistance of leaf surfaces. Interception loss is greater in environments with high temperature and low humidity than in environments with low temperature and high humidity.

Vegetation factors that influence interception, throughfall, and stemflow include leaf area index, stand density, vegetation age, and species composition. Leaf area index is the ratio of total leaf surface area of vegetation to ground area and is expressed in units of m²/m². A positive relationship occurs between leaf area index and interception. Vegetation with a larger leaf area index has a greater potential to intercept more water during a rainfall event because there are more surfaces for the water to adhere. Because leaf area index strongly influences interception, leaf phenology is also an important control on interception. Deciduous species during the growing season intercept a greater proportion of precipitation than deciduous species during the dormant season because of differences in leaf area index between the seasons. Stemflow may be enhanced during the dormant season in deciduous species. Although needles persist year-round for evergreen species in temperate and high latitude regions of the world, the leaf area index is less during the winter months than during the growth season. Small changes in leaf area index can produce significant changes in interception.
The presence of epiphytes in the canopy of cloud forests and temperate rainforests increases leaf area index and canopy storage capacity.

Vegetation age influences interception insofar as the leaf area index of younger forests is lower than the leaf area index of older forests. Stand density can influence the spatial distribution of throughfall beneath a canopy. For example, forests with low stand densities create larger canopy gaps between individuals. This allows more throughfall and reduces interception. Well-stocked stands have greater interception losses than understocked stands. The variety of spacing between individual trees produces large variation in quantity of throughfall to the forest floor.

The influence of species composition on interception is perhaps the most understudied aspect of plant–water interactions. Of the thousands of different plant species that occur on Earth, only a small percentage have been used to study interception, throughfall, stemflow, and canopy storage capacity. Besides leaf area index, the canopy of each plant species has unique properties that influence hydrological fluxes. These properties include the canopy architecture, leaf characteristics, and bark characteristics. Branch angle is a component of canopy architecture. In general, branches that are upright tend to channel intercepted water down to the stem and generate more stemflow than branches that are horizontal with the surface. Abrupt changes in the angles of branches in the canopy create drip points for stemflow that increase throughfall. The anatomical structure of the bark also varies between species. For species with flaky or rough bark, the surface area of the canopy is increased, which causes water to be easily retained by the canopy, increasing interception and canopy storage capacity. Species with smooth bark do not retain as much water during a rainfall event.

Variation in leaf characteristics (i.e., area, angle, shape, surface properties and chemistry) also influences interception and canopy storage capacity. Leaf angle or leaf orientation relative to the horizontal of the petiole and lamina of a leaf influences the ease with which water drains from the leaf surface. Several plant species have developed drip tips to channel water off the leaf surface. Leaf angle, leaf surface structure, and leaf surface chemistry affect leaf hydrophobicity and water droplet retention (Rosado and Holder 2013). Leaf hydrophobicity is a measure of how repellent a leaf surface is to a water droplet, and is commonly measured by calculating the contact angle between a sessile water droplet and the leaf surface. Water droplet retention is a measure of how easily a water droplet drains off a leaf surface, and is commonly measured as the angle at which a sessile water droplet will begin to drain off a leaf surface as the leaf surface is incrementally tilted. The significance of leaf characteristics such as leaf hydrophobicity and water droplet retention as a mechanism that influences hydrological processes is an underexplored research topic in ecohydrology. Several studies have found that the contact angles between a leaf surface and a water droplet range from 22° to 180°, depending on the species and the chemical properties of the leaves. Many leaf surfaces producing contact angles exceeding 150° may not be true surfaces, with the droplet instead held away from the surface by large numbers of projections of wax or trichomes. A contact angle exceeding 110° indicates leaf surfaces that are nonwettable, or repellent, and leaves with contact angles <110° are considered wettable, or nonrepellent. Although the contact angle between the leaf surface and the water droplet may be large, the ability of the water droplet to drain off the surface of the leaf (water droplet retention) may be small because of contact angle hysteresis. A
leaf surface has a low water droplet retention if a water droplet sheds from a leaf surface that is tilted <20° from horizontal. A leaf surface has a high water droplet retention if a water droplet remains on a leaf surface tilted >60°.

Leaf hydrophobicity and water droplet retention may be common adaptations among plant species in habitats exposed to daily precipitation during the summer growth period. The selective pressure for reducing the wettability of leaf surfaces is usually thought to be physiologically driven. Water droplets on leaf surfaces restrict photosynthetic carbon exchange because carbon dioxide diffuses approximately 10,000 times slower in water than in air, and the beading of water on leaf surfaces enables the maintenance of high photosynthetic rates. Older leaves are less hydrophobic and wet more evenly than newer leaves. Leaf hydrophobicity and water droplet retention may be important variables that influence canopy storage capacity during a rainfall event (Holder 2013). Several studies have addressed the influence of canopy architecture and precipitation characteristics on canopy storage capacity, but few studies have directly addressed how leaf hydrophobicity and water droplet retention influence canopy storage capacity. Species with highly repellent leaf surfaces may reduce canopy storage capacity, and therefore, result in a decrease in interception.

The hydrology of cloud forests and temperate rainforests differs from other environments because of the presence of fog precipitation. Although the term “fog precipitation” is not universally used, early writers in various locations suggest people have had knowledge of the process for many years. Fog precipitation is called horizontal precipitation, occult precipitation, fog drip, and fog stripping by different authors. Fog precipitation occurs when fog droplets pass through the canopy of the forest and are filtered by vegetative surfaces. The intercepted fog droplets coalesce on the vegetative surfaces and drip to the forest floor. The environments that are especially likely to have fog precipitation are high-elevation regions where cool temperatures result in the condensation of water vapor and coastal regions on the western side of continents where cool air off the oceans condenses and moves inland. Local factors influencing the quantity of fog precipitation include canopy height, canopy architecture, wind velocity, leaf surface chemistry and structure, hillslope orientation, and orientation of foliage and branches.

Fog can contribute 25% or more of total precipitation in localized cloud forests. Fog precipitation represented a greater proportion of hydrologic input in the cloud forest of Guatemala during the dry season (19%) than it did in the rainy season (<1%) (Holder 2004). Because the dry season has a significant quantity of fog precipitation, management of the cloud forest is particularly important in maintaining water resources for arid lowland communities that ration water during the dry season. Without the canopy, fog precipitation would not exist. Deforestation of the cloud forest will impact this hydrological input and may reduce water yield because of the decrease in fog precipitation. With changes in species composition and stand characteristics, the filtering of water droplets to produce fog precipitation may be directly affected and fog precipitation inputs will likely change. Very few details are known about plant–water interactions and the canopy storage capacities of the cloud forest species that are being cleared by humans.

In temperate, high-latitude, and high-elevation areas, snow can be the primary form of precipitation. Snow interception totals vary between species. Dense conifer forests intercept the largest amounts of snow and consequently cause the greatest loss from the canopy by sublimation.
Thin and leafless hardwoods or open lands intercept the least amount of snow. Snow accumulation and water equivalent are greater in the open than in the forest. The forest canopy, however, modifies microclimates at the forest floor by producing lower temperatures, less shortwave radiation, higher relative humidity, and slower wind speed. These microclimatic conditions reduce energy inputs to snowpacks under the canopy and make the rate of snowmelt slower beneath the canopy. Snow intercepted by plant surfaces that is exposed to direct shortwave radiation and greater wind speed sublimates at a faster rate than snow at the shaded forest floor. During the low-sun season, canopy aspect can influence the rate of sublimation by creating different canopy microclimates based on exposure to direct shortwave radiation.

Numerous studies have examined the influence of vegetation on rainfall interception and stream discharge from undeveloped experimental watersheds. Although the results presented in these studies expanded knowledge of plant–water interactions, experimental watersheds that examine the role of vegetation in hydrological fluxes do not often include urban landscapes within the catchment area. Because the majority of humans live in urban areas, urban ecology has emerged as a rapidly growing discipline. Urban ecohydrology is an important subdiscipline within urban ecology. Urban watersheds represent a complex mosaic of land uses, including buildings (residential, commercial, and industrial), infrastructure (roads, sidewalks, etc.), landscaped vegetation, agriculture, and undeveloped open space (forests, grasslands, etc.). Leaf and canopy characteristics between common species in urban watersheds vary significantly (Holder 2011). Information on how changes in vegetation (e.g., via landscaping, conversion of open spaces to housing developments, etc.) influence hydrological processes such as rainfall interception and discharge within watersheds is important for city and environmental planners as the population of citizens continues to increase and land cover continues to change. Additional studies on the interactions between the physical properties of canopy traits and water droplets on vegetative surfaces would be useful to develop enhanced models of ecohydrological processes.

Further reading

Plate tectonics deals with the motions of the Earth’s rocky shell, or lithosphere, which cause the gradual shift of continents and are also responsible for mountain building, volcanic islands, and thermal vents. These geological processes have influenced the distribution of biodiversity. Prior to the identification of a geophysical mechanism that could drive movement at the Earth’s surface, its effects had been predicted. The concept of “continental drift” is usually attributed to Alfred Wegener, who presented his ideas on the origin of continents and oceans in 1915. However, in the 1500s the Belgian mapmaker Abraham Ortelius had noted that the coincidence of the coastal outlines of the Americas, Africa, and Europe implied former juxtaposition. In the 1800s, the “father of biogeography,” Alfred Russell Wallace, developed his ideas with the benefit of geographer Charles Lyell’s Principles of Geography. Lyell had noted that “Continents … shift their positions entirely in the course of ages.” Nevertheless, in the 1900s continental drift was strongly opposed by many, and the rejection of this hypothesis, which was built on extensive evidence, represents a notable failure of twentieth-century scientific method. The claim that consideration of the theory required demonstration of a geophysical mechanism was unjustified, but was nevertheless assuaged in the 1950s and 1960s when a tectonic model was presented. Today, paleomagnetism, radiometric dating, stratigraphy, and spatial information allow detailed interpretation and paleogeographic reconstruction.

One type of evidence presented in support of continental drift by Wegener and others was (paleo)biogeographic: the widespread distribution of certain fossil animals and plants across landscapes that are now disconnected (Figure 1). However, although widely reiterated even today, the occurrence of fossils did not in truth inform on the process of continental isolation. An alternative idea (land bridging) resolves the spatial discontinuity of biota problem equally well and makes the same biological assumptions. As with continental drift, land bridging assumes that the organisms of interest were unlikely to disperse between patches of suitable habitat. Thus both hypotheses require habitat continuity if species (or their lineages) are to be shared among areas. In biogeography, distribution patterns are often taken as evidence of past processes but they provide only the basis for formulating alternative hypotheses about the processes that might explain them. This is a subtle but vital distinction that underpins scientific method; a proposition cannot be simultaneously proposed and tested using the same observations.

In later editions of his book, Wegener recognized that his continental drift hypothesis was not to be tested with fossils, or for that matter a coincidence of continental crust outline. Rather, the best approach to testing the hypothesis was geodetics (Earth measurement), because the hypothesis that continents had moved in the past generated the prediction that continents would still be moving. Wegener died in his tent during a trip to Greenland to confirm longitudinal drift,
PLATE TECTONICS IN BIOGEOGRAPHY

Figure 1  Distribution of four Permian and Triassic fossil groups used as biogeographic evidence for continental drift, and land bridging. *Mesosaurus* included a small number of meter-long marine reptile species recorded in early Permian time (299–280 Ma). It is said that *Mesosaurus* could not have crossed the Atlantic but this is speculative, and at least one popular web resource incorrectly states that these were freshwater reptiles. *Lystrosaurus* included a debated number of species of pig-like land reptiles less than 1 m long. The genus is unusual in being present on either side of the Permian–Triassic extinction boundary (255–241 Ma). *Cynognathus* (*C. crateronotus*) was a meter-long predatory mammal-like reptile usually treated as one species that existed in early to mid-Triassic time (247–237 Ma). *Glossopteris* was a group of woody gymnosperm plants with wide but mostly southern (i.e., Gondwanan) distribution in the Permian (290–252 Ma). The identification of *Glossopteris* from northern areas has been questioned, and estimates of diversity vary.

Fossil sites were mapped using the database and tools of the Fossilworks Paleobiology Database, Macquarie University (John Alroy). Paleogeographic reconstruction is for Permian–Triassic time (250 mya). The inset on left is a version of a popular iconographic but misleading depiction of the fossil distributions (The Snider-Pellegrini Wegener fossil map; WikiCommons). Permian Map by C.R. Scotese, PALEOMAP Project. Reproduced by permission of C.R. Scotese.

but geodetic data have since demonstrated the fact that continents move. Plate tectonics explains how. Geological (rather than biogeographic) data informs paleogeographic reconstruction, and in doing so provides the context for biogeography. Plate tectonics is not, however, only about drifting continents; it generates short- and long-term environmental changes that influence the distribution and evolution of biological diversity, in many different ways.

Continental drift vicariance

Recognition of the potential for continental-scale effects of plate tectonics on biology developed
PLATE TECTONICS IN BIOGEOGRAPHY

side by side with plate tectonic theory. The founding concept of continental drift was that most of the Earth’s land had formerly been connected in a single supercontinent (Pangea). Fossils of Permian age indicate that Pangea existed more than 250 mya, and modern evidence supports this (see Figure 1). In fact the key fossils occur primarily across the southern part of this continent, a region usually referred to as Gondwana (or Gondwanaland), and it is noteworthy that this term was also used by land-bridgers who also envisaged a former extensive continent, parts of which subsequently disappeared. Although the geophysical evidence for a supercontinent is very clear, we now know that it did not include all continental areas at any one time. The idea that past breakup of a supercontinent (up to 200 million years later) could result in the establishment of biotas that are visible today makes many assumptions, among them that a supercontinent would have a homogeneous environment with continuous distributions of plants and animals, that other global events did not cause local changes in biotic assemblages, and that dispersal between continents had little influence on biological assemblages. In fact, paleoecological evidence indicates diverse and sometimes extreme environmental conditions existed across Pangea. Continental drift itself resulted in changes in climatic conditions so that natural selection on the biota would change, an extreme case being the wholesale extinction of Antarctic biota due to the drift of the continent over the South Pole. Mass extinctions across the globe radically altered biotas and dispersal between continents influenced regional biotic composition through time.

Intriguingly, although vicariance biogeography associated with continental drift is a highly attractive and popular idea, contrary evidence of the power of biota to disperse and colonize across habitat discontinuities is abundant and well understood (e.g., colonization and speciation on oceanic islands such as the Galapagos). In studies of living biota, evidence for plate tectonic vicariance can come from dated phylogenetic analysis (see Phylogeography and landscape genetics). Appropriate sampling and fossil calibration (see Figure 2) allow the timing of evolutionary events and continental drift to be compared. A match between the estimated time of origins of regional biota and the time of continental separation is consistent with, but not proof of, vicariance.

Land bridges and sea barriers

Plate tectonics can result in the connection of formerly disjunct land areas and simultaneously the sundering of marine environments, through volcanics, accretion, orogenics, and deformation. Although land bridging has been largely rejected from consideration of ancient biological history of Earth, younger examples show its influence. The Central American (or Panama) isthmus between North America and South America is a narrow strip of land (60–177 m wide) that finally shut off the equatorial link between Atlantic and Pacific oceans (the Central American seaway) in the late Pliocene (about 3 million years ago). Several tectonic plates intersect in the region (Figure 3) and their interaction appears to have led to the formation of numerous volcanic islands starting at about 5.5 mya. Sediment accumulation between these islands is one mechanism proposed for the land bridge.

Closure forced the Gulf Stream to carry warm equatorial water into the northern Atlantic Ocean, where it influences the composition and ecology of regional marine biota. Separation was accompanied by other environmental change; upwelling on the Pacific side see ms to have increased while salinity has increased in the Caribbean. Around Central America,
Figure 2  Dated phylogenetic analysis of four Madagascan mammal lineages using multiple nuclear DNA gene sequences and fossil calibrations. Origins and diversification of the Madagascan mammal fauna substantially postdate the pre-Cretaceous plate tectonic separation of Madagascar (red) from Africa (yellow) (≈83 mya). Very different dates for each of the mammal groups suggest no single mechanism for their arrival in Madagascar is supported. Tectonic crustal movements may have resulted in some parts of the Mozambique Channel being raised above sea level in the upper Eocene. Although there is no evidence for a continuous land bridge, islands might have facilitated mammals colonizing Madagascar. However, this speculation is not supported by the current phylogenetic analysis. Red branches lead to Madagascan species, yellow branches to nearest African relatives, grey branches represent outgroup taxa. Green and blue bars at nodes indicate 95% credibility intervals (bounds of uncertainty) for Madagascan stem and crown group, respectively. Tertiary time periods are Paleocene (Pa), Eocene (Eo), Oligocene (Ol), Miocene (Mi), and Pliocene (Pl). Adapted from Poux et al. 2005, by permission of Oxford University Press. Animal photographs from WikiCommons.
populations of marine creatures (and even seabirds that are reluctant to fly over land) were split between western Atlantic and eastern Pacific communities. On land, the isthmus led to changes in rainfall and climate patterns and facilitated the exchange of land creatures (a.k.a. the Great American Biotic Interchange). Many animals are inferred to have moved between continents and contributed to biotic mixing and thus elevated biodiversity in Central America.

The late Pliocene formation of the Panama Isthmus demonstrates a way that plate tectonics influences biogeography, which is counter to the effects of continental drift vicariance. This geologically, ecologically, and phylogenetically well-studied phenomenon is precisely the type of land bridge proposed by Charles Schuchert and others to explain exchange of biota between continents in past times. Their ideas replaced earlier, simplistic land bridge models that required special, unknown, processes to destroy large parts of continents. Systems similar to the Panama Isthmus might be geologically short-lived and thus hard to detect after the passage of time. Clearly, however, small and short-lived geophysical phenomena can have a profound influence on biogeography.

Intriguingly, while many mammals appear to have walked between continents once the Panama Isthmus formed, molecular and fossil data indicate that habitat connectivity is not essential for exchange. For example, the best explanation for the initial presence in South America of several mammal lineages involves oversea dispersal from Africa. This includes some that were subsequent North American colonists (e.g., porcupine). The marsupials, for instance, are represented by just one species in North America, about 100 in South America, and about 230 in Australia. However, the oldest fossils (65 mya) are from North America. Expansion southwards through South America and Antarctica probably took marsupials to Australia and eventually Borneo and Sulawesi, while the group disappeared from North America. Genetic analysis suggests that all living marsupials have their ancestors in South America. This makes sense because the only living marsupial in North America (opossum) arrived over the Panama Isthmus. Little is known about how these types of animal interacted when they met, and consequently ad hoc interpretations are common. For example, the extinction of placental mammals in Australia is often attributed to the arrival of marsupials, yet the reverse (replacement of marsupials by placentals) is suggested for North America. Very little is known about the marsupial fauna that must have existed in Antarctica, and none of course are there today. Modern species distributions are therefore revealed to be poor indicators, in many cases, of biogeographic history.

Other land bridges have resulted not from tectonic activity but from sea level change. Most recently, during the Pleistocene (<2.6 mya),...
Figure 3
lowered sea level resulting from water being locked into polar ice caps created land connection in many parts of the world. Habitable continents were linked as recently as 13,000 years ago through features such as the Bering land bridge between Siberia and Alaska that enabled the migration of many plants and animals, including humans.

**Mountains**

Linear mountain ranges form when continental plates collide, and it is routinely suggested that the formation of mountain ranges is a likely driver of allopatric speciation in terrestrial ecosystems. Populations sundered by geophysical barriers such as mountain ranges could evolve independently of one another if gene flow between them was sufficiently impeded. Mountain formation provides an appealing scenario for terrestrial vicariance because it generates abrupt environmental discontinuity (similar to land bridges dividing marine environments). Abrupt changes in environmental conditions are expected to influence population density, range sizes, and natural selection, but proven examples of the emergence of mountains causing speciation through vicariance are few. Cases where related species occupy habitat either side of mountains provide the expected distribution patterns but might also have resulted from occupation of habitat patches after mountains formed. They might also be the remnants of species distributions that predate mountain formation.

Mountain building contributes to biogeography in another way. The steep environmental gradients and habitat mosaics that mountain ranges produce appear to have stimulated adaptive radiations in many taxa. Examples include alpine buttercups in New Zealand, paper daisies in South Africa, and Andean hummingbirds in South America. Species that evolve to use alpine conditions in one location may also be successful on other ranges where similar ecological opportunities exist even though these are island-like, and this can result in disjunct distributions that are suggestive of vicariance.

Numerous studies in Europe and elsewhere show that plants and animals responded to Pleistocene climate cycling by range shifting, and this is contrary to the idea that mountains (and other geophysical features) routinely make biological barriers. The distribution across Europe of genetic variation within species and species groups shows that only in some cases do some mountain ranges correspond with species limits. In these cases, of course, the mountains are already present but the climate zones and species move. Distinguishing between mountains (and similar features) as drivers of lineage splitting and their longer-term influence on environmental gradients and ecosystem processes is challenging and exposes a general problem for biogeography. Mountains may come to be correlated with the limits of species and assemblage ranges or they might provide convenient landscape markers for biogeographers, even if they were not the mechanism of population sundering in the first place. Instead of looking for absolute interactions between geology and biology that focus on allopatric processes of lineage splitting, modern biogeography now recognizes the ways gene flow, environmental gradients, environmental fluctuations (e.g., climate change), extinction, sympatry, and uneven selection pressures across species ranges influence biotic composition.

**Deep sea hydrothermal vents**

Mineral-rich hot water emerges at temperatures of 400°C or more in submarine conditions where tectonic plates meet. The heat and chemical resources fuel specialized faunas
that constitute the only major biological systems that do not draw their energy from the sun. Secondary production from Archaea and chemosynthetic bacteria supports faunas that include giant worms, shrimps, clams, and limpets, at depths of 1–4 km below the sea’s surface. The habitat of hydrothermal vent faunas is dictated almost entirely by tectonic processes that result in a patchy distribution around the globe. These islands have histories tens of millions of years long but their biological isolation appears to be influenced by their chemistry and the ecology of their fauna. Gene flow between invertebrate populations living around widely spaced geothermal vents is mediated by planktonic larvae. Plate tectonic activity may be implicated in the origins of life in the ancient seas of Earth as it has been proposed that the thermal, chemical (e.g., acidity), and physical (e.g., high pressure) conditions around hydrothermal vents could have supplied the environment suitable for initial emergence of replicating organic molecules and protocells. There is evidence for hydrothermal vents in the Earth’s oceans in the appropriate time frame more than 3 billion years ago.

Volcanoes

Oceanic volcanoes create virgin land that is physically separate from existing, inhabited land areas. Although separated from other pieces of land, islands are not isolated. Island biogeographers recognize that the fauna and flora of islands develops through the interaction of colonization, speciation, and extinction and these components are in some cases quantifiable. There is some evidence that the rate of colonization is influenced by the size and distance of islands from potential biological sources, but increasingly it is apparent that establishment of migrant species is strongly influenced by the composition of the biota that has already arrived.

Classically, Charles Darwin’s observations of life on the Galapagos archipelago were instrumental in the founding of evolutionary theory (Figure 3). Volcanic island systems of this sort provide natural laboratories where the effects of colonization, natural selection, and population isolation can be observed. Because volcanic rocks are readily aged using radiometric analysis, maximum ages for the local biota can be determined.

Volcanoes both destroy life and create opportunities, as has been demonstrated on a local, recent scale in systems such as Krakatau in Indonesia. On a much more profound scale, volcanic activity is implicated in one or more ancient global mass extinctions. Extreme volcanic activity associated with the Central Atlantic Magmatic Province is strongly indicated as driving end-Triassic (201 mya) extinctions. Flood basalt eruptions at the end of the Permian (252 mya) are likely to have contributed to extinction via increased atmospheric carbon dioxide, climate warming, and associated ice melt methane production. The end of the Permian was marked by the extinction of about 70% of land animal species and 90% of marine animals. Among the casualties were the formerly widespread Glossopertid plants, the fossils of which were so influential in paleogeography. The Triassic saw the emergence of new ecological strategies in mammal and dinosaur diversification. Ammonites emerged in the oceans, and crocodiles, pterosaurs, frogs, and sphenodonts diversified on land.

Conclusion

On large and small scales, short and long time frames, plate tectonics influences the formation and distribution of biological diversity; however,
many of the details of how this happens remain to be thoroughly tested. A traditional focus on spatial effects (vicariance) is gradually being replaced by more in-depth analysis of the way geophysical attributes of the planet influence evolutionary ecology.

Point pattern analysis

Seth E. Spielman
University of Colorado at Boulder, USA

Point pattern analysis is a set of methods for statistical inference about the pattern of points on a map. A point pattern is a set of observed coordinates, typically the digital analog of a paper map with locations indicated using push-pins. Point pattern analysis is typically used to determine if points are clustered relative to some reference distribution or spatial process. For example, Austin et al. (2005) examined the spatial distribution of fast food restaurants relative to the spatial distribution of schools and found that fast food restaurants “cluster” near schools. Intuitively, a cluster is simply a group of geographic events/objects; however, this naive definition belies some of the complexities and subtleties of point pattern analysis. The identification of clusters, or any patterns of points on a map, depends on some a priori assumptions about the expected number of points at any given area of a map; a cluster of points is a statistically significant deviation from that expectation. The following entry defines key terms, describes the analytical methods used to test for patterns in maps of points, and discusses the future prospects for point pattern analysis.

Point pattern analysis consists of two sets of methods: those that examine the absolute number of points within regions of the map (e.g., quadrant analysis) and those that examine the distributions of points relative to each other by counting the number points within some distance \( (h) \) of each point on the map (e.g., Ripley’s K-function). The example in the previous paragraph is an instance of the latter; it examined the number of fast food restaurants around schools, not the absolute number of fast food restaurants in a given area of the map. Methods which characterize the distribution of points relative to each other, work through the estimation of a function describing the expected number of points as a function of distance. This distance function is used to perform statistical inference on the observed spatial pattern of points on a map.

In order to make any statistical statement about the pattern of events on a map, the location of the events has to be compared to some reference distribution. Consider Figure 1, a map of all deaths due to car accidents in the State of Colorado during 2012. These deaths clearly appear clustered along a line in the center of the state. This line represents the eastern edge of the Rocky Mountains and the Front Range metropolitan corridor extending from the city of Colorado Springs in the south to Fort Collins in the north, inclusive of the Denver metropolitan area. The pattern of vehicular deaths may merely reflect the pattern of traffic: there are many more cars in the Front Range than there are in the mountainous interior of the state, and thus there are more deaths.

Statistical inference about point patterns depends upon some assumptions about the expected pattern of points on a map; these assumed patterns are called null models or point process models and play a central role in point pattern analysis. These reference distributions...
form the null hypothesis against which a map of points is compared. In spite of the relative simplicity of points as a mode of representation, point pattern analysis is a complex endeavor; key terms in point pattern analysis, such as cluster and pattern, can only be defined relative to these reference distributions.

The simplest null model is called complete spatial randomness (CSR) or a Poisson point process. Under this null model it is assumed that points are equally likely in all parts of a study area. In this model, the number of expected events in a region of the map is a function of the size of the region and an intensity parameter (denoted with the Greek letter \( \lambda \)). This intensity parameter is the mean/variance of a Poisson distribution; under CSR the same Poisson distribution applies to all locations on the map. CSR is not really an appropriate assumption for Figure 1 because car accidents are constrained to roads, and their frequency is related to the amount and speed of traffic, thus not all locations within the State of Colorado have an equal probability of a car crash occurring. Within a fixed study area, a higher-intensity point process will result in more points than a lower-intensity point process. With this definition of a null model, a “cluster” is an area of the map that contains more points than would be expected under the Poisson distribution describing the null model. For example, if we had a 1 km\(^2\) region of the map, and expected five vehicular deaths per square kilometer (\( \lambda = 5 \)), we would expect to find five points within the square kilometer. However, we live in a random world and will never get exactly what is expected; sometimes there will be slightly less than five events in the square, sometimes more. The Poisson distribution could be used to determine the probability of observing a given number of points; given \( \lambda = 5 \) it would be exceptionally rare to observe 13 or more points in the square kilometer – by random chance this would only occur 1 in 1000 times. The excess number of points relative to our expectation can be understood as a “cluster.” However, if we expected 10 points per square kilometer, 13 or more points would happen 50% of the time due to random chance. The key point is that the null model determines the definition of a cluster.

Point pattern analysis is rapidly gaining relevance as mobile devices facilitate the large-scale collection of point datasets. However, not all geolocated information can be appropriately analyzed with point pattern analysis techniques. Point pattern analysis operates in a specific conceptual framework that views points as events for which an expected probability of occurrence at any location within the study area can be estimated. For example, the locations of restaurants, as in Austin et al. (2005), is constrained by municipal regulations and macro-economic trends, making it difficult to view their locations as events governed by some probability distribution.
Defining a point

From a geographic perspective, a point is a set of coordinates designating a location. At a minimum, a point is described by two numbers, an x and a y coordinate. These two coordinates allow a point on a plane to be located; in the discipline of geography, this plane is usually some section of the surface of the Earth.

The ubiquity of global positioning systems makes it relatively easy to collect point data. However, not all point data are well suited to point pattern analysis. Typically, in point pattern analysis, a point is defined as an event. Events are things that occur with some nonzero probability at all locations in a study area. For example, the location of a lightning strike could be conceptualized as an event, but the location of a lake would be difficult to see as an event. Viewing points as events has certain implications; most importantly, it implies that at any location within the study area, the probability of an event occurring is known. In practice, this probability is seldom known and has to be estimated.

Events occur at a location in space but also at a specific time. The concept of a point can be extended into the temporal dimension, such that events can occur at a discrete location in space and during a specific instant of time. This extends the notation for points to include x, y, and t. Historically, points were often collected on a static map; events occurred at a location but little was known about the instant of their occurrence. In a modern computing environment where data are collected by mobile devices, it is common for events to be tagged with a time stamp. Furthermore, these same mobile devices can collect elevation data. While not commonly used in applied analysis, points often contain a vertical dimension and are not necessarily constrained to the surface of the Earth. For example, a map of property crime in a large city might include the story (floor) of the building on which the crime took place. Thus, points can contain a vertical dimension (z), extending the notation for points to include four coordinates: x, y, z, and t.

In point pattern analysis, it is assumed that all events within the study region have been captured. A study region is defined spatially or as a spatiotemporally bounded region. Point pattern analysis generally does not deal with samples of events; instead, the assumption is that events have been completely measured and mapped within the study area. This complicates analysis of some types of events— for example, some small-scale property crimes may not be reported to the police, or a disease may be undiagnosed or misdiagnosed; unless these omissions were purely random in space and time, they would make it difficult to analyze the locations of such events using point pattern analysis methods.

Defining a cluster

Often the goal of point pattern analysis is to identify the presence (or absence) of clusters of events in space and/or time. Point pattern analysis is sometimes called “cluster analysis,” which is an understandable but unfortunate label because of potential confusion with a large literature of the same name in pattern recognition and statistics. The object of point pattern analysis is the identification of “clusters” of events in space and/or time; it differs from “cluster analysis” in the use of a null model for statistical inference. Spatial point pattern analysis explicitly tests null hypotheses about the arrangement of events whereas nonspatial cluster analysis aims to identify latent structure in a dataset; the two sets of methods should not be confused. On
the other hand, ontological problems arise in both literatures because the meaning of the term “cluster” is sometimes vague.

In point pattern analysis a map is said to exhibit clustering if an arbitrarily drawn region of the map contains more points than would be expected under some assumed data-generating process (i.e., a null model). This is an odd idea – how many points should be expected in some arbitrarily drawn region of a map? A toy example may make this concept easier to understand. Imagine a landscape filled with magic coins that flip themselves when one says “flip” and magically land in the exact same spot. Assume that the coins are evenly spaced 1 m apart and fill the landscape. When one says “flip,” a map of heads emerges (also magically) in your computer; the map shows you the locations of the heads but not the tails. Each time you say “flip” there will probably be a different outcome and a different map. All the magic coins are fair and equal, so heads/tails are equally likely in all places. If you selected a 4 × 4 m square region of the landscape, you would expect to find 8 heads because there are 16 coins, half of which would land heads-up. Of course, we live in a random world and might not get exactly 8 heads; sometimes you might get 9 or 10 heads but this would not be too surprising. However, if you got 14 heads it would be unusual indeed. You might say that the 4 × 4 m square study area with 14 heads and 2 tails constituted a “cluster” of events (points), where an event is the act of a coin landing heads-up when tossed. Conversely, it would be equally surprising if you found 2 heads; this would be an instance of dispersion or anticlustering. The opposite of a cluster is either the absence of events or the uniform, nonrandom patterning of events; it is a substantively interesting finding that can be empirically identified via point pattern analysis methods.

In the above example the null model was a random flip of a fair coin. What if the coins were unfair and landed heads 90% of the time? Fourteen heads out of 16 coin flips would not constitute a cluster in this case because it would be in line with expectations. A cluster can only be defined relative to some hypothesis about the probability of events (points) occurring within some arbitrarily defined area.

Scale in point pattern analysis

All point pattern analyses are constrained to a bounded region of space (or space–time) within which data are collected. This bounded region, or window, describes the full extent of the area for which events were monitored. Events can, and probably do, occur outside of the observed area, and this must be accounted for in statistical procedures. For example, if the State of Colorado was the analysis window, the motor vehicle related fatalities in Figure 1 are clearly clustered in the major metropolitan areas of the state. However, if the window shrunk to a section of Denver, and only events within the red box in Figure 1 were observed, the accidents might not appear to be clustered. The window within which events are collected has an important effect on statistical inference. Patterns and the interpretation of patterns are scale–dependent.

Scale dependence in point pattern analysis raises important questions about the design of studies. Since statistical inference is scale–dependent, the analyst must choose an analysis window that has some substantive experimental/policy relevance. If possible, given the sensitivity of inference to the analysis window it is sometimes advisable to ensure that results are not affected by a random shift of the analysis window.
Point process models

Point pattern analysis conceptualizes points as events. Statistical analysis of a map of events requires estimating the probability of an event occurring at a given location. In the simplest and most widely used form of point pattern analysis this probability is assumed to be uniform across the study area; that is, the probability of an event occurring is equal at all locations within the study area. This assumption of constant intensity yields a relatively simple point process model CSR.

A full understanding of this idea, of a constant intensity, requires some discussion. The idea that the probability of an event occurring is equal at all locations in a study area implies that the locations of events are independent from each other. That is, the location of a lightning strike, or a car crash, does not affect the location of other events. The chances of lightning striking the same location twice are the same as the chance of lightning striking any two separate locations; the same may not be true of car crashes. CSR means that the location of an event does not affect the location of other events. This assumption is entirely reasonable for certain types of phenomena, but it is not reasonable for others.

Thus there are two general ways to specify a null hypothesis for point pattern analysis: the process perspective and the probability perspective. In the process perspective the null hypothesis takes the form of a point-generating process. For example, the patterns of seedling locations for plants with low seed mobility are constrained by the locations of their parent plant. If seeds cannot travel long distances, seedlings have to be located near their parent. This type of process is called a Neyman–Scott point process. A Neyman–Scott point process is different from a Poisson point process because the probability of an event occurring at a given location is related to how close the location is to a “parent” and the amount of dispersal from a parent. By contrast, in the probability perspective spatially varying covariates might be used to estimate a surface describing the probability of events occurring at all locations within a study area. This type of approach is also called an inhomogeneous model because it contrasts with CSR, which assumes that the probability of events occurring does not vary within the study window (i.e., lambda is homogeneous within the analysis window). Viewing intensity as a function of covariates allows the creation of a point-generating process based on the relationship between events and covariates. For example, in Figure 1, if the volume of cars is associated with vehicular mortality, traffic volume could be used in the construction of a null model.

Test statistics

In order to evaluate the pattern of points observed on a map it is necessary to describe the pattern on the map quantitatively. This is done through the construction of statistics that counts points as a function of distance \( h \). Counting points as a function of distance allows the pattern of points on a map using a graph to be statistically described. For example, consider a simple test statistic, called the “nearest neighbor” function (or the G-function; equation 1).

\[
G(h) = \frac{1}{n} \sum_{i=1}^{n} (I(d_{ij} < h))
\]

\( n \) is the number of points on the map, \( d_{ij} \) is the distance between the \( i \)-th point and its nearest neighbor, and \( I(d_{ij} < h) \) is an indicator function that takes the value 1 if the expression \( d_{ij} < h \) is true, and zero otherwise. \( G \) is simply the cumulative distribution function of the
nearest neighbor distances. The test statistic is bounded by \([0,1]\); however, the rate at which the curve approaches 1 will be determined by the spatial distribution of points. If points tend to be separated by a fixed distance, say \(h = 3\, \text{km}\), \(G\) will rapidly approach 1 around that distance. If, however, interpoint distances are random, \(G\) will monotonically approach 1.

The obvious problem with \(G\) is that it neglects to fully exploit the information contained within the map of points. Only the distances between nearest neighbors are measured. A fuller picture of the distribution of points could be obtained if a test statistic was constructed that considered all interpoint distances. Ripley’s \(K\)-function measures the number of points within \(h\) units of each point. Rather than simply counting the number of nearest neighbors, pairs were taken into account. The \(K\)-function, because of its treatment of interpoint distances and the ability to modify null hypotheses, is one of the (if not the) most widely used test statistics for point pattern analysis.

Cressie (1993) writes the \(K\)-function as in equation 2.

\[
\hat{K}(h) = \frac{1}{\text{intensity}} \mathbb{E}(\text{number of points within } h \text{ of an arbitrary point})
\]  

Expressing the \(K\)-function in this way makes it fairly intuitive. Think of a circle of radius \(h\) centered on each point. As the area of the circle increases the number of points contained by the circle will grow. The \(K\)-function measures the average number of points around each point on the map as a function of distance. In this formulation, “intensity” (or \(\lambda\)) is the number of points per unit area of the analysis window. This can be written as equation 3.

\[
\hat{K}(h) = \frac{A}{n^2} \sum_{i=1}^{n} \sum_{j=1, j \neq i}^{n} I(d_{ij} < h)
\]  

\(n\) is the number of points on the map, \(A\) is the area of the analysis window (in square units), and \(d_{ij}\) is the distance between the \(i\)-th and \(j\)-th points. However, when points are near the edge of the analysis window, or when \(h\) is large, the circle used in the calculation of \(K(h)\) spills over beyond the boundary of the analysis window. Thus, an edge correction factor \((w)\) is often applied to \(K(h)\), yielding equation 4.

\[
\hat{K}(h) = \frac{A}{n^2} \sum_{i=1}^{n} \sum_{j=1, j \neq i}^{n} I(d_{ij} < h) w
\]

This correction factor is generally \(w_i = 1\) if the \(i\)-th point is more than \(h\) units away from the edge of the window. If the \(i\)-th point is close to the edge of the study region then \(w < 1\). Various software packages implement different (or several) edge correction strategies, with the main practical difference between them being computational efficiency.

One nice feature of the \(K\)-function is that if points are randomly distributed within the analysis window, \(K\) rises proportionally to the area of the circle described by \(h\). This makes

\[
L(h) = \sqrt{\frac{\hat{K}(h)}{\pi} - h}
\]

a useful transformation because the expected value for a random pattern will be nil and positive or negative values suggest spatial patterns. More details on statistical inference regarding the presence (or absence) of patterns is given in the next section.

There are a number of extensions of the \(K\)-function that allow for testing of dependencies among “marks” in point patterns. A map of points is said to be “marked” if points contain categorical information, for example if points represent different species of trees or different types of criminal events (property versus violent crime). These marked points modify the logic of a \(K\)-function; instead of considering all interpoint distances the distribution of one type of
event is studied relative to other types of events (equation 6).

\[
\hat{K}(h) = \frac{1}{\text{intensity}} E(\text{number of type } i \text{ points } h \text{ of an within } h \text{ of an type } j \text{ point})
\]  

For example, the interest might be in understanding if murders are co-located with other types of violent crimes. In this case, one type of mark would be “violent crime, not murder” and another type would be “murder.” Case-control data, as collected in experimental situations, are a special case of marked point pattern. Test statistics for marked point processes are similar to those for unmarked patterns (equation 7).

\[
\hat{K}(h) = \frac{A}{n^2} \sum_{i=1}^{m} \sum_{j=1}^{n} \frac{I(d_{ij} < h)}{w}
\]

Inference

Test statistics, like the K-, G-, or L-function, simply provide a numerical summary of the pattern of points on a map. Further work is necessary to understand if the pattern represents a statistically significant deviation from expectations. The methods used to make statistical inference about point patterns have evolved substantially since the mid-2000s even though the test statistics have remained basically unchanged during that period.

Inference about point patterns involves simulation of the null hypothesis. These simulations are used to establish a range of plausible point patterns conditional upon the null hypothesis being true. These simulated point patterns are summarized using a test statistic. The range of the test statistics computed from the simulated data is used to establish a range of expected values. For example, Figure 2 shows two plots, each containing a grey region; this region represents the range between the highest observed K-function under the null hypothesis and the lowest observed K-function under the null hypothesis. The red dashed line shows the mean of the simulations. The black line measures the actual map of points/events. It can be noticed that in the graph on the left the black line is entirely contained within the grey simulation envelope; this is considered evidence that the observed pattern is consistent with the null hypothesis. On the right, however, the black line is outside of the simulation envelope; this might be considered evidence that the observed pattern is not consistent with the null hypothesis.

However, recent work by Loosmore and Ford (2006) shows that using graphs like Figure 2 to evaluate the null hypothesis can be misleading; the use of simulation envelopes to visually evaluate point pattern statistics leads to an elevated rate of Type I error. That is, the null hypothesis is rejected more frequently than it should be. In some situations Loosmore and Ford (2006) found that the null hypothesis led to patterns that exceeded the simulation envelope 74% of the time; that is, random chance alone can, and often will, lead to an observed point pattern falling outside of the simulation envelope. If one used this chance occurrence as evidence of a statistically significant pattern one would be committing a Type I error. Thus, while it is common practice to evaluate point patterns visually using simulation envelopes, there is some reason to believe that this approach is not effective. An alternative set of tools for inference about point patterns has emerged in recent years. These newer modes of inference also exploit simulations of the null hypothesis, but they use simulation to calculate a single statistic by examining the variance within the simulated patterns.
Many of the simulations used to assess point pattern analysis are unconstrained in space. Thus, for networks (constrained patterns, like the car accidents in Figure 1) special tools and/or simulation models may be necessary. Software for the analysis of network and 3-D point patterns exists (see Okabe and Yamada 2001, and the SANET software (http://sanet.csis.u-tokyo.ac.jp)). In addition, it is possible to simulate “inhomogeneous” point patterns (see SpatStat R Library (http://spatstat.github.io)). These are useful when the intensity of events is a function of spatially varying covariates (like population density). These inhomogeneous intensity surfaces can be estimated at all locations within an analysis window using regression-like methods.

**Software**

Many geographical information system (GIS) packages have basic facilities for point pattern analysis. The National Institutes of Justice publishes CrimeStat, a free, stand-alone software package for point pattern analysis. Special purpose software, such as SANET for network-based point pattern analysis, exists. The most advanced and flexible tool for point pattern analysis is the free and open source Spatstat R Library, which is well documented and structured such that specialized null hypotheses are relatively easy to implement and simulate.

**Prospects for point pattern analysis**

Point pattern analysis is unique among spatial analysis methods in that it requires an analyst to explicitly develop a null hypothesis. This can be a challenge because much of the geographers’ toolkit is descriptive. Point pattern analysis methods can be used to comparatively describe patterns but are generally used to make statistical inferences. These inferences, because they require the use of simulation, force an engagement with geographical processes, that is, there has to be a meaningful null hypothesis for the results of an analysis to be interesting. In the absence of such a hypothesis, all comparisons are
made with CSR, which is naive for most social and geographic phenomena.

Points may be the geographic data type of the future. Area-level statistical data, such as those collected by national statistical agencies, are in decline as agency budgets shrink and response rates dwindle. Spatial “big data” is often point-level data. For example, the growing interest in Twitter among geographers is an example of using point-level data in a purely descriptive, non-inferential mode. These novel point-based data sources suggest point pattern analysis is an area ripe for innovation.

Further reading

Humans ascribe names to features on the Earth’s surface, and use those names in everyday discourse to obtain directions, to associate information with features, and for many other routine purposes. Recently a number of new applications of such names have emerged, in support of Internet-based services. An index of named features (place names) is needed by mapping services (“Where is San Diego?”), wayfinding services (“Find me a route from my home to the nearest Starbucks”), and information-retrieval services (“Where can I get a digital map of recent earthquake activity around California?”). When these needs were first recognized in the early 1990s two existing sources of such indices existed. Gazetteers are lists of officially recognized place names and their locations, compiled by mapping agencies such as the US Board on Geographic Names in the interests of standardizing spelling and avoiding duplication, and often providing an index to the named features shown in atlases or on topographic maps. Point-of-interest databases (POI databases) were originally compilations of businesses and their locations, assembled by companies such as Dunn and Bradstreet and sold to businesses seeking to evaluate potential sites. Both of these traditional databases included names, locations in geographic coordinates such as latitude and longitude, and limited additional information such as the type of feature that is named.

Traditionally, gazetteers have been limited to officially recognized place names, and to the types of features normally shown on comparatively coarse-scale maps: cities, lakes, mountains, rivers, and so on. Because of the economics of map-making such features tend to be permanent, or at least semipermanent. POI databases have been limited to businesses, prominent features that provide landmarks for wayfinding (churches, parks, etc.), and locations providing services (libraries, schools, etc.). Such features are more likely to change through time than gazetteer entries, and may also be too small to be shown on topographic maps. Today, however, these distinctions are rapidly becoming irrelevant as both types of database have the potential to support the same Internet-based services, and as the costs of acquiring and maintaining such data continue to decline. The discussion that follows avoids making any distinction, using the term “place-name database” (PND) throughout.

### Place and space

Geographers have long distinguished between concepts of place and space. Places are human constructions, associating characteristics such as esthetic qualities, safety, and wealth with named places, without necessarily giving those places precise geometric locations or limits. By contrast, geographic information technologies have traditionally taken a spatial perspective, using coordinates such as latitude and longitude to define, measure, and represent position on the Earth’s surface, computing properties such as distance
and direction, and using geometry to define topological relationships between features: adjacency or containment, for example. Measured locations have been used to link together disparate kinds of information, a primary function of geographic information systems (GIS). Place names traditionally played a minor role in these technologies, for example being omitted from the list of seven datasets identified in the 1990s as the framework layers of the National Spatial Data Infrastructure. Geographic information systems were seen as tools for performing spatial analysis based on coordinates, and little attention was paid to place names, their associations, or their study.

More recently, however, place names and the human dimensions of geographic information technologies have assumed much greater importance, and there is growing interest in a platial as distinct from spatial perspective. The average citizen is now engaged as a user of geographic information, and expects to be able to interact with it through an intuitive interface. Citizens should not have to take advanced courses in GIS to undertake such simple tasks as wayfinding; instead, systems should emulate the everyday language of human discourse, which means using place names rather than coordinates. Suppose, for example, that a citizen is searching for real estate in and near Niagara Falls, NY, and compare two equivalent responses: “Three-bedroom house at 43.08097N, 78.95198W” and “Three-bedroom house in Love Canal neighborhood.” The second is clearly much more useful, since it immediately conjures important (and largely negative) associations with the notoriously polluted Love Canal. In short, to people place names have associations, while coordinates largely do not. Place names can be used to link information in ways that may be more powerful than coordinates, and may be less subject to errors of measurement.

Place has also become much more important as citizens have become engaged not only in the consumption of geographic information, but also in its production. The phenomenon of volunteered geographic information (VGI), and crowdsourcing in general, has created a new source of readily available data on named features and for their updating, and companies providing Internet services rely heavily on such processes to keep their PNDs current. The term “neogeography” has been suggested as a catch-all term for this engagement of the average citizen in both the consumption and the production of geographic information, and in new kinds of mapping that address the day-to-day needs of citizens.

This is not to claim that place is now as important as space in GIS. Many of the less tangible associations of place, ably discussed by generations of human geographers, lie beyond the simplifications and formalizations of geographic information technologies. Instead, PNDs offer only a crude caricature of the concept of place, but one that is rapidly growing in importance and suitable for use in computational systems. A suite of interesting questions emerges. If machines reason about nearness by evaluating the spatial property of distance, how do humans traditionally reason about nearness, when they have no such ability to compute? Could it be, for example, that humans reason that San Francisco must be nearer to Seattle than is Mexico City because the first two lie within the higher-level place United States while the third lies in a different higher-level place, Mexico? In other words, is the place name hierarchy, which lacks any measured geometry, nevertheless the basis for such reasoning processes? Or similarly, do humans reason that San Diego must be west of Reno because the West Coast runs roughly north-south and San Diego is on the coast while Reno is not? In other words, is reasoning based on place enabled by caricatures of real feature geometry, such as a rectangular continental
United States, that are simple enough to be represented in human memory?

Space can be examined and represented at any level of detail, from global to very local scales. The principles of GIS can be applied equally readily to the analysis of patterns of global climate change and to the organization of furniture within a room. Similarly, place names exist at every scale, from the continents, oceans, and countries of the global scale to the street addresses, building names, and internal building layouts of the very local. Places form hierarchies: my house lies in the (vaguely defined) Bryant neighborhood of Seattle, which lies in the (formally defined) State of Washington, which is one of the United States, which is a country in the (again vaguely defined) continent of North America. Consistent with the possible vagueness of their geometry, places are not necessarily subject to precise rules of hierarchical containment: France is in Europe, but the nation of France includes islands in the South Pacific; and most people think of Disneyland Paris as part of Paris, though it lies outside most formal definitions of Paris, such as the boundary of the municipality or the Périphérique. Unlike the polygons of GIS, named places are likely not enclosed within well-defined boundaries. This inherent vagueness associated with places (and with many aspects of human communication) has often been used as an argument against attempting to deal with them in computational systems, and as an argument for the greater formality and potential precision of spatial perspectives.

Unlike spaces, places are social constructions that reflect cultural, linguistic, and other human agendas and contexts. The decision to name a feature is driven by a host of social priorities, as is the very identification of a feature as something worthy of naming. Different cultural and linguistic groups will attach different names to the same feature – the English Channel to the anglophone, and La Manche to the francophone. Strong emotions are sometimes associated with these differences, as in recent arguments over the use of the name Persian Gulf. Thus it can be important to identify both the name of a feature and also who calls it that.

With this background, the next section addresses issues in the construction of PNDs.

**Construction of PNDs**

**Names**

Most applications of PNDs begin by searching for a name through a list. Many web services assist the user with autocompletion, that is, by suggesting names that the user might be in the process of typing. Often these lists are compiled from previous searches by the user, and from knowledge of the user’s current position, obtained from his or her IP address, an Internet Protocol code that is automatically sent to a server by a user attempting to access a web service located on that server. By typing “3” into Google Maps, for example, I am immediately given five suggestions of street addresses beginning with 3, all of them in the Seattle area, since my IP address identifies me as likely located in Seattle. Typing the full house number, 3334, results in the suggestion “3334 NE Blakeley St, Seattle,” my full home address, based on my having frequently used that address in requests to Google Maps in the past. Typing the same sequence into Google Maps using the same computer, but located now in the Netherlands with a different IP address, results in an entirely different sequence of suggestions.

Large features often have names that are globally unique – there is only one North America, for example. But the names of smaller features
may be repeated many times, and there are hundreds of millions of features named “The kitchen” in the United States alone. Humans resolve such ambiguities in a number of ways. Context provides a frequently successful strategy: spoken in a house, “The kitchen” will be assumed to refer to the kitchen in the same house, while “London” spoken in London, Ontario, Canada, will be assumed to refer to that London, and not the much larger and better-known London in England. Autocompletion achieves a similar result: typing the highly ambiguous “Downtown” into Google Maps on my computer in Seattle results in several suggestions, the first being downtown Seattle.

Consider the name “Springfield.” In the United States, 32 states have recognized places named Springfield, according to Wikipedia. Wisconsin has a Springfield in no fewer than five counties. Context suggests that the Springfield most likely being sought by the user is the one closest to the user’s location; but some Springfields are more important than others. Springfield, IL, is the only state capital, while Springfield, MA, is the most populated; neither is the closest to Seattle. Google ranks Springfield, IL, as most likely when I query the name without attempting to resolve ambiguity by specifying the state.

Human behavior differs significantly from the actions of such web services in one important respect, however. While web services attempt to resolve ambiguity through context and by offering suggestions, humans often resolve ambiguity through extended discourse. Thus “London” may be followed by a response: “Which London do you mean?”

Many features have multiple names, as we have already seen. Transliteration of names is a frequent source of problems between language groups that use different alphabets – Beijing has been rendered as Peking in the past, and still is in the case of Peking University, though Peking’s two Chinese characters have not changed for centuries. Names change through time, and successive names may bear no linguistic or phonetic relationship to each other. Hastings (2008) has documented six names that have been used at various times and by various groups for the feature commonly known today as Lake Tahoe. All of these issues contribute to the practical difficulties of matching a user’s request to a list of names.

Vast amounts of digital text are being created in the form of emails, blogs, tweets, and other user-generated content, and the conversion of audio records such as phone conversations to text is now a well-developed technology. Optical character recognition allows text to be extracted from images, such as photographs of maps. Recognition of place names in such data is of interest in many fields, including intelligence. Thus there has been significant research in recent years in what is sometimes termed “geoparsing,” the automated recognition of place names in text. Metacarta, for example, is a powerful and widely used set of geoparsing tools. The task is made complex and difficult because of the vagaries of spoken and written syntax, the complications of different languages and alphabets, and the importance of context. For example, a reference to “Shanghai” in text could be interpreted as a reference to the Chinese city or to kidnapping. A reference to “Boston, New York” could be a reference to two large cities or to a single small town in upstate New York near Buffalo. Another challenging problem occurs with place names that may exist in text but not in any PND, that is, how one can determine that a sequence of letters is in fact a place name, and, if it is, its likely location. Syntax can provide clues, as in the use of certain location-related prepositions such as “near,” as well as direction-related phrases such as “north of.”
Location

The power of PNDs stems from their ability to link names to locations, and to marshal the functions of geographic information technologies to address user needs, whether they be in query, wayfinding, information retrieval, or a range of more sophisticated decision-making. The historical focus of PNDs has been on providing a single point location, the result of least effort, irrespective of the physical extent of the feature. Because they dealt with small features, this was a reasonable choice for POI databases. For gazetteers that were built as indices to atlases it was sufficient to locate a feature to a page in the atlas, and perhaps to a part of the page, but again for all but the largest features a point was sufficient to direct the reader to the appropriate point in the atlas. In other cases, conventions were adopted: the point location for a large feature was sometimes given as the location of the center of the feature’s label; the location of a mountain is conventionally its summit; and in the case of rivers, location was sometimes given as a point at the mouth. Today’s PNDs still often reflect these conventions and simplifications. For example, the US Geological Survey offers a digital gazetteer known as the Geographic Names Information System. A query for “Mississippi River” will return a point in Plaquemines Parish, LA (at the river’s mouth), despite the 3734 km length of the feature. A query to Google Maps for driving directions from “Colorado” to “Wyoming” will return a complex itinerary, using roads that are sometimes seasonally closed, from an uninhabited point in the geographic center of Colorado (CO) to a similarly uninhabited point in the geographic center of Wyoming (WY), despite the fact that the two states share a lengthy common border. Clearly this service could be greatly improved if the states were represented as areas rather than as points, and if the user were required to specify the point locations of the origin and destination.

Some well-defined features have complex geometries that are readily available in digital form, and it would be easy to provide a more intelligent response to the CO-WY problem. In other cases, however, it would be costly to capture the feature’s complex geometry, and in still other cases the feature lacks a formally defined and agreed geometry. There is no accepted geometry, for example, for the feature “downtown Seattle”; instead, services such as Google Maps use a single, representative point that may or may not be at the focus of the user’s interest.

Montello et al. (2003) interviewed a sample of subjects, asking them in various ways to identify “downtown Santa Barbara” on a map, and exploring alternative ways of representing the results in a spatial database. Recently, attempts have been made to use novel sources of information from which to impute feature geometries. Many collections of user-generated content include references both to place names and to geographic coordinates: this is true, for example, of many of the photographs stored in the Flickr database, and of some tweets. Figure 1 shows the result of searching the Flickr database for photographs that have been both georeferenced and tagged using the words “Eiffel Tower” in any of several languages. As with many such sources, the data include various kinds of noise: photographs taken from distant vantage points such as the Sacré Coeur basilica or Montparnasse; photographs that are georeferenced or tagged as a group, and may have been taken over a period of time at several locations; or cases where the georeferencing malfunctioned. It is possible also that some errors are malicious.

The result of such efforts is a continuous surface that can be interpreted in one of two
ways, depending on how the surface is constructed and normalized. First, the value $z$ at some location $\mathbf{x}$ is the probability that $\mathbf{x}$ lies within the feature; and second, the probability of the feature lying in some area $A$ is the integral of $z$ over the area $A$. The first interpretation makes $z$ a probability surface, constrained to the range $\{0,1\}$, while the second makes $z$ a probability density function whose integral over the entire plane is 1. Surfaces can be represented in spatial databases using any of the standard methods for representing continuous fields, including rasters and digitized contours. It is also possible to extract a suitable isoline from the surface as one possible representation of the extent of the named feature, though there is no guarantee that the extent will be convex or singly bounded.

Recent years have seen a rapid growth in the variety and volume of such data sources, consistent with what is often termed “big data.” It seems that in future, if not already today,
there will always be more than one source of the geometry of a named feature, so the integration or fusion of such sources to obtain or synthesize a single, best estimate is becoming a significant challenge. The general problem of conflating PNDs is discussed at greater length below.

Another challenging problem arises in dealing with museum and other collections of artifacts, if, as is often the case, the location from which an object was collected is given in text rather than coordinates. Today, of course, it is trivial and routine to record GPS coordinates whenever an observation or collection is made in the field. But verbal descriptions are often the only information available about earlier locations, especially when such locations were visited before an area was mapped in detail. Verbal descriptions often refer to prominent features, with estimated directions and offsets (“five miles northwest of the river junction”). GEOlocate is a widely used tool for converting text descriptions to coordinates, though its ability to deal with offsets is limited. Liu et al. (2009) have developed methods for capturing both the most likely location and also uncertainty bounds, when offsets are used. It is important in all such cases to capture both the most likely location and also uncertainty bounds, when offsets are used. It is important in all such cases to capture both the most likely location and also the methods used to impute it, along with associated uncertainties, since these can be of great value later in trying to conflate data from several sources.

Type

The third element in the traditional gazetteer is the type of feature. Many national and subnational mapping agencies have developed classification schemes, and these have been widely used to categorize features in gazetteers. For POI databases, however, the typing of features is traditionally more nuanced. The type “grocery store” is important for assessing competition, but it also encompasses a range of distinct subtypes, from the full-featured supermarket to the corner convenience store. Today’s web services support multiple types: for example, coffee shops often offer a range of baked goods and thus may call themselves bakeries, while many supermarkets also include both bakeries and coffee shops.

The principle of spatial heterogeneity holds that the geographic world is fundamentally heterogeneous, exhibiting uncontrolled variation. Left to its own devices, therefore, it follows that any administration whose responsibility covers only a fraction of the Earth’s surface will adopt a classification scheme that best fits its own purposes, based on the variation found within its jurisdiction. A mapping agency for Saudi Arabia will develop different types from one responsible for Alaska, for example, and will include terms for ephemeral streams or oases that have little relevance in Alaska, where periglacial features such as pingos may be more important. Similarly, and at a more detailed scale, a predominantly urban county in the United States will likely adopt a classification scheme for land use that is different from that adopted by a rural, and perhaps neighboring, county. Such differences are likely exacerbated by cultural variation: as Mark and Turk (2003) have shown in their work on what they term “ethnophysiography,” the landscape features that are important to one culture may be of no importance whatever to another, co-located culture.

Many well-meaning efforts have been made over the years to find universal typing schemes. In 1913 an international agreement was signed to create an International Map of the World at a scale of 1:1 000 000 – the “Millionth Map.” Some 2500 sheets were planned, using a uniform standard of content and cartographic rendering,
but only a fraction were produced before the project was finally abandoned. More recently, a Japanese-led International Steering Committee for Global Mapping was established in 1996 to achieve a similar objective in the Internet era. In 2011 the schema.org project was established by a consortium of major web service providers, as a universal markup that could be used to type objects, including geographic features. Although it has universal aspirations, the types recognized clearly reveal the scheme’s origins in the dominant consumer-oriented culture of the United States and its manifestation in Silicon Valley.

Several research projects have been dedicated to the development of methods to match such universal feature-type taxonomies to locally derived typing schemes. But matches are rarely simple and 1:1, and it is clear that any universal scheme must be much coarser than local schemes. Debates continue over whether the benefits of a universal scheme outweigh the costs of its inevitable local suboptimality.

Typing presents additional issues in the volunteer world of crowdsourced PND content. In principle, it is desirable that such typing schemes emerge from the community, rather than being imposed from above as in the traditional gazetteer. The term “folksonomy” has been coined to describe such bottom-up approaches to taxonomy. But many types are inherently vague and may even carry emotive and political associations. Lake Tahoe, for example, can legitimately be classified as a reservoir rather than a lake, since its level is controlled by a dam. In the case of the VGI project OpenStreetMap, differences between American and British English have led to separate types “harbor” and “harbour,” and “tag wars” have erupted between contributors who are unwilling to accept each other’s assigned tag or type (Mooney and Corcoran 2012).

In summary, it seems that any attempt to build a comprehensive PND in today’s environment must accept that a feature can have multiple types, and that each type should be identified with the community or culture for which that type is appropriate. This would allow a user to see different “views” of a PND depending on his or her preferred perspective. This perspective might be permanent, as in the case of cultural differences, or might be transitory, as in the case of a user searching for a bakery.

Hierarchy
Reference has already been made to the importance of hierarchy in human reasoning about places. Links between places and the higher-level places of which humans consider them to be part is important in resolving ambiguity: for example, identifying the containing US state immediately resolves ambiguity over which Springfield is meant, while “my kitchen” immediately identifies the specific kitchen referenced in a conversation by implicitly linking it to the higher-level place “my house.” We have also seen that hierarchy can be a useful basis for reasoning about relative proximity, based on the principle that two places that are linked to the same higher-level object are likely nearer to each other than to a third place that is linked to a different higher-level object. Other heuristics for relative proximity are discussed below.

Hierarchy is not a rigid or well-organized structure, despite the clarity of the hierarchy of administrative units that exists in most countries. Places can span administrative boundaries (Kansas City extends to two states), and vernacular places such as “the tri-counties” or “the Midwest” are frequently used in human discourse. A lower-level place is frequently part of more than one higher-level place, and while administrative hierarchies may formalize the
concept of a level (county, state, nation), in other
cases the concept of a level in the hierarchy can
be vague. It seems that two types of relationships
can exist within a place hierarchy: those between
features at adjacent levels (“is in,” “is part of”),
and those between features at the same level (“is
at the same level”).

Applications of PNDs

Reference has already been made to various
applications of PNDs, even in their simplified
form as today’s gazetteers or POI databases.
Place names and street addresses are used to
drive a host of online mapping and wayfinding
services, typically by converting user-supplied
names to coordinates and then using those coor-
dinates as an interface to simple GIS functions.
Mention has also been made of geoparsing, the
identification of place name references in text.

Other more sophisticated applications con-
tinue to emerge. The term “mashup” refers to
the linkage of information, in this case through
the occurrence of common place names, to
create new information. Many new kinds of
maps have been created by mashing independent
sources, and such operations are now enabled
by highly sophisticated tools. For example, it is
now possible to take the information in an Excel
spreadsheet and to use a place name in each
record to link the data to a digital map, creating
a thematic map of any of the variables in the
spreadsheet.

In another example, the textual information
in travel blogs has been mined for references to
places, and for terms that can be interpreted as
associations of those places. Adams and McKen-
ze (2013) have analyzed such data, finding
groupings of terms that co-occur frequently,
and the places associated with each grouping,
and producing a series of compelling maps of
the concepts associated with geographic places
and regions (Figure 2). It is clear that techniques
such as these will permit the acquisition and
synthesis of much richer data about places and
their associations.

As PNDs proliferate, and as new sources of
data on named places become available, the
problem of conflation, or the merging of PND
records about the same place, is becoming more
and more important. If a place can have multiple
names and types, if its location measured in
a geographic coordinate system is subject to
uncertainty, and if its geometric representation
can range from a point to a line to an area, the
question arises of how it is possible to know if
two records actually refer to the same feature.
Conflation can have several useful purposes:
combining the geometric representations of
a feature can produce a better representation;
and one dataset may have better geometry,
but another may have richer associations, so
their combination will be more valuable and
useful. Conflation is one form of synthesis or
mashup, and is likely to become more and more
important as data sources proliferate.

Hastings (2008) has compared the three
attributes of a traditional gazetteer – name, loca-
tion, and type – as keys to successful conflation.
Of the three, he finds that location is the most
important guide to whether two records refer to
the same feature, because locations will always
have some degree of similarity however they
are represented. Type is also useful, because the
alternative types assigned to a feature are likely
to have some degree of similarity. But the names
assigned to a feature can bear no relationship
whatever to each other. In his example of Lake
Tahoe, a point representation will almost cer-
tainly lie within a polygon representation, and
both “lake” and “reservoir” are types associated
with water bodies. But there is no similarity in
the alternative names given to the feature in the
past, some of them by different language groups.

Points in polygons

Yu Liu
Peking University, China

Definition

There are three possibilities for the topological relationship between a point and a polygon: the point can be inside, outside, or on the polygon’s boundary. A point-in-polygon (PIP) algorithm returns one of the three relations, or a binary value indicating whether the point is located inside the polygon.

Algorithms

Nordbeck and Rystedt (1967) summarized a number of PIP algorithms, in which the ray-casting algorithm is widely used. Later Huang and Shih (1997) and Žalik and Kolingerova (2001) also made a summary of PIP algorithms.

Ray-casting algorithm

The ray-casting algorithm indicates whether a point is located inside a polygon according to the number of intersections between a ray starting from the test point and the polygon. In general, an odd number of intersections indicates that the point is located inside the polygon. Hence, this algorithm is also called the even/odd rule algorithm or crossing-number algorithm. The implementation of the algorithm is rather straightforward. It can be simplified by comparing the \( y \)-coordinate of the ray and edges of the test polygon. It is suitable for both convex and concave polygons. The time complexity of the algorithm is \( O(N) \), where \( N \) denotes the number of polygon edges. If the intersection point coincides with a vertex of the polygon, then the intersection counts only when the second vertex of the edge is below the ray. As shown in Figure 1, edges \( a, b, \) and \( c \) are considered but the intersections with edges \( d \) and \( e \) do not count.

Winding number algorithm

The winding number algorithm is designed to compute the polygon’s winding number for a test point. The winding number is the number of times that the polygon’s boundary travels counterclockwise around the point (Figure 2).

If the winding number is non-zero, then the point is located inside the polygon. The axis-crossing algorithm can be applied to determine the winding number (Alciatore and Miranda 1995). Let the test point be at the origin. Determine whether edges of the polygon cross the positive \( x \)-axis and in which direction. Then count the winding number according to the principles shown in Figure 3. This algorithm is applicable to both convex and concave polygons. For simple polygons (Figure 4a), the ray-casting algorithm and the winding number algorithm provide consistent results. For complex polygons, however, the two algorithms may yield different results. As shown in Figure 4b, point \( a \) is outside the polygon according to the ray-casting algorithm. But its winding number is not zero. Hormann and Agathos (2001) pointed out that
Points in Polygons

Figure 1 Ray-casting algorithm.

Figure 2 Winding number algorithm.

the criterion can be changed from a non-zero winding number to an odd winding number to get the same result from the winding number algorithm as the ray-casting algorithm.

Sum of angles algorithm

For this algorithm the polygon is divided into \(N\) triangles by linking the test point with node-pairs of the polygon edge in sequence. If the sum of angles is \(360^\circ\), the point is located inside the polygon. This algorithm is applicable to both vertex and concave polygons. It is very slow to calculate angles using inverse trigonometric functions, the angles have rounding errors, and there is accumulation of these errors.

Sum of areas algorithm

In this algorithm the triangles are formed in the same way as in the sum of angles algorithm. The test point is located inside the polygon if the sum of areas of triangles is equal to the area of the polygon. Using the determinant formula to calculate the area of triangles is very easy and the result does not contain round-off errors. This algorithm is not applicable to concave polygons. The determinant formula is shown in equation 1.

\[
2T_n = \{P_1, P_2, P_3, \ldots, P_{n-1}, P_n\}
\]
\[
= \begin{vmatrix} x_1 & x_2 & x_3 & \cdots & x_{n-1} & x_n \\ y_1 & y_2 & y_3 & \cdots & y_{n-1} & y_n \end{vmatrix}
\]
\[
= (x_1y_2 + x_2y_3 + x_3y_4 + \cdots + x_{n-1}y_n)
- (y_1x_2 + y_2x_3 + y_3x_4 + \cdots + y_{n-1}x_n)
\]  

where \(T_n\) is the area of the polygon. Note that the area should be the absolute value.

Swath algorithm (Salomon 1978)

For this algorithm the polygon is first divided into a set of horizontal swaths. Then the swath containing the test point is selected. Finally, the ray-casting algorithm is applied to the edges inside the swath. This algorithm is efficient for multi-point queries because only the edges inside the swath are selected to count the number of intersections, instead of all the edges. Even though the preprocessing procedures take a little time, the overall efficiency is high, especially for multi-point queries.
**Points in Polygons**

**Figure 3** Winding number update criterion. Source: Modified from Alciatore and Miranda (1995). $V_i$, vertices of the polygon; $W$, winding number.

**Figure 4** (a) Simple polygon; (b) complex polygon.

**Wedge algorithm (Preparata and Shamos 1988)**

Here the polygon is first divided into a set of wedges using a random point inside the polygon. Then, similar to the swath algorithm, the wedge containing the test point is selected. Finally the point is tested to see whether it is located inside the polygon, based on whether it is on the same side of each triangle edge. Three methods can be applied to determine the position of the test point relative to the triangle edges:
POINTS IN POLYGONS

1. the sign of $ax + by + c$ can reflect the side of the point relative to the edge when the edge equation is $ax + by + c = 0$; 
2. let $p_1, p_2, \ldots, p_n$ be the vertices of a polygon and $q$ be the test point. The sign is the cross product between vector $a = (p_{i+1} - p_i)$ and $b = (q - p_i)$; 
3. the third-order determinants to calculate the area of a triangle can be applied to determine the sign. If the sign is the same for all edges, the test point is located inside the triangle.

This algorithm is only applicable to convex polygons. Similar to the swath algorithm, the wedge algorithm is suitable for multi-point queries.

All these algorithms are vector-based. Raster-based PIP is rather straightforward (Huang and Shih 1997). Huang and Shih (1997) compared the complexities of eight algorithms and found that for practical applications the ray intersection algorithm and the swath algorithm are suitable.

Applications

Alciatore and Miranda (1995) summarized the application fields of PIP, such as determining whether a point is within the reachable workspace of a robot. In geographical information systems (GIS), PIP can be used in a wide range of applications. Point queries are a typical example. Point queries can be divided into two parts: single-point and multi-point queries. Single-point queries determine whether a single point is located inside a polygon. For example, when selecting one from a set of polygons, we click a point inside the polygon. In this procedure, the PIP algorithm is applied to determine which polygon the point is located inside. For multi-point queries, one needs to determine whether many points are inside a polygon or which polygon they are inside. When points with associated attribute data are available, comprehensive and summarized information can be obtained for administrative or arbitrary regions (Nordbeck and Rystedt 1967), such as the average real-estate price of neighboring blocks, or the number of schools in a county.

Points-in-polygon overlays are another application in GIS. The points-in-polygon overlay assigns the attributes of the polygon to coincident points, creating a new point layer. The new point attributes come from the polygon in which the point falls. The geographic data on polygons are not incorporated into the point attributes. In practice, we might have questions such as which category of land use a point of interest falls into (Figure 5). Each point of interest would be added to the land-use attribute of the polygon it falls into using the PIP algorithm.

Implementation in spatial databases

Determining the spatial relationship between two geometries in structured query language (SQL) is implemented based on the nine-intersection model (9IM; Egenhofer and Franzosa 1991) and the dimensionally extended 9IM (DE-9IM). The two possible relations between points and polygons, Within and Contains, are defined in equation 2 (Open GIS Consortium 1999).

\[
\begin{align*}
\text{a.} & \text{Within}(b) \iff (a \cap b = a) \land (I(a) \cap I(b) \neq \emptyset) \\
\text{a.} & \text{Contains}(b) \iff b.\text{Within}(a) \\
\text{a.} & \text{Contains}(b) \iff (a \cap b = b) \land (I(a) \cap I(b) \neq \emptyset)
\end{align*}
\]

where $I(x)$ denotes the interior of a geometry $x$. In terms of the PIP problem, both the Within and
the Contains relations can determine whether the point is located inside the polygon.

The 9-IM and DE-9IM are used in many spatial databases like PostGIS, Oracle Spatial, and ArcSDE. In PostGIS, the Within and Contain relation functions are ST_Within (PostGIS 2012c) and ST_Contains (PostGIS 2012a). The function ST_Relate (PostGIS 2012b) outputs the standard Open GIS Consortium’s DE-9IM string code. In Oracle Spatial, the Within and Contain relation functions are SDO_INSIDE (Oracle 2009a) and SDO_CONTAINS (Oracle 2009b). The spatial predicates can be used to build SQL statements for point query and spatial join operations.

**Extension of conventional PIP**

In practice, the position of a point or a polygon may contain uncertainties because of the random errors produced in the procedure of data capture and processing. Thus it seems irrational to determine definitely whether a point is located inside a polygon. Cheung, Shi, and Zhou (2004) proposed a probability-based uncertainty model, which calculates a probability index to describe the closeness between an uncertain point and an uncertain polygon. The probability density function (PDF) of a point $P$ is applied to denote the probability that any point is the true location of $P$. The uncertainty of a polygon $A$ is determined by the PDF of the vertices of $A$.

When $A$ is certain, the probability $Pr$ that $P$ is located inside $A$ is given by:

$$Pr(P \in A) = \int \int_{(x,y) \in A} f_P(x,y) dx dy$$

(3)

where $f_P(x,y)$ is the PDF of $P$. Whether the point is located inside the polygon is determined by the probability index $Pr$, equal to the volume of the bell-shaped figure bounded by $A$.

When $A$ is uncertain, the equation becomes the conditional probability $Pr(P \in A|A)$. The probability $Pr$ that $P$ is located inside $A$ is given by equation 4.

$$Pr(P \in A) = E(Pr(P \in A|A))$$

$$= \int \ldots \int h_A(x_1, y_1, \ldots, x_N, y_N)$$

$$\times Pr(P \in A) dx_1 dy_1, \ldots, dx_N dy_N$$

(4)

where $h_A(x_1, y_1, \ldots, x_N, y_N)$ is the PDF of all the vertices of $A$. To reduce the number of variables in equation 3, the problem is divided
POINTS IN POLYGONS

into different cases according to the intersection between the polygon and the error ellipse of the point. This model is feasible to solve the PIP problem when positions of points or polygons are uncertain.

Current activities or projects

The institute carries out studies for public and private activities involving, among others:

• spatial development at the national, regional and local scales;
• evaluation of investment projects and developmental programs (including EU projects);
• transformation of urban agglomerations;
• transformation of Polish transport systems, analysis of traffic and demand for transport, and transport accessibility (http://www.igipz.pan.pl/accessibility/pl/);
• the geography of agriculture (e.g., land use, spatial differentiation of crop and animal production, rural population);
• assessment of environmental quality for the purposes of spatial planning on the basis of potential vegetation, sedimentation, and sediment transfer in lowland and mountainous fluvial systems;
• assessment of climatic and bioclimatic conditions in spas and holiday resorts; and
• specialist spatial analysis utilizing cartographic computer techniques as well as a wide spectrum of GIS methods.

Brief history

The Institute of Geography and Spatial Organization PAS, established in 1953, is an important Polish research center in the field of socioeconomic geography, physical geography, and spatial organization. The Central Library of Geography and Environmental Protection is part of the Institute and is one of the largest thematic library centers of this kind in the world. The IGSO PAS carries out scientific research studies and participates in numerous applied projects. Its active involvement in international scientific collaboration that, in recent years, has resulted in its participation in more than fifty scientific and practical programs and undertakings, including EU framework projects, as well as the ESPON scientific platform – the Institute’s most significant project. Furthermore, in the
last decade there have been approximately two hundred national research and practical projects, expert evaluations, and so on, carried out by the IGSO PAS. Our research staff’s annual publishing output amounts to a total of approximately four hundred published items (e.g., peer-reviewed articles, monographs, notes, etc.). The institute is also actively engaged in collaboration with Polish ministries such as the Ministry of Infrastructure and Development (contract agreement), the Ministry of Agriculture and Rural Development, as well as with local authorities, especially at the voivodeship (provincial/regional) level. In recent years it participated in, among others, preparation of the National Spatial Development Concept 2030 and was involved in activities associated with the Polish presidency of the EU council in 2011.

Description and purpose

The Polish Geographical Society (PTG) is one of the oldest geographical institutions in Poland. Among its members are teachers, academics, practitioners from a wide spectrum of professions, and students.

The purpose of the society focuses on the popularization of geographical knowledge, education, and gathering and representing geographers. The main activities of the PTG are research, organization of conferences and seminars, excursions, and publications. The society is the largest geographic conference organizer in Poland and publishes the largest number of books and magazines related to the discipline.

Journals or major publication series

Current activities or projects

The Polish Geographical Society represents the discipline as well as geographers on both national and international levels. The society supports periodic conferences and seminars organized by the different committees (e.g., on cultural landscape, hydrology, rural areas, etc.) and numerous publications (20–30 per year). It organizes an annual competition for the best master thesis of the year. An important activity of the society is the organization of the Geography Olympiad and participation (with a lot of success) in the International Geography Olympiad. In 2014, the Polish Geographical Society, as a member of the consortium of eight Polish geographical institutions, will organize the IGU Regional Conference which will be held in Krakow.

Brief history

The Polish Geographical Society was established in 1918. In addition to geographers, the founding members came from different professions and scientific disciplines, including economists, historians, sociologists, meteorologists, geologists, botanists, zoologists, and anthropologists. In 1934, the Society co-organized the Congress of the IGU in Warsaw. After a forced break caused by World War II, the society resumed its activity in 1945. In 1953, the existing structure of the PTG underpinned the establishment of the Institute of Geography and Spatial Organization of the Polish Academy of Sciences. The institute took over a large part of the society’s research activity.
After 1953, and throughout the period until 1989, the society was mainly involved in the promotion of geography and its teaching methodology. It published a scientific monthly aimed at the general public, *Poznaj Świat*, and also organized research expeditions.

The 1980s and the early 1990s saw a dramatic collapse, both in membership and in the financial base of the society. The PTG had to face the new economic reality in which state financing of all scientific societies and associations was terminated. In the late 1990s, the situation of the society considerably improved. In 2001, certain provisions of the statute were amended to adapt to the new socioeconomic reality. As of 2006, the PTG has operated as a public benefit organization.

Polar climates

Roger G. Barry
University of Colorado Boulder, USA

Basic characteristics of the polar regions

The two polar regions exhibit distinct geographical differences. The Arctic comprises a sea ice-covered ocean that is surrounded by the landmasses of North America, Greenland, and Eurasia, but is well connected to the North Atlantic Ocean. The Antarctic is occupied by the massive Antarctic continent, which is 98% covered by a 3–4-km-thick ice sheet, surrounded by a circumpolar ocean with seasonal sea ice. The Greenland ice sheet, which rises to 3200 m, is much smaller and has only regional effects on the Northern Hemisphere’s climate. In climatic characteristics there are similarities. In both regions there is a six-month winter night and six-month summer day. Surface temperatures are well below freezing in the winter in the Arctic and year-round in most of Antarctica. Surface-based temperature inversions predominate in both polar regions, especially in the cold months. Both regions are overlain by a deep polar vortex in the troposphere around which circle the global westerly winds, extratropical cyclones, and mesocyclones, but their surface climates are in strong contrast due mainly to their geographical characteristics.

Following a long interval of mild climatic conditions, the climate cooled and the Antarctic ice sheet developed rapidly about 33 million years ago (Ma). It has essentially been present ever since, although its extent has fluctuated significantly, particularly in West Antarctica. The Greenland ice sheet probably formed about 5 Ma, but perennial sea ice may have covered the Arctic Ocean since 14 Ma. Its recent sharp decline in extent and thickness in late summer is unprecedented in the palaeoclimatic record.

Observational networks

The observational database in both polar regions is limited because the regions are remote and weather conditions are extreme, making the setting up of weather stations costly and difficult. The climate of the Arctic Ocean has been monitored through the North Pole (NP) Drifting Station Program operated by the Soviet Union with NP1 in 1937–1938, NP2 in 1950, and then continuously with one or two stations from 1954 to NP31 in 1991, installed on multiyear sea ice or ice islands. The program resumed through the Russian Federation in 2003 with NP32, and continues to operate with NP39 established in October 2011. The United States has operated several ice island stations, notably T-3 from 1952 to 1978 and ice station SHEBA (Surface Heat Budget of the Arctic) from October 1997 to October 1998. For coastal and island locations there were 65 Russian and 24 Western stations for a period that includes the early 1950s through 1990. Many arctic coastal stations in Eurasia were closed in the 1990s, whereas most of those in the North American Arctic continue to operate. A valuable compendium of arctic climatological data and charts spanning 1893–1995 is contained in Arctic Climatology Project (2000). Corresponding sea ice data are collected in
Polar Climates

an atlas of the Environmental Working Group (2000) and updated for 1933–2006 in Arctic and Antarctic Research Institute (2007). There are coastal weather stations around Greenland, Summit Station that was installed in 1980, and the Greenland Climate Network of automatic weather stations (AWS) around the ice sheet, that began in 1991 and expanded to 19 stations.

In Antarctica, 51 coastal and island stations were operating during the 1957–1958 International Geophysical Year (IGY). Currently there are 11 manned stations and over 60 AWS sites that were mainly installed in the 1980s and 1990s. A majority of these are in the Ross Sea sector and West Antarctica. Beginning about 2004, ARGO floats were deployed in the Southern Ocean and these now provide extensive real-time oceanographic data.

Satellite visible and infrared coverage began around 1970, primarily from National Oceanic and Atmospheric Administration (NOAA) polar orbiting satellites. Currently, there is a wide range of passive microwave, radar, and altimetric sensors that are operated mainly by the National Aeronautics and Space Administration (NASA) and the European Space Agency (ESA). These provide a wealth of global data on numerous environmental variables, including sea ice and Greenland ice sheet melt.

Radiation regime

In winter in each polar region there is an absence of sunlight and the surface radiation balance is negative due to the outgoing infrared radiation from the snow and ice surfaces. The net radiation budget over the Arctic Ocean is $-80 \text{ MJ m}^{-2}$ in January. In July over Antarctica it is approximately $-50 \text{ MJ m}^{-2}$, as a result of the low surface temperatures that reduce the longwave emission. In each case there is a small downward transfer of sensible heat to the colder surface. Over the Arctic Ocean in summer there is initially strong surface reflection of incoming solar radiation by the snow-covered sea ice. The snow cover has an average depth of about 40 cm. Gradually, this snow melts and melt ponds form on the surface, increasing the absorption of solar radiation. The surface albedo (reflectivity) decreases from 0.8–0.9 in May to 0.4–0.5 in July and August. The net radiation budget at the surface of the Arctic Ocean in July is 50–60 MJ m$^{-2}$.

By comparison, over the tundra, net radiation amounts in mid-summer reach 1000–1300 MJ m$^{-2}$ as a result of the long days and large amounts of solar radiation absorbed at the surface, where the albedo is in the range 0.12–0.18.

The temperature structure in the lower troposphere in winter features a pronounced surface-based temperature inversion in both polar regions. At the South Pole the temperature at 500–600 m above the surface can be up to 23°C higher than those at the surface, and the inversion can extend up to 1000 m altitude. In the Arctic inversion depths average 350–800 m and intensities range from 5 to 14°C. Values are greatest in northeastern Siberia. Inversions are stronger and deeper in winter and autumn than in spring and summer. The inversion is caused by a combination of warm air advection in the atmosphere and strong radiative cooling at the surface, which is usually snow-covered.

Polar amplification

A notable feature of the high latitudes is the regional enhancement of global warming during the twentieth century. The global mean temperature increased by about 0.7°C over the twentieth century, but this increase was amplified several times in the Arctic and around the Antarctic Peninsula. Analysis for land stations north of
59°N shows a warming rate of 1.36°C per century for the period 1875–2008, almost twice as strong as the Northern Hemisphere trend (0.79°C per century).

The polar amplification has been more pronounced during the past three decades, particularly over the Arctic Ocean, and is especially apparent in autumn and winter. A major factor is the decrease in autumn sea ice extent that acts to strengthen the ice-albedo feedback process. The increased area of open water leads to greater absorption of incoming solar radiation and hence more heat transfer to the atmosphere, raising the air temperature. Increased low cloud as a result of the open water provides a further positive feedback and warm advection is another major factor. Amplification is observed in the Arctic throughout the lower and middle troposphere and is evident in all seasons, implying a significant role for heat flux convergence in the atmosphere.

Recent work by Francis and Vavrus (2012) suggests that arctic amplification is having an effect on middle latitude atmospheric circulation. They identify weaker westerly winds and increased Rossby wave amplitude, both of which contribute to a slower eastward progression of the upper tropospheric Rossby waves and may lead to more persistent weather patterns. The effects are most apparent in autumn and winter, linked to the reduction in sea ice area.

In the Antarctic, warming has been most rapid in the Antarctic Peninsula, where temperatures have risen by about 3°C since the 1950s. Sea ice in the Bellingshausen-Amundsen seas has declined over this interval and air masses from those seas affects the peninsula. Elsewhere in Antarctica, there have been only minor temperature changes.

The effects of polar warming are evident in the accelerating mass loss from the two ice sheets. Based on changes in ice sheet elevation measured by ICESat-2 for 2011–2012, Helm, Humbert, and Miller (2014) determine a loss of 96 ± 93 km³ a⁻¹ for the Antarctic and 353 ± 29 km³ a⁻¹ for Greenland.

**Atmospheric circulation**

In winter there is a ridge of high pressure at sea level over the Beaufort-Chukchi seas and low pressure over the eastern Arctic Ocean (Figure 1). The ridge links the persistent, eastern Siberian high pressure and highs over the Yukon. North Atlantic cyclones track northeastward from the east coast of the United States, across Iceland, into the Barents Sea, where they decay. Only in spring is there an arctic anticyclone situated over the western Arctic Ocean, north of the Canadian Arctic Archipelago. In summer, there is a weak mean low located over the central Arctic. This pattern is associated with an influx of lows generated over the Eurasian continent and cyclogenesis that is attributable to baroclinicity over the Arctic Ocean itself.

The arctic frontal zone in summer is located near the arctic coasts, especially over Eurasia, and its location is largely determined by the large thermal gradient between the bare land and the cold ocean. It involves maritime arctic air and continental polar air, although the latter is relatively moist at low levels due to the high proportion of small lakes and the often-waterlogged peat vegetation cover that supplies moisture to the air through evaporation.

On monthly timescales there is an Arctic Oscillation (AO) or Northern Annular Mode (NAM) between low pressure over the pole and high pressure in mid-latitudes (37–45°N). This pattern extends through the troposphere and is a major control of Northern Hemisphere climate, especially in Europe and North America. A positive index, with strong westerlies, tends to keep arctic air to the north, while a negative index
can lead to cold air intrusions into mid-latitudes. Its sign fluctuates irregularly and its time series shows no periodicities. The index was mostly positive from 1900 to 1930, then mainly negative to 1990, and subsequently mainly positive until 2010. Components of the AO at sea level are the North Atlantic Oscillation (NAO) between low pressure over Iceland and the Azores anticyclone and the North Pacific Oscillation (NPO) between the Aleutian low pressure
and the subtropical anticyclone in the eastern North Pacific. These are sometimes linked and sometimes independent of one another.

In the Northern Hemisphere troposphere there is a deep polar vortex accompanied by strong westerly winds. In winter, there are two deep wave troughs – over eastern Asia and eastern North America – with a weaker one over eastern Europe. The former two are determined by two factors. One is upwind topography – the Tibetan Plateau and the Rocky Mountains, respectively. These act through the conservation of potential vorticity to set up a ridge in the airflow over the high terrain and a downstream trough over the eastern part of the two continents. The second factor is the thermal gradient in winter between cold land and warm ocean, which leads to a trough developing. In summer, there is a single weak trough over eastern North America as the land–sea thermal contrast is now reversed. The wave pattern irregularly breaks down and blocking anticyclones may develop that disrupt the westerlies. There is either an omega pattern or split flow in the westerlies. There are about 25 such events annually around the Northern Hemisphere. Each event lasts between about one and four weeks. The preferred regions for the blocks to develop are over the North Pacific between 60° and 70°N and over Scandinavia between 50° and 60°N.

The Antarctic is overlain by a deep polar vortex with extratropical cyclones and mesoscale polar low systems. The former spiral in towards the continent over the Southern Ocean (Figure 2), whereas the polar lows move equatorward. The polar lows are comma clouds and spiraliform systems, with an approximate ratio of 10:1. In many, but not all, winters there is a correlation between more extensive sea ice and an increased frequency of polar lows. Unlike in the Northern Hemisphere, the southern polar vortex is nearly circular, making for stronger, more persistent westerlies. In winter it expands equatorward but, in contrast to the Northern Hemisphere, the southern westerlies show little seasonal variation in strength. There is a basic wave number 1 pattern as the vortex is displaced towards the Indian Ocean. This is related to the fact that the most remote sector of the ice sheet (the “pole of inaccessibility” at 83°S, 55°E, and the highest part of the ice sheet) is displaced away from the pole towards the Indian Ocean and southwest South Pacific. Hence, the continent is asymmetric with respect to the South Pole. Occasionally, there is a wave number 3 pattern with the troughs over the major ocean basins. Blocking is less common in the Southern Hemisphere and is concentrated primarily around New Zealand. Close to the Antarctic continent the mean flow is easterly as a result of average high pressure over the ice sheet. There is a circum-Antarctic trough around the continent that has centers near the major embayments of the Ross Sea and Weddell Sea, and off Wilkes Land in East Antarctica. These centers reflect the locations towards which mid-latitude systems move, undergoing stagnation and cycloysis. Cold air outbreaks on their western sides often give rise to the formation of mesocyclones.

The Antarctic trough shifts equatorward at the solstices and poleward at the equinoxes in response to the semi-annual (half-yearly) pressure oscillation. This is a mid-tropospheric feature that involves the different annual cycles of air temperature between the Antarctic and the surrounding mid-latitude oceans. The temperature difference is strong at the equinoxes. At latitude 50°S cooling in autumn is rapid compared with the warming in spring (September), the opposite being the case at latitude 65°S. The semi-annual maximum tropospheric temperature gradients shift the circumpolar trough poleward during the transition seasons. In turn, this produces a semi-annual oscillation in the
pressures (≈5–6 mb) and in the winds over the area affected by the trough.

Corresponding to the NAM there is a Southern Annular Mode (SAM) in the atmospheric circulation between the Antarctic and southern mid-latitudes. This is the dominant circulation mode in the Southern Hemisphere. The SAM index was mostly negative from 1980 to 1993, positive to 2000, then negative to 2008. There has been an increasing trend in the SAM in the austral summer since the mid-1960s, and in austral autumn since 1958, that has been linked to the intensification of the ozone “hole” in the lower stratosphere. This develops each spring as a result of chemical interactions between the solar ultraviolet (UV) radiation and chlorofluorocarbons (CFCs). The UV radiation interacts with the CFCs, producing free radicals that break down the ozone molecules catalytically. This hole is projected to be repaired by
around 2050 as the CFC concentrations are reduced by natural decay following the implementation of the Montreal Protocol in 1989, when nations agreed to phase out the production of harmful chlorine chemicals.

The Pacific–South America (PSA) pattern links pressure anomalies in a standing wave train across the South Pacific and South Atlantic oceans. There is an out-of-phase relationship between pressure anomalies in the Bellingshausen-Amundsen seas and the Weddell Sea sector. This relationship east and west of the Antarctic Peninsula comprises an Antarctic Dipole. It appears to link anomalies of temperature and pressure in the seas around Antarctica with tropical Pacific sea surface temperatures and surface air temperatures; the relationship is best developed during cold La Niña events in the eastern tropical Pacific.

An Antarctic Circumpolar Wave (ACW) in the atmosphere that consisted of a wave number 2 pattern, that propagated eastward around the continent over an eight-year interval, was observed from 1985 to 1994, but was largely absent before and after that time. It appears to have originated in the southern extratropics. The troughs and ridges gave rise to a suite of ocean anomalies that propagated eastward, maintaining their signatures over seasons and the different regions of the Southern Ocean.

The phases of El Niño Southern Oscillation (ENSO) in the tropical East Pacific have substantial effects in the Southern Ocean and over Antarctica. During El Niño (warm events in the tropical Eastern Pacific) most of Antarctica is colder than usual, with enhanced katabatic winds. East of the Antarctic Peninsula there are more southerly winds giving cold conditions with more extensive sea ice. In La Niña, with opposite sea surface temperature anomalies, there is a strengthened Amundsen Sea low and a weaker Weddell Sea low. Cold conditions west of the Antarctic Peninsula then lead to more extensive sea ice in contrast to the conditions to the east.

Climatic elements

Air temperature

Mean annual air temperatures over Antarctica average −60°C or below over the 4000-m-high East Antarctic Ice Sheet (EAIS) and around −10° to −30°C at the coast. Along the Antarctic Peninsula in winter the temperature increases about 1°C per degree of latitude. The mean annual range is about 30°C over the plateau with a range between extremes of 70°C. At the coasts, temperatures in summer rise to near freezing; they are affected by onshore winds and in the Dry Valleys they generally increase with distance inland. In winter at the coast, katabatic winds generally prevent very low temperatures as a result of turbulent mixing in the boundary layer.

Over the central Arctic, mean temperatures range from −30°C in January to near 0°C in July. Away from the coasts, temperatures drop to between −40 and −50°C in January and rise to between 10 and 20°C in July.

Cloudiness

There is high cloudiness (80–90%) over the Southern Ocean throughout the year, while over the central plateau amounts average 40–50% annually, and less than 10% in summer, due to the very dry air and the absence of cyclones.

In the Arctic the areas with open ocean have high cloudiness all year round. Over the pack ice, cloud amounts in winter average around 50%, while in summer there is a high percentage of low stratiform cloud cover due to a combination of evaporation from melt ponds and leads, and moisture advection from the south.
Polar Climates

Precipitation

The Antarctic Plateau is a polar desert with very low snowfall amounts; 50 mm or less is typical. “Diamond dust” (suspended ice crystals) and rime deposition are common. There is considerable drifting and blowing snow. Along the coasts, annual totals of 200–300 mm are typical.

Over the Arctic Ocean, precipitation totals are around 250 mm, with at least half of it falling as rain in the summer months. Totals are higher over the Kara Sea (up to 400 mm) and over the Bering Sea (400–800 mm) as a result of more cyclone activity and higher winter temperatures and specific humidity.

Winds

The surface winds in Antarctica are a persistent, downslope, katabatic flow driven by gravity and thermal gradients. They turn to the left of the maximum downslope gradient as a result of Coriolis acceleration in the Southern Hemisphere. They are shallow systems (100–200 m deep). Winds are strongest at the coast where the ice sheet slope is greatest and topographic channeling is common; mean annual speeds of 20 m s\(^{-1}\) are recorded at Cape Denison, for example. These winds play a major role in opening leads (linear cracks) and coastal polynyas (irregular-shaped openings) in the sea ice.

Climatic types

There are three major climatic types in polar latitudes on land: tundra, polar deserts, and ice plateaus. Over the open polar oceans there is a polar maritime type and over sea ice there is a seasonally dependent regime.

Tundra

Tundra means “treeless” in Lapp, and this zone occurs north of the treeline in arctic Canada, arctic Siberia, the Siberian islands, coastal Greenland around the ice sheet, and in Svalbard. Winters are long and cold while summers are short, with temperatures around 5–10°C. In winter, temperatures are around −25 to −30°C, except when low-pressure systems bring warmer air masses from the North Pacific or North Atlantic. Figure 3 shows mean monthly temperatures for Alert on the north coast of Ellesmere Island, in stark contrast with South Pole Station in Antarctica. Most of the limited precipitation falls as rain in summer. Annual precipitation totals are between 150 and 250 mm in high latitudes. Winter snowfall amounts are low and snow depths range from about 60 to 160 cm. The region is windswept and blowing snow is common in winter. Snowmelt is rapid in June, as a result of the long days, and the ground thaws to depths of 30–100 cm above the permafrost table. In consequence, the ground is frequently waterlogged. Permafrost (permanently frozen ground) is continuous beneath most of the arctic tundra.

Figure 3  Mean monthly temperatures (°C) at Alert (81°N) and South Pole Station. Source: Barry and Hall-McKim (2014). Reproduced with kind permission from American Meteorological Society.
and has typical depths ranging from 100–600 m in arctic Canada and Siberia. At its southern margins it is rapidly degrading, and ground temperatures in much of the tundra are rising.

Cold polar deserts

Cold polar deserts occur on the poleward margins of the tundra in the northern portion of the Canadian Arctic Archipelago, northern Greenland, and the Siberian Arctic islands, and in the Dry Valleys of Antarctica. They are attributable to low atmospheric humidity and infrequent weather systems that result in low precipitation (100–300 mm). Temperatures average between −30 and −40 °C in winter and between 1 and 5 °C in the summer. In polar deserts the ground is usually frozen below a shallow active layer in summer, and the permafrost may be hundreds of meters thick.

Ice plateaus

The two major ice plateaus are the Greenland and Antarctic ice sheets. Greenland is basically an ice dome rising to 3200 m at latitude 72 N. It extends 2400 km north to south and is over 1000 km wide at its widest point, covering 1.7 million km². Numerous small ice caps and glaciers surround it. Antarctica is 98% ice and it covers 14 million km². It is made up of the larger EAIS that rises to 4500 m and the smaller West Antarctic Ice Sheet (WAIS), flanked by the floating Ross ice shelf in the Ross Sea and the Filchner-Ronne ice shelf in the Weddell Sea. There are many other smaller ice shelves around the coastline and along the Antarctic Peninsula. The ice shelves are composed of floating land ice that flows out into the ocean and they are typically several hundred meters thick.

Greenland is affected by storm systems that enter Baffin Bay from the south, or move across it from the west. They also redevelop off the southeast coast, bringing significant precipitation in southeasterly onshore flow. The northern part of the ice sheet, however, is very dry. Mean annual accumulation on the ice sheet is approximately 340 mm water equivalent (w.e.), with over 2000 mm in the southeast. The higher part of the ice sheet is dry snow but near the margins there is substantial melt in summer. Ponds and small lakes form on the ice surface, some of which drain rapidly through moulins (shafts in the ice). At Summit Station (73°N, 39°W, 3207 m) the winter mean temperature is −41 °C and the summer mean is −15 °C. Temperatures at coastal stations average 4–6 °C in summer. The wind regime is dominated by katabatic drainage winds that can reach gale force, especially near the coast where they are channeled by valleys and fiords.

The climate of Antarctica is the most severe on Earth. The mean monthly temperature at South Pole Station, located at 2835 m altitude, varies between −29 °C in December–January and −59 °C in July–August (Figure 3), with extremes of −13 °C and −83 °C. Notice that, unlike Alert, the winter temperatures remain low for six months in a pattern referred to as a “coreless” winter – there is no mid-winter core of cold. This pattern is caused by the consistently negative radiation balance, in the absence of solar radiation. Vostok Station (78°S, 107°E, 3488 m) on the East Antarctic Plateau has recorded a world record low temperature of −89 °C. Satellite data have recently been used to calculate record minima of approximately −93 °C near the East Antarctic ice divide. As noted earlier, there are strong surface temperature inversions. The surface winds over the continent are almost always downslope due to gravity and thermal gradients, deflected by the Coriolis effect. They are typically decoupled from the synoptic gradient winds above; they are shallow and best
developed on the slopes of the ice sheet. In winter (April–October), Antarctica is encircled by extensive sea ice, covering approximately 20 million km² in September, which augments the low temperatures of the continent. This sea ice shrinks and largely disappears in March.

**Polar maritime climate**

The polar maritime (or marine) climate is delimited by the mean temperature of the coldest month being below −6.7°C, where the poleward margins approximately coincide.
with the maximum winter extent of pack ice. Summers are cool (5–10°C) and cloudy. This climatic type occurs in three regions: (a) a southwest-to-northeast zone in the North Atlantic, from south of Greenland through the Denmark Strait to the Barents Sea north of
POLAR CLIMATES

Norway and the Kola Peninsula; (b) the southern Bering Sea and Aleutian Islands; and (c) a circumpolar zone over the Southern Ocean and sub-Antarctic islands between about 49 and 60°S (Figure 4). There is a cold season precipitation maximum and a large proportion of the annual precipitation falls as rain, with many days of precipitation. It also has a high storm frequency, extensive cloud cover, and strong winds.

Ice-covered seas

The extent of sea ice in each polar region changes dramatically with time of year. In the Arctic it ranged from 13–15 million km² in March to 4–5 million km² in September over the last decade. In September 2012 there was a record minimum of 3.4 million km². In the Antarctic it ranges from 15–16 million km² in September to 2 million km² in March. The seasonal sea ice zone (SSIZ) in the Antarctic extends to 55–60°S in September and its overall area has increased slightly over the past few decades, perhaps in relation to a reduction in sea surface temperatures. Earlier, from the 1930s to the 1950s, the sea ice edge was about 2–4° latitude north of its average location in the 1980s. The climatic conditions both determine and in turn are affected by the surface properties – snow-covered sea ice, melt ponds, leads, and polynyas. In the Arctic, in January, temperatures average just below −30°C, rising to 0°C in July. Precipitation peaks in late summer/autumn in response to the cyclonic activity. Even in July about half of the precipitation falls in solid form.

Little is known about the Antarctic ice zone except in the Weddell Sea sector. Snowfall depresses the sea ice and flooding of the floes leads to the formation of snow ice and slush. Ice thickness is typically 0.6–0.8 m at maximum, but in the western Weddell Sea it ranges up to 1.5–2.5 m along the Antarctic Peninsula.

The sea ice zone is a transition region between Antarctica and the sub-Antarctic. Near the coast, the sea ice moves westward, steered by the persistent easterly winds. Farther north, in the westerly wind belt, cyclones form in the lee of the Antarctic Peninsula, where winds are forced over the topographic barrier. Generally, lows from mid-latitudes move southward, slow down, and decline near the continent, but give rise to little precipitation.

Polar region ecosystems

David M. Cairns
Texas A&M University, USA

Polar ecosystems represent some of the extremes of life on Earth. The continental landmass of Antarctica contrasts strongly with the sea ice-dominated oceans of the north polar regions. In addition, the lack of significant ice-free land at south polar latitudes results in limited tundra environments there. In general, the predominant polar ecosystems can be divided into terrestrial and marine systems.

Terrestrial polar ice-free environments are dominated by tundra. The arctic tundra and polar desert biomes constitute about 20% of North America. Traditional views of arctic vegetation have relied upon vegetation maps with bioclimatic zones as the defining top-level hierarchical unit. These conceptualizations of the Arctic have divided the region into the High and Low Arctic based on a multivariate set of environmental characteristics including temperature, soils, and vegetation cover and functional type. Recently, the Arctic has been mapped using bioclimate subzones and vegetation physiognomy (growth form). The circumpolar arctic vegetation map (CAVM) retains the High and Low Arctic differentiation, but further divides each zone into finer units (Figure 1). Bioclimatic subzones A, B, and C represent the traditional High Arctic conditions and are associated with low-stature vegetation on mainly mineral soils. Subzones D and E are the Low Arctic with typically more vegetation cover on organic soils. Overall, the vegetation of the circumpolar Arctic is classified as barrens, graminoid tundras, prostrate-shrub tundras, erect-shrub tundras, or wetlands. Barrens and graminoid tundras dominate the High Arctic (bioclimatic zones A and B). Shrub tundras are present in the warmest part of the High Arctic (bioclimatic zone C) and common in the Low Arctic (bioclimatic zones D and E). Wetlands are topographically determined and present in all bioclimatic zones.

The amount and nature of woody vegetation within the Arctic is indicative of summer temperature regimes. Woody vegetation gradients thus tend to follow the temperature gradient. As such, the zonal vegetation of the coldest bioclimatic zone lacks woody shrubs and is nearly barren of vegetation or characterized by a thin cover of herbaceous plants, mosses, and lichens. Woody vegetation shifts from prostrate dwarf shrubs (e.g., Dryas and Salix spp.), to hemiprostrate dwarf shrubs (semi-erect or trailing stems and less than 0.15 m tall: e.g., Cassiope tetragona) to erect dwarf shrubs (<0.5 m tall: Betula, Vaccinium, Ledum, and Empetrum spp.), and finally to low shrubs (0.4 to 2 m tall: many of the same species as erect dwarf shrub tundra with the addition of Alnus spp. and some taller Salix spp.) with increasing temperatures.

Surface ice dominates the vast majority of land at southern polar latitudes. In ice-free locations some plants do survive. Antarctic flora is unique because it is the only terrestrial continental flora dominated by mosses, lichens, and a few liverworts. There are only two species of flowering plants, and therefore classifications of antarctic vegetation rely on two broad classes of vegetation: lichens and bryophytes. Bryophyte distribution is associated with ground moisture. The gradient in lichens, however, is
more complex and is associated with substrate conditions, the availability of nitrogen, and physiological responses to moisture.

Phytoplankton form the base of the trophic chains in polar seas and warm-blooded air-breathing predators are at the top of the food chain. Historically, polar marine ecosystems have been thought to be characterized by short, low-diversity food chains. More recent research, however, has indicated that the low-diversity conceptualization of the marine polar ecosystems is overly simplistic. The diversity of plankton forming the base of the food chain is no different than in other nonpolar systems. There are differences between the poles in the key prey organisms for the higher trophic level vertebrates. In the Antarctic, crustaceans are the primary prey for vertebrates, whereas in the Arctic it is fish and
benthos. High-level predators such as whales and seals have been subject to human exploitation for centuries and it is difficult to disentangle the impacts of human populations from decade-scale fluctuations in climate and hydrography.

Quaternary history of polar vegetation and animal communities

Prior to the Pleistocene glaciations, a circum-polar arctic flora that consisted of around 1500 species developed. By contrast, the modern circumarctic flora is around 1000–1100 species. The modern flora biodiversity of the Antarctic is far less and is comprised mostly of lichens and mosses.

The most recent Pleistocene glaciation resulted in ice sheets that covered much of the north polar region. Large areas of Beringia (from Alaska to eastern Siberia) were left ice-free and were a dry arctic desert. Much of northern Europe, extending from Scandinavia east to the Urals, was also covered in ice. Arctic-adapted plants survived either in refugia associated with the ice-free areas or migrated southward beyond the glacial margins.

The reduction in size of the modern flora for the Arctic relative to that of the pre-Pleistocene glaciations resulted from multiple advances and contractions of the polar ice caps. During the last glacial maximum (LGM, about 18 ka) in North America, polar vegetation species survived in ice-free refugia in central Alaska and to the south of the ice sheets. Modern genetic analysis indicates that Beringia served as a refuge and a source of recolonization for arctic flora during the LGM; whereas western Siberia served primarily as a refuge, but not as much as a source of gene flow for recolonization of newly ice-free areas.

The late Pleistocene and early Holocene can be divided into three vegetation periods for the Northwestern part of Canada. The oldest, the full- and late-glacial, extended from 25 ka to 11 ka and was dominated by herbaceous arctic and alpine taxa. During the early Holocene (11–7 ka) there was a period of rapid vegetation change. Dwarf shrub tundras and forests became common at the southern margin of the arctic landscape. The late Holocene (7 ka to present) began with an increase in the amount of alder pollen and has led to a period of relative stability in species composition.

During the LGM, populations of large herbivores, such as the wooly mammoth (*Mammuthus primigenius*), decreased and moved southward. After the LGM the populations migrated northward along with the vegetation characteristic of the mammoth steppe, but eventually died out, probably due to the speed of the changes in climate, the presence of humans in North America, and the increased prevalence of conifers, peatlands, and birch (*Betula* spp.) in the North American arctic landscape. Birch spp. can be toxic to cecal digesters such as mammoths.

The importance of ice

In addition to ice having been a dominant determinant of the distribution of life within the polar regions over long time periods, it remains an important driver of patterns of life and diversity today. Direct effects of sea ice are felt most strongly in the marine portions of the polar environments. Sea ice serves as the substrate for an array of micro-organisms and also acts as habitat for a set of vertebrates such as walrus, polar bears, and seals. Sea ice algae and sub-ice phytoplankton account for more than half of the Arctic Ocean primary productivity. Ice-algae and phytoplankton blooms are tightly
POLAR REGION ECOSYSTEMS

linked to the extent, duration, and timing of melt of the sea ice. Ice-algae and phytoplankton are the base of the tightly coupled polar marine food web. Zooplankton populations rely upon the phytoplankton blooms which are linked to fish such as cod and their avian and marine mammalian predators. In addition to providing substrate for ice-algae and modifying the light environment for phytoplankton, the sea ice also facilitates foraging, reproduction, and resting of vertebrate species in the polar regions. Polar bears, seals, and walruses are the most prominent users of the sea ice in this fashion.

Most of the land in the Arctic is ice-free; in contrast, only about 2% of the antarctic continent is ice-free. Permafrost, however, is a common occurrence in both the Arctic and the Antarctic. Permafrost is defined as any subsurface material that remains at or below 0°C for longer than two years. Polar regions may experience permafrost up to 1500 m deep, and although much more prevalent in continents, offshore permafrost conditions do exist below unfrozen marine sediments in some cases. Deep permafrost has relatively little influence on the ecology of the surface. Permafrost in areas that are rich in ground ice has significant impacts on topography, hydrology, and ecology. An active layer (substrate that freezes and thaws seasonally due to air temperature oscillations) is characteristic of terrestrial permafrost zones. Complex topographic surfaces that are created by the differential thaw of ice-rich permafrost (thermokarst) have been developing across the Arctic as temperatures have risen over the past century.

Melting of ice-rich permafrost has the potential to alter the hydrology of an environment producing significant shifts in vegetation on the surface. For example, large areas of birch forest in central Alaska have been transformed into bogs and fens. There is also the potential for the release of carbon to the atmosphere from its storage in frozen ground as the climate warms.

The presence of permafrost associated patterned ground influences the distribution and patterning of vegetation. For example, in the Russian Low Arctic (and other locations around the Arctic) alder savannas are common. Individual alder shrubs and clumps of alders are regularly spaced across a landscape. There is a spatial association between patterned ground microsites and the alders. At these locations “circles” or “frost boils” develop in which a circular patch of mineral soil develops surrounded by larger clasts. These circles are regularly spaced and zones of these types of features may be very widespread. Recently, using a combination of satellite imagery with field data collection, Frost et al. (2013) have shown that there is a strong correlation between the patches of mineral soil and the presence of alders. Alders preferentially establish in the mineral soils as opposed to the more rocky surrounding environment. This preference results in a regular pattern of alder on the landscape. The underlying geomorphology is controlling the pattern of the vegetation in this environment which in turn has implications for the distribution of nutrients, patterns of permafrost, and future colonization of other vegetation.

Interaction of plants and animals

Plants and animals are linked in the Arctic through their phenology (the timing of events in their life cycles) and by the disturbances or perturbations that their presence can have on the ecosystem. Phenological linkages can occur through the timing of migrations, and in the synchronization of life stages with available forage. For example, caribou migrations in Alaska, Canada, and West Greenland have historically shown tight coupling of the calving
season and the emergence of plants from winter dormancy. Similar phenophase synchronization occurs in nonmigratory animals. For example, in Fennoscandia, the autumnal moth (*Epirrita autumnata*) is an important component of the dominant subarctic forest systems. The timing of the hatching of the moth eggs and their early development is linked to bud flush of their primary forage – the leaves of the mountain birch (*Betula pubescens ssp. czerepanovii*). The chemical composition of the leaves changes through time so that as the moth larvae grow, the leaves become less palatable to the moths. Disruptions of the linkage between the phenophases of the two organisms can cause significant perturbations to the ecosystem.

Animals on a landscape influence the vegetation communities in both positive and negative ways. One conceptual model of the impact of animal activity on vegetation outlines three possible responses of the vegetation to increasing amounts of animal activity. Increased animal activity may have a positive, a negative, or an intensity-limited effect on vegetation communities. In cases where increases in animal activity lead to increased productivity or abundance of certain species, the driving mechanisms include animal-facilitated dispersal of plants and the fertilization of the environment.

Animals may disperse plant seeds by carrying them either inside or outside of their bodies. The distance that species are carried in any single dispersal event varies with the travel distances of the animal vector. Mammals tend to travel shorter distances than birds, for instance. In the Arctic, reindeer and caribou have been shown to carry seeds in their digestive system, and the presence of the animals on the landscape facilitates the dispersal of those seeds. Most of the seeds are for herbaceous plants. Birds are also important dispersal vectors and can carry seeds very long distances.

An example of how increased animal activity may influence the productivity and diversity of a site through fertilization comes from Antarctica. At some antarctic locations, penguins serve as a conduit for transferring nutrients from the marine to the terrestrial environment. In the vicinity of penguin colonies, diversity of vegetation tends to increase over short periods after abandonment (5–6 years). Areas fertilized by penguin guano tend to have higher amounts of vascular flora compared to unfertilized areas that are dominated by bryophytes and lichens. This example illustrates that animal activity may not be good for all species in an area. The presence of animals therefore has the potential to alter vegetation composition. In the antarctic example, vascular plants were facilitated by the fertilization of the environment by penguins, but at the expense of the bryophytes and lichens.

Defoliating outbreaks are an example of the second (negative) mode of interaction between plants and animals. For example, increases in autumnal moth larvae populations reduce the productivity of the birch trees in arctic Scandinavia that are their primary forage. Clear evidence exists from tree rings illustrating the reduction in growth of mountain birch for between two and three years after an outbreak. Outbreaks of the autumnal moth not only have the potential to reduce the growth and productivity of the large trees that are their primary forage, but in some cases they also reduce the productivity and biomass of the ground vegetation. The regular rodent cycles in these systems are also tied to the variability of the vegetation biomass, and consequently the impacts of one species in a system may cascade through the larger ecosystem. Similarly, the presence of reindeer significantly reduces the ground vegetation in terms of both the size and the abundance of keystone species such as *Cladina stellaris* (one of the main species of lichen
**Polar Region Ecosystems**

in the region). In Alaska, ptarmigan (*Lagopus* spp.) browse heavily on shrubs above the snow surface at sites north of the Brooks Range. Browsing by ptarmigan has an influence on their height and growth form and stimulates stump shooting.

Importance of disturbance and human activity to polar ecosystems

No ecosystem is static. Changes to an ecosystem occur naturally through autogenic processes of succession over time or can be imposed by exogenous factors. Polar ecosystems are no different in this regard. To understand the impacts of exogenous disturbances resulting from development at the poles (mostly in the Arctic) it is important to first understand the natural successional pathways that occur there.

In contrast to successional processes at temperate and tropical locations, polar ecosystems tend to undergo successional changes very slowly. For example, in the High Arctic where vegetation cover is often less than 1%, the interspecies interactions are quite limited. The physiological and genetic attributes of colonizing individuals determine successional pathways rather than interactions between the plants. In these environments, physical disturbances or climatic conditions can continually reset the successional clock thereby extending the time for passage along the successional trajectory. Although the vegetation cover is typically higher at Low Arctic sites, the rate of change remains slow due to incomplete plant cover, physical disturbance, and a low resource base. Limited resources for plant growth in the Low Arctic are associated with low temperatures, a short growing season, and limited nutrient turnover due to slow decomposition rates.

Normal successional trajectories in the Arctic can be modified by nutrient additions. Additional nutrients result in the rapid establishment of graminoid vegetation and can ultimately change the end point of the successional process. For example, at fertilized sites, the growth of the woody shrubs *Betula* and *Salix* occurs at the expense of the tussock cottongrass (*Eriophorum vaginatum*).

The depauperate flora of Antarctica create more simplified successional trajectories than in the Arctic. On continental Antarctica, primary succession is understood better than secondary succession. Studies of successional trends on recently deglaciated foregrounds have shown that the lichen and bryophyte communities that dominate these environments are divided into three stages of development. Pioneer communities may develop within a few decades of glacial recession, intermediate-aged communities develop on surfaces 300–400 years old, and climax communities occur on the oldest terrains. Age is the most dominant factor that influences the vegetation composition of these sites, but duration of snow cover and substrate characteristics may modify successional trajectories. Although newly deglaciated terrains can be invaded relatively quickly, their successional pathways can be impeded or halted at intermediate stages due to environmental conditions.

There is a long history of human impacts on polar ecosystems. The type of human impact differs between the Arctic and Antarctic. Resource exploitation and human settlements are common in the Arctic, but are virtually absent in the Antarctic. The Madrid Protocol to the Antarctic Treaty was adopted in 1991 and has designated Antarctica as a “natural reserve, devoted to peace and science.” It has banned mining and oil exploration on the antarctic continent. Recent increases in research and tourism activity there have begun to produce human impacts that
are having an influence on soil biota and may also alter ecosystem processes such as carbon cycling. Trampling due to limited foot traffic in the Dry Valleys near McMurdo can also reduce populations of various soil biota. In contrast, the subantarctic islands are and have been less well regulated and human impacts are more common.

The natural ecosystems of subantarctic islands were significantly impacted by the arrival of people involved in whaling and sealing prior to the middle of the twentieth century. There was a transfer of nutrients to terrestrial environments by scavengers and an introduction of a variety of exotic species (both plants and animals). Because there were no baseline ecosystem studies performed before the human activities began, there is limited understanding about what the “natural” conditions of these islands were like. In some cases, the extirpation of local seal populations allowed for increased vegetation productivity.

Exploration for and extraction of natural resources have become more prevalent in the Arctic during the last 50 years. The development of oil and gas fields by both North America and Russia has produced changes in the local ecosystems. On the Alaskan North Slope, winter seismic exploration has had an effect on vegetation on permafrost soils. Vehicle traffic due to oil and gas exploration in the mid-1980s resulted in plant community composition change. Over the long term, vegetation communities lost cover of evergreen shrubs and mosses and increased cover in gramminoid plants. The changes persisted over at least two decades, and the intensity of the disturbance influenced recovery rate. Vascular plant cover declines along the exploration lines in all types of tundra relative to undisturbed reference plots. Diversity decreases, as does abundance.

At High Arctic sites, vascular and cryptogamic species richness has been shown to be greatly reduced after low-intensity disturbance by tracked vehicles in both mesic hummock vegetation and wetter meadows. Seedling establishment is virtually nonexistent at sites subjected to multiple passes by tracked vehicles. There is some evidence that the persistent vegetation changes that result from older exploration activities (10–30 years) have reduced bird abundances.

In addition to the direct effects of resource exploitation in the Arctic, on the Yamal Peninsula in northwest Siberia, the discovery of large natural gas fields in the 1960s has resulted in changes in land use. Large portions of the land have been taken out of traditional usage (primarily for reindeer herding) and have been set aside for oil and gas exploration. The result has been to concentrate the traditional activities of the native Yamal Nenets into much smaller areas. The increased density of reindeer in these areas has resulted in the trampling of and grazing of the tundra. The changes in vegetation have resulted in the development of thermokarst, and initiated Aeolian erosion. There has been an extensive transformation from shrub- to grass- and sedge-dominated tundra. Land-use changes in northern Finland have also significantly affected the reindeer pastures and the herding system.

Disturbed arctic tundra sites recover very slowly due to the arrested successional processes. Comparisons between archeological sites and more recent disturbances due to pedestrian traffic show similar responses in the Canadian Arctic and other Low Arctic locations. The relatively low number of species present at High Arctic locations provide only a limited number of avenues to recovery from disturbance. Assisted revegetation of arctic sites disturbed by human activity has occurred across the Arctic. The success of these attempts has varied, and has occasionally relied on the introduction of non-native species. Rates of revegetation differ between wetland soils and those characterized more by gravel, sandy, and saline soils.
Climate change implications for the polar ecosystems

As the temperature in the Arctic has risen over the past 100 years, the land surface has also begun to change. The permafrost underlying much of the terrestrial arctic land masses has begun to thaw, changing the terrain, the hydrology, and the availability of nutrients. One impact of these changes has been the “greening of the Arctic.” In the late 1980s, satellite data became available to illustrate the distribution and magnitude of this change. Advanced Very High Resolution Radiometer (AVHRR) data indicated that the Arctic was becoming significantly greener. This change was concentrated particularly in much of Alaska, eastern Siberia, and the northern part of Fennoscandia. Subsequent monitoring efforts using similar data have shown that the pan-arctic greening trend has continued into the twenty-first century.

Although the satellite data have been able to illustrate that some change is occurring, they are at relatively coarse scales and are not capable of clearly illustrating what is happening on the ground. Other methods of monitoring change have been necessary to illustrate the details of what is happening. One example of this is the increased shrub cover across the Arctic. Using aerial photographs taken from low-flying airplanes in the mid-twentieth and early twenty-first centuries, Sturm, Racine, and Tape (2001) have shown that for the Coleville River basin on Alaska’s North Slope tall shrubs have been growing larger, filling in the non-shrub interstices, and expanding into new areas. Research from other locations in the Arctic have confirmed that this pattern is occurring world-wide and that it is a component of the greening that had been previously identified using satellite data. Recently, some evidence has become available that addresses the spatial heterogeneity of the response of these shrubs to the changing arctic climate.

The tundra has also been changing over the past 50 years. The international tundra experiment (ITEX) is a coordinated set of experiments using similar methodologies at tundra locations around the globe. The results of this experiment have illustrated that the impacts of climate warming differ between sites: shrubs increase with warming at sites that were warmer at the start of the experiment, and graminoids increase more at sites that were colder at the start of the experiment. Fertilization studies at tussock tundra sites have indicated that increased nutrient availability, coupled with warmer temperatures, leads to increased biomass and losses of carbon and nitrogen from deep soil layers. These changes in soil nutrients may form a positive feedback to climate warming if they are sustained.

Polar marine systems are also likely to experience changes under a warming climate. The most dramatic change documented to date has been the decrease in sea ice. Sea ice change occurs as a reduction in extent, thickness, and duration. The lowest arctic sea ice extent based on a satellite record occurred in 2005. Since 1979 there has been about a 3% per decade reduction in sea ice extent measured in February in the Arctic. Such reductions produce fewer days for foraging of polar bears, and a reduced area for walrus to pull out of the ocean for reproduction and as a base for foraging. Changes in sea ice may also have an impact on gene flow, and the transmission of pathogens.

In the Antarctic, sea ice is linked to population dynamics of the emperor penguin (*Aptenodytes forsteri*), and declines in sea ice are predicted to result in severe declines of their populations. Changes in synoptic climatology related to changes in sea ice may influence atmospheric and oceanic circulation patterns. The impact of these changes may outweigh that of temperature
change for terrestrial subantarctic ecosystems characteristic of the subantarctic islands.

The poles of the Earth represent integrated systems that are more than the sum of their parts. The processes that determine the functioning of polar ecosystems are linked through direct connections and also by feedbacks that can either lead to stability or contribute to change. The most readily observable of these feedbacks is the surface albedo-temperature feedback. As the surface albedo changes (due to the melting of sea ice, changes in the distribution of plant communities on land, and the melting of glaciers), temperatures are expected to increase at faster rates than have been yet observed. The changes in temperatures will induce continued change. Polar ecosystems will adapt to these changes and may eventually reach an environmental state that is very different from the current system state.

Political ecology and scale

Matthew D. Turner
University of Wisconsin–Madison, USA

The relationships between humans and their biophysical environment operate at multiple spatial and temporal scales. For example, the clearing of a patch of temperate forest for agriculture leads to a rapid transformation of its biochemical cycles and ecological populations. The farming of the cleared piece of land has a slower but ultimately more transformative effect on soils and the prospects for forest regeneration. Forest regeneration after field abandonment occurs over a longer time period with multiple possible trajectories shaped not only by the characteristics of how the forest was originally cleared and by subsequent farming, but also by climate, the surrounding landscape matrix, human uses of the forest, and chance during the decades of forest succession. Clearly, what one observes in terms of ecological change depends on the length of time that one observes and when one observes. Moreover, one’s ecological assessment may vary depending on whether one is making observations at the edge or in the middle of the cleared patch, which would both differ from observations over a broader spatial extent that encompassed many such patches in a shifting mosaic of transition. The spatial and temporal scales of society’s material exchanges with the biophysical world are affected not only by intentional resource management and policy but also by the scaling effects of the broader political economy.

Given the importance of spatial and temporal scales in both producing environmental change and affecting our observations of it, the way we talk and think about human–environment relations often involves simplified, sometimes underexamined, categorizations of spatial and/or temporal scale. Terms such as “landscape scale,” “watershed management,” “community-based conservation,” “connectivity,” “sustainable use,” “buffer zones,” “disturbance,” and “resilience” very much animate the worlds of environmental research and practice. The use of these and other terms in environmental science and policy discourse invoke particular spatial or temporal scales. For instance, watershed management, a popular approach in water quality and soils management, is seen to improve previous management approaches in that the “natural” unit of the watershed is adopted as the scale of management. In this way, the downstream effects of the (mis)management of a farmer’s field could be incorporated into policy and management decisions. While it may better match the scales at which water moves, watershed management may not match the scales of rural land-use dynamics or existing management institutions. Effective management, therefore, necessarily results from a recognition of both biophysical and social scales, not in isolation from one another, but as coproduced.

Political ecology, as an approach, seeks to understand the material landscape transformations and contestations around them within the context of broader social change. This commitment has compelled political ecologists to explicitly or implicitly address scaling issues in their work. As a result, political ecological work has made important contributions to
our understanding of scaling questions in the fields of environmental change and governance. The topic of political ecology and scale will be addressed here by providing: (i) a basic understanding of what is meant by questions of scale in the social and biophysical sciences; (ii) a description of the treatment of scale in political ecology’s conceptual framework; and (iii) a discussion of the treatment of scale in political ecology’s study of environmental governance.

The concept of scale

Scale is an important concept for all subfields of geography, with a corresponding diversity of meanings attached to it and the processes that reflect and produce it. Questions of scale have also elicited significant attention within ecology and the biophysical sciences more broadly. Much political ecological work can be characterized as analyses of society–environment relations, contextualized by history and place, with a particular emphasis on the environmental and social justice implications of broader political economic change (Zimmerer and Bassett 2003; Robbins 2004). The field of political ecology includes work that privileges ecological concerns over political concerns (a minority), and that which is less concerned with ecology per se than with the politics surrounding the meanings attached to, the use of, and struggles over access to the nonhuman world. Given this diversity, political ecologists’ engagements with scale span the epistemological divisions between and within human and physical geography. As such, it potentially offers much to contemporary understandings of scale, particularly with respect to the interplay of the social and biophysical processes that produce scale. Prior writings on this subject by Sayre (2005, 2009), Cohen and Bakker (2014), and Neumann (2009) are particularly insightful and have informed this entry.

Sayre’s work (2005), comparing treatments of scale in ecology (sharing commonalities with physical geography) and human geography, is particularly helpful – not only for introducing greater clarity to the scale debates in human geography at the time, but also for its discussion of scale in ecological and social processes (operational scale). As Sayre (2009) observes, the multiple meanings of scale include size, level, and relation. Scale as size is the meaning attached to scale as a quantitative measure that dominates in cartography and/or geographical information science, as well as in the biophysical sciences, with its use both referring to the extent and resolution of observation and display. This meaning of scale sits squarely within what Sayre describes as the epistemological moment – namely, what one observes (and therefore understands) about socioecological dynamics is shaped by the temporal and spatial scales that one adopts as a researcher, policymaker, or land manager. Thus, as described, one’s assessment of ecological response to human activities can be quite different depending on the temporal and spatial scales that one adopts to make observations.

Scale as level is a more qualitative measure, referring to the scale categories that we impose on the world (epistemological) and the discontinuities that exist in human societies and ecologies (ontological). Social and biophysical worlds are structured and as such show discontinuities in the nature of social and biophysical processes. The watershed represents one such discontinuity in hydrological systems (ontological). Still, the branching drainage and river patterns reveal that watersheds of different orders are nested within each other. Therefore, uses of the term “watershed scale” reflect not only ontological discontinuities but also, owing to the choice of the level within the nested hydrological network
to call the “watershed,” observational or epistemological discontinuities. We as observers have simplified the complexity of hydrologic networks. Similarly, social scientists may, in referring to the “household” or “village” implicitly as a closed social group, ignore or downplay the social networks that transcend these social group categories. In short, the categories that we impose on complex realities may impose harder boundaries or discontinuities on social or biophysical processes and properties than actually exist. In both these cases, the levels or categories in question reflect both discontinuities in social and biophysical processes and discontinuities introduced by the observer. Therefore, scale as level often has what Sayre describes as both ontological and epistemological moments. These moments are highly intertwined in the sense that our conceptions of the world can help produce material discontinuities in the world. Sayre goes on to argue that a major source of confusion is the conflation of these two moments – focusing on one of these moments of scale as level to the exclusion of the other – not only among social scientists but also among ecologists.

Scale as relation focuses on the biophysical and social processes that move through scale to produce, through their interaction, a scaled, leveled, or structured world (ontological). Most political ecologists or ecologists would argue that they are not inherently interested in scale alone but instead are interested in the social and biophysical processes that reflect and produce the ontological moment of scale as level. Using the earlier example, the patterns of conversion of forest to cropland (distribution and sizes of cleared parcels) is shaped not only by the physical environment (soil types, topographic position) but also by the infrastructure (roads and access to markets), technology, and the distribution of the control over productive resources (labor, capital, land). The resulting mosaic of land cover will influence scale-dependent variables in landscape ecology such as connectivity and edges, which will shape not only forest succession (at different levels) but also wildlife movements (at different levels) and human–wildlife conflict. In these ways scaled landscapes are both produced by and shape social and ecological dynamics over time (at annual, decadal, centennial, millennial levels).

“Chains of explanation” and spatial scaling

Scale also lies at the heart of the persistent attractiveness and challenges facing political ecology as an approach. As admirably reviewed, for example by Rangan and Kull (2009), Neumann (2009), Brown and Purcell (2005), and Robbins (2004), a major feature of early political ecology was its embrace of the interaction of social and ecological processes operating at different scales. It promised to link broader political economic processes to on-the-ground management and environmental change through the concept of “chains of explanation” (Blaikie 1985). In referring to the power of the approach, Blaikie (1985, 88) states that “soil erosion problems can be analyzed in a framework of Chinese boxes, each fitting inside the other,” with the boxes being social organization levels such as the individual, household, village, district, and so on. Very early on, the concept was critiqued by those aligned with political ecology as an approach that was theoretically underdeveloped, leading to seemingly ad hoc, contingent, and empirically derived explanatory sequences tying broader political economic changes to changes in local society–nature relations (Peet and Watts 1996). Since then, political ecology as a field has grown and diversified from its agrarian
POLITICAL ECOLOGY AND SCALE

political economic roots (Blaikie 1985). Political ecologists have become more comfortable with muddling through without an overarching theory tying political economic change at broad scales to local communities while still raising concerns about the implicit hierarchical or fixed container model that underlies the chain of explanation concept (e.g., Rangan and Kull 2009; Brown and Purcell 2005; Zimmerer and Bassett 2003; Robbins 2004). As a result, it has been argued that Blaikie’s analogy of nested Chinese boxes has had a persistent effect, with subsequent political ecologists relying on a hierarchical framework to interpret the processes that animate “scales of relation.” A number of scholars have argued for a greater reliance on networks (horizontal and vertical), conceptualized variously, to analyze relations that work across and produce scale (Rocheleau and Roth 2007; Robbins 2004; Birkenholtz 2011).

Brown and Purcell argue along these lines to raise the point that political ecologists’ rigid adherence to this scaling hierarchy leads them to fall into a “local trap” where the key to desirable environmental and social justice outcomes is seen to be the “devolution of power to local-scale actors and organizations” (2005, 608). This represents an important caution. Still there is reason to believe that these issues are not as inherent or ubiquitous to political ecology as some may argue. First, there is much political ecological research, some of it very early in its history, that critically engages with “the local” and calls for checks on local-scale authority. More importantly, Neumann (2009) argues that political ecologists, while they do not often cite the scale literature coming out of political economic geography (exceptions include Zimmerer 2000; Rangan and Kull 2009; Cohen and Bakker 2014; Swyngedouw and Heeynen 2003; McCarthy 2005), treat scale not as rigid but as fluid, historically contingent, and socially malleable. Indeed they are not theoretically constrained to a particular scale, and in fact there are many examples of political ecological work (e.g., Turner 1999) that address Swyngedouw’s call for scale research that “never resides in a particular geographical scale, but rather in the [social] processes through which particular scales become (re)constituted” (1997, 169, quoted in Brown and Purcell 2005). Moreover, one can point to the literatures on territorialization, decentralization, counter-mapping, commodity chains, and boundary construction, to which political ecologists contribute, as very much treating “scale” as politically contested and constructed. In this work, social processes working across scale or political contestations having scalar implications are the concern, with little analytical leverage lost by not explicitly invoking scale per se.

In short, treatments of scalar politics by political ecologists demonstrate that many have not been captured by a hierarchical vision of scale or fallen into a “local trap.” Still, the local trap debate provided a caution to the methodological commitments shared in political ecology. Political ecology is dominated by place-based approaches through which the researcher makes causal claims connecting observed society–nature relations in place to broader political economy and ecology through a combination of secondary research, tracing networks, or progressive contextualization as interpreted by a combination of mediating middle-level theories. Place-based research does not necessarily result in the researcher being captured by the local, but it can result in local places being more richly characterized and understood. This is not a problem faced solely by political ecology but by all place-based approaches seeking to make causal connections beyond that experienced and observed in research.
Scale and environmental governance

In this section, the various ways in which political ecology has treated the malleability of scale (size, level, relation) in environmental governance and politics are described — in other words, how scale is produced, invoked, and circulated. Environmental governance is a major area of inquiry within political ecology. It not only encompasses government and non-governmental programs that specifically focus on environmental conservation or resource management but also the environmental consequences of other forms of governance or use of social power. There is a politics to all of these instances — power is contested and therefore environmental governance research is necessarily concerned with resource-related conflict. The politics that surround environmental governance includes not only overt contestations over authority in electoral, bureaucratic, legal, and less formal political venues, but also the “knowledge politics” over acceptance of different understandings of environmental response to human activities. The politics of knowledge takes place not only in scientific labs, environmental NGO offices, ministry buildings, debates at conferences, or the pages of journals but more generally in the broader discourses surrounding environmental management and governance that shape what counts as valid environmental knowledge and what serves as widely accepted common knowledge within epistemic communities.

Observational scale and knowledge politics

How is scale implicated in such politics? Environmental analysis, policy, and politics are very much shaped by the temporal and spatial scales adopted by different observers (e.g., Sayre’s observational scale). At a fundamental level, environmental changes are seen as problems by human society (and social groups) only if they are observable, valued by humans as important, and elevated as problems by individuals and institutions with power. In short, the scaling of environmental change in relation to the observational scales used by human observers has a significant effect on what, among the myriad of biophysical variations that are occurring, is treated as directional change and a problem to be addressed (Cohen and Bakker 2014). Different temporal frames placed over environmental variation will often result in quite different assessments whether change is directional, seemingly random, or cyclic. Gradual environmental changes over timescales that exceed the human life span are often ignored or are not measurable owing to the limitations of data or measurement technology. Even over shorter timescales (decades), directional change in an environmental variable that fluctuates widely at shorter timescales (years) may also not be identified as change. As landscape ecology has clearly demonstrated, high variation at more spatially resolved levels can mask changes at broader levels.

Environmental monitoring and assessment are very much bounded in that they necessarily focus on the change of particular variables within circumscribed areas. This bounding defines the spatial scale of observations, which in turn shapes the processes that can be observed and our normative assessments of changes. The statement that someone’s environmental improvement is another’s degradation reflects not only different values held about changes in the biophysical environment but also different people’s placement within the spatially specific array of changes resulting from a human activity. Soil erosion is a common example of this, whereby topsoil loss from a farmer’s field is associated with material flows which, as one
POLITICAL ECOLOGY AND SCALE

expands out spatially, may result in a gain of topsoil to other farmers’ fields or stream silation downstream in the watershed. Almost all environmental changes have this characteristic, with the effective observational scale affecting normative assessments and political responses to environmental change.

In these ways, scale as size plays an important role in environmental monitoring and assessment and their influence on environmental governance. Terms such as scarcity, biodiversity, competition, or connectivity, which very much frame contemporary ecological management, are highly scaled concepts – their value, no matter how they are defined, is strongly shaped by the scale of observation (temporal and spatial). Thus we can see differences in how scientists of different disciplines and agencies interpret the same landscape, and how, in turn, their perceptions differ from those living and working on these landscapes. On a deeper level, differences in knowledge systems – spanning the problematic dichotomy between Western scientific and indigenous knowledges – are often associated with different temporal and spatial framings, either explicitly or as matters of belief or tradition. In this way, strategic or nonstrategic spatial and temporal framings underlie the knowledge politics that surrounds environmental questions of interest to political ecologists.

Scale as level in the politics of scale

Our social and biophysical worlds, while open-ended and dynamic, do display levels of structure. As described earlier, social and biophysical scientists make sense of their worlds by dividing the world into organizational categories that variously relate to spatial scale. Social scientists speak of the scales of the individual body, household, community, district, nation-state, and globe. Ecologists similarly speak of the population, community, ecosystem, and biome or, in a more spatially explicit fashion, watershed, landscape, and ecosystem. It should be clear that these organizational typologies are variously related to scale as size. In addition, they incorporate organizational framings (social, biological, jurisdictional, population ecological, hydrological, etc.). The confusion and ambiguities that exist in how such categories relate to scale have produced significant debate in ecology, physical geography, and human geography. The confusion stems in part from the fact that these levels do reflect the scaled nature of different processes (scale as relation) that produce structure in the world and, therefore, are not simply epistemological but have ontological moments (Sayre 2009). Still, their epistemological content, often unexamined, has created barriers to the integration of social and ecological analyses in political ecology and other fields.

Such barriers are often described as mismatches – a mismatch between the scales of sociopolitical research, governance, or jurisdiction with the appropriate scales of ecological functioning. This has led to calls for greater attention to ecologically informed spatial units such as the watershed or eco-region to address the problems associated with community-based or national approaches to development and conservation. For effective programs, it is argued that social and ecological scales should match (e.g., the soil erosion example provided in the previous section). However it is difficult to assign a single scale for management to a web of interacting processes. Ecological communities are composed of organisms that interact with each other and the physical environment at quite different scales. The assignment of an appropriate scale at which human society should manage diverse ecologies has therefore proven illusionary.
When ecologists or land change scientists seek to bridge ecological and social scales, they are often seeking to identify levels of management or governance that would encompass the ecological processes threatened by a human activity. This view of social scaling is different from that offered by the political ecologist who may focus on the levels of social organization at which social processes and relationships work to shape a human-organized activity that produces the particular threat. Policy or management responses to these two approaches may be quite different, with political ecologists more likely to identify multiple areas of intervention at different scales.

It is not surprising that ecological and social scales have entered into environmental management not as spatial scales in their abstract form but as bounded spatial units. The “watershed scale” has become the bounded watershed, with the underlying assumption that, as a hydrologic unit, it represents, like an island, some degree of ecological separation from other such units. The watershed, long a unit of international hydrologic management, has also become a unit for local environmental management, particularly in highland areas. Given the networked, hierarchical nature of river systems and associated watersheds, the watershed represents a convenient biophysical unit for management jurisdictions of different sizes. For low flat or dryland areas of the world, visible hydrological units such as the watershed are not as useful in this regard. As a result, we are more likely to see a switch in conservation discourse where levels of social organization (e.g., community) are used to define the scale of conservation and development programs in these parts of the world. This does not necessarily reflect their ecologies (or social geographies, for that matter) but their hydrologies and the seeming lack, to the human eye, of clear ecological boundaries.

It is important to restate that these categories — whether ecological or social — may reflect ecological and social organization, but their use will often sharpen boundaries and distinctions. Moreover, the invocation of a particular scale for governance — whether defined through physical (e.g., watershed, eco-region) or social (e.g., community) geographies — affects the loci of authority over natural resources and people. An obvious example would be whether management authority is accorded to a local community or to a national ministry (community vs a national forest reserve). Not only do these entities rely on different modes of decision-making, but shifts in authority across these different levels will fundamentally affect the allocation of authority. In this way, there is a politics of scale surrounding the Sayre’s epistemological moment of scale as level (Swyngedouw and Heynen 2003). The politics of scale of concern to political ecologists encompasses but transcends the scalar mismatch of concern to ecological managers. Despite the rhetoric, much of the scale shifting in environmental governance is less about proper ecological management and more about control over natural resources. By engaging with questions of how scales of governance are defined and manipulated by science and politics in combination, political ecologists can consider both the distributional and ecological implications of such moves.

**Scale as relation and the production of scale**

Shifts in the scales of governance and the associated reterritorializations of resourced landscapes have material effects on peoples’ livelihoods and on the ecologies on which they depend.
Political ecology offers much to the understanding of how social and biophysical scales are coproduced, an area of inquiry that has been identified as very important by scale scholars and others (Swyngedouw and Heynen 2003; Cohen and Bakker 2014; McCarthy 2005). Social and ecological processes interact across scales (scale as relation), with these relationships potentially reshaping social and ecological organization. For example, as the body of work on forestry in India has shown, shifts in the authority over forested land between community and national ministries not only have an effect on how forests are managed, but also exert a shaping influence at a broader landscape scale, affecting the size and distribution of forest cover, with significant implications for biodiversity and ecosystem functioning.

Political ecology’s early focus on understanding the livelihood practices of people in place (Blaikie 1985) lends itself well to exploring scales of governance in relation to people’s livelihood practices rather than relying on preconceived categories of social or ecological levels. Political ecologists, through their engagement with not only ecology but people’s livelihood practices, have identified inappropriate features of prescribed resource management practices which have been transported from one socioecological context to the other. An example of such work by political ecologists is work that critically engages with the equilibrium assumptions that underlie many forms of conventional resource management (range management, fisheries, forestry, conservation biology). In the West African Sahel, such assumptions, coupled with sporadic, crisis-led environmental attention, led to circular logics that equated poor range condition with livestock presence. Such assessments contributed to the malign neglect by governments and donors of mobile forms of livestock husbandry. These views have changed but nongovernmental and government organizations continue to pay little heed to the mobility requirements of livestock husbandry in these arid lands. More recent development emphases of granting greater authority to local “communities” have worked in favor of certain social groups, with the consequent enclosure of key pastoral resources. As a result, there is some evidence for a decline in the mobility of livestock owned by pastoralists and farmers alike, which in turn has increased the potential for localized overgrazing and social conflict.

**Conclusion**

Political ecologists, who are interested in how social and ecological processes interact across time and space, necessarily grapple with serious questions of scale in their work. The way they address scale has been largely through careful identification of the interactions of interest and tracing those interacting relations or processes over space and time. Therefore, despite early invocations and the persistent appeal of concepts such as chains of explanation, political ecology’s understanding of how socioecological scales are produced in the world has developed through the tracing of networks, relations, and processes within and between interlinked places (Rocheleau and Roth 2007; Birkenholtz 2011). Scalar ontologies are generally seen as emerging from these interactions.

In environmental governance, political ecology has also exposed the malleability of both observational scale and scalar categories or levels. The spatial and temporal scales that one adopts very much affect what one observes in terms of anthropogenic environmental change. The use of different spatial or temporal scales by different actors reflects not only assumptions
embedded in standard methodologies but, in some cases, choices made by scientists or policymakers to portray society–environment relations in a certain way (scale is an important part of environmental narrative construction). Moreover, environmental governance is very much shaped by a politics of scale where the appropriate scalar levels at which authority is invoked over resource access and monitoring are highly contested. From public lands policy in the western United States to wildlife management in East Africa to forestry policy in Southeast Asia, scale and its malleability figure prominently.

Political ecology is a cluster of theoretical and methodological approaches to the study of nature–society relationships, developed largely through and with respect to the study of agrarian dynamics in the Global South, but increasingly applied to a wide range of human–environment relationships throughout the contemporary world. Within Anglophone geography, it has a specific genealogy, recounted below. Yet it has increasingly become a capacious umbrella term used to denote research into any aspect of nature–society relations that shares certain analytical and methodological assumptions and commitments. Moreover, there are other vibrant strands of inquiry and practice, related but distinct from the lineage in Anglophone geography, developing under the label “political ecology” in other linguistic, regional, and political traditions, and there is increasing traffic among these multiple political ecologies (see Bridge, McCarthy, and Perreault 2015, 6; McCarthy, Perreault, and Bridge 2015, 620). Such breadth makes any concise or tightly bounded definition of the field challenging and necessarily incomplete. This entry focuses on political ecology in and from the perspective of Anglophone geography. Attempts at comprehensive introductions to and overviews of the field can be found in Neumann (2005) and Robbins (2011/2004), while a sense of the contemporary composition and range of the field can be found in the volumes edited by Perreault, Bridge, and McCarthy (2015) and Bryant (2015).

Origins

Political ecology grew out of multiple research traditions, in geography and related disciplines, organized around understanding the interactions between human societies and their biophysical environments. In particular, it grew directly out of analyses of how human societies adapted both to the everyday parameters of their environments (e.g., human ecology, cultural ecology, and ecological anthropology) and to their extremes (e.g., the natural hazards tradition). These, in turn, should be understood relative to the understanding of geography as the analysis of human responses to naturally given environments, the dominant conception in the early twentieth century. Political ecology emerged directly out of a critique of such traditions, particularly their conception of adaptation as a functional, unidirectional social response to an environment conceived of as ontologically prior to and separate from society, and their failure to theorize social structures or processes in the modern world that directly impacted the human–environment relationships at the very hearts of those fields (see Watts 2015).

Both the term and the field “political ecology” had multiple moments and sites of origin in the 1970s, which is unsurprising inasmuch as they reflected larger social and intellectual currents (see Bridge, McCarthy, and Perreault 2015). Two of the most directly relevant antecedents for political ecology in geography were uses
by anthropologists: Eric Wolf used “political ecology” in a 1972 article examining property relations in land and resource management, but did not really elaborate on the term beyond the title (Wolf 1972), while in 1977 medical anthropologist Meredith Turshen published an article on “the political ecology of disease” that directly linked human disease patterns in Tanzania to the political and economic relations of the colonial and postcolonial eras. In geography, Richard Walker published a pair of articles in 1973 and 1974 arguing that wetlands management was inseparable from its political-economic context and from power relations, while in 1974 David Harvey published a critique of Limits to Growth and the neo-Malthusian environmentalism it represented, which has since become one of the canonical analyses of environmental questions from a Marxist geographic perspective (Walker 1973, 1974; Harvey 1974). While the latter three pieces critiqued events and actors in the Global North, analytically they contain much that became central to political ecology. Likewise, while Michael Watts’s classic Silent Violence (1983a) does not use the term “political ecology,” all the major elements of what became the field are present in it. Given all of these antecedents, it is surprising both that so many accounts of the development of political ecology begin with Blaikie’s admittedly classic 1985 study, The Political Economy of Soil Erosion in Developing Countries (Blaikie 1985), and that the phrase “political ecology” does not appear in a research article in a geography journal until 1988 (Bassett 1988). The quest for first usages and single origin points is not especially productive, however. What matters is the clearly shared and growing sense in the 1970s and through the 1980s that human–environment relations are always, necessarily, social and political.

Cultural ecology was the most direct antecedent of political ecology, along with the intellectually and disciplinarily closely related fields of human ecology and ecological anthropology. This discussion emphasizes cultural ecology in geography, but the major analytical points apply to all three fields. As noted above, cultural ecology attempted to analyze how human societies adapted to their biophysical environments, with culture understood as a key regulatory mechanism of such adaptation (i.e., specific activities central to how a given society used and reproduced itself in its environment, such as planting or harvesting certain crops, engaging in or abstaining from hunting of a given species or in a certain area, holding feasts, going to war, and so on, were understood as mediated through culture in such a way as to maintain a dynamic equilibrium in the local ecosystem) (see, e.g., Rappaport 1984/1968).

Several important points are critical to an understanding of cultural ecology in the geographic tradition. First, there were strong, direct continuities between the “Berkeley School” of Carl Sauer and its work on cultural landscapes and what became “cultural ecology” by the mid-twentieth century: the former arguably bequeathed to the latter a central empirical focus on premodern agricultural systems, a methodological commitment to fieldwork as essential to understanding such systems, and an analytical focus on purportedly discrete “cultures” or communities as the most significant actors in shaping landscapes, rather than either individuals or extra-local networks. Other key sites and figures for work in cultural ecology in geography included the University of Chicago, the University of Wisconsin, Madison, and the Australian National University in Canberra. Closely related was much work in mid-twentieth-century anthropology, including the work of Julian Steward, who coined the term cultural ecology, and cognate work under the banner of ecological anthropology (e.g., Rappaport
Second, cultural ecology became both more positivist and more intellectually ambitious than Sauer’s more descriptive approach, making serious efforts to trace, quantify, and analyze flows of energy and materials through local human–environment systems, and to identify systemic dynamics such as positive and negative feedback loops. Such calculations and analyses, while inevitably incomplete, made real and substantial contributions to knowledge and understandings of human–environment systems, and especially of the complex causal pathways within them (Robbins 2011/2004; Watts 2015; Huber 2015). Third, the shortcomings of cultural ecology provide nearly a negative image of what became political ecology. Specifically, by the late 1970s and early 1980s, cultural ecology was increasingly criticized for treating small-scale human–environment systems as if they were closed systems in which all material and energy flows were internal and traceable, rather than as connected to a wider world, and for underestimating or leaving unanalyzed increasingly important extra-local sources of change in those systems; for assuming that the societies it examined normally maintained a homeostatic relationship with their environments; and for viewing culture through a functionalist lens, in which everything that a “culture” did somehow functioned to maintain that equilibrium with its environment (Rappaport 1984/1968; see Neumann 2005 for a discussion). Grossman’s (1984) work in Papua New Guinea, which explored precisely how relatively isolated subsistence communities were reorienting their production toward global markets, identified these problems and emblematized a shift within the field toward reversing each of those assumptions (see Watts 2015, 33).

Similar critiques were being raised within and about the natural hazards tradition, a line of work that also informed political ecology. The natural hazards tradition shared with cultural ecology a focus on human adjustments to biophysical environments, but it emphasized, as the name suggests, specifically hazardous aspects of, or events in, those “natural” environments: floods, droughts, and the like. Those hazards were generally treated as “natural” in origin, meaning arising from outside of society, and the hazards tradition focused on analyzing the wide range of human responses and adjustments to them, which could range from decisions about land use and the evolution of building styles to variations in market prices and the development of insurance. In geography, the hazards tradition was especially associated with the geography departments at the University of Chicago, Clark University, the University of Toronto, and the University of Colorado, Boulder (Watts 2015). Analytically, the hazards tradition typically assumed that society was made up of rational individual actors, and it theorized social responses to hazards as the collective outcomes of countless individual decisions. As with cultural ecology, the hazards tradition was subject to substantial internal and external critique in the 1970s that questioned its core assumptions and lack of attention to critical aspects of the phenomena it claimed to study. First and foremost, critics noted that exposure and vulnerability to hazards were not uniform within any society, but were in fact highly unequal based on entirely “social” structural inequalities within any social formation (of gender, of class, etc.) and that such differential exposure was often intimately connected to contemporary economic and geopolitical dynamics (O’Keefe, Westgate, and Wisner 1976; Watts 1983b; Watts and Bohle 1983). In the common formulation, a drought might be natural, but the resulting famine is inescapably social, at least as much about the production and distribution of food and risk as about physical conditions. For example, in
one of the field’s foundational studies, Watts (1983a) argued that the famine in the Sahel in the 1970s was due less to drought than to the fact that colonial and postcolonial shifts in land use, including changes in which crops were planted in the context of a strong national focus on maximizing export earnings, and a shift toward an increasingly monetized economy in which wage labor, debt, and class differentiation were all increasingly prominent, had eroded earlier agrarian production systems and associated moral economies that had successfully reduced risk, redistributed some surplus, and seen people in the region through many previous droughts without famine. The critical point is not merely that exposure and vulnerability to hazards is differential within a given society, but that those differentials are direct results of social structures and processes, such that truly theorizing the social experience of hazards would require a theory of power and inequality within a given society. Second, critics argued that the natural hazards tradition failed to account for the fact that many environmental hazards, far from having origins exogenous to society, are themselves the result of social processes and structures (e.g., climate change). Watts (1983a, 1983b, 2015) argued in particular that dominant versions of the hazards tradition and cultural ecology erred in treating adaptation as a functionalist and unidirectional process in which rational social actors make strategic choices in response to the pressures of a nature external to society.

The foregoing critiques of cultural ecology and the natural hazards tradition were partially informed by, and very much animated by, a combination of peasant studies and specifically third world Marxism that became important across the social sciences in the 1960s and 1970s for both analytical and political reasons (see Watts 2000, 2015; Bridge, McCarthy, and Perreault 2015). In the aftermath of widespread decolonization from the 1950s through the 1970s and in the context of Cold War geopolitical struggles over political allegiances and development trajectories in the resulting “Third World,” political and scholarly interest in so-called area studies (and, especially, in the character and dynamics of peasant-based production systems and political movements) surged, including an analytical focus on the household as the production unit in that context (Watts 2000; Bridge, McCarthy, and Perreault 2015). Such regional production systems and their articulations with the global economy were often analyzed through the related lenses of Marxist dependency theory and world-systems theory. Not surprisingly, “local” communities and their relations with their environment looked quite different through this lens than through a lens that assumed discrete local cultures were working to maintain equilibria with local environments. As Watts (2015, 28) puts it: “In the face of transformations wrought by global capital flows, the second great wave of marketization, and the dynamics of postcolonial development, talk of self-regulating systems, of third-world communities adapted to the ecological niches they occupied, and cognized models in the service of evolutionary flexibility all appeared increasingly problematic.”

The final critical element of the origins of political ecology within geography is the broader turn toward Marxist analysis in economic geography (Bridge, McCarthy, and Perreault 2015; McCarthy, Perreault, and Bridge 2015; see also Bakker 2012; McCarthy 2012; Robertson 2012). Led by David Harvey (e.g., Harvey 1974), many geographers in the late 1960s and 1970s interested in environmental questions began turning to Marxism for ways of thinking about the origins and dynamics of environmental problems that provided an alternative and counter-narrative to the
neo-Malthusian analyses that dominated popular discourse in the Global North in the decade and that were typically punitive and restrictive in their implications for the Global South (see Bridge, McCarthy, and Perreault 2015, 4; Watts 2015, 32). Alternative analyses rooted in Marxist geography that emphasized the unity of society and nature and the economic origins of environment-development dynamics provided critical intellectual resources and frameworks as political ecology developed over the subsequent decade. Moreover, the tension between dominant neo-Malthusian analyses and predominantly Marxist ones espoused by political ecologists became a continuing theme in the field, as seen in the repeated predictions and analyses of so-called resource wars or resource conflicts produced by mainstream sources and the alternative analyses provided by scholars such as Le Billon (see, e.g., Le Billon 2005).

The intertwining of all of these strands – internal and external critiques of cultural ecology and the hazards tradition; a focus on peasant-based production systems in the Global South and how they were changing in the context of postcolonial integrations into global circuits of capital; and anti-Malthusian, Marxist-inspired analyses of the “global environmental problems” newly discovered and articulated by mainstream environmentalists and policy apparatuses – gave birth to what we now refer to as “political ecology” in geography. Again, this is very much a genealogy of political ecology within and from the perspective of Anglophone geography. There are other “political ecologies” as well, particularly in the present (discussed later).

**Places and topics**

Given the origins above, it is no surprise that early work in political ecology focused almost entirely on the dynamics and consequences of changing patterns of access to and control over rural lands and resources in the Global South (see Bridge, McCarthy, and Perreault 2015, 5; Watts 2015, 32). Indeed, Bryant and Bailey (1997) later defined the field as specific to the “third world.” Several themes were especially prominent in this early work, each of which can be illustrated clearly through one or two major early works.

First, one of the greatest differences between earlier cultural ecology and emergent political ecology was the degree of attention paid to the effects of increasing integration with global markets. For rural regions in the Global South, this most often took the form of shifts toward the production of commodities for export (often at the behest of colonial or postcolonial national governments), most commonly agricultural crops or of natural resources such as timber or oil. A focus on increased primary commodity production and export figures prominently in, for example, Watts (1983a), Grossman (1984), and Bassett (1988). The point in part was that increased production of commodities for export usually came at the expense of production of a more varied and resilient range of subsistence goods for local use, but the capitalist relations and dynamics that tended to accompany this shift – toward wage labor, private property, more debt, class differentiation, and infinite accumulation – were also inherently antithetical to and corrosive of the sorts of human–environment equilibria posited and ostensibly studied in cultural ecology. As Watts put it (1983a, xxii), “famines were and are organically linked to the rupture of the balance between peasant subsistence and consumption precipitated by the development and intensification of commodity production.”

Second, political ecology recognized from its inception that states were active architects
POLITICAL ECOLOGY

of the market transformations above, and had additional agendas of their own as well. The emphasis on primary commodity production and export was often driven primarily by the desire of colonial or postcolonial administrations to increase revenues and export earnings, as above. States had other, and broader, agendas as well: to pursue particular development strategies and trajectories; to consolidate control over territory and, in many cases, over the state apparatus itself; and to demonstrate compliance with evolving international norms regarding conservation – even when such projects came at the expense of pre-existing human–environment relations. New postcolonial national governments often pursued such projects aggressively. Analyses of the reasons behind and consequences of state projects figured centrally in, for example, the work of Hecht (1985), Hecht and Cockburn (1989), and Peluso (1992) – all classics of the “first” generation of political ecology.

Third, these questions of use of, access to, and control over the rural lands and resources above were connected to strongly policy-relevant debates regarding the political and political-economic causes of environmental degradation. In two of the field’s foundational works, Blaikie (1985) and Blaikie Brookfield (1987) made powerful arguments that the roots of soil erosion (and, by extension, many other forms of environmental degradation) in such locations lay not in the ignorance, poor judgment, or reproductive decisions of those who directly worked the land (assumptions that still seemed to shape many development interventions and environmentalist discourse), but in the larger political and political-economic contexts in which those “land managers” lived and worked. Specifically, they argued that social and economic marginality each contributed to environmental degradation, as producers, burdened by debt, struggling to feed their households, and often forced on to less productive lands, knowingly “mined” the soil’s fertility in an effort to make ends meet. In the context of debates at the time, the critical point was that economic and social marginalization were causes of environmental degradation, rather than inevitable results of exceeding absolute natural carrying capacities.

A fourth prominent topic that emerged early in political ecology was the criminalization of customary patterns of resource use, often in the context of the establishment or expansion of protected natural areas in the name of conservation. This line of work drew strongly from the work of British Marxist historian E.P. Thompson and his emphasis on “history from below,” particularly his volume *Whigs and Hunters* (1975), as well as from Scott’s (1976) subsequent work on “moral economies.” Its emergence in political ecology was marked by Peluso’s *Rich Forests, Poor People* (1992). This theme connected with the field’s roots in cultural ecology inasmuch as it emphasized how landscapes and livelihoods were co-produced over long periods in ways that, while often informal, were deeply structured and effective, in ways that the expansion of centralized state control often disrupted. It also forged a direct link between political ecology and the study of common property regimes, which sought to delineate and analyze such systems, and environmental history, which was also engaged in a critical reexamination of the concept of “wilderness” and its effects. The point that “wilderness” and “protected nature” were simplifying constructs imposed on complex landscapes of which humans were important co-producers is captured perfectly in the title of another major work in this domain, Neumann’s *Imposing Wilderness* (1998), which historicizes conservation in East Africa. The fact that such impositions are backed by powerful
discourses in which all human activity is assumed to be negative for the environment (sometimes erroneously) was demonstrated by Fairhead and Leach (1996) in a critical analysis of standard accounts of deforestation in West Africa.

Methods

Political ecology is defined and distinguished almost as much by its methodological commitments and approaches as by its theoretical or geographical ones. From its inception, the field has been committed to, and is in large part defined by, intensive, place-based research that seeks to understand the complexities of specific nature–society interactions in one or a handful of cases in historical and geographical context. Ethnographic and other qualitative methods typically figure prominently, as political ecologists, following a model inspired by anthropology and social history, endeavor to understand what the dynamics in question mean for participants from the “bottom up.” Fieldwork is essential, inasmuch as political ecology tends to focus its inquiries on precisely those elements of nature–society relations that cannot be seen or explained from a social or spatial distance – through, for example, national survey data, or remotely sensed images (McCarthy, Perreault, and Bridge 2015, 623). While political ecologists might certainly use the latter sort of data, they would also seek to contextualize them and to see how the local subjects of such surveillance viewed them. Such an approach also means that the methods employed will vary from case to case, and so political ecologists typically employ mixed methods in highly varied ways. In all of these respects, there are strong continuities with cultural ecology, human ecology, and environmental anthropology.

Such a methodological approach requires multiscale analysis (see Neumann 2015; Sayre 2015). Two highly influential formulations in the field are those of Vayda’s (1983) “progressive contextualization,” and Blaikie and Brookfield’s (1987) “chain of explanation.” While there are subtle differences between them, in each, the researcher begins from an observed phenomenon (e.g., soil degradation, deforestation, shifting patterns of resource access or use), and then constructs a causal chain of explanation reaching outward, upward, and backward as necessary. So, to return to our previous examples, soil degradation might result from intensified production of export crops, which might in turn be the result of farmers trying to pay higher taxes, which were in turn put in place by the national government raising taxes precisely to spur greater production and export of cash crops in order to increase revenues to the national treasury, which were needed to pay back international loans dating to efforts to promote national development in the years immediately following decolonization and independence, with the focus on cash crops occurring in a context of national participation in international trade agreements on unfavorable terms due to unequal geopolitical and geoeconomic relationships traceable directly to the colonial era. The larger-scale variables could then themselves be interpreted in light of, for example, changing food regimes and the global historical geographies of capitalism and imperialism.

This approach, which directly or indirectly informs most work in political ecology, brings with it significant strengths and significant challenges. At its best, it refuses many of the dramatic simplifications and reductions so common in academic analysis, including the ontological division between nature and culture. It is historically materialist both in its insistence on beginning from and working through
what is actually happening in people’s lives and environments, and in its acute consciousness of the ways in which history and geography matter. It takes seriously the knowledges and priorities of the people researchers engage, and it maintains a constant attention to the multiple ways in which power works, as well as at least a presumptive sympathy with the less powerful.

Yet, such an approach also carries significant challenges, methodological and analytical. First, tracing relevant causal chains may sound simple in theory or in the hypothetical example above, but it is much less so in reality: causal chains proliferate in many directions, not all of which can be followed. In fact, choices must be made at every moment: in a complex, dynamic world, what temporary stability or claimed observation do we begin from as the alleged “phenomenon” at the start of the chain of explanation? As we move upward and outward, which of many potentially relevant causal pathways do we follow? Also, causality is often inferred more than conclusively demonstrated: what if others do not agree with our assessments that a given branching pathway is clearly the most relevant causal one? Each such choice and its justification is thus necessarily shaped by theory and politics: a purely empiricist or inductive approach is neither possible nor desirable. Peet and Watts criticized Blaikie’s chain of explanation approach for its lack of a strong theoretical framework (Peet and Watts 1996, 8), which would provide a way to narrow, guide, and justify such choices along the way. Conversely, other scholars in this domain have criticized political ecology for the opposite reason, contending that commitments to particular theoretical frameworks lead researchers to seek only evidence that confirms conclusions preordained by the theory (e.g., Vayda and Walters 1999).

Political ecology’s greatest methodological challenge may be the inclusion of ecological data and methods. While the field’s name and alleged objects of study would imply their presence, and they certainly figured prominently in the cultural ecology that preceded it, in-depth ecological methods, data, and analysis have become less prominent in most political ecology (with important exceptions, to be sure: see, e.g., Zimmerer and Bassett 2003 and Goldman, Nadasdy, and Turner 2011). For this reason, the field has been subject to a steady critical refrain that it emphasizes politics over ecology (Vayda and Walters 1999), reinscribes an ontological division in privileging social over natural processes and scales, and more generally struggles to integrate its critical perspectives on science and politics (see Forsyth 2015; Zimmerer 2015). Most political ecologists still advocate methodological pluralism and indeed see openness to the same as one of political ecology’s strengths (see, e.g., Doolittle 2015), and many do practice it, but the constraints of graduate training and other disciplinary pressures toward specialization make it an ongoing challenge. Debates about the epistemological, ontological, and political significance of the divergent trajectories of political ecology and other contemporary approaches to nature–society research in geography, such as land-change science, and whether and how those trajectories can fruitfully converge again, are ongoing (see, e.g., Brannstrom and Vadjunec 2013).

Another important methodological challenge is the question of historical depth: one of the choices above is how far back in history to go in constructing explanations. Political ecology has arguably been very focused on what we might call a meso–temporal scale of somewhere between several decades and roughly two centuries: less would almost certainly be considered too shallow, but more is rare indeed (see the
commentary by Wilson 2014). This focal length presumably reflects the field’s original central focus on the consequences of recent or current incorporation into a modern global capitalist economy. Yet many have argued that it is too shallow, and that the fuller understanding of many of the nature–society dynamics at the heart of political ecology demands a deeper and perhaps more rigorous engagement with historical evidence and analysis (see, e.g., Biehler 2009; Davis 2015; Zimmerer and Bell 2015). The treatment of historical depth and analysis remains a plane of friction between political ecology and environmental history (again, see Wilson 2014).

Questions of generalizability and comparability present an additional set of challenges, both methodological and analytical, for political ecology. Given the field’s insistent focus on the specific and the local (albeit contextualized), it is difficult to treat its substantial corpus of fine-grained case studies as strictly comparable, or to draw generalizable results from them. Yet policymakers, other academic fields, and students frequently ask for such generalizations and comparisons, and the cumulative knowledge production in a field that they often represent (see Castree 2008a, 2008b on “neoliberal natures”). To be clear, many political ecologists do not aspire to produce such results as inputs into the circuits that demand them. Yet in their absence, it can be difficult to convey or translate the field’s knowledge beyond its boundaries, and political ecologists frequently find themselves in the position of criticizing work – of policymakers, development specialists, or those promoting climate resilience, for example – without being able to offer concrete alternatives.

Development of the field

Political ecology grew out of the political and theoretical developments of the 1970s, including the turn toward Marxism in geography and other social sciences. But, while the pivotal works of David Harvey and others were important intellectual resources in the field’s development (see Bridge, McCarthy, and Perreault 2015; see also Bakker 2012; McCarthy 2012; Robertson 2012), the earliest works of political ecology in geography were all tightly focused on how agrarian production systems and social relations, especially those of peasants, in the Global South were being transformed by capitalist transitions and associated state strategies and interventions (e.g., Watts 1983; Hecht 1985; Blaikie 1985; Bassett 1988; Blaikie and Brookfield 1987; see also Peet and Watts 1996, 5). That first wave of political ecology was overtly Marxist, focusing on how individuals, households, and even particular classes were responding to and being transformed by the extension and deepening of capitalist social relations in particular places (although different authors used different variants of Marxist theory, in varying depths). So, questions of capital accumulation, changing relations of production and class structures, new commodities and commodity chains, and the unequal distribution of economic surplus were central (see Watts 2015; McCarthy, Perreault, and Bridge 2015). These early works of political ecology also paid attention to the materialities of agricultural ecology, including soil fertility and forest cover, with a consistency that later became much more uneven in the field.

Three points about political ecology’s Marxist foundations are critical. First, they are arguably what most decisively distinguished the field from its antecedents in cultural ecology, both in advancing an explicit theory of contemporary society, including its macroscopic structures and processes, and in then making those macroscopic structures and processes central to the analysis of “local” nature–society relations in rural areas around the globe. Second, they built into
the field a set of political as well as analytical commitments: most political ecologists neither are, nor aspire to be, neutral with respect to their objects of study (McCarthy, Perreault, and Bridge 2015, 622). As Robbins has put it, what makes the field “political ecology” is precisely that it is an alternative to supposedly “apolitical ecology” (Robbins 2011/2004, 5). This remains a fundamental point of difference with many otherwise overlapping approaches to the same objects of study. Third, these theoretical and political commitments have made the issue of the field’s engagements with policy a difficult one: on the one hand, most political ecologists strongly believe the situations they study can, and should, be different in ways that would make them more just and sustainable: that is, they are anything but politically neutral or clinically objective with respect to intentional change, and they often claim to have insights into the key processes and relations that matter the most in producing objectionable outcomes. And so, many have worked with communities, national governments, and international agencies, including both funders and deliverers of development interventions, in order to try to put their knowledge to work. On the other hand, many believe that the changes needed to truly alter the processes and relations at the heart of the field’s critique are extensive, structural, and beyond the parameters of conventional policy discussions and options. They believe that working with the major players in international environment and development is a form of co-optation that dulls critique, and they can contribute more to change by keeping their analyses as sharp and unvarnished as possible. This tension has been present in the field since its inception, in ways explored in depth in a 2008 special issue of Geoforum focused on the career of Piers Blaikie (Muldavin 2008); see also Carr and Simon (2014), Bebbington (2015), and Wisner (2015).
others detailed the ways in which access to and control over resources and surplus, distribution of the costs and benefits of socioecological transformations, environmental knowledge, modes of political engagement, and more were deeply structured by gender (see Feminist political ecology). Analytical attention to categories of social difference other than class threw into question analytical units such as “the household,” showing that, far from being unitary economic units, they were themselves sites of exploitation and contestation, and that they and other units sometimes taken as given, such as “communities,” were shot through with multiple, intersecting axes and categories of social difference that affected the dynamics political ecologists studied (see, e.g., Carney 1993; Schroeder 1999). From an initial focus on gender, this line of work broadened to analyses of other categories and dimensions of identity, such as indigeneity, ethnicity, and race, and their imbrications with environmental politics (see, e.g., Moore, Kosek, and Pandian 2003; see Yeh and Bryan 2015 for a review). Deeply informed by poststructuralism (see below) and anthropology, thinking around these questions in political ecology has come to focus on intersectionality, the effort to understand the multiple dimensions and categories of identity as always existing and operating in fluid (yet not voluntarist) constellations (see, e.g., Sundberg 2004). These insights from feminist theory have become as much part of the fabric of political ecology as Marxism: the field now takes it as established that categories such as gender and race are dynamic social constructs shaped by unequal power relations, and that they affect the starting points, dynamics, and outcomes of all socioecological processes.

Deeper engagement with feminist theory and questions of gender coincided and overlapped with a turn toward poststructuralist theory in political ecology in the 1990s. Drawing on Foucault, Gramsci, and others, political ecologists broadened their understanding of the sites, means, and substance of environmentally relevant politics. Authors such as Moore (1993), Fairhead and Leach (1996), and Agrawal (2005) began to investigate power and politics as pervasive, and as operating through micropolitics, discourses, scientific knowledge, and the production of new subjects, subjectivities, and consent as well as through formal state policies, capital investments, outright impositions, and coercion. Already evident in the publication of a 1993 special issue of Economic Geography which formed the basis for the first issue of Liberation Ecologies (Peet and Watts 1996), this poststructuralist turn led political ecology to focus increasingly on the investigation of new terrains and dynamics of politics created by environmental interventions, including new processes of subject formation in which “environmental” categories and goals figure centrally (see, e.g., Agrawal 2005; Li 2007). While not strictly poststructuralist, Gramsci’s work on hegemony and the production of consent became increasingly central to work in this vein, providing critical resources for thinking about how environmental claims were used to contrast and contest political legitimacy and create new political identities and coalitions.

As political ecology broadened theoretically, it broadened empirically as well, with the two trends amplifying each other. To the early focus on changing peasant production systems in the immediately postcolonial third world were added studies of the new commodity chains that resulted, producing work that examined not only some of the classic sites and settings of political ecology but also the cultural economies of the global cities where those commodities were consumed (e.g., Freidberg 2004), and the evolution and uneven consequences of myriad attempts to make such commodities and commodity chains more transparent and ethical (see Otto and
Conservation and its impacts on local, and especially indigenous, peoples became a major topic as well, with studies examining both conflicts around protected natural areas (e.g., Neumann 1998) and indigenous social movements that made strategic use of claims regarding identities rooted in, and knowledge of, their environments (see Yeh and Bryan 2015 for a review). Drawing largely from work in anthropology (e.g., Agrawal and Gibson 1999), political ecologists were among the few to question an otherwise largely celebratory turn toward “community-based” resource management and conservation that emerged in the late twentieth century as an alternative to fortress conservation, based on the recognition above that “communities” are typically not unitary actors but rather internally divided terrains of struggle between unequal actors.

As the example of community-based resource management indicates, approaches to resource management travel widely and quickly through global networks in the modern world: consider other examples such as scientific forestry, payments for ecosystem services, or the many iterations of sustainable development. Commodities also flow round the world. As political ecologists began to pay more attention to such networks and flows, undertaking ethnographies not only of small producers but of the international organizations and networks that so affected the latter’s livelihoods (e.g., Goldman 2001), they began to be more interested in the points of origin of some such ideas, and also in the counterflows that complicated simplistic models of the top-down or center-out diffusion of ideas (e.g., foundation program officers who brought ideas with them back to their points of origin). It is thus not surprising that political ecologists began to see many of the dynamics studied in the field thus far at work in other settings and situations: in marine biosphere reserves, where traditional fishers were being displaced by conservation efforts; in North America, where rural people and others engaged in direct primary production also complained that the environmental priorities of environmental nongovernmental organizations (NGOs) and bureaucracies of the central government were displacing and undermining their livelihoods (e.g., McCarthy 2002; St. Martin 2001; Schroeder, St. Martin, and Albert 2006), and where informal and subsistence activities in forests persisted despite dominant discourses that relegated them to the distant past (e.g., Emery and Pierce 2005). This could also be seen in the rapidly growing hegemony of neoliberal approaches to conservation, in which the assignment of individual property rights and payments for ecosystem services were touted as solutions to nearly any problem of environmental management (see, e.g., Dempsey and Robertson 2012); and for that matter in cities around the world, where access to and benefits from environmental goods and amenities such as potable water or green space, as well as exposure to environmental hazards, were markedly unequal, based on race and class and demonstrably shaped by processes of capital accumulation and state formation (see, e.g., Heynen, Kaika, and Swyngedouw 2006; see also Urban political ecology). Finally, political ecology’s increased attention to not just primary production, but the full array of metabolic processes involved in the contemporary global economy, led also to research in the field on waste, using roughly the same mixture of theory and methods used to study production assemblages and their consequences (see Moore 2012).

Current and future directions

Given the growing ambit of political ecology, no summary discussion can do justice to the field’s
POLITICAL ECOLOGY

current and likely future directions. Yet some major trends, reviewed here briefly, are clearly evident.

First and foremost, perhaps, is a surge of work on the interrelated topics of climate change and energy production. With respect to climate change, the topic seems in many respects ideally suited to political-ecological analysis: geographers can contribute careful analyses of how multiple actors, especially the most marginalized and vulnerable, are affected by and respond to changes in their local environments wrought by climate change, understood as a set of physical processes driven by greenhouse gases released mainly in the service of capital accumulation and left unchecked, due in part to the political limitations and imperatives of an interstate system that is itself largely an artifact of the colonial and Cold War eras. Moreover, much of the discipline of geography and some related fields, including many policy networks, claim to have internalized the insights and lessons of political ecology in their thinking about climate change, dutifully acknowledging highly differential vulnerability within social formations based on gender, poverty (although rarely class), and other axes of difference, and at least superficially questioning a single-minded focus on economic growth as the sole good. Indeed, much of the currently tremendously popular and influential work on “resilience” claims to incorporate precisely these insights. Yet, as Bassett and Fogelman (2013), Watts (2015), and others have scathingly demonstrated, many of these recent efforts to “mainstream” the insights of political ecology arguably miss the heart of its critique. First, they rely upon notions of adaptation and adaptive capacity quite similar to those that dominated cultural ecology, in which local actors react to current or imminent changes in their proximate environments in ways that allow them to survive – or not. But, as Watts argues, “it was precisely the limits of adaptation as a form of thought which constituted the very ground on which political ecology emerged during the 1970s and 1980s” (2015, 21). It is a long way from an acknowledgment of differential exposure and vulnerability to a coherent theory of the global capitalist economy and its imbrications with formal and informal political structures and power relations that produce those differential exposures and vulnerabilities, and it is precisely those latter things that are absent from, and indeed incompatible with, currently popular theories of resilience and adaptation. Also mostly absent is a sense of human beings as active producers of environments as well as inhabitants of them. So, while political ecology has contributed to analyses of climate change and should certainly continue to do so (see Liverman 2015 for a review and commentary), it is vital that such work retains the field’s defining critical insights and perspectives.

Closely related to the interest in climate is a boom in work on the political ecology of energy and extractive industries. While the two are not identical, a major impetus for much of this work is undeniably a keen attention to the continued extraction of fossil fuels, especially so-called unconventional ones, in the context of accelerating climate change, as well as the new geographies of energy production, transmission, and consumption occurring as a result of both the ongoing extraction of fossil fuels, and the increasing use of renewable energy sources (see, e.g., Zalik 2009; Bridge et al. 2013). Political ecology’s attention to the energy flows that sustain the global capitalist economy echoes, at a global scale, cultural ecology’s earlier efforts to quantify energy flows within local ecosystems as essential to analysis of those systems (see Huber 2015).

Political-ecological research on fossil fuels (focused mainly on the sites of their extraction)
can be seen as part of a recent growing wave of research on what Bebbington (2012) has called “underground political ecologies.” Bebbington argues that until quite recently, political-ecology research focused overwhelmingly on biotic resources and systems on the surface of the land. While there is a certainly a long tradition of research on the political economy of extractive industries and regions, a large body of research on these topics explicitly identifying as, and drawing on the cumulative insights and frameworks of, political ecology has developed only in the past decade (see Bebbington 2012 for citations and commentary). The intensified search for fossil fuels above is one reason (Zalik 2009); the turn by many putatively postneoliberal Latin American governments to extraction as a source of revenue is surely another (see Bebbington and Bury 2013).

Another important development in political ecology has been the increasing attention to how neoliberalism has reworked environmental governance in many places and sectors, with profound consequences for human societies, nonhuman species, and ecosystems alike (see, e.g., many of the cases collected in Heynen et al. 2007; see Castree 2008a, 2008b for a review and commentary emphasizing the challenges of definition, comparability, and research design). Two things stand out about this body of work with respect to the development of political ecology. First, most of this work draws from, and shares, the key characteristics of political ecology: the research is nearly all intensive and place-specific, often focused on a single natural resource or resource-based industry, overtly Marxist or neo-Marxist, attentive to social context and complexity and the other theoretical resources and developments detailed above, and normatively anti-capitalist. Yet overall, this body of work draws as much from, and identifies with, economic geography as much as political ecology. In this sense, it represents a strong return to one of the early theoretical wellsprings of political ecology – the Marxist turn in economic geography that began in the late 1960s and gathered strength in the 1970s and early 1980s – but also draws directly and strongly on more recent economic geography, including the proliferation of work theorizing the neoliberal turn. It thus draws tighter and more explicit connections between political ecology and economic geography (see Bakker 2012; McCarthy 2012; Robertson 2012 for discussions of this relation). Second, this body of work is defined more by theme than region: its common feature is examination of the consequences of the neoliberal turn for the production of particular socio-natures; inasmuch as that turn has been extremely widespread (if variegated), this body of work examines cases from both the Global North and Global South and emphasizes certain similarities between them, and so perhaps represents a somewhat different geographic imaginary within political ecology (see, e.g., Fletcher, Dressler, and Büscher 2015).

If one new direction for political-ecological research has been downward, looking underground, another has been “inward,” looking at human bodies, their health, and their immediate domestic environments as new objects of research within political ecology. While “traditional” political ecology looked primarily at how individuals and households used the surrounding landscape to support themselves within the constraints of highly structured and rapidly changing contexts, emphasizing accumulation, marginalization, and degradation, it took the actual bodies, health, and homes of those actors largely for granted, beyond placing them with respect to categories and dynamics related to class, gender, race, and ethnicity. By contrast, a new wave of work building on political ecology is looking,
on the one hand, at how human health and disease are deeply interwoven with the production and reproduction of specific livelihoods and socio-natures (see, e.g., King and Crews 2013), and on the other at human bodies as themselves terrains through which capital circulates and accumulates, producing environmental transformations and often degradation in the process (see, e.g., Guthman and Mansfield 2015), including in specific domestic environments not usually examined in political-ecological research focused on the “nature” of productive landscapes and protected conservation areas (Biehler 2009; Biehler and Simon 2011).

Still other new research in political ecology decenters humans entirely, breaking with the field’s undeniably anthropocentric past and focusing instead on how many of the dynamics above – of capital circulating through bodies and landscapes, of new commodity chains, of states exerting control over their territories, of conservation projects and displacements – affect nonhuman animals and ecosystems, including those at the heart of agrarian production systems, domesticated animals and pests, “wild” ones, and ones that blur such categories, regarding them all as significant actors, legitimate subjects of ethical concern, or both (see, e.g., Biehler 2009; Emel and Neo 2015; Gillespie and Collard 2015). Collectively, this direction in the field can be read as breaking new ground for what Sundberg (2011) has called a “posthumanist political ecology.”

One final development in political ecology merits discussion here: as should already be evident from the preceding review, political ecology is an increasingly polycentric field in disciplinary, linguistic, and geographical terms. Intellectually, it draws from and overlaps with anthropology, economic geography, environmental history, science studies, and many other fields. Linguistically and regionally, it is a term increasingly used and recognized in other linguistic and national research traditions beyond Anglophone geography and beyond the Global North, with a plethora of journals, conferences, research networks, and other undertakings developing under the label of “political ecology” in Europe, Latin America, and elsewhere, and connecting political-ecological work in English with work in French, Spanish, Portuguese, and other languages (see multiple chapters and the editors’ introductions and conclusions in Perreault, Bridge, and McCarthy 2015 and Bryant 2015; see also ENTITLE 2015). Recognizing and promoting such connections is a major theme of the collections edited by Perreault, Bridge, and McCarthy (2015) and Bryant (2015), as well as the EU-funded ENTITLE network and its training activities (see www.politicalecology.eu). Geographically, the field is responding to ongoing changes in the structure of the global economy and geopolitics that call into question the North/South framing central to its early decades (McCarthy, Perreault, and Bridge 2015, 628). While political ecology may once have been a field specific to, or about, the third world (Bryant and Bailey 1997), recent and contemporary political-ecological scholarship belies such framings (see, e.g., McCarthy 2005; Schroeder, St. Martin, and Albert 2006; Joshi 2015; Zimmer 2015).

Conclusion

Such a large and growing diversity of topics under the heading of “political ecology” raises the question of what, if anything, this range of work has in common. But careful readings of the above work reveals a continuing commitment to several of the core projects and themes discussed above. Political ecology remains the ambitious effort to understand
specific human–environment interactions both in all of their dynamism and social complexity, and in their larger historical-geographical contexts. The field retains a conviction that this goal requires place-based, intensive research on the one hand, and multiscalar analysis of relevant actors and processes operating at larger, often international or global, scales on the other, inasmuch as the latter directly affect the former. Capitalist processes, state projects, and the priorities of other powerful international actors, such as NGOs and scientific networks, still figure prominently in the latter set. Marxist, feminist, poststructuralist, and increasingly postcolonial theory animates the great majority of this work, which assumes that actors always make decisions in contexts highly structured at multiple scales under conditions of radical asymmetries of power. The goal of such intensive, place-specific research is both an understanding of the specific case as an end in itself – often as part of a long-term engagement between the researcher and a particular group of people – and the generation of insight into other cases, which, while not directly comparable, may have important similarities inasmuch as they are also affected by the same, or parallel, multiscalar actors and processes. The field also remains deeply normative and political, typically focusing on developments researchers find objectionable, often overtly taking sides between opposing claimants, and advocating alternative, often non-capitalist, ways of interacting with environments. What has changed the most, perhaps, is that political ecologists have increasingly applied this framework to the interrogation and analysis of nearly any aspect of contemporary society, whether urban or rural, production or consumption, in the Global South or North, and whether focused on natural resource industries or other sectors. In sum, political ecology is increasingly used to examine the metabolism of global society, often in ways that deliberately span or reject such binary categories.

Political economy and regional development

Danny MacKinnon
Newcastle University, UK

Political economy approaches became highly influential in geography and regional development during the 1970s and 1980s, and have remained important. In geography, they emerged out of a critique of the so-called quantitative revolution in the late 1950s and 1960s for its perceived lack of social relevance and concern at a time of intensive social and political ferment and profound economic restructuring in the late 1960s and early 1970s. In response, these critics turned to political economy, and to the writings of Marx in particular, in their search for new intellectual foundations. By the 1980s, political economy had became “the dominant discourse of human geography influencing debate, research and the very sociology of the discipline” (Barnes 1995, 423). It was subsequently displaced from the cutting edge of the discipline by a host of competing, though sometimes overlapping, approaches which have variously emphasized culture, institutions, and processes of historical evolution. Yet political economy remains an important source of insight in economic geography and regional development studies, not least in terms of providing a framework for understanding the uneven development of cities and regions in the wake of the financial crisis of 2007–2008 and the subsequent recession.

Political economy should be seen as a broad framework of analysis, encompassing a range of strands and traditions, rather than as a single theory or concept. Its origins lie in the classical political economy of Adam Smith and David Ricardo in the late eighteenth and nineteenth centuries, becoming most associated with Marx’s radical critique and reformulation of their work. Political economy analyzes the economy within its social and political context, rather than seeing it as a separate entity driven by its own set of rules based on individual self-interest. It is concerned not only with the exchange of commodities through the market but also with production and the distribution of wealth between the various sections of the population, while it differs from mainstream economics in its conceptualization of economic life and of the principal drivers of growth and development.

While the classical political economy of the nineteenth century was not concerned with geography, economic geographers have sought to apply a political economy framework to geographical topics such as regional development and urban restructuring. This has given rise to what Sheppard (2011, 320–321) terms “geographical political economy,” which is defined by three key characteristics. First, capitalism is just one way of organizing the economic activities of a society rather than being historically inevitable or natural. This reflects the historically specific nature of political economy as an approach concerned with analyzing the transformation of social and economic relations over time. Second, geography is not passive or external to the economy but is actively produced alongside economic activities. This is
evident in terms of new forms of economic activity giving rise to new growth regions, often alongside the decline of older industrial regions. Third, economic processes must be considered in relation to parallel biophysical, social, and cultural processes such as the utilization of natural resources, social class, gender relations, and identity formation. It is in this sense that geographical political economy approaches should be seen as open and adaptable, being receptive to insights from other perspectives, and evolving in line with capitalism as their main object of analysis.

The remainder of this entry is organized into three main sections. First, it examines the rise of political economy approaches in the 1970s and 1980s and discusses a number of landmark contributions to the study of regional development. The next section assesses the repositioning of political economy approaches to regional development in the 1990s and early 2000s in response to some high-profile criticisms and the emergence of a number of other approaches. This is followed by a section which highlights the continuing relevance of political economy to contemporary issues in regional development, and indicates how it continues to inform research in several key areas.

The rise of political economy approaches, 1970s and 1980s

In response to the pressing social issues of the late 1960s and early 1970s, such as racial divisions in US cities, the Vietnam War (symbolizing the imperialism of US foreign policy), gender inequalities, and the rediscovery of poverty in inner-city ghettos, a group of US-based geographers sought to fashion a new radical geography. This radical geography turned to political economy and the writings of Marx, in particular, to provide a framework for the critical analysis of advanced capitalism. In general, Marxism emphasizes processes and relationships rather than fixed things, adopting a dialectical perspective which sees change as driven by the tensions between opposing forces. Capitalist society in particular is characterized by continual change and flux, driven by the search for profits in the face of competition which requires, as Marx and Engels wrote in *The Communist Manifesto* of 1848, the continual revolutionizing of production in search of competitive advantage and thereby the wider relations of production in society.

While the writings of Marx provided only a few scattered comments and insights into the geography of capitalism, Marxist geographers such as David Harvey sought to build on these by developing a distinctively Marxist analysis of geographical change. From this perspective, the economic landscape is shaped by the conflict-laden relationship between capital and labor, mediated by the state, which provides a stark contrast to the harmonious equilibrium state of regional balance posited by mainstream neoclassical economic theory.

The first phase of Marxist geography concentrated on establishing how capitalism produces specific geographical landscapes. In *The Limits to Capital* – the classic landmark theoretical text of Marxist geography – Harvey (1982) identified a central contradiction between the geographical fixity and motion of capital. There is a need, on the one hand, for fixity of capital in one place for a sustained period, creating a built environment of factories, offices, houses, transport infrastructures, and communication networks to enable production to take place. Such fixity is countered by the need for capital to remain mobile, on the other hand, enabling firms to respond to changing economic conditions by seeking out more profitable locations. This may require
them to withdraw from existing centers of production in which they have invested heavily. Capital is never completely mobile but must put down roots in particular places to be effectively deployed. Nonetheless, its relative mobility lends capital an important spatial advantage over labor, which is more place-bound.

Harvey argues that capital overcomes the friction of space or distance through the production of space in the form of a built environment that enables production and consumption to occur. Indeed, such investment in the built environment can act as a “spatial fix” to capitalism’s inherent tendency toward overproduction by absorbing excess capital, hence performing an important displacement function. As economic conditions change, however, these infrastructures can themselves become a barrier to further expansion, appearing increasingly obsolete and redundant in the face of more attractive investment opportunities elsewhere. In these circumstances, capital is likely to abandon existing centers of production and to establish a new spatial fix involving investment in different regions. The deindustrialization of many established centers of production and to establish a new spatial fix involving investment in different regions. The deindustrialization of many established centers of production in the Rust Belts of North America and Western Europe since the late 1970s and the growth of new industry in Sun Belt regions and the newly industrializing countries of East Asia can be understood in this light.

One of the most notable contributions to Marxist political-economic thinking about regional development is Neil Smith’s theory of uneven development. This is based on the idea that capital moves to the areas that offer the highest profits for investors, leading to differentiation as these areas experience rapid development while other regions are left behind. Over time, the process of economic development in a particular region tends to undermine its own foundations, leading to higher wages, rising land prices, lower unemployment, and the development of trade unions, reducing profit rates. In other regions, underdevelopment leads to low wages, high unemployment, and the absence of trade unions, creating a basis for profit that attracts capital investment. Over time, capital will seesaw from developed to underdeveloped areas, “jumping” between locations in its efforts to maintain profit levels. It is this movement of capital that creates patterns of uneven development. In this sense, “capital is like a plague of locusts. It settles on one place, devours it, then moves on to plague another place” (Smith 1984, 152).

In addition to the abstract analyses developed by Harvey and Smith, another strand of Marxist work was developing more concrete analyses of specific situations and circumstances. One key research question was how particular places were affected by wider processes of economic restructuring, focusing attention on questions of uneven regional development. In a seminal text, Doreen Massey investigated the changing location of industry in the United Kingdom, developing the concept of “spatial divisions of labor.” Massey demonstrated how production was becoming “stretched” across different regions as large corporations sought to capitalize on pre-existing regional differences, particularly those related to the availability of labor. Increasingly, higher-order functions such as research and development were being located in metropolitan regions like the southeast of England, where large reserves of qualified, professional labor could be found, while skilled manufacturing was being concentrated in industrial regions such as the Midlands of England, which contained skilled engineering labor. At the same time, less skilled work related to the assembly of components was being relocated in peripheral regions of the United Kingdom and in less developed countries, where labor costs were much lower.
As such, different types of region were specializing in different parts of the production process. This approach successfully brought together a concern with general processes of capitalist development, relating the locational decisions of corporations to the dynamics of accumulation or investment, and an emphasis on local uniqueness in the form of individual regions.
